The mutual adaptation between man-machine opens new possibilities in the development of better user-friendly interfaces that not only adapt to the user's characteristics, but also permits the adaptation of the user to the machine. There are several examples of the use of feedback to improve the man-machine interface. One example is the use of sound to acquire cues in the interaction with the machine (Rauterberg, 1999). These studies show the improvement in the interaction when we increase the number of communication channels between the man and the machine. The problem with sound cues is that need the conscious effort to be recognized. Hunter, Katz, and Davis (2003) show another example of the importance of increasing the communication channels in the interaction between man and machine. In this study, they show how the multiple sensory stimuli contribute to the conscious awareness of the body, and how it can be used to change the abnormal body awareness that occurs after limb amputation. This effect is also known as cortical reorganization, where the brain after losing the stimuli from the amputated limb, due to the cross-modality, received input signals from the adjacent neurons, resulting in what is called "phantom limb."

With the proper stimuli combination, the body image can be changed, allowing for the human body to adapt to external devices. In order to test this hypothesis, we proposed the used of an adaptable, EMG-controlled prosthetic hand with tactile feedback using electrical stimulation. Lotze (1999; Lotze, Grodd, Birbaumer, Erb, Huse, & Flor, 1999) and Maruishi et al. (2004) showed the positive effects in the use of myoelectrical prosthesis to revert cortical reorganization. Giraux, Sirigu, Schneider, and Dubernard (2001) also show the possibility to revert cortical reorganization in the brain. This is possible, due to the combination of the intentionality from the amputee to move the absent limb, which results in muscular movement, and the visual feedback provided by the myoelectric device. We think that if we include even more sensory channels—in this case, tactile feedback—the adaptation to the prosthetic device can be enhanced, resulting in subconscious control of the device.

BACKGROUND

The development of myoelectric prosthetic hands has advanced incredibly since their introduction in 1960 (Katoh, Yokoi, & Arai, 2006). The myoelectrically controlled devices are preferred over the body powered ones, because the latest are restricted in their area of application, and the cosmetic ones do not provide any advantage to their user on his activities (Stein & Walley, 1983). Still, one mayor drawback of the EMG controlled devices is the minimal or nonexistent biofeedback—that is, information on the status of the prosthetic device, hand, or leg to the body. Our body is a multimodal system that uses several channels to obtain the current status of our bodies; if one channel fails, there are still others that help to provide the missing data. The user of a prosthetic hand needs to overcome the lack of tactile and proprioceptive data with visual feedback, which causes to fatigue faster because of the increment of conscious effort to control the hand (Weir, Childress, & Licameli, 1998). These mechanisms need the implementation of a feedback source that enables the user to develop extended physiological proprioception (Simpson, 1974). We find some examples in the application of "tactile feedback" using vibration (Rios Poveda, 2002) or electrical stimulation (Nozomu, Takashi, & Yasunobu, 1998; Shimojo, Suzuki, Namiki, Saito, Kunimoto, Makino, Ogawa, Ishikawa, & Mabuchi k, 2003; Yoshida, Sasaki, & Nakayama, 2002). On the other hand, in the man-machine interfaces studies, we find haptic interfaces that provide tactile feedback. Their direct application to prosthetics is limited, due to the fact that all these researches focus on the sensory substitution using the finger tips (Samuel, 2002). Regrettably, those cannot be applied to prosthetic devices where the user presents partial or complete loss of the arm, which are our interest in this study. Therefore, we need to find a different way to provide with sensorial information to the human body. It is been demonstrated that the brain works with correlative information; therefore, when provided with simultaneous stimuli, the brain can associate the stimuli into a unique event (Carrie Armel & Ramachandran, 2003). Using this knowledge, we can force the brain into producing new sensations, provided that the stimulus is simultaneous, so the person using a prosthetic hand can have sensorial feedback besides the visual.

INTO THE CROSS-MODAL INTERACTION

The prosthetic system in our laboratory uses an adaptive discrimination method to classify the human intention using the electromyography (EMG) signal from three sensors placed on the forearm of the user (Katoh et al., 2006; Nishikawa, Yu, Maruishi, Watanabe, Yokoi, & Kakazu, 2000). In order to provide the tactile sensation, we use in this study transcutaneous electrical stimulation. This method does not interact directly with the nerves, is easier to develop, does not require complex surgical interventions, and the rejection from the body is minima, also it can be applied during the scanning inside the functional magnetic resonation imaging chamber.

The use of visual or auditory feedback only is not reliable enough to provide with sensory feedback for proper subconscious control of the artificial limb. In order to solve this drawback, we need to provide with tactile or proprioceptive information—that is, a way for the body to interact directly with the environment. In previous studies, the electrical stimulation has been used to provide an on-off signal as sensory feedback, with promising results, but lack of more objective system evaluation. The participants to these experiments shows an improvement in their use of the prosthetic device, and even voice the opinion of "feeling" the robot hand more as part of their bodies. Although these studies present promising results, we still need to understand more the relationship between the man and the machine for better future applications.

We transmit the tactile information from the prosthetic hand to the body using a transcutaneous electrical stimulator developed in our laboratory that works as a transducer between the forces applied over the pressure sensors installed on the finger tips and the palm of the robot hand and the biphasic square signal applied to the body (Hernandez Arieta, Yu, &Yokoi, 2004).

Experimental Setting

Using the prosthetic system described above, we performed a series of experiments to measure the activation on the somatosensory region S1 of the brain to see the effects of the electrical stimulation as tactile feedback for the myoelectric prosthetic hand. In order to measure the effects, we first evaluated the response of the body to the stimulation alone as an unrelated event. Following, we measure the brain activation to the electrical stimulation when is applied as a result of the robot hand touching and object, working along with the intention from the body and the visual feedback.

As stated above, we regulate the stimulation by changing the duty rate of the signal, thus any reference to the intensity in the stimulation will be stated according to the percentage of the duty ratio. The neural transcutaneous electrodes were placed on the upper left arm. This is done in order to avoid the insertion of electrical noise, due to the electrical stimulation on the EMG signals. The distance between electrodes was set to 1 cm. Our control group consisted of two healthy men in their 20s, who do not present any visible physical alteration. We placed the sensors similarly to the amputee.

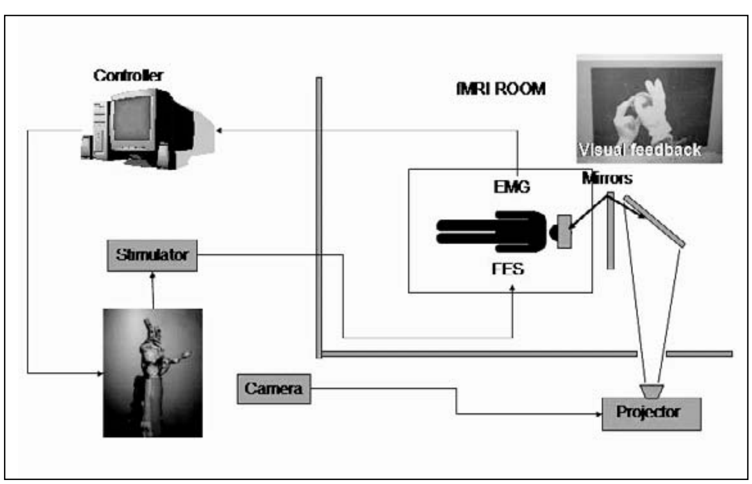
Our test subject for this experiment is a right arm amputee woman in her 50s. The amputation was performed five years previously to this study. The amputation was performed over the wrist level, leaving most part of the forearm intact. The surface EMG sensors were placed over the right forearm, below the elbow joint as shown for the pattern classification process. For this experiment, we trained the classifier with the following motions: fingers flexion/extension, wrist flexion/extension, thumb flexion.

In order to provide with visual feedback, we used a video camera to show the subjects the prosthetic hand movements while inside the f-MRI device. The subjects see the image through a set of mirrors that allow transmit the image from the video camera (Figure 1). This is necessary, because the f-MRI does not allow the inclusion of the robot hand inside the room, due to the strong magnetic force produced by it.

Cerebral activity was measured with f-MRI, using blood oxygen level-dependent contrast (Logothetis, 2002). After automatic shimming, a time course series of 59 volumes was obtained using single-shot gradient-refocused echo-planar imaging (TR = 4000 msec, TE = 60 msec, flip angle = 90 degree, inter-scan interval 8 sec, in-plane resolution 3.44 x 3.44 mm, FOV = 22 cm, contiguous 4-mm slices to cover the entire brain) with a 1.5T MAGNETOM Vision plus MR scanner (Siemens, Erlangen, Germany) using the standard head coil. Head motion was minimized by placing tight—but comfortable—foam padding around the subject's head. The first five volumes of each f-MRI scan were discarded because of non-steady magnetization, with the remaining 54 volumes used for the analysis.

The f-MRI protocol was a block design with one epoch of the task conditions and the rest condition. Each epoch lasted 24 seconds equivalent to three whole-brain f-MRI volume acquisitions. Data were analyzed with Statistical Parametric Mapping software 2000 (http://www.fil.ion.ucl.ac.uk/spm/). The functional magnetic resonance test was set to eight seconds, with a scan time of three seconds, and a rest time of five seconds between scan. 54 scans were acquired for each test. The scans were realigned and transformed to the standard stereotactic space of Talairach using an EPI template. Data were then smoothed in a spatial domain (full width at half-maxim = 8 x 8 x 8 mm) to improve the signal to noise ratio. After specifying the appropriate design matrix, delayed box-car function as a reference waveform, the condition, slow hemodynamic fluctuation unrelated to the task, and subject effects were

Figure 1. Experimental setup; the subject lies inside the f-MRI device with the EMG sensors on the right hand and the neurostimulation electrodes on the left arm; the visual feedback is provided by an array of mirrors that shows the image of the prosthetic hand inside the f-MRI device



estimated according to a general linear model taking temporal smoothness into account. Global normalization was performed with proportional scaling. To test hypotheses about regionally specific condition effects, the estimates were compared by means of linear contrasts of each rest and task period. The resulting set of voxel values for each contrast constituted a statistical parametric map of the t statistic SPM {t}. For analysis of the each session, voxels and clusters of significant voxels were given a threshold of P < 0.005, not corrected for multiple comparisons.

Experimental Procedure

For the experiment related to the hand movement with biofeedback, we first configured the EMG motion classifier (Katoh et al., 2006; Nishikawa et al., 2000) for the subject, that is; we trained the neural network to match the EMG signals for each participant and its corresponding motion in the robot hand. In particular, for this experiment, we used the fingers flexion/extension motion to grab a sphere using the robot hand.

The subject was requested to grab the sphere as soon as she sees it approached by the prosthetic hand in the image produced by the camera inside the f-MRI room. When grabbing the sphere, the pressure sensors placed on the hand were activated, and its pressure signal translated into the transcutaneous electrical stimulation signal of 44% duty rate to ensure that the test subjects perceived the stimulation while inside during the scan acquisition process. We took three scans sessions, with a month between each scan. During this time, the amputee was requested to practice at home with the same set of hand actions using both the EMG classifier and the transcutaneous stimulation.

Results

For the f-MRI data analysis, we used a value of p=0.005 (spm2), resulting in a threshold value of 2.59. Figure 2 shows the evolution of the cortical reorganization and functional specialization in the amputee's brain, due to the myoelectric prosthesis, along with the application of electrical stimulation.

The amputee subject presented activation of the frontal lobe, for the application of electrical stimulation at 44% on the left arm (healthy arm). The f-MRI analysis shows that the electrical stimulation is not detected on the somatosensory area S1 (Figure 3), but is spread on the parietal lobe, in charge of the somatosensory information processing. The test shows that the test subject presents some cortical reorganization.

For the amputee, when grasping the sphere using the robot hand, the activation in the amputee brain increased along the primary motor cortex (M1) related to the right hand. When asked, this person affirmed that there is still the image of the right hand, which is what she used in order to control the prosthetic hand.

Figure 2. Shows the evolution on the amputees brain after the 3 months training period of using the EMG prosthetic hand with biofeedback; at the beginning of the experiment (left) the activation of the brain was spread, showing little specialization of function; this might be caused by the cortical reorganization on the amputee's brain; after the training period (right), the activation in the brain presents a more function specific activation

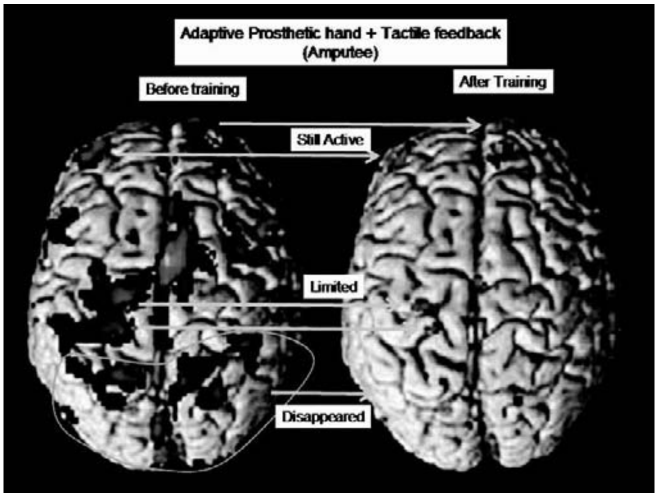


Figure 3. Shows the f-MRI resulting after applying the transcutaneous electrical stimulation on the left arm for the amputee; it is important to notice the activation on the frontal lobe, which identifies the stimulation as new information for the body

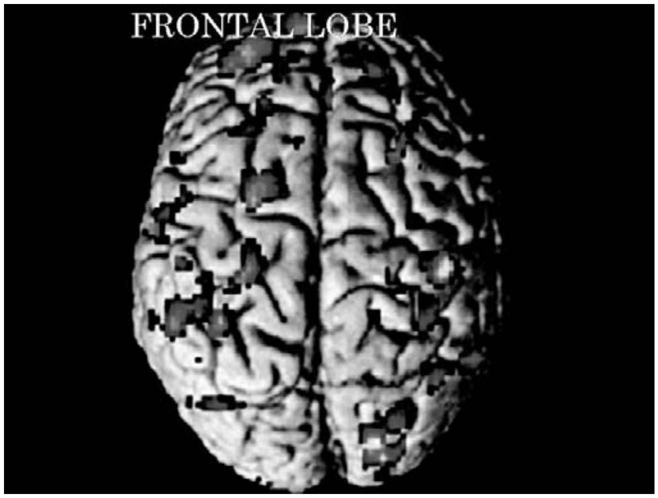

Figure 4 shows an increase in the activation in the primary somatosensory area (S1), principally in the area related to the hand, but also, we see the activation on the area related on the left arm, where the stimulation is actually performed. After the f-MRI scanning, the subjects were questioned on the sensation perceived during the grasping task. The illusion of feeling as if the right hand were touching the object is found in most of the cases.

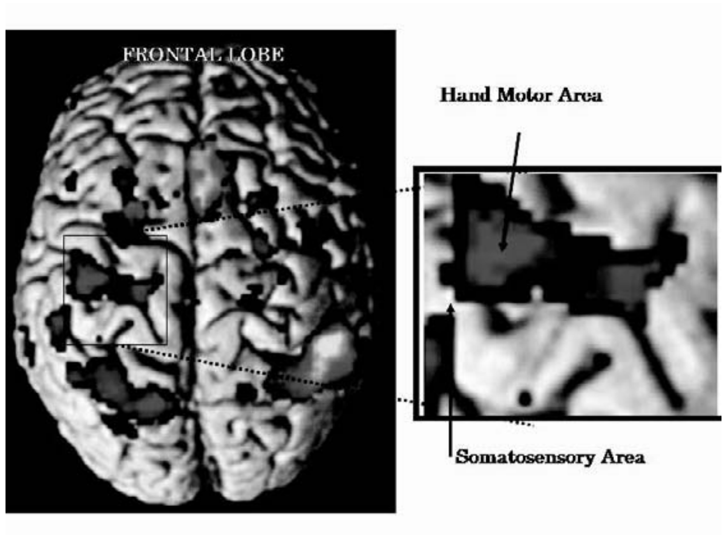
Discussion

Corroborating the findings in neuroscience, the brain does react to the application of electrical stimulation (activation of the frontal lobe), but the activation on the somatosensory region of the left arm is not high enough to appear in the f-MRI image. Therefore, the electrical stimulation alone does not produce an activation of the primary somatosensory area (S1), the area in charge of the processing of sensation in the specific parts of our bodies. When the stimulation is applied in concordance with the action of grabbing an object, we have three channels working altogether: the intention from the subject, the visual feedback, and the stimulus provided by the electrical stimulation. This action is done several times during the scanning process (8 min), which allows the brain to correlate this information as a simultaneous and repetitive event. The f-MRI resulting shows how the brain changes the perception of the electrical stimulation applied on the left arm. Now, the primary somatosensory area (S1) related to the hand presents an activation high enough to be detected in the f-MRI image.

This makes us think that the brain is correlating the multisensorial input as a single event, localizing it in to the right hand (in this case, the prosthetic hand). It is important to notice that the subjects do not interact directly with the object in question, but through the robot hand. They receive only visual feedback through the video display and the stimulation on the left arm.

The application of electrical stimulation does seem to affect the adaptation of the amputee to the use of the prosthetic hand. The application of electrical stimulation as tactile feedback, does allows the body to identify the interaction of the hand with the environment, allowing for a new channel of information to work in benefit of the adaptation to the new “limb.” Also, the results of our experiments over time show the specialization on the activation area in the brain, related to the motor control cortex (MI) and the somatosensory cortex (SI). Another interesting point to discussion is the cross-modality that appears in the brain. In the f-MRI scan, the activation of the somatosensory area is related to the right hand, even though the stimulation is performed on the left arm. This makes us think of a cross-relation in the brain, between the two lobes, allowing adapting the sensory input, and correlating it into a single event. This effect needs to be study with more detail.

Figure 4. Shows the image resulting after the f-MRI scanning for the amputee grabbing a cylinder using the robot hand with electrical stimulation functioning as tactile feedback; the image on the right is the zoom out of the motor and somatosensory area related to the hand and arm; the upper part shows the activation of the motor area in charge of the right hand movement, the lower part shows the reaction from the somatosensory area related to the hand; it is important to notice that the subject does not have the right arm to touch any object



These results show the possibility to use the brain plasticity into the generation of new communication channels with the robotic system. The f-MRI proved a useful tool to measure objectively the changes in the cortical activation, due to the use of the prosthetic system, and allowing a more detailed feedback on the workings of the amputee brain. This allows for a more detailed medical evaluation for the rehabilitation process of an amputee.

The EMG prosthetic hand allows reverting, to some extent, the process of cortical reorganization that occurs when the brain stops receiving the information from the missing limb. This process is even sped up when the use of the EMG prosthetic hand includes feedback to the body. Our experiments with an amputee shows that the electrical stimulation allows an easier adaptation to the prosthetic hand, and actually develop the "illusion" that the robot hand is part of his/her own body, due to the activation on the sensory motor cortex in the brain.

FUTURE TRENDS

As these technologies develop, we can expect an increase on the welfare of those who, for some reason, do not enjoy complete health, with devices helping them to do what others just took for granted. The symbiosis between man and machine will help overcome those barriers that avoid persons with some incapacity enjoy a normal life.

CONCLUSION

In the course of these experiments, we confirmed the importance of the simultaneous stimuli needed for the brain to correlate events, in order to identify them as a single event, opening new channels in the man-machine interaction. The f-MRI is a useful tool to measure objectively the changes in the brain for the interaction with the system proposed. Using the knowledge acquired from previous studies in neuroscience on the brain mechanics, we can now have more efficient man-machine interfaces. Along with continuous use and training, the correlation between visual and sensorial stimuli can be improved, strengthening the illusion of "ownership" of, for example, prosthetic devices. In the future work, we expect to continue measuring the development in the sensorial cortex, due to continuous use of the prosthetic hand with sensorial feedback.

ACKNOWLEDGMENT

We appreciate the collaboration of the Dr. Onhishi Takashi from the Department of Radiology of the National Center Hospital for Mental, Nervous, and Muscular Disorders of Japan for their invaluable support for which this study was possible. This research was partially supported for the project RobotCub: Robotic Open-architecture Technology for Cognition, Understanding and Behavior (Project no. 004370), and the Ministry of Education, Science, Sports and Culture, Grant-in-Aid for Scientific Research (B), 2004, No.16360118.

KEY TERMS

Cortical Reorganization: Process believed to occur after a limb amputation due to the lack of stimuli from usual channels. Cause of phantom limbs and phantom pain.

Duty Rate: In electronics is the percentage of time where an square signal presents "On" state.

Electromyography (EMG): A medical technique for evaluating and recording properties of muscles at rest and while contracting. EMG is performed using an instrument called electromyograph, to produce a record called electromyogram. An electromyography detects the electrical potential generated by muscle cells when these cells contract, and also when the cell are at rest.

Echo-Planar Imaging(EPI): MRI Protocol developed by Peter Mansfield to increase the collection speed for T2* weighted images.

Epoch: A reference date. An instant of origin chosen as the date from which time is measured in a computer system.

f-MRI: Functional MRI (fMRI) measures signal changes in the brain that are due to changing neural activity, by a mechanism referred to as BOLD (blood-oxygen-level dependent) effect. Increased neural activity causes an increased demand for oxygen, and the vascular system actually overcompensates for this, increasing the amount of oxygenated hemoglobin (haemoglobin) relative to deoxygenated hemoglobin. Because deoxygenated hemoglobin attenuates the MR signal, the vascular response leads to a signal increase that is related to the neural activity.

Frontal Lobe: Located at the front of each cerebral hemisphere, frontal lobes are positioned in front of the parietal lobes.

Hemodynamic: Literally "blood dynamics," or hemorheology, is the study if the properties and flow of blood. The study of hemodynamics with regard to neural function (the hemodynamic response) is the basis for functional magnetic resonance imaging.

Myoelectric: Also called a motor action potential, is an electrical impulse that produces contraction of muscle fibers in the body. The term is most often used in reference to skeletal muscles that control voluntary movements. Myolectric signals have frequencies ranging from a few Hertz too about 300Hz, and voltages ranging from approximately 10 microvolts to 1 milivolt.

Primary Motor Cortex (M1): Works in association with pre-motor areas to plan an execute movements. M1 contains large neurons known as Betz cells which send long axons down the spinal cord to synapse onto alpha motor neurons which connect to the muscles. Pre-motor areas are involved in planning actions (in concert with the basal ganglia) and refining movements based upon sensory input (this requires the cerebellum).

Primary Somatosensory Area (S1): Brodmann areas 3,1 and 2 comprise the primary somatosensory cortex of the human brain. This area of cortex, as shown by Wilder Oenfield and others, has the pattern of a homunculus. That is, the legs and trunk fold over the midline; the arms and hands are along the middle of the areas shown here; and the face is near the bottom of the figure.

Proprioception: From latin proprius, meaning "one's own" and perception) is the sense of the relative position of neighboring parts of the body. Proprioception is an interception sense that provides feedback solely on the status of the body internally.

Sensory Substitution: Is the principle to transform characteristics of one sensor modality into stimuli of another sensory modality. It is hoped that systems that base on sensory substitution can help handicapped people restore the ability to perceive certain sensory modality.

Transcutaneous Electrical Nerve Stimulation: More commonly referred as TENS unit and pronounced tens, is an electronic device that produces electrical signals used to stimulate nerves through unbroken skin. The name was coined by Dr. Charles Burton. The unit s usually connected to the skin using two or more electrodes.

Fractal Dimension of the EEG in Alzheimer's Disease

INTRODUCTION

Alzheimer's disease (AD) is the most frequent cause of dementia in western countries, and is characterized by progressive impairments in cognition and memory, whose course lasts several years prior to death (Jeong, 2004). These clinical features are accompanied by histological changes in the brain, which include widespread cortical atrophy, intracellular deposition of neurofibrillary tangles, and extracellular deposition of senile plaques, particularly in the hippocampus and the cerebral cortex. Although a definite diagnosis is only possible by necropsy, a differential diagnosis with other types of dementia and with major depression should be attempted. Magnetic resonance imaging and computerized tomography can be normal in the early stages of AD, but a diffuse cortical atrophy is the main sign in brain scans. Mental status tests are also useful.

The analysis of the electromagnetic brain activity can provide important information to help in the diagnosis of several mental diseases. The electroencephalogram (EEG) has been used as a tool for diagnosing dementias for several decades. The hallmark of EEG abnormalities in AD patients is a shift of the power spectrum to lower frequencies, and a decrease of coherence among cortical areas (Jeong, 2004).

Recent progress in the theory of nonlinear dynamics has provided new methods for the study of the EEG (Jeong, 2004). Nonlinearity is found in the brain even at the cellular level. Given the highly nonlinear nature of the neuronal interactions, the EEG appears to be an appropriate area for nonlinear time series analysis.

BACKGROUND

There are many studies in which the EEG has been studied with nonlinear time series analysis techniques. These investigations have revealed possible medical applications, since analysis based on nonlinear dynamics yields information unavailable from traditional EEG spectral-band analysis (Pritchard, Duke, Coburn, Moore, Tucker, Jann, & Hostetler, 1994). Moreover, they have given rise to the possibility that the underlying mechanisms of the brain function may be explained by nonlinear dynamics (Röschke, Fell, & Beckmann, 1995; Stam, Jelles, Achtereekte, Rombouts, Slaets, & Keunen, 1995). Particularly, several studies have examined the nonlinear dynamics of the EEG in AD. It has been found that AD patients have lower correlation dimension (D_2) values—a measure of dimensional complexity of the underlying system—than control subjects (Jeong, Chae, Kim, & Han, 2001; Jeong, Kim, & Han, 1998; Pritchard et al., 1994; Stam et al., 1995). The first Lyapunov exponent ($L1$) has also been used to characterize nonlinear behavior. AD patients have significantly lower $L1$ values than controls in almost all EEG channels (Jeong et al., 1998; Jeong et al., 2001a). However, the amount of data required for meaningful results in the computation of D_2 and $L1$ is beyond the experimental possibilities for physiological data (Eckmann & Ruelle, 1992). Thus, different nonlinear techniques are needed to study the EEG background activity.

Mutual information analysis (Jeong, Gore, & Peterson, 2001) has been used to assess information transmission between different cortical areas in AD. Furthermore, some studies have confirmed the decrease of EEG complexity in AD with suitable nonlinear techniques like Lempel-Ziv's complexity (Abásolo, Hornero, Gómez, García, & López, 2006) or multiscale entropy (Escudero, Abásolo, Hornero, Espino, & López, 2006).

As it can be noted, very different nonlinear analysis techniques have been proposed to analyze the EEG background activity in AD patients, although some of them are not suitable to study biomedical signals. In this study, we have evaluated the usefulness of the fractal dimension (*FD*) to characterize the AD patients' EEG background complexity.

FRACTAL DIMENSION OF THE EEG BACKGROUND ACTIVITY

EEG Recording

Ten patients (four men and six women; age = 74.80 ± 3.94 years, mean ± standard deviation (SD)) fulfilling the criteria of probable AD were recruited from the Alzheimer's Patients' Relatives Association of Valladolid (AFAVA) and referred to the University Hospital of Valladolid (Spain), where the EEG was recorded. All of them had undergone a thorough clinical evaluation that included clinical history, physical and neurological examinations, brain scans, and a Mini-Mental State Examination (MMSE), generally accepted as a quick and simple way to evaluate cognitive function (Folstein, Folstein, & McHugh, 1975). The mean MMSE score for the patients was 13.1 ± 5.9 (Mean ± SD).

The control group consisted of 10 age-matched, elderly control subjects without past or present neurological disorders (six men and four women; age = 73.10 ± 6.37 years, mean ± SD). The MMSE score value for all control subjects was 30. All control subjects and all caregivers of the patients gave their informed consent for participation in the current study, which was approved by the local ethics committee.

More than five minutes of data from the 19 scalp loci of the international 10-20 system (electrodes Fp1, Fp2, F3, F4, C3, C4, P3, P4, O1, O2, F7, F8, T3, T4, T5, T6, Fz, Cz, and Pz) were recorded from each subject using a Profile Study Room 2.3.411 EEG equipment (Oxford Instruments). Sample frequency was 256 Hz, with a 12-bit A-to-D precision. Recordings were made with subjects in a relaxed state, and under the eyes-closed condition, to obtain as many artifact-free EEG data as possible. All EEGs were visually inspected by a specialist physician, and only EEG data free from electrooculographic and movement artifacts, and with minimal electromyographic (EMG) activity were selected. EEGs were organized in five-second artifact-free epochs (1280 points). Furthermore, prior to the *FD* analysis, all recordings were digitally filtered with a band-pass filter with cut-off frequencies at 0.5 Hz and at 40 Hz to remove residual EMG activity.

Fractal Dimension

Fractal geometry is a new language used to describe, model, and analyze complex forms or curves found in nature. Whereas Euclidean shapes have one, or at most a few, characteristic sizes or length scales, fractals, like a coastline, possess no characteristic sizes, and are said to be self-similar and independent of scaling (Accardo, Affinito, Carrozzi, & Bouquet, 1997). A fractal curve in an n-dimensional space has topological dimension n, and a noninteger or fractional dimension called fractal dimension (*FD*). It also possesses the characteristic that each portion of it can be considered a reduced-scale image of the whole for all time scales. If the scaling factor is the same for all time scales, then the curve is said to be self-similar. Many algorithms developed to estimate the *FD* are based on the assumption of self-similarity and independence of scaling (Esteller, Vachtsevanos, Echauz, & Litt, 1999).

FD can be considered a relative measure of signal complexity (Accardo et al., 1997; Katz, 1988). It provides an alternative technique for assessing signal complexity in the time domain, as opposed to the embedding method of assessing this complexity by reconstructing the attractor in the multidimensional phase space, something that is a notable advantage over traditional chaotic techniques, such as D_2 (Accardo et al., 1997). Furthermore, *FD* can characterize different pathophysiological conditions, and it has been particularly useful in the analysis of EEG to characterize neurophysiological states (Esteller et al., 1999; Henderson, Ifeachor, Hudson, Goh, Outram, Wimalaratna, Del Percio, & Vecchio, 2006).

The *FD* also has the advantage of data volume reduction. It is calculated over time in an overlapping sliding window, which greatly reduces the number of data points stored. The exact amount of data depends upon the sliding window size, and on the overlap used for the analysis.

We have estimated the *FD* with Katz's algorithm (Katz, 1988):

$$FD = \frac{\log_{10}(L)}{\log_{10}(d)} \quad (1)$$

L is the length of the curve—the analyzed signal—and *d* its diameter. The length *L* of a signal $x(t) = \{x(0), x(1), ..., x(n)\}$ can be obtained as the sum of the distances between consecutive points:

$$L = \sum_{k=1}^{n} abs\left[x(k-1) - x(k)\right] \quad (2)$$

The diameter *d* is estimated as the distance between the first point of the sequence and the point that provides the farthest distance (Esteller et al., 1999):

$$d = \max\left\{dist\left[x(i), x(0)\right]\right\} \quad (3)$$

The *FD* compares the actual number of units that compose a curve with the minimum number of units required to reproduce a pattern of the same spatial extent. *FD*s computed in this fashion depend on the measurement units used (Esteller et al., 1999). Katz's approach solves this problem by creating a general unit: the average step or average distance between successive points *a*. Normalizing distances in Equation 1 by this average results in:

$$FD = \frac{\log_{10}\left(L/a\right)}{\log_{10}\left(d/a\right)} \quad (4)$$

If we define *n* as the number of steps in the curve, then $L = n \cdot a$, and we can obtain *FD* as:

$$FD = \frac{\log_{10}(n)}{\log_{10}\left(\frac{d}{L}\cdot n\right)} = \frac{\log_{10}(n)}{\log_{10}\left(d/L\right) + \log_{10}(n)} \quad (5)$$

Statistical Analysis

Student's *t*-test was used to evaluate the statistical differences between the *FD* values for AD patients and control subjects. Differences were considered statistically significant if the *p* value was lower than 0.01.

The ability to discriminate AD patients from control subjects at the electrodes where $p < 0.01$ was evaluated using Receiver Operating Characteristic (ROC) curves (Zweig & Campbell, 1993). We define the sensitivity as the rate of patients with a diagnosis of AD who test positive (true positive rate), whereas the specificity represents the fraction of controls correctly recognized (true negative rate). Accuracy is a related parameter that quantifies the total number of subjects precisely classified. The optimum threshold is the cut-off point in which the highest accuracy (minimal false negative and false positive results) is obtained. In addition, leave-one-out cross validation was used to prevent problems like over-fitting and bias.

Results

To estimate *FD*, we defined an overlapping sliding window. We evaluated the *FD* of each EEG epoch with windows of 256 samples (1 s) and a sliding of 64 samples (250 ms, hence an overlap of 750 ms between consecutive windows). For each window, we obtained a *FD* value. In order to obtain a single value for each subject and electrode, the *FD* results were averaged.

FD was estimated for channels Fp1, Fp2, F3, F4, C3, C4, P3, P4, O1, O2, F7, F8, T3, T4, T5, and T6. The *FD* values (Mean ± SD) for the AD patients and control subjects, and the *p* values of the Student's *t*-tests performed to examine the differences between both groups are summarized in Table 1. As it can be seen, AD patients had lower *FD* values than control subjects at all electrodes, with significant differences between both groups at electrodes T5, P3, P4, O1, and O2 ($p < 0.01$).

Table 1. Average FD values of the EEGs for the AD patients and control subjects for all channels. Significant group differences are marked with an asterisk.

Electrode	Control subjects (Mean ± SD)	**AD** patients (Mean ± SD)	*p*-value
F3	2.1313 ± 0.1334	2.0052 ± 0.0856	0.0215

P3*	2.1675 ± 0.1191	1.9225 ± 0.1508	0.0008
P4*	2.1838 ± 0.1230	1.9489 ± 0.1543	0.0014
O1*	2.2744 ± 0.1749	2.0035 ± 0.1696	0.0025
O2*	2.2490 ± 0.1865	1.9968 ± 0.1826	0.0068

Finally, we evaluated the ability of the *FD* to discriminate AD patients from control subjects at the electrodes, where significant differences were found using ROC plots and a leave-one-out cross-validation procedure. This technique works by training the models using all available data except for data from one subject; this excluded set is then used to test the performance of the models. The sensitivity, specificity, accuracy, and average optimum thresholds values (*FD* values) obtained are shown in Table II. It can be seen that the accuracy was higher than 75% in 4 of the 5 electrodes, where significant differences between the *FD* values of both groups were found, with a maximum value of 85% at P4. Specificity was 80% at the parietal and occipital electrodes, while sensitivity was 70% at P3, O1, and O2, and 90% at P4. It should be noted that the accuracy was especially poor at T5 (50%).

Discussion

In this pilot study, we analyzed the EEG background activity of 10 control subjects and 10 patients with AD, applying *FD*. *FD* is a nonlinear technique that estimates the complexity of a signal, with increasing values corresponding to increasing complexity. Our results show that *FD* of AD patients' EEG is lower than in control subjects, with significant differences between both groups at electrodes T5, P3, P4, O1, and O2 ($p < 0.01$). These results suggest that the EEG background activity of AD patients is less complex than in a normal brain in the parietal, occipital, and back left temporal regions. The decrease of complexity in AD found with *FD* is in agreement with other studies where the EEG complexity in AD patients was estimated with D_2 (Besthorn, Zerfass, Geiger-Kabisch, Sattel, Daniel, Schreiter-Gasser, & Förstl, 1997; Jeong et al., 2001a; Pritchard et al., 1994; Stam et al., 1995). However, *FD* does not require a large number of samples to be correctly estimated (Accardo et al., 1997). Moreover, the computational cost of estimating *FD* is much lower than in other classical nonlinear techniques derived from chaos theory, given the fact that the reconstruction of the signal attractor in the phase space is not necessary (Accardo et al., 1997). The reduction of complexity in the EEG of AD patients could be explained by a decrease of dynamical complexity of part of the brain. However, the pathophysiological implications of this decrease of EEG complexity are not clear. Among others, three

Table 2. Average sensitivity, specificity and accuracy values obtained with ROC curves and a leave-one-out cross-validation procedure; the average optimum threshold (FD value) that provides these values is also included.

Electrode	Threshold (mean±SD)	Sensitivity (%)	Specificity (%)	Accuracy (%)
T5	2.0876 ± 0.0738	50	50	50
P3	2.0486 ± 0.0274	70	80	75
P4	2.0818 ± 0.0018	90	80	85
O1	2.0567 ± 0.0265	70	80	75
O2	2.0755 ± 0.0047	70	80	75

mechanisms can be responsible for it: neuronal death, a general effect of neurotransmitter deficiency, and loss of connectivity of local neural networks as a result of nerve cell death (Jeong, 2004).

We evaluated the diagnostic accuracy of *FD* with ROC curves and a leave-one-out cross-validation procedure, obtaining accuracy values over 75% for the parietal and occipital electrodes, with a maximum value of 85% at P4. Good accuracies have been reported when classifying AD patients and control subjects with nonlinear techniques. D_2 correctly classified AD patients and controls with an accuracy of 70% (Besthorn et al., 1997). Moreover, the addition of D_2 and a neural net classification procedure to linear methods improved the classification accuracy of AD up to 92% (Pritchard et al., 1994). Furthermore, we obtained accuracies between 72.72% and 90.91% with sample entropy (Abásolo, Hornero, Espino, Álvarez, & Poza, 2006), Lempel-Ziv's complexity (Abásolo et al., 2006b), or multiscale entropy (Escudero et al., 2006) with a set of patients similar to the one considered in this study, but without a leave-one-out cross-validation procedure. Finally, it has been recently reported that an appropriate *FD* measure could achieve 67% sensitivity to probable AD with a specificity of 99.9% (Henderson et al., 2006). However, the comparison of results is not straightforward, due to the different sets of patients and control subjects studied.

Certain limitations of our study merit attention. Firstly, the sample size was small. Hence, to prove the usefulness of *FD* as a diagnostic tool, this approach should be extended on a much larger patient population before any conclusion can be made of its clinical diagnostic value. Moreover, the detected decrease of EEG complexity is not specific to AD. It appears in several physiological and pathological states, including anesthesia (Zhang & Roy, 2001), vascular dementia (Jeong et al., 2001a), schizophrenia (Röschke et al., 1995), and Parkinson's disease (Stam et al., 1995). Thus, although *FD* might be a helpful tool for recognition of AD, further work must be carried out to examine nonlinear EEG activity in other types of dementia.

FUTURE TRENDS

In the last years, nonlinear analysis has been used to study the EEG background activity in AD patients. The use of nonlinear analysis techniques has offered valuable information on cortical dynamics. In fact, nonlinear dynamics suggest that AD can be a dynamical disease characterized by changes in the qualitative dynamics of physiological processes. However, in order to diagnose AD accurately, a large pool of sample data for autopsy-confirmed AD patients, and the age- and sex-matched healthy controls, and other patient groups, are needed to compare their nonlinear measures with the algorithm and the parameters fixed (Jeong, 2004).

Furthermore, the improvement of the accuracy of differential diagnosis and early detection of AD based on multimodal approaches (i.e., the combination of EEG with other structural and functional neuroimaging methods), drug effects on the EEG dynamics in AD and the association of nonlinear dynamics and cognitive performance in AD should be investigated.

CONCLUSION

Although nonlinear EEG analysis cannot yet be applied as a diagnostic tool, our findings show the possibility to analyze the dynamical behavior of the brain in AD patients, and to detect significant differences with *FD*. Our experimental results prove the potential applications of this nonlinear analysis technique in reflecting differences in the complexity of EEG data time series of patients with a diagnosis of AD and control subjects. The decrease of the EEG *FD* found in the parietal, occipital, and left temporal posterior regions in AD patients leads us to think that EEG analysis with *FD* could be a useful tool to increase our insight into brain dysfunction in this disease.

KEY TERMS

Alzheimer's Disease (AD): A neurodegenerative disease characterized by progressive cognitive deterioration, together with declining activities of daily living and neuropsychiatric symptoms or behavioral changes.

Attractor: In dynamical systems, a set to which the system evolves after a long enough time, after transients have died out.

Correlation Dimension (D_2): A measure of the complexity of a nonlinear system. It characterizes the distribution of points of the attractor in the phase space.

Electroencephalogram (EEG): Neurophysiologic recording of electrical brain activity by positioning electrodes generally on the scalp.

Fractal: A self-similar structure whose geometrical and topographical features are recapitulated in miniature on finer and finer scales.

Fractal Dimension (*FD*): Statistical quantity that gives an indication of how completely a fractal appears to fill space. It can be considered a measure of signal complexity.

Nonlinear Analysis Techniques: Mathematical techniques to analyze nonlinear systems, whose behavior is not expressible as a sum of the behaviors of its descriptors, or signals whose behavior is nonlinear.

Receiver Operating Characteristic (ROC) Curve: A graphical plot of the sensitivity vs. (1–specificity) for a classifier system, as its discrimination threshold is varied.

A Framework for Information Processing in the Diagnosis of Sleep Apnea

Udantha R. Abeyratne
University of Queensland, Australia

INTRODUCTION

Obstructive sleep apnea (OSA) is one of the most common sleep disorders. It is characterized by repetitive obstruction of the upper airways during sleep. The frequency of such events can range up to hundreds of events per sleep-hour. Full closure of the airways is termed *apnea,* and a partial closure is known as *hypopnea*. The number of apnea/hypopnea events per hour is known as the AHI-index, and is used by clinical community as a measure of the severity of OSA.

OSA, when untreated, presents as a major public health concern throughout the world. OSA patients use *health facilities at twice the average rate* (Delaive, Roos, Manfreda, & Kryger, 1998), causing huge pressures on national healthcare systems. OSA is associated with serious complications such as cardiovascular disease, stroke, (Barber & Quan, 2002; Kryger, 2000,), and sexual impotence. It also causes cognitive deficiencies, low IQ in children, fatigue, and accidents. Australian Sleep Association reported (ASA, 1999) that in the state of New South Wales alone 11,000–43,000 traffic accidents per year were attributable to untreated-OSA.

OSA is a highly prevalent disease in the society. An estimated 9% of the women and 24% of the men in the U.S. population of 30 to 60 years was found to be having at least mild OSA (Young, Evans, Finn, & Palta, 1997). In Singapore, about 15% of the *total population* has been estimated to be at risk (Puvanendran & Goh, 1999). In a recent study in India (Udwadia, Doshi, Lonkar, & Singh, 2004), 19.5% of people coming for routine health checks were found to have at least mild OSA.

The full clinical significance of OSA has only recently been understood. Partly as a result of this, the public awareness of the disease is severely lacking. Healthcare systems around the world are largely unprepared to cater to the massive number of OSA patients. This problem is especially severe in the developing world, where OSA diagnostic facilities are rare to find.

BACKGROUND

Definition of Sleep Apnea and Hypopnea

Sleep apnea refers to a cessation of breathing at night, usually temporary in nature. The American Academy of Sleep Medicine Task Force formally defines *apnea* as:

a. Cessation of airflow for a duration ≥10s, or
b. Cessation of airflow for a duration < 10s (for at least one respiratory cycle) with an accompanying drop in blood oxygen saturation by at least 3%.

Hypopnea is defined as a clear decrease (≥50%) in amplitude from base line of a valid measure of breathing (eg., airflow, air pressure) during sleep for a duration ≥10s, *plus* either:

a. An oxygen desaturation of ≥3%, or
b. An EEG-arousal (EEGA) (Flemons & Buysse, 1999).

The average number of obstructive sleep apnea and hypopnea events per hour of sleep, as computed over the total sleep period, is defined as the *Apnea Hypopnea Index (AHI).*

The Current Standards in Apnea/Hypopnea Diagnosis

The current standard of diagnosis of OSA is Polysomnography (PSG). Routine PSG requires that the patients sleep for a night in a hospital *Sleep Laboratory*, under video observation. In a typical PSG session, signals/parameters such as ECG, EEG, EMG, EOG, nasal/oral airflow, respiratory effort, body positions, body movements, and the blood oxygen saturation are carefully monitored. Altogether, a PSG test involves over 15 channels of measurements *requiring physical contact* with the patient.

Drawbacks of PSG and Possible Improvements

At present, the hospital-based PSG test is the definitive method of diagnosis of the disease. However, it has the following drawbacks, particularly when employment as a community-screening tool is considered:

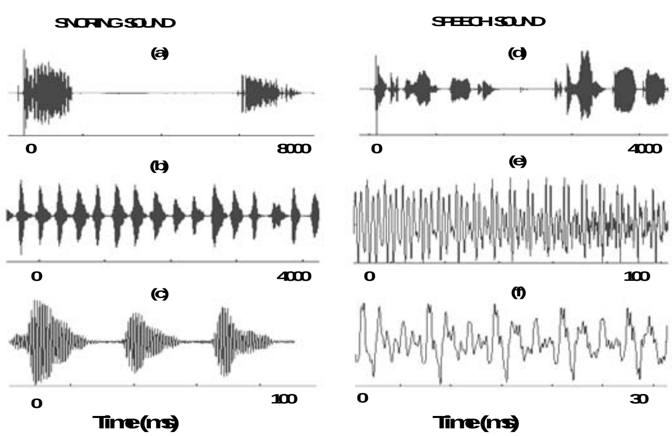
1. *Poor data integrity is a common problem* in routine PSG tests. Even when the test is done in the hospital, it is common to see cases of data loss (or quality deterioration), due to various reasons (eg., improper sensor contact due to electrodes/sensors coming loose, SpO2 sensor falling off, and measurement problems, such as movement artifacts).
2. *PSG interpretation is a tedious task,* due to the size of the data gathered, complexity of the signals, and measurement problems such as data loss.
3. *PSG requires contact instrumentation*; channels such as EEG/ECG/EOG/EMG require Galvanic contact with the patient. It is especially unsuited for pediatric use.
4. *PSG is not suitable for mass screening* of the population. A trained medical technician is required to connect the patient to the PSG equipment, and the patient needs to be monitored overnight to avoid incurring data losses.
5. *PSG is expensive;* this is another factor working against mass screening uses.
6. *AHI index* (and a variant of it known as the respiratory disturbance index, RDI) is used as the golden clinical measure on the severity of apnea. However, AHI (or RDI) does not always correlate strongly with the symptoms of apnea as experienced by patients.

There is an enormous clinical need for a simplified diagnostic instrument capable of convenient and reliable diagnosis/screening of OSA at a home setting (Flemons, 2003). Similarly, hospital-based, full PSG testing requires better measures to characterize the disease. This article explores possible solutions to both of these problems.

There has been a flurry of recent activities at developing technology to address the issue of home screening of OSA. Four different classes of OSA monitors are under development (Flemons, 2003, and references therein). These devices varied from two-channel (eg., airflow and oximetry) systems (designated Type-IV), to miniaturized full-PSG (Type-I) units. Their major drawbacks are:

- Existing take-home devices have *at least* one sensor which requires physical contact. This makes them difficult to use by untrained persons, and cumbersome to use on pediatric populations. TYPE-IV systems, with the smallest number of sensors, suffers from the fact that oxymetry identifies oxygen saturation in blood only as a surrogate for OSA, and the absence of significant desaturation does not mean the absence of the disease (Flemons, 2003).

Figure 1. Similarities and differences between speech and snoring: (a),(b),(c) snoring at different time scales; (d),(e),(f) speech at different time scales



- Presence of a medical technologist is still required, if acceptable sensitivity/specificity performance is required. High rates of data loss (up to 20% loss at home compared with 5% at sleep lab) (Flemons, 2003) (nine) have been reported when a medical technologist is not in attendance. Unattended systems have not led to high enough sensitivity/specificity levels to be used in a routine home monitoring exercise (Flemons, 2003; Portier, 2000).
- Type-I and II devices use channel counts from 7–18 and are difficult to use by an untrained person. The quality and the loss of data is a serious problem.

In this article, we present an instrumentation and signal processing framework addressing current problems in OSA diagnosis.

METHODS

A Framework for the Noncontact Diagnosis of OSA

Snoring almost always accompanies OSA, and is universally recognized as its earliest symptom (Hoffstein, 2000; Kryger, 2000; Puvanendran & Goh, 1999). Logic dictates that it should be providing us with the earliest opportunity to diagnose the disease. At present, however, quantitative analysis of snore sounds is not a practice in OSA detection. The vast potential of using snoring in the noninvasive diagnosis of OSA remains unused.

In this article, we argue that the human speech and snore sounds share many similarities (see Figure 1), and biological "wetware" used for the generation processes. The upper airway acts as an acoustic filter during the production of snoring sounds, just as the vocal tract does in the case of speech sounds. Episodes of OSA, by definition, are associated with partial or full collapse of upper airways. As such, changes to the upper airways brought about by this collapse should be embedded in snoring signals.

Figure 2 shows a typical snore sound recorded from a patient undergoing routine PSG testing at the sleep diagnostic laboratory. The data acquisition system used a sampling rate of 44.1k samples/s, and a bit resolution of 16bits/sample. The system had a 3dB bandwidth of 20.8kHz. A typical hospital based routine PSG test runs for up to eight hours, and it is quite common to observe up to 8,000 events of snores within a recorded sound data.

Snore Sounds: A Working Definition

One of the major problems towards automation is that *there is no objective definition* of what a "snore" is (Hoffstein, 2000). Recently, we proposed (Abeyratne, Wakwella, & Hukins, 2005) an objective definition for "snoring" *independent of the sound intensity*. It is based on the observation that sounds perceived as "snores" by humans are characterized by repetitive packets of energy that are responsible for creating the vibratory sound peculiar to snores (Figure 2, bottom). We call the distance between such packets as the "*pitch*" of snoring. A snoring episode (SE) will consist of a segment with pitch ("voiced-segment"), and possibly "silence" and segments without pitch ("unvoiced segment"). An inspiration-expiration cycle without any segment associated with a pitch is termed as a pure breathing episode (PB).

Mathematical Framework for Sound Analysis

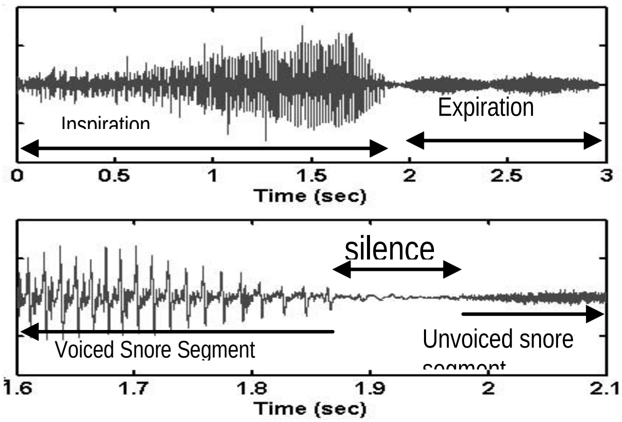
Snoring originates from acoustical energy released by the vibratory motions of upper airway site(s) during sleep. The airway cavity acts as an acoustical filter, and modifies the source sounds to produce snoring sounds we hear. Inspired by the source/vocal-tract system for human speech synthesis, we model a block of recorded sound *s(n)* as a convolution between: (i) "source signal *x(n)*" representing the source acoustical energy, and (ii) "Total Airway Response (TAR) *h(n)*," which captures the acoustical features of the upper airways as given by:

$$s(n) = h(n) * x(n) + b(n) \qquad (1)$$

The symbol *b(n)* denotes background activities, x(n) is the source excitation, "*" denotes convolution, and *h(n)* is the *TAR* function. The term *b(n)* is due to a range of independent reasons and hence considered a Gaussian distribution independent of *x(n)*.

The nature of *x(n)* depends on the nature of the sound segment under consideration. For the case of a segment without any pitch (i.e, either a PB or unvoiced-snoring segment), we model the source excitation, *x(n)* as

Figure 2. (Top) A snore episode (SE); (bottom) different segments in SE



a white random process. The *x(n)* for *voiced snoring segments* is modeled by a pseudo-periodic pulse-train, drawing from techniques used in speech analysis.

The *TAR* function *h(n)* is modeled in this article as a *mixed-phase system* considering that in OSA, multiple-source locations with temporal relations between eachother can be found, and thus, phase-information cannot be neglected in general.

It is our hypothesis that the state of the upper airways can be characterized by the pair $\zeta = \{g\{x(n)\}, f\{h(n)\}\}$, where *g* and *f* represent the operation of extracting features out of the *x(n)* and *h(n)*.

We developed a snore segmentation algorithm (Abeyratne et al., 2005), which takes in full night sound data, and separates into snoring and pure-breathing episodes. It then further divides snore episodes into sub-categories "voiced," "unvoiced," and "silence" sections. The category "voiced" will then be further analyzed to estimate the pitch associated with each segment.

Consider an arbitrary *j*-th Snoring Episode (SE) in the sound recordings. Divide the voiced segment $s_{sv,j}$ of the *j*-th Snoring Episode into L_j number of data blocks $\{B_{jk}\}$, $k = 1\ldots L_j$, each of length *N*. Thus, at the output of the pitch-detector, each data block in the set $\{B_{jk}\}$ is associated with a pitch period μ_{jk}. We term the series $\{\mu_{jk}\}$, k=1,2, .., L_j as the *Intra-snore Pitch Series* for the *j*-th Snoring Episode.

We consider the structure of the *Intra-snore Pitch Series*, and show that it is characterized by discontinuities, which can be used in the diagnosis of OSA. We propose a new measure called *ISPJ-Probability* to capture intra-snore jumps in pitch, via *Definition-1* and *Definition-2* given below:

- ***Definition-I:*** Suppose that in the *j*-th arbitrary snoring episode $s_{sv,j}$ there are at least q ($< N_j + 1$) data blocks in the set $\{B_{jk}\}$, $k = 1\ldots N_j$ with pitch periods μ_{jk} greater than a pitch threshold γ. Then the entire Snoring Episode *j* is labeled as having the feature ISPJ at level (q, γ). We call the quantity q as the "jump multiplicity."
- ***Definition II:*** Define a quantity ISPJ-probability $Pq\gamma(r_D)$ at level (q, γ) for the signal s(n) of a length D as: $Pq\gamma(r_D) = 100\ n_{q\gamma}(r_D)/r_D\%$, where r_D is the total number of snore episodes contained within the data of length D. The quantity $n_{q\gamma}(r_D)$ is the number of episodes within D that were labeled as having the feature ISPJ according to Definition-I.

The snore sound based *test statistic* proposed in this article is $Pq\gamma(r_D)$, with the corresponding decision threshold symbolized by P_{th}. If $Pq\gamma(r_D) > P_{th}$, the *snore-based test* is positive for OSA, and vice versa.

For each subject in the database, a set **S** of *ISPJ-Probabilities* is defined by:

$$S = \{Pq\gamma(r_D) \mid q = 1,2,3 \text{ and } \gamma = 10,11, \ldots 25\text{ms}\} \tag{3}$$

where $Pq\gamma(r_D)$ is calculated via (2). We use S to derive ROC curves of $Pq\gamma(r_D)$ at different *ISPJ* levels (*q*, γ).

To draw Receiver Operating Characteristics (ROC curves, Figure 3), we need to know the "*true clinical diagnosis*" of the patients. The PSG based diagnosis is considered the absolute truth in this article. The diagnosis based on the test statistic $Pq\gamma(r_D) > P_{th}$ is compared to the "absolute truth," and the nature of the decision is noted as one among (i) true positives (TP), (ii) true negatives (TN), (iii) false positives (FP), or (iv) false negatives (FN). Sensitivity, a measure of success in detecting TPs is defined as: TP/(TP +FN)%.

Specificity, a measure of success in rejecting non-diseased subjects, is defined as TN/(TN +FP)%. The ROC curve is a graph of sensitivity vs. 1-specificity.

The ROC curve (Figure 3) allows us to conclude that snoring carries valuable information on the disease of OSA. The performance of the *ISPJ-probability* indicates the possibility of using the feature to diagnose OSA. Large-database trials are needed for further validation of results.

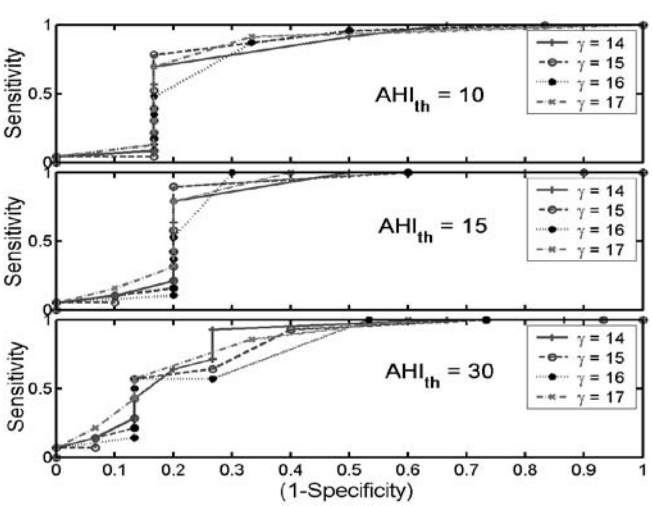
The noncontact nature of the snore acquisition process should provide a significant advantage over competing techniques in developing a community-screening device for OSA. Results obtained in this article have been based on snorers referred to the sleep clinic for suspected OSA. For this reason, the screening utility of the proposed method needs further investigation with healthy snorers who do not display symptoms normally associated with OSA.

The estimation of the TAR, the quantity h(n), can be carried out by using any established technique of blind signal identification (eg., Abeyratne, 1999). This article will not discuss the methodology involved. Interested readers are referred to the article by Karunajeewa (2005).

A Framework for Arousal Analysis in Understanding and Characterizing Sleep Disorders

Electrical activities measured on the scalp, as emanated from the brain, are called EEG signals. EEG is one of the most important signals in overnight PSG recordings. In assessing sleep disorders such as apnea, EEG plays an indispensable role. In the current clinical practice it is being used to study the sleep structure of a patient during sleep, mainly via determining the sleep stages. It is also used to estimate the total sleep time of a patient in computing the AHI and RDI indices.

Figure 3. ROC curves for AHIth =10, 15 and 30 at q=2 and γ = 14−17



In the past, (Deegan & McNicholas, 1995; McNicholas, 1998) researchers have developed various hypotheses and experimental methods to investigate the changes in EEG signal during sleep apnea and hypopnea. Spectral analysis of the EEG has revealed that termination of apnea and hypopnea events are often associated with changes in EEG power in the δ- band of frequency (0.5 – 4Hz) (Dingli & Assimakopoulos, 2002; Svanborg, 1996).

The issue of asymmetry of brain during sleep has been investigated by groups of researchers (Bolduc, 2002; Goldstein & Stoltzfus, 1972; Sekimoto, 2000). Asymmetry studies have been confined to undisturbed sleep in normal individuals. None of these studies considered the significance of apnea/hypopnea on the hemispheric correlations, or how the correlation behaved in the cases of peoples with symptoms of sleep apnea.

Despite the importance of EEG in studying sleep disorders, the main index used to measure the severity of apnea, AHI (or RDI), does not use EEG, except for the total sleep time derived indirectly through EEG. EEG, however, is a high-temporal resolution window to the brain, and contains much more information than what is currently being used in clinical practice. We hypothesize that EEG may provide one avenue to alleviate the important problem mentioned under the Background Section.

Recently, the phenomenon known as the EEG Arousals (EEGA) has received attention as a possible pointer of sleep disorders. EEGA in sleep is defined as an abrupt shift in EEG frequency, lasting for 3s or more. According to the criteria developed by the American Sleep Disorder Association (ASDA), EEGA are markers of sleep disruption and should be treated as detrimental.

Excessive Daytime Sleepiness (EDS) is one of the defining symptoms in OSA patients (Martin, & Wraith, 1997; McNicholas, 1998). The reason for EDS in SDB patients is the modification of sleep texture, due to reoccurring episodes of EEGA causing sleep fragmentation.

In this article, we show that there exists a relationship between the EEGA and information-flow between the left and right hemispheres of the brain, as revealed via the left-right correlation of EEG. This finding may open up a new vista of research in understanding how information flows in the brain during phenomena associated with sleep (eg., EEGA, sleep spindles, and so on) and help with localizing sources of origin of some brain activities. Furthermore, considering the relationship between EEGA and dominant symptoms of OSA (ie., day time sleepiness), we believe a proper understanding of EEG will help in designing a better measure for OSA severity.

Figure 4 shows (Vinayak, 2007) the spectral correlation coefficient computed between EEG signals measured from electrode pairs A1-C4 and A2-C3 (of the International 10/20 electrode system) during an overnight sleep study. In Figure 4, (f) and (g) arousal events and apnea event have been marked to help visualize their relationship with interhemispheric EEG correlation. In Figure 4(a), 4(b), 4(c), and 4(d) correlation coefficients have been computed separately in the δ,θ,α, and β spectral bands of the measured EEG.

Our results showed that apnea/EEG arousal events generally lead to an increase in IHA. This change is most prominent during NREM sleep affected by EEGA, particularly in θ, α, and β frequency bands. Our results strongly suggest that the information flow between the left-right hemispheres of the brain is affected by events of apnea/EEG-arousals (Vinayak, 2007).

FUTURE TRENDS

With the rapidly increasing public awareness of the apnea syndrome, the demand for in-home noncontact methods for screening sleep apnea are expected to rise in the future. Noncontact measurement techniques based on snore (and breathing) sound analysis will, if successful, provide enabling technology for home-monitoring applications.

Once the home-based screening test identifies individuals who should be properly diagnosed, hospital-based PSG testing should be considered. In a hospital-based PSG test, we expect EEG signals to play a pivotal role in the future, in diagnosing sleep apnea. The role of EEG is expected to expand far beyond its current role of sleep-staging (using decades old criteria), making significant inroads into the subject of characterizing apnea. EEG will also help understand the brain mechanisms associated with the processes of sleep and sleep disturbances.

CONCLUSION

In this article, we explored two techniques that addressed a range of difficult problems associated with diagnosing/ screening obstructive sleep apnea. The snore sound-based technique provided a basis for noncontact methods suitable community screening of the disease. Our results indicate that the performance of the feature Intra-Snore-Pitch-Jump Probability (ISPJ-probability) is on par with other competing technologies, in terms of the sensitivity/specificity characteristics. Snore-based diagnosis proposed in this article is superior, in that it does not involve contact instrumentation, thus solving a major problem in population screening of the disease.

We investigated the interhemispheric asymmetry of the brain during apnea and EEG-arousals (EEGA) events. The EEG asymmetry was determined via the Spectral Correlation coefficient of data, which computed the correlation between EEG measured from the two hemispheres of the brain. Results showed that apnea/EEG arousal events generally lead to a decrease in correlation. This change is most prominent during NREM sleep affected by EEGA, particularly in θ, α, and β frequency bands. Our results strongly suggest that the information flow between the left-right hemispheres of the brain is affected by events of apnea/EEG-arousals.

The data used in this article came from: (i) patients medically diagnosed with sleep apnea, and (ii) subjects medically deemed to be without apnea, but nevertheless displaying some symptoms of the disease.

KEY TERMS

β, α, θ and δ EEG Frequency Bands: Bandpass components of EEG signals respectively covering the frequency bands of 18-30 Hz, 8-13Hz, 4-7Hz, and 1-3.5Hz.

EEG Arousals: An abrupt shift in EEG frequencies during sleep which may include α, θ, and/or frequencies <16Hz, excluding structures known as sleep spindles.

International 10/20 Electrode System: A standard placement of electroencephalographic (EEG) electrodes on the scalp to measure signals from the brain.

Oxygen Desaturation: A decrease in the blood oxygen levels often associated with sleep apneas.

Respiratory Disturbance Index (RDI): The number of all respiratory disturbances per hour, averaged over the entire duration of sleep.

Functional Characteristics and Supporting Methods for Maintaining Independent Life of the Elders

Hiromi Nishiguchi
Tokai University, Japan

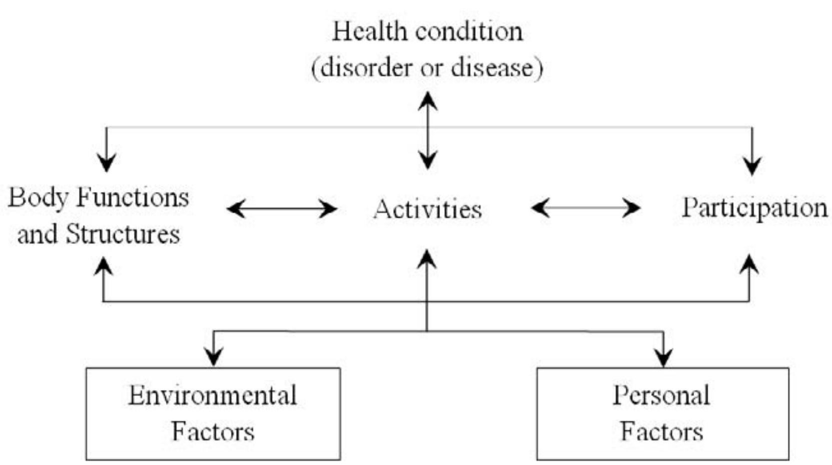
INTRODUCTION

At first, it is necessary to measure physical and intellectual function objectively to support independence of the elders who need care in daily life, and to analyze the reason why the elders cannot move or take action, and why the barrier occurs. An effective use of a survival or substituted function and also the improvement of physical environment, such as housing accommodation in private and public sectors, require removing barriers. In addition, social resources are useful to support independence of the elders in their daily lives. In this chapter, two issues were the focus: functional characteristics that change in accordance with the increase of age, and the methods of removing barriers for elders to move as they like.

BACKGROUND

We take actions with physical and intelligent functions in our daily life, but their functions change as they get old. Some activity limitations or participation limitations will occur when the necessary function for the action declines, as shown in ICF (International Classification of Functioning, Disability and Health) offered by WHO (2001) (cf. Figure 1). Therefore, to support independence of elders who need care in daily life, we must grasp declining status of physical and intellectual functions objectively, and barriers should be removed that cause activity limitations or participation limitations. In addition, an independence of the elders in their community life is feasible by positive utilization of social resources (Nishiguchi, Saito & Ozeki, 1997; 1998).

Figure 1. Interaction between the components of ICF



F

MAIN FOCUS OF THE CHAPTER

Functions of the Elders

How to Grasp Functions of Elders

There are two representative methods to grasp changes of human being functions (cf. Figure 2). One method is the longitudinal survey, which measures functions of one certain elder group as investigation subject. The other is the cross-sectional survey, which is a method to compare functions of different ages.

Change of Physical and Intellectual Functions by Aging

It is generally mentioned that many human being functions change by aging (Charness, 1985). Most physical functions become the highest values at the 20-year-old generation (Nishiguchi, Saito& Ozeki, 1996). On the other hand, it is known that some intellectual function is maintained or raised (Dennis & Tapsfield, 1996). This knowledge was reported by Horn and Cattell (1966), and they classified the intellectual ability into "fluid ability" and "crystallized ability."

Furthermore, Thurstone and Thurstone (1941) proposed that intellectual ability of human beings is composed of "seven ability factors." They are as follows: Memory (M), Number (N), Perception (P), Reasoning (R), Word fluency (W), Space (S), and Verbal comprehension (V).

Cross-Sectional Comparison of Intellectual Ability

The authors made a description-style test to measure the previously mentioned seven ability factors (Nishiguchi & Saito, 2000). This test carried out to two subject groups: one elder group (20 people with an average age of 63.1 years), and a young group (20 people with an average age of 20.9 years).

In this test, four phases of degrees of difficulty (a degree of difficulty rises by order of I→IV) are set for

Figure 2. Cross-sectional and longitudinal survey

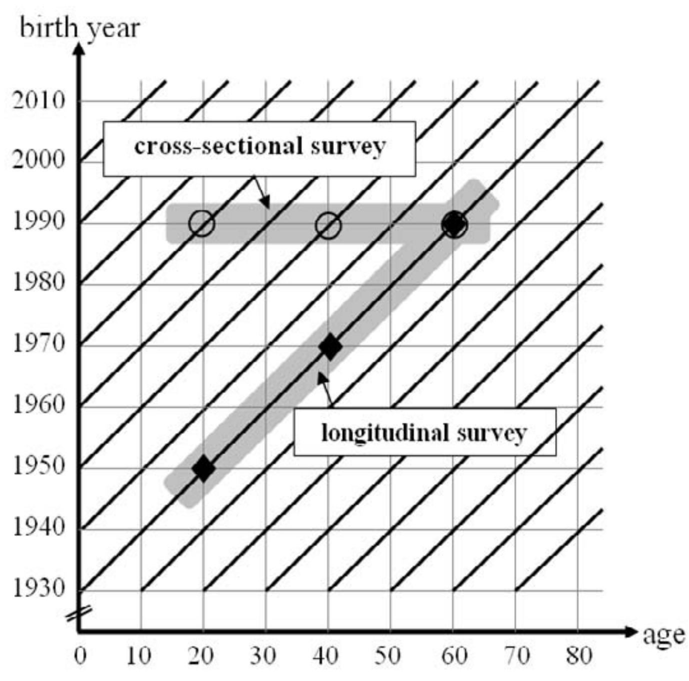


Figure 3. The work performance ratio of the elders group for the youngers

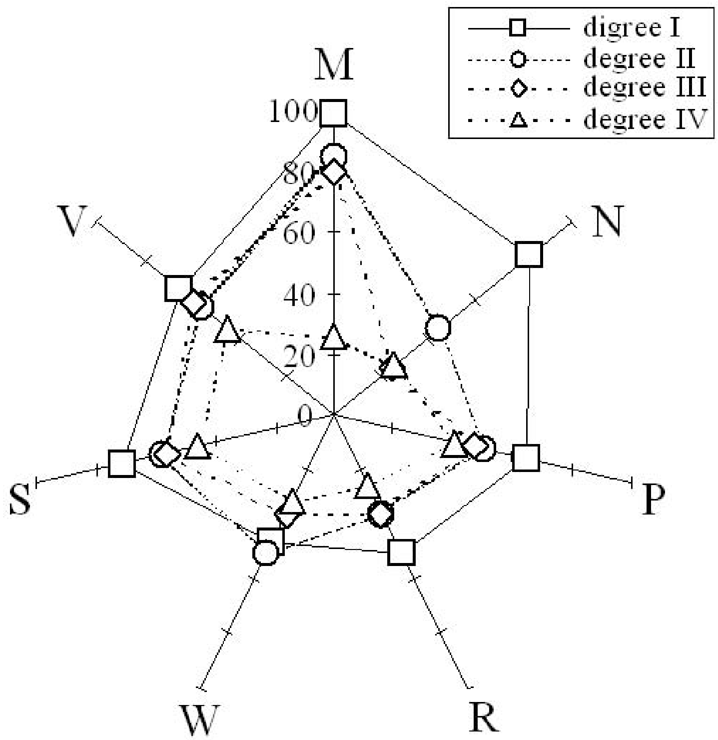


each question. "Work performance" was calculated by the following calculation type.

*work performance(%) = number of correct answers / number of problems * 100*

Figure 3 showed the work performance ratio of the elders group for the young. In two ability factors, ("Memory (M)" and "Number (N)"), the work performance ratio is high, and a difference is not recognized between two groups when a degree of difficulty is low. But the difference between two groups grew bigger as the degrees of difficulty rose. These abilities are "fluid ability," which decline by aging. Furthermore, the elders did not seem to be flexible for a change in difficulty of the tasks comparison with the young.

On the other hand, in Word fluency (W) and Verbal comprehension (V), which are "crystallized abilities," the elders were flexible in changing the difficulty, although they performed lower in comparison with the young.

Activity of Daily Living and Removing Barriers

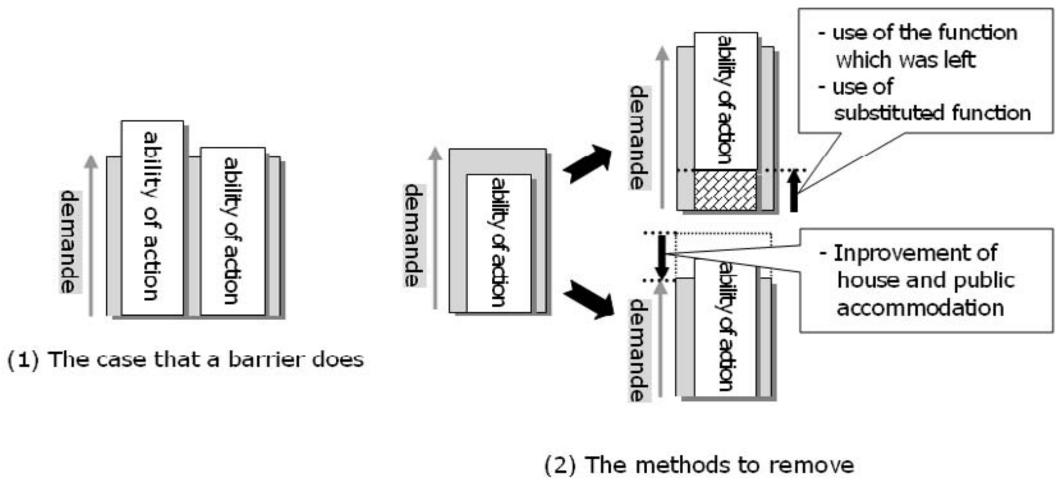
Activity of Daily Living (ADL)

Activity of daily living is the aggregation of movements necessary at the minimum when a human being runs his or her own daily life. ADL consists of seven kinds of body action: lying down or getting up, place movement, eating a meal, excretion, bathing, wearing or taking off clothes, and conditioning a figure. At first, it is necessary to judge whether an elder who needs care can run his or her own daily living to support an independent life. If there is any action that the elders cannot do (i.e., "barrier"), a discussion is necessary to remove their barriers and support them.

Methods to Remove Barriers

In the situation that someone is going to accomplish some actions in everyday life, a barrier occurs when his or her ability does not satisfy the ability required, as shown on the right side as (2) of Figure 4. When a

Figure 4. Methods to remove barriers



survival or substituted function can be used, the barrier will be removed by using some jig or self-help device (Nishiguchi, Saito & Ozeki, 1993), and then, the objective action becomes easy to perform for the elders who need care. In addition, it is effective to apply an architectural barrier-free design to housing and public accommodation.

FUTURE TREND

Institution care or home care is usually provided for the elders who need care in daily life. In that case, it is very effective to utilize "social resources" such as a welfare service providing system, welfare manpower (e.g., a social worker, care worker, local volunteer), welfare technical support (e.g., welfare machinery/tool). Providing higher quality social resources by developing health care networking systems are expected in the future.

CONCLUSION

In this chapter, focus was placed on the changes in functional characteristics by aging and methods of removing barriers in elders' daily lives. Functions of human beings change by aging, but ways of change are different in the two functions. Many physical functions become the highest values at the 20-year-old generation, but some intellectual functions, "crystallized abilities," is maintained, or rather raised. Particularly, when a physical function deteriorates, a daily living activity will become difficult, and barriers will occur. In removing a barrier, it is indispensable to use survival or substituted function and improve living environment. It is of importance that good social resources are provided to the elders and they are able to live independently, based on their own needs and faith in the future (Rouse, 1993).

World Health Organization. (2001). International classification of functioning, disability and health.

KEY TERMS

Activity of Daily Living (ADL). ADL consists of seven kinds of body actions, and there is IADL (Instrumental ADL), which is another classification of activities in daily life. IADL is composed of activities requiring intellectual ability, such as money management, telephone calls, housework (shopping, meal preparation, cleaning).

ICF: ICF was defined by WHO (World Health Organization) in 2001. This classification is the revised version of ICIDH (International Classification of Impairments, Disabilities and Handicaps), which was composed from a viewpoint of disorder. In the ICF model, human behavior was classified into three categories (body functions and structures, activities, and participation).

Independence in Daily Life. Independence in daily life means the condition in which a person with a disorder can live according to his or her own will (influenced by needs and belief).

Seven (Ability) Factors: Details of "seven factors" proposed by Thurstone and Thurstone (1941) are as follows: Memory—the ability to memorize and recall; Number—the ability to solve arithmetic problems; Perception—the ability to see differences and similarities among objects; Reasoning—the ability to find rules; Word fluency—the ability to produce words rapidly; Space—the ability to visualize relationships; and Verbal comprehension—the ability to define and understand words.

Social Resources: In welfare services, social resources are indispensable and have to be easy to use for elders who need care or for their families.

Survival and Substituted Function: A survival function is a function that has been left a little after disease, and it can be used effectively with some jig or self-help device. A substituted function has a supplementary roll for the function with disorder, such as an auditory function in the blind.

Generating Simulated DT-MRI Dataset

Dilek Goksel Duru
Bogazici University, Turkey

Mehmed Ozkan
Bogazici University, Turkey

INTRODUCTION: DIFFUSION TENSOR IMAGING

Diffusion tensor magnetic resonance imaging (DT-MRI), also known as diffusion tensor imaging (DTI), needs post processing by adequate image analysis and visualization tools. White matter tractography using DTI is becoming a routine MR technique to study white matter properties, connectivity, and alterations of fiber integrity due to pathology. The success of the method depends on the accuracy of the tracking algorithms. The disadvantage on the evaluation of such methods is that there is no gold standard regarding the true geometry of the brain anatomy or fiber bundles reconstructed in each particular case.

Considering the increasing number of reports on DTI post-processing research, it is observed that most of the methodology is applied only to real data, acquired from human or animal test subjects. This approach has the following drawbacks: (i) the true anatomy of each imaged subject is not known in detail, (ii) the image noise is of little control, (iii) cost of scanner time is usually high, (iv) the comparison of the methods and the results from different studies is difficult because the data has been acquired on various MR scanner hardware, and often scanned with different imaging protocols, and finally, (v) the test data is collected from different subjects, each having unique characteristics in gross anatomy and tissue micro-architecture. In order to reduce these problems, a synthetic DTI dataset with known geometric and signal properties has been developed.

The accuracy of white matter anatomical maps obtained by DTI is still unclear due to the general inability of the diffusion tensor model describing a single voxel with multiple orientational maxima. Verification and validation of the synthetic data analysis' aims to elucidate the white matter fiber tractography in eliminating the uncertainty areas and understanding the connectivity more clearly and reliable.

A model must describe how water diffuses in the synthetic dataset. For simplicity, we have in this work considered only two very basic models. In this work two separate models with different geometric properties characterized by anisotropic Gaussian diffusion are specified. These models are sampled and their output is similar to those obtained from MR scanners are generated. The efficient calculation of the diffusion tensor is achieved from that output. It is used to generate several common measures and visualizations describing Gaussian water diffusion. The project covers the geometric model, discrimination, sampling, tensor calculation, parameter calculation, and the visualization.

BACKGROUND

DT-MRI Pulse Sequences: Encoding for Diffusion

Diffusion-weighted images are the raw data source used to calculate the diffusion tensor. In DTI, each voxel is assigned a tensor that describes local water diffusion. The relationship between the loss of phase coherence in the transverse spin radio frequency (RF) signal S_0 and S_i, and the gradient pulse $g=[g_{ix}\, g_{iy}\, g_{iz}]^T$ with $\hat{g}_i^T D \hat{g}_i$ the apparent diffusivity along g_i is given by the Stejskal-Tanner equation (Stejskal, 1965):

$$S_i = S_0 e^{-b\hat{g}_i^T D \hat{g}_i} \qquad (1)$$

A Stejskal-Tanner imaging sequence may be implemented by adding diffusion encoding gradients to standard anatomical MRI pulse sequences (Ciccarelli et al., 2003).

By systematically applying diffusion gradients in multiple directions, a mathematical construct known as the diffusion tensor, D, could be estimated at each point in the tissue. The utility of the diffusion tensor is that it provides the direction in three dimensional space in which the rate of diffusion is greatest (Basser, Pajevic, Pierpaoli, Duda, & Al-droubi, 2000; Borisenko & Tarapov, 1979).

Estimation of the Diffusion Tensor

Derivation of structural information follows a measured displacement characteristic related by means of a model to the physical and geometrical properties of the tissue. Diffusion coefficients and shapes of semipermeable membranes of compartments in the system are these related characteristics. The behavior of the MR signal and the measured *apparent diffusion coefficient* (ADC) as anisotropic diffusion indexes are greatly affected by the cellular architecture of a tissue, mainly because cellular membranes are relatively impermeable to water.

The relationship between loss of phase coherence in the transverse spin RF signal and the gradient pulse *g* is given by the Stejskal-Tanner equation (1), where *b* is the diffusion weighting factor (Ciccarelli et al., 2003) given by:

$$b = \gamma^2 \delta^2 \left[\Delta - \left(\frac{\delta}{3}\right) \right] |g|^2 \qquad (2)$$

Here, γ is the gyromagnetic ratio, δ is the gradient pulse width, Δ is the time between the gradient pulses, $|g|$ is the strength of the diffusion gradient pulses.

Basser (Basser, Mattiello, & Le Bihan, 1994), building on the work of Stejskal and Tanner (Stejskal, 1965), has shown that the diffusion tensor can be calculated from knowledge of signal attenuation and magnetic gradient strengths applied during a diffusion weighted spin echo experiment using the following equations;

$$\ln\left(\frac{A(b)}{A(b=0)}\right) = -\sum_{i=1}^{3}\sum_{j=1}^{3} b_{ij} D_{ij} = -\left(b_{xx}D_{xx} + 2b_{xy}D_{xy} + 2b_{xz}D_{xz} + b_{yy}D_{yy} + 2b_{yz}D_{yz} + b_{zz}D_{zz}\right) \qquad (3)$$

$$Trace(D) = D_{xx} + D_{yy} + D_{zz} = 3\langle D \rangle = \lambda_{xx'} + \lambda_{yy'} + \lambda_{zz'} \qquad (4)$$

where *A(b)* is the voxel attenuated signal (echo) intensity recorded in the presence of gradients (3), *A(0)* is the gradient-free, unattenuated echo intensity, D_{ij} is the (symmetric, positive definite, 3 by 3) diffusion tensor (3), and b_{ij} is a matrix specified by the magnetic field gradients applied during the spin echo. In eq. 3:

$$\sum_{i=1}^{3}\sum_{j=1}^{3} b_{ij} D_{ij} \equiv b : D$$

is the standard scalar product of two tensors. This so called *b-matrix* (2, 3) has the form: $A = A_0 e^{(-b:D)}$.

Tensor Analysis and the Diffusion Tensor: PCA

Principal component analysis (PCA) is a classical statistical method widely used in data analysis and compression. PCA is based on the statistical representation of a random variable. The method reduces data dimensionality by performing a covariance analysis between factors. PCA method is based on linear transformations; however, nonlinear extensions exist. PCA is a technique for reducing second-order dependencies in the data by rotating the axes to correspond to orthogonal directions of maximum covariance (decorrelation).

From a symmetric matrix such as the covariance matrix, an orthogonal basis by finding its eigenvalues and eigenvectors can be calculated. The diffusion tensor *D* is a real, symmetric second order tensor, represented in matrix form as a real, symmetric 3x3 matrix (5).

$$D = \begin{bmatrix} D_{xx} & D_{xy} & D_{xz} \\ D_{yx} & D_{yy} & D_{yz} \\ D_{zx} & D_{zy} & D_{zz} \end{bmatrix} \qquad (5)$$

The diagonalization of the positive definite and symmetric diffusion tensor results in a set of three eigenvalues, $\lambda_1, \lambda_2, \lambda_3$, listed in decreasing order. The eigenvectors e_i and the corresponding eigenvalues λ_i are the solutions of the diagonalization of *D* (5), where the eigenvectors e_i are the principal diffusion directions $e_i (i = 1, 2, 3)$. The eigensystem of the diffusion tensor may be interpreted graphically as an ellipsoidal surface with semimajor axis oriented in the e_1 direction and semiminor axis oriented in the e_2 and e_3 directions regarding to $De_i = \lambda_i e_i$.

The lengths of the axis in this ellipsoidal interpretation are given by the corresponding eigenvalues of each eigenvector, with semimajor axis length λ_1 and semiminor axis lengths λ_2 and λ_3. In order for the analogy between the symmetric real tensor and the ellipsoid to be physically realizable, the eigenvalues of *D* must be nonnegative (Bammer, 2000; Pajevic & Pierpaoli, 1999). In cases of purely isotropic diffusion, the diffusion ellipsoid takes on a spherical shape, as $\lambda_1 = \lambda_2 = \lambda_3$. The two extreme cases of physically realizable anisotropic diffusion where the ellipsoidal description degenerates are purely linear anisotropic diffusion, $\lambda_1 = c$, and $\lambda_2 = \lambda_3 = 0$, where the diffusion ellipsoid degenerates into a line pointing in the e_1 direction, and the purely planar anisotropic diffusion, where the diffusion ellipsoid becomes oblate, meaning that $\lambda_1 = \lambda_2$, $\lambda_3 = 0$.

Using the three-dimensional Gaussian Stejskal-Tanner model, the six unique elements of the diffusion tensor *D* may be solved by acquiring at least six diffusion weighted measurements in noncollinear measurement directions *g* along with a nondiffusion-weighted measurement S_0 (6). Taking more than six diffusion weighted measurements creates an over constrained system of equations which may be solved using least square methods (Basser, 2002; Basser et al., 2000). The advantage of over-constraining the solution for *D* is a reduction in the amount of noise propagating from diffusion weighted measurements S_i into the calculated diffusion tensor. The linear system of $n \geq 6$ diffusion weighted measurements constraining the diffusion tensor *D* may be represented in matrix form as in Equation 6.

$$\begin{bmatrix} x_1^2 & y_1^2 & z_1^2 & 2x_1y_1 & 2y_1z_1 & 2x_1z_1 \\ x_2^2 & y_2^2 & z_2^2 & 2x_1y_1 & 2y_2z_2 & 2x_2z_2 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ x_n^2 & y_n^2 & z_n^2 & 2x_ny_n & 2y_nz_n & 2x_nz_n \end{bmatrix} \begin{bmatrix} D_{xx} \\ D_{yy} \\ D_{zz} \\ D_{xy} \\ D_{xz} \\ D_{yz} \end{bmatrix} = \begin{bmatrix} -\frac{1}{b}\ln\frac{S_1}{S_0} \\ -\frac{1}{b}\ln\frac{S_2}{S_0} \\ \vdots \\ -\frac{1}{b}\ln\frac{S_n}{S_0} \end{bmatrix} \quad (6)$$

In the linear system of equations $Ad = s$ (6), A is the encoding matrix containing the $n \geq 6$ unit normalized gradient measurement directions, *d* is a vector specifying the 6 unique elements of the diffusion tensor *D*, and s is a vector containing natural logarithmic scaled RF signal loss resulting from the Brownian motion of spins.

Although not commonly mentioned in DTI literature, the existence of nonphysically realizable diffusion tensors must sometimes be accounted for as a special case in tractography algorithms (Basser et al., 2000; Hasan & Narayana, 2003; Poupon et al., 2000; Taylor, 2004; Westin, Maier, Khidhir, Everett, Jolesz, & Kikinis, 1999; Taylor & Hsu, 2004).

Creating the Synthetic DT-MR Dataset

In order to study, validate, and compare various denoising and fiber tracking methods, a mathematical phantom consisting of various tract geometries with well-known diffusion characteristics is needed. A model must, for each voxel, provide an orthogonal set of directions of water diffusion as well as a measure of the amount of diffusion in each of these directions.

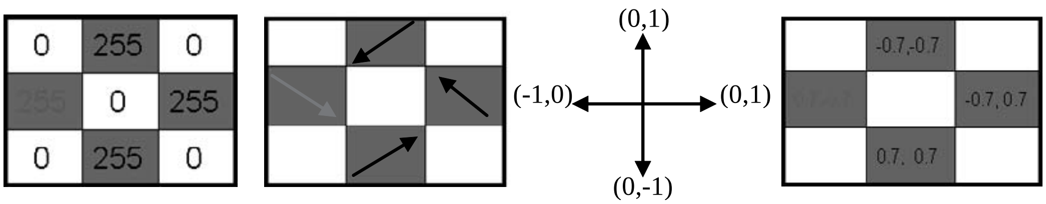
The diffusion tensor is a symmetric positive semidefinite matrix, at least in the absence of noise. Therefore it is known that the eigenvectors of *D* form an orthogonal basis for the diffusion in each voxel and that the eigenvalues are positive. The diffusion is dominant in the direction corresponding to the largest eigenvalue, meaning *principal diffusion direction*. Where the analysis is based on the PCA as explained in a previous chapter.

One common way of visualizing both the eigenvectors and the eigenvalues is to let the eigenvectors be the basis of an ellipsoid where the distance from the center to the surface in each basis direction is equal to the eigenvalue of the corresponding eigenvector.

Gram Schmidt Orthogonalization

Assuming that the b factor in the matrix form b=[bxx byy bzz bxy bxz byz] is [1 0 0 0 0 0], it is obvious that the diffusion tensor (*D*) will have only one element with the value D_{xx}. *D* should be calculated in order to generate the image data *S* for each pixel *(i, j)*. As explained previously, *D* consists of the eigenvectors and eigenvalues of a given pixel *(i,j)*. $D = U\Sigma V$, where *U* contains the eigenvectors, and Σ contains the eigenvalues. As an example, taking the pixel (2, 1) into account, assume the eigenvalue is [6, 0, 0], the eigenvector for pixel (2, 1) is, [0.707, –0.707, 0], so *U* can be found by Gram-Schmidt orthogonalization.

Figure 1. The pixelwise representation of the calculation explained in Equation (8)



Creating $D = [Dxx, Dyy, Dzz, Dxy, Dxz, Dyz] = [2.9, 2.9, 0, –2.9, 0, 0]$, the image data will be calculated as in (7) regarding to (1):

$$S(i, j) = T_2(i, j)e^{-bD} \quad (7)$$

$$S(2,1)=T_2(2,1) * \exp(-b.D) = 255 * \exp(-2.9)= 255 * 0.05 = 14.03 \quad (8)$$

Given a set of k linearly independent vectors $\{\underline{v}_1, \underline{v}_2, \ldots \underline{v}_k\}$ that span a vector subspace V of R^n, the Gram-Schmidt process generates a set of k orthogonal vectors $\{\underline{q}_1, \underline{q}_2, \ldots, \underline{q}_k\}$ that are a basis for V.

$$\hat{q}_i^T \hat{q}_j = \begin{cases} 1 & \text{for } i = j \text{ (unit norm)} \\ 0 & \text{for } i \neq j \text{ (orthogonality)} \end{cases}$$

$D = U \Sigma V^t =$

RESULTS

After post processing the donut-shaped synthetic data, the original values and the calculated results do match, so the algorithm determines the diffusion process and the tracking path successfully (Figure 2). Also the synthetic data is examined for different signal to noise ratio (SNR) values, the results for SNR=10 are shown Figure 3. The developed toolbox analyzing different types of geometries like kissing, branching, and linear trajectories with different SNR values is validated. The tractography algorithm may be followed after that verification, and a validated fiber tractography may be visualized.

The b factor in our study, which gives information about the direction and amplitude of the diffusion gradient, is a 1x7 matrix in form $B = [B0, Bxx, Byy, Bzz, Bxy, Bxz, Byz]$. In the self created synthetic data, 6 diffusion weighted images and a null image namely the T2 image creating a set of intensity images of size 256x256x7 is generated for the analysis, and in the real human brain dataset (Figure 4), the matrix is of size 256x256x31. In a human myocardium sample, 10 diffusion weighted images and the T2 image creating a set of intensity images of size 256x256x11 is used for the analysis (Figure 5). The relation can be expressed generally; $B(n,:)$ has the information of the intensity image $S(:,:,n)$. Based on the Stejskal Tanner equation, the diffusion tensor $D = [Dxx, Dyy, Dzz, Dxy, Dxz, Dyz]$ is calculated in the algorithm. For the validation of the algorithm, real data sets of human cardiac and brain diffusion MR images are used.

FUTURE TRENDS

In a future work, the fiber tractography will be accomplished via a bootstrap method for the estimation of the dispersion associated with pathological tissue, where the data are drawn with replacement; many more feasible DT-MRI volume realizations can be extracted than with a one acquisition one data set approach. With this approach, likelihood maps of the tracts from the pathological brain region of interests will be created. The algorithm will also be used as a probabilistic tractography method to determine connection likelihoods between two or more DT regions of interest. The

tracking problems in the uncertainty areas as crossing, branching, and so forth are aimed to be solved regarding the upgrading of the proposed method where the calculation will be implemented on a neural system basis and physiological background to allow better understanding of how impairment in neural circuitry is associated with neuropsychiatric disease.

CONCLUSION

There are still many drawbacks in the literature on the analysis of DTI, especially in neurological disorders. The classification of brain white matter fiber tracking is of great importance. One of the important goals is to better describe the apparent diffusion process in these multiple fiber regions, thus overcoming the limitations of classical DTI. Developing a reliable and rapid tractography tool for the clinical use based on probabilistic approach determines the major part of the future study of the work in progress in that sense. Diffusion tensor imaging is limited in its ability to accurately describe local tract orientation in cases of branching or crossing structure. Because the ellipsoidal geometry associated with the Gaussian tensor model has only one orientational maximum, the tensor model is inadequate when multiple tract orientations exist within a single voxel (Bammer, 2003; Basser et al., 1994; Barisenko, 1979; Basser et al., 2000; Berg, 1983; Ding, Gore, & Anderson, 2003; Ulug & van Zijl, 1999). Mathematical formalisms for describing the information content of the diffusion tensor have been developed by different groups (Ciccarelli et al., 2003; Hasan & Narayana, 2003; Lori, Akbudak, Shimony et al., 2002). The quality of the estimated parameters depends strongly on the strengths and directions of diffusion-encoding gradients (Ding et al., 2003) and the noise efficiency of different gradient configurations (Kindlmann, Weinstein, & Hart, 2000; Mangin, Poupon, Clark, Le Bihan, & Bloch, 2003; Masutani, Aoki, Abe, Hayashi, & Otomo, 2003; Ozarslan, Vemuri, & Mareci, 2004).

In our study, first the diffusion tensor MR data is simulated, and this is followed by the diffusion tensor analysis. In the proposed study, the algorithm is verified on phantom DT images. The diffusion tensor analyzing toolbox is written in Matlab. The PCA helps to get the eigenvectors and eigenvalues of the system, and these denote the diffusion tensor. In our experimental data, circular, kissing, branching, crossing, linear, and curved trajectories with different SNR values are analyzed, and the results of the synthetic data and the known values do match, as seen in Figure 2 and Figure 3, where blue represents the original, known values and red the calculated results. Regarding this validation and verification, the tool is applied to real human data (Figure 4 and Figure 5). To conclude, the simulated data experiment on diffusion tensor analysis has succeeded. As a further conclusion, according to these validated results, a verified tractography may be done, which is still missing in the literature.

ACKNOWLEDGMENT

The authors thank P. Helm and Stefan Skare for the real DT-MRI data.

KEY TERMS

Anisotropic Diffusion: Any restriction in the Brownian movements of the free water protons due to physiological obstacles or any other anatomical barriers in a tissue.

Brownian Motion: The random movement of particles suspended in a fluid and the mathematical model used to describe such random movements.

Diffusion Coefficients: Characteristic parameters of the diffusion process such as apparent diffusion coeffient, fractional and relative anisotropy, linear, planar, and spherical anisotropy.

Fiber Tractography: The process of using DTI data to estimate white matter structures.

Gram-Schmidt Orthogonalization: A procedure which takes a nonorthogonal set of linearly independent vectors and constructs an orthogonal vector basis.

Principal Diffusivity: The dominant diffusion direction determined by the largest eigenvector of the diffusion tensor.

Spin Echo (SE) Imaging Sequence: MRI imaging pulse sequence generated by applying 90^o and 180^o pulses for dephasing and rephasing the spins before the readout.

Stejskal Tanner Imaging Sequence: Spin-echo MRI imaging sequence with the addition of two diffusion-encoding gradients right before and after the 180^o RF pulse.

Guided Interactive Diagnostic Assistance

Giovanni Maria Sacco
Università di Torino, Italy

INTRODUCTION

One of the significant challenges and opportunities in computer-assisted healthcare is how to improve diagnosis and treatment of patients. With respect to the past, diagnosis and treatment have become more and more difficult because of two major reasons: a global society where people, goods, and, consequently, diseases travel very easily; and a growing awareness and emergence of very rare "orphan" pathologies that affect an extremely small percentage of the population. Physicians are very often required to diagnose and correctly treat diseases that they are not familiar with. Especially in this context, but also with more frequent pathologies, computer assistance can become an essential tool in healthcare, especially if it supports all relevant information such as protocols, exceptions, best practices, condition-specific guidelines, and so on, in addition to diagnosis.

BACKGROUND

Medical diagnostic systems have a relatively long history with prototype systems developed as early as the '70s. The emphasis was on Artificial Intelligence (AI) techniques with an evolution from systems in which diagnostic knowledge from experts was captured in the form of empirical classification rules (Buchanan & Shortliffe, 1984) to theoretical and model-based approaches, such as set-covering (Reggia, Nau, & Wang, 1983), abductive diagnosis (Console, Theseider Dupré, & Torasso, 1989), and consistency-based diagnosis (de Kleer, Mackworth, & Reiter, 1992).

Regardless of the theory of diagnosis used, a dramatic limitation of most diagnostic systems is their system-centric, rather than user-centric approach. This implies a master-slave relationship in which the system is in charge of diagnosis, and the user is used to supply the system with observations. This architecture limits the application of diagnostic systems in areas such as healthcare, where highly skilled professional users do not readily accept a subordinate role. In addition, not taking users into account is one of the known causes of failure in knowledge-based systems (Brézillon, 1999). Finally, the cost of building and maintaining a diagnostic system based on AI techniques may very well be so large as to be impractical.

Alternatively, the diagnostic problem can be recast in terms of information access, rather than in terms of artificial intelligence. Complex AI architectures can be replaced by a collection of electronic texts that describe pathologies, which is searched by traditional techniques. Although this approach greatly simplifies knowledge base creation and maintenance, the limitations of information retrieval have been known for some time (Blair & Maron, 1985), and they indicate that locating the right information may be quite hard, and the result is usually not exhaustive.

More recently, systems based on hypertext technology have been proposed. An example is OncoDoc, a system for the assisted selection of clinical practice guidelines for cancer treatment (Bouaud et al., 1998; Séroussi et al., 2001). OncoDoc is an interactive system that encodes domain knowledge in the form of a decision tree implemented through a number of pages linked by hypertext links: the physician is presented with a sequence of choices that lead her to the guideline to be applied. Systems based on decision trees are less system-centric than conventional AI diagnostic systems, but user interaction is still quite rigid and follows predefined paths. Creation and maintenance are expensive, and the addition of a single new pathology may well disrupt the entire structure, and consequently user familiarity with the system.

DYNAMIC TAXONOMIES

In order to overcome the problems in current diagnostic systems, we propose a user-centric architecture in which the diagnostic system guides the user in exploring and systematically reduce the number of candidate pathologies until their number is sufficiently small for manual inspection. This architecture is based on a new information access paradigm represented by dynamic taxonomies (Sacco, 1987, 2000; also called *faceted search systems*), that focuses on exploratory, guided searches, rather than on traditional retrieval-based on precise specifications. Emphasis is placed on the user, on interactivity and on transparent operations, so that the main causes of failure in practical applications of diagnostic systems are removed. In addition, dynamic taxonomies easily support dynamic knowledge "encyclopedias," which include not only pathologies, but also emergency alerts, guidelines, and, in general, all relevant information. Since information items need not be textual, photos, x-rays, and so on can be easily accommodated.

Dynamic taxonomies are a general knowledge management model for complex, heterogeneous information bases. The intension is a taxonomy that does not require any other relationships in addition to subsumptions (e.g., IS-A and PART-OF relationships). Dynamic taxonomies require a multidimensional classification (i.e., items are classified under several topics at any level of abstraction, as appropriate). A concept C is just a label that identifies a set of items (items(C)), the set of the items classified directly under C, or under any of C's descendants (i.e., the *deep extension* of C).

This set-oriented approach has two important consequences. First, logical operations (and, or, not) on concepts can be performed by the corresponding set operations on their extension. Second, dynamic taxonomies can infer all the concepts related to a given concept C, which represent the conceptual summary of C. Concept relationships other than subsumptions are inferred by empirical evidence, through the extension only, according to the following *extensional inference rule*: two concepts A and B are related iff there is at least one item D in the infobase which is classified at the same time under A (or under one of A's descendants) and under B (or under one of B's descendants). For example, we can infer a (unnamed) relationship between Raphael and Rome, if an item that is classified under Michelangelo and Rome exists in the infobase. At the same time, since Rome is a descendant of Italy, also a relationship between Raphael and Italy can be inferred.

Dynamic taxonomies can be used to browse and explore the infobase in the following way. The user is initially presented with a tree representation of the initial taxonomy for the entire infobase. Each concept label has also a count of all the items classified under it (i.e., the cardinality of items(C) for all Cs). The initial user focus F is the universe (i.e., all the items in the infobase). In the simplest case, the user can then select a concept C in the taxonomy and zoom over it. This operation changes the current state as follows. First, concept C is used to refine the current focus F, which becomes $F \cap items(C)$; items not in the focus are discarded. Second, the tree representation of the taxonomy is modified in order to summarize the new focus. This means that all and only the concepts related to F are retained, and the count for each retained concept C' is updated to reflect the number of items in the focus F that are classified under C'. The reduced taxonomy is a conceptual summary of the set of documents identified by F, exactly as the original taxonomy is a conceptual summary of the universe.

The retrieval process can be seen as an iterative thinning of the information base: the user selects a focus, which restricts (thins out) the information base by discarding all the items not in the current focus. Only the concepts used to classify the items in the focus (and, because of subsumptions, their ancestors) are retained. These concepts, which summarize the current focus, are those and only those concepts that can be used for further refinements. From the human computer interaction point of view, the user is effectively guided to reach his goal, by a clear and consistent listing of all possible alternatives. Though guided, exploration is unconstrained because the user can freely focus on any concept, with the exception of those concepts not in the reduced taxonomy. These concepts are not related to the current focus, and focusing on any of them would produce a (useless) empty result.

The advantages of dynamic taxonomies over traditional access methods are dramatic in terms of convergence of exploratory patterns (Sacco, 2006), and in terms of human factors (Yee, 2003). Dynamic taxonomies have been successfully applied to a number of very diverse information access problems (Sacco, 2005a) and efficient implementations exist (Sacco, 1998).

DIAGNOSTIC ASSISTANCE THROUGH DYNAMIC TAXONOMIES

A dynamic taxonomy is used to recast the diagnostic problem in terms of guided information access to items that represent pathological situations, rather than in terms of logic manipulation. Each item is classified under one or more concepts that represent features that characterize it, including symptoms or causes of the pathology, but also locations in which a pathological situation is common, or age groups that exhibit it, and so on. In short, all the available information that can be used to characterize an item can be used as features. Features can be taxonomically organized in order to support generalization/specialization in accessing the knowledge base, and to simplify the selection of a specific feature when many features are present.

The diagnostic process is an interactive exploration of the knowledge base. Initially, the user is presented with the original taxonomy of features. From this taxonomy, he will zoom on the first symptom, say *fever*. The system will show a reduced taxonomy in which all and only those features (e.g., *chest pain*) related to high body temperature are retained. Related features are automatically computed on the basis of the extensional inference rule defined in the previous section: thus, *fever* and *chest pains* are related iff there is an item, such as pneumonia, in the knowledge base which is classified under both concepts. Related features can be used to further restrict the focus, and hence, the number of candidate items to be manually inspected. Focus refinement is obtained by AND'ing the previous focus with the selected new symptom/feature C.

Differently by traditional diagnosis, the goal is not to find the exact pathology, but rather a sufficiently small set of candidates that the user will finally and independently evaluate. Consequently, the diagnostic process can terminate at any time, and usually when the number of candidate items in the current focus is sufficiently small for manual inspection.

The reduced taxonomy indicates related features and symptoms, and clearly shows unexpected features that can be used to discriminate among items. This is especially important, since the practical importance of diagnostic systems is in dealing with the unknown and unexpected: a physician will hardly use a computer system to diagnose a flu; diagnosing a rare tropical disease that he has never seen nor read about is a completely different story (Sacco, 2005b).

DYNAMIC TAXONOMIES VS. DECISION TREES

There are superficial similarities between dynamic taxonomies and decision trees: both models use a decision structure to "drill down" and find appropriate items. In addition, after examining and selecting a value for a certain feature, only a subset of the remaining features needs to be tested. However, dynamic taxonomies are quite different from decision trees, both in information access (i.e., how the decision structure is used to identify an item) and in information classification (i.e., how the information structure is actually constructed).

The main difference in information access is that the user of a decision tree is presented with a fixed, predefined decision structure that he has to explore in the order defined by the designer (Moret, 1982). In current implementations such as OncoDoc, the decision tree must be followed in its entirety down to a leaf, with no indication of candidate items after each test.

Dynamic taxonomies, on the contrary, enforce no order among features, and the user can freely focus on any feature he finds relevant, in order to restrict the portion of the information base to be considered and to determine all the other features that can be tested, in a totally dynamic way. By selecting an arbitrary sequence of zoom operations, a specific decision tree out of all the possible ones is synthesized.

Such a freedom in selecting the sequence of tests has two important consequences. First, the sequence of tests can be tailored by the user, as to account for the actual cost of tests and to perform low-cost tests first, according to his specific environment. The cost of a test can depend on the specific capabilities of the medical unit: thus, a test that can be performed immediately in a central hospital might require the transportation of a patient from a decentralized unit. Therefore, any predefined sequence will be suboptimal in certain cases.

Second, selection by decision trees is the analog of interacting through a predefined modal dialog in which the system asks the questions: again, a system-centric master-slave architecture, although much more user-friendly than traditional AI systems. Access through dynamic taxonomies guides the user to reach his goal by simply hiding selections and features that do not apply in the current state produced by user selections. As such, interaction is modeless, and the system is actually the slave in the master-slave relationship, and is consequently perceived as an unobtrusive assistant.

At any stage, the user of a dynamic taxonomy system has a complete list of all the items that satisfied the tests performed so far. Consequently, the user can often rely on his knowledge/memory to select the right item in the candidates list, instead of applying additional tests. This can provide a significant speedup in locating appropriate items, especially when the corresponding decision tree is skewed. Finally, dynamic taxonomies support the notion of a taxonomic organization that guides users in easily locating available tests, and is especially important for all support material (guidelines, alerts, and so on).

As regards information classification, the notion of order required in decision trees is again critical. First, the total cost of tests must be minimized by anticipating low-cost tests, and deferring high-cost ones. As we argued above, some tests may have different costs in different environments, so that no fixed order is appropriate in all situations.

Second, the average or the maximum number of tests required should be minimized. Decision trees are usually incomplete binary trees, so that very skewed trees can arise in practice. Since the probability of selecting a specific information item is usually not uniform, it would make sense to select a tree that minimizes the number of tests for the most frequently occurring pathologies. But the frequency of pathologies depends on specific locations so that, in practice, the optimization of decision trees for diagnostic purposes is impossible.

The construction of a decision tree requires that n features that can be used to *discriminate* among items are identified, and then used to construct the decision structure. But, first, the addition of a new item requires, in general, that the existing decision tree be modified. In practical situations, modifications may well disrupt the entire structure, so that users have to relearn how to move in the structure.

Second, and more importantly, each item has to be compared against any other item in order to define appropriate discriminators. This results in a quadratic complexity in the number of items, and indicates that simple applications of decision trees do not easily scale up. By contrast, in dynamic taxonomies, features are used to *describe* each item in isolation. Consequently, the classification of a single item i depends on i only, and is therefore independent of the size of the information base.

CONCLUSION

Dynamic taxonomies are a promising approach for user-centered assisted diagnosis and decision support in healthcare. This model provides an interaction model that is guided and, at the same time, allows the user to freely focus on appropriate symptoms and features as desired. This allows to model the sequence of test required for diagnosis, as to account for local test costs and local frequency of pathologies. Current research focuses on building the taxonomy, possibly by automatic derivation from existing ontologies/thesauri such as UMLS (Lindberg et al., 1993) and SNOMED (2001). Other research directions include using electronic patient records for recommendation, and accounting for the probability of pathologies in guiding the search.

KEY TERMS

Decision Tree: A rooted, ordered, and labeled tree. Given a boolean function on n-variables (tests), a decision tree is a deterministic algorithm for deciding which variable to test next, based on the previously tested variables and the results of their evaluation, until the function's value can be determined.

Deep Extension: Of a concept C, denotes the shallow extension of C union the deep extension of C's sons.

Extensional Inference Rule: Two concepts A and B are related iff there is at least one item *d* in the knowledge base which is classified at the same time under A (or under one of A's descendants) and under B (or under one of B's descendants).

Facet: One of several top-level (most general) concepts in a multidimensional taxonomy. In general, facets are independent, and define a set of "orthogonal" conceptual coordinates.

Monodimensional Taxonomy: Taxonomy where an item can be classified under a single concept only.

Multidimensional Taxonomy: Taxonomy where an item can be classified under several concepts.

Reduced Taxonomy: In a dynamic taxonomy, a taxonomy, describing the current user focus set F, which is derived from the original taxonomy by pruning from it all the concepts not related to F.

Shallow Extension: Of a concept C, denotes the set of documents classified directly under C.

Subsumption: A subsumes B if the set denoted by B is a subset of the set denoted by A ($B \subseteq A$).

Taxonomy: A hierarchical organization of concepts going from the most general (topmost), to the most specific concepts. A taxonomy supports abstraction and models subsumption (e.g., IS-A and/or PART-OF) relations between a concept and its father.

User Focus: The set of documents corresponding to a user-defined composition of concepts; initially, the entire knowledge base.

Zoom: A user interface operation that defines a new user focus by OR'ing user-selected concepts and AND'ing them with the previous focus; a reduced taxonomy is then computed and shown to the user.

Haptic Rendering for Laparoscopic Surgery Simulation and Related Studies

INTRODUCTION

This project concerns the application of haptic feedback to a virtual reality laparoscopic surgery simulator. It investigates the hardware required to display haptic forces, and the software required to generate realistic and stable haptic properties. A number of surgery-based studies are undertaken using the developed haptic device.

The human sense of touch, or haptic sensory system, is investigated in the context of laparoscopic surgery, where the long laparoscopic instruments reduce haptic sensation. Nonetheless, the sense of touch plays a vital role in navigation, palpation, cutting, tissue manipulation, and pathology detection in surgery. The overall haptic effect has been decomposed into a finite number of haptic attributes. The haptic attributes of mass, friction, stiction, elasticity, and viscosity are individually modeled, validated, and applied to virtual anatomical objects in visual simulations.

There are times in surgery when the view from the camera cannot be depended upon. When visual feedback is impeded, haptic feedback must be relied upon more by the surgeon. A realistic simulator should include some sort of visual impedance. Results from a simple tissue holding task suggested the inclusion of haptic feedback in a simulator aids the user when visual feedback is impeded.

BACKGROUND

Introduction to Haptic Feedback

Haptic perception is equivalent to humans' sense of touch, and incorporates both tactile and kinesthetic perception. Haptic feedback is present whenever the haptic receptors are engaged. All physical objects intrinsically display haptic feedback to humans when they interact with them, and include texture, weight, and heat. In relation to this document and simulators in general, haptic feedback is the term given to the forces displayed by a mechanical haptic device able to simulate an objects haptic information.

Surgery simulation and robotic surgery is an area where haptic feedback use is increasing. The sense of touch provides useful information to surgeons when orientating themselves, diagnosing pathologies, and manipulating tissue. Visual-only simulators can improve surgical training and education, but hands-on experience can only be achieved by including haptic feedback (Nudehi, Mukherjee, & Ghodoussi, 2003, p. 4563). To ensure a completely immersive and realistic VR simulator, haptic feedback must be included. Due to computing power issues in the past, the implementation and development of a haptic feedback system has come secondary to the highly computational visual graphic components. Improvements in technology and further research will lead to haptic feedback becoming more reliable, stable, and commonplace.

Haptic Perception

The sense of touch in human is extremely important and often underrated (Robles-De-La-Torre, 2006). A realistic surgery simulator must provide sufficient visual and haptic information to the user. Simulated haptics and graphics is not real life, but by exploiting the limitations of humans' senses, realism is created. To synthesise haptic feedback to such a level, an understanding of the biomechanical, sensorimotor, and cognitive abilities of the human is required (Tan, Srinivasan, Eberman, & Cheng, 1994, p. 353).

One way of testing and comparing humans' abilities is to use the Just-Noticeable-Difference (JND) measure. The Just-Noticeable-Difference (JND) describes the smallest amount of change of an arbitrary stimulus which can be detected, just as often as it cannot be detected. Therefore, the JND, in the context of force perception, is defined as being the minimum amount of force change to an initial force that a user can detect in 50% of trials (Wikipedia, 2006). It can be used to test many haptic attributes, and provides a means to validate hardware and software capabilities in a haptic system. This value lies mostly between 5% and 15% for humans, depending on the stimulus type and limb or joint where it is applied (Hinterseer & Steinbach, 2006).

Sense Perception During Laparoscopic Surgery

There is significant degradation and distortion of forces encountered by surgeons during laparoscopic procedures. The force feedback from tissue interaction, including tasks such as tissue palpation, is effected by friction at the trocar, weight of the instrument, and length of the instrument (Patkin & Isabel, 1995; Tavakoli, Patel, & Moallem, 2006). As a reference, a metal trocar can introduce about 0.4N of friction (Sallé, Gosseli, Bidaud, & Gravez, 2001), and the weight and length of a typical laparoscopic instrument are about 100grams (1N) and 400mm respectively.

Depth perception cues are lost, due to viewing the scene on a 2D monitor. Patkin and Isabel (1995) found that five out of 16 depth perception cues are lost including stereopsis, convergence, and texture fade. Also, the field of view reduces from 150° to 60°, and viewing distance reduces by 90%, compared to open surgery. Hand-eye coordination is reduced by the indirect method of observing and manipulating tissue. Breedveld and Wentink (2001, p. 155) suggest this is due to a mislocation of the camera picture, and a misorientation of the instrument movements. The instruments movement on the monitor are different than expected, and the "effects are very confusing." They, however, make no mention on the role force feedback plays in compensating for the hand-eye coordination effect. Bingham et al. (2000) does consider haptic feedback in a hand-eye coordination experiment. It does not directly relate to laparoscopic surgery, but results suggest that distance and shape distortion created by visual illusions can be corrected somewhat by haptic feedback.

Training simulators should include haptic feedback to improve users' awareness of its role. Development of a surgeons' sense of touch can reduce damage to organs and tissues, and improve recognition of the slightest difference of tissue density, improving the ability to identify blood vessels and other structures merely by touch alone (Patkin, 2005; Patkin et al., 1995).

Haptic Hardware

An ideal mechanical interface acts as a transparent medium in which force is displayed to the user from the data calculated in the virtual anatomy model. It should be friction free, have zero mass and inertia, have zero backlash, and display a wide magnitude of forces without error. This ideal will never be realised in the real world, so we strive for a device as close to ideal as possible.

Haptic Modeling

Surgery simulation requires a force reflecting deformable model of the anatomy. The quality of visual and haptic information must be sufficient to simulate a high level of realism to the user. Accurate physical-based models are computationally demanding, whereas simple geometric models do not generate realistic information. A balance between realism and real-time operation is required.

Validation

In order to determine the effectiveness of various haptic models developed within this project, validation studies need to be undertaken. The hope is that haptics enable surgeons to improve skills faster than if haptics were not included. However, there are two other scenarios, being that haptics may achieve no improvements, or may actually hinder the surgeon's learning. Therefore, validation studies must be conducted to justify the inclusion and measure the quality of the haptics.

SYSTEM OVERVIEW

Figure 1 provides an overview of the mechanical interface setup for a two-instrument and one-camera task. The mechanical interface provides a two-way flow of haptic and positional information between the users hands and the virtual reality world. Positional information is fed via positional encoders to the PC, and haptic information is fed via the PC, through the motor amplifiers, motors, and gimbal, up to the instrument handles. Information flow occurs simultaneously in 3D for each instrument.

Haptic Hardware

The mechanical interface was designed and built by the authors (McColl, Brown, Seligman, Lim, & Alsaraira, 2005; Seligman, 2003). Gears have been used to multiply torque transfer for parallel transmission, ensuring the required display of continuous 6N forces to the instrument handles are met. A pulley and belt provides smooth torque transfer, but the belt tension to drive required forces without slippage caused mechanical distortion. Gears are nonslip, but have inherent backlash. The backlash is not noticeable in normal operation. Figure 2 shows gimbal movement and geared torque transmission setup.

A virtual hemisphere study was performed to compare subjects' ability to locate the apex of a virtual hemisphere with the haptic device under maximum force capabilities of 2N, and then 6N. The 6N mean error was 21.7% with standard deviation 13.5. This suggests a marked improvement from the 2N results (mean error 29.7%, standard deviation 17.3). The navigational results found by increasing available force output improves navigational ability, and corresponds with findings from O'Malley and Goldfarb (2002).

The Faulhaber (Faulhaber Group, http://www.faulhaber-group.com) ironless core DC motor with graphite commutation (Model Number: 3863-048C) was chosen for the larger parallel motors. The serial motors used are Faulhaber (Faulhaber Group) ironless core DC motors with precious metal commutation (Model Number: 2224-006SR). They are much smaller than the parallel motors, and only generate about 1.5% of the torque in comparison. The light weight is essential as the motor moves along the pitch and heading axes with the instrument. It directly contributes to the device inertia. A capstan with a small moment arm was designed to maximise the force output from the small torque capability.

The brush DC motors were chosen for their low inertia, low stall torque, ironless core, no magnetic cogging, and low axial play. Other options for motors include brushless and stepper motors. Brushless motors require extra control circuitry and complexity, and suffer from reluctance cogging and torque ripple phenomena (Tavakoli et al., 2006, p. 164). Stepper motors are noisier, have greater torque ripple, and also require

Figure 1. Overview of haptic interface

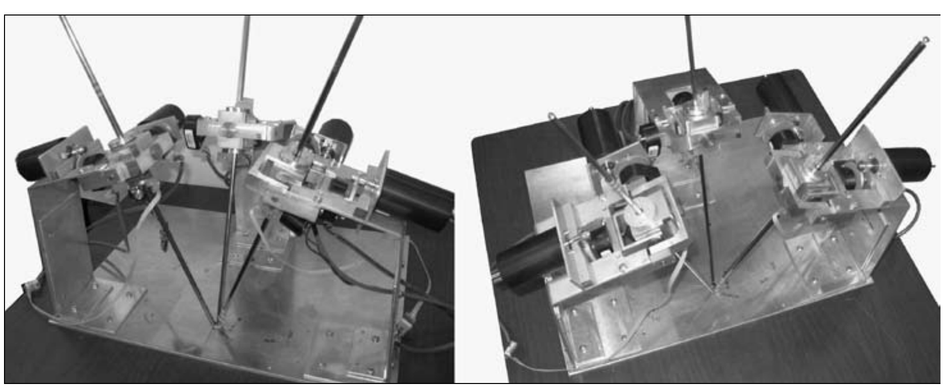

Figure 2. Gimbal movement and geared torque transmission

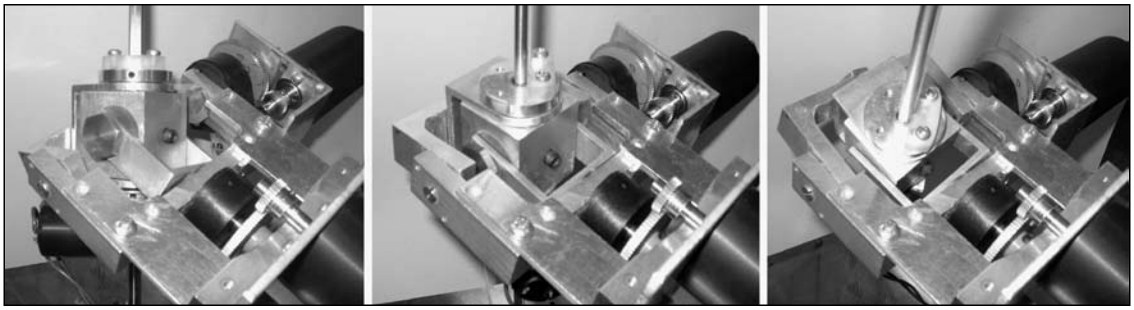


more complex circuitry, in comparison with brush type DC motors (Chen & Marcus, 1998, p. 526).

Haptic Software

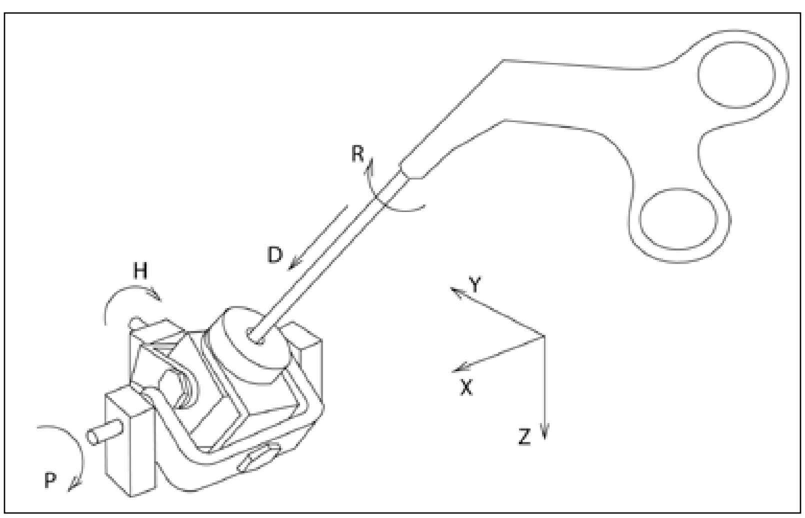
The gimbal allows instrument movement in four degrees of freedom (H,P,R,D). In the current hardware implementation, the H axis (heading) reflects rotation of the instrument left and right, the P axis (pitch) represents rotation forward and back, the R axis (roll) represents rotation of the handle about its own axis, and the D axis (depth) represents axial movement of the instrument through the centre of the gimbal. Cartesian coordinates (X,Y,Z) are used by the visual loop, and relationships must be made in order to pass information between visual and haptic loops. The relationship between polar and Cartesian coordinates for the gimbal is shown below in Figure 3.

A Cartesian normal surface vector is passed from the visual loop when contact is made between an instrument and an object. This is converted to a force vector based on attributes of the organ, such as mass or deformation. In order to display this force to the user through the mechanical interface, the Cartesian vector must be separated into polar coordinates, which allows the signals for the force feedback motors to be generated.

Haptic attributes are decomposed properties of the overall haptic effect. It is part of the haptic modeling process to determine how to decompose the overall effect into attributes that can be modelled, and then rendered onto 3D deformable objects. This project provides a unique decomposition which is suitable for laparoscopic surgery simulation.

The overall haptic effect can be effectively created by the summation of the individual attributes. Each virtual anatomical object is defined a set of attributes

Figure 3. Coordinate system



which sum together, creating an overall force. Attributes, which in programming terms can be thought of as objects, can be added, subtracted, and reprogrammed without affecting other attributes. This nature of this object-oriented approach model lends itself neatly to the addition of new objects and features into the VR model.

The process of decomposing the overall complex haptic effect into simple attributes began with discussion with a medical consultation group (Healy & Rombauts, 2005), and observation of real laparoscopic surgical procedures in theatre and on video. The technique involved generation of a potential attribute list, programming potential attributes, parameter adjusting, algorithm modification, subjective evaluation, and objective validation.

The overall haptic effect has been decomposed into five attributes: mass, elasticity, friction, stiction, and viscosity. This is not a definitive decomposition of the overall haptic effect.

The haptic effect is too complex to expect that the breakdown here can satisfy an entirely realistic response. This list is one solution to a haptic modeling problem, and is believed to be a good method for this application.

Forces relating to mass stem from gravitational effects and acceleration. Elasticity is a combination of a stiffness and a damping component. Friction, which is used for simulating texture and cutting, is modeled simply using modified random noise functions. Parameters for the attributes have been subjectively tuned using real tissue properties as baselines.

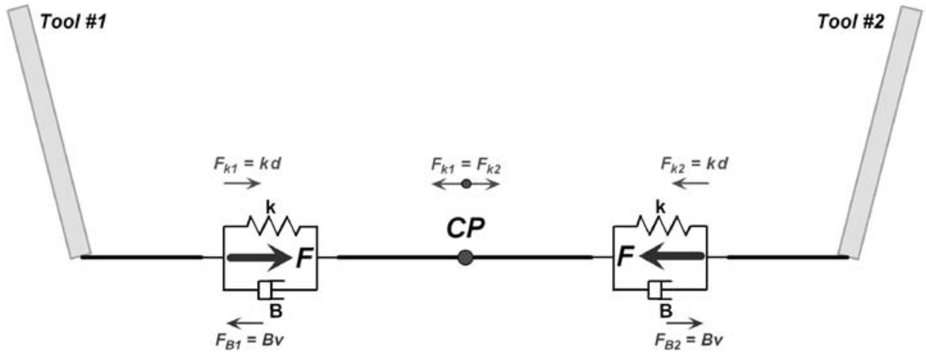
A representation of both viscosity and stiction has been achieved using the following algorithm. Stiction can be thought of as any force which opposes motion along the surface of an object. An example is a diathermy tool sticking to tissue or resistance, due to viscous surface fluid.

- When contact is made between the Tool Tip (*TT*) and an object, store the Point of Contact (*POC*). Note that inside viscous liquid, the *TT* is always touching an object.
- As the *TT* moves away from the *POC*, apply a force to the *TT* in the direction of the *POC,* based on the distance between the two points.
- Whilst the *TT* remains in contact with the object, the *POC* moves towards the *TT* at a speed based on the distance between the two points.
- Once the *TT* is no longer geometrically touching the object, a force is maintained for a length of time based on distance between the *POC*. This ensures there remains some physical contact, or stiction.
- Properties can be varied greatly by adjusting parameters related to distance, speed, and time.

The haptic loop obtains information from the virtual world via the visual loop. The geometric visual models are rendered with one or more of the haptic attributes. This, along with some simple passivity algorithms, adds a physical element to the geometric models.

Multiple instruments acting upon the same object has historically been a challenge and a cause of instability. Presented here is a simple approach which combines the modular concept of Yoshikawa and Ueda (1996), and the simple spring-damper model used by Basdogan, Ho, Srinivasan, and Slater (2000). The simplest case is an elastic ligament held by two instruments. The ligament has a stiffness and damping component, but displays no mass. Forces are generated only when the ligament is stretched beyond its nominal (or resting) length. The stiffness component generates forces for both instruments, equal in magnitude but in opposite directions. The direction of the force vector points directly towards the centre point (CP), which in this case is the same direction as the opposing tool tip. The damping component acts along the same vector direction as the force component, but the magnitudes of each instrument are not necessarily the same. The damping magnitude is based on the velocity each individual instrument is travelling. An ideal damper, as used for this ligament model, absorbs energy, and does not transmit force through itself. Each instrument acts independently, not requiring knowledge about the other instrument. The only shared data is the CP location and the ligament properties. A visual representation is shown in Figure 4. This concept can be used for more complex objects by adding ligaments attached to fixed locations or part of an object. The simulation displays accurate and stable forces for one-person (one-handed and two-handed) operation, and two-person operation.

Figure 4. Multiple instrument ligament interaction



EXPERIMENTAL STUDIES

Threshold Perception Study

- **Aim:** To validate the haptic attributes by measuring the JND for each attribute. This ensures both that forces that cannot be perceived are not unnecessarily displayed, and that our mechanical interface accurately reproduces forces to users, and is suitable for further studies investigating surgery-based haptic tasks.
- **Overview:** Studies have shown humans can detect change in forces of approximately 10% through their fingers (Allin, Matsuoka, & Klatzky, 2002; Doerrer & Werthschuetzky, 2002; Pang, Tan, & Durlach, 1991). The validation of subjects' ability to detect changes in haptic attributes is more difficult to quantitatively measure, as equations used to model attributes vary from the physical world. A simple way to achieve validation is to determine what the JND for force is through the changing of parameters in the attribute equations. For example, what were the forces involved in a subject detecting a change in viscosity of 10%?
- **Method:** The following perception studies were undertaken with each subject: mass, tissue elasticity, surface stiction, liquid viscosity, and detection of an arterial pulse (displacement). Following familiarisation and a trial run, subjects were tested 30 times for each attribute, 10 times for each of three default levels. The increment and direction of the changes were randomly generated. A computer-generated tone sounded each time the attribute changed. Subjects were then given a chance to determine if a change had occurred. Five male subjects aged 20–35 in total were tested.
- **Results:** Average JND for mass was 12.5%. The smallest change detectable from a zero base was 0.13N. The instrument weight of 1N makes JND 13% about a zero base. For base forces of 1.25N and 2N, JND was 12%.

The JND for an elastic membrane with stiffness of 100N/m and 500N/m was 10%, and for 1500N/m, was 16.7%.

The average JND for stiction was 13%. A change in stiction parameters is proportional to a change in force for a given velocity. Each subject has control over their velocity during this experiment, so the JND is based on both force and velocity.

The average JND for viscosity was 8%. As with the stiction calculations, force change is proportional to viscosity change, but forces generated depend on the velocity of the instrument.

Subjects were able to detect, on average, 5% changes in the height of a simulated arterial pulse. The arterial pulse is modeled as a height changing membrane with stiffness of 1000N/m. Perception is dependent on users' ability to detect both a change in force and change in displacement.

The overall JND for purely force related tests is approximately 12%. This suggests our interface is suitable for use with surgery-based tasks. The higher JND for the high stiffness membrane suggests the mechanical limitations of the interface may be being approached. The remaining attributes tested depend on force perception, and either velocity or displacement perception. Further studies are required to comprehend further, but low percentage JND's suggest our modeling techniques provide measurable information to users, which can be applied to deformable visual graphic models.

Object Localisation Study

- **Aim:** To test the value of various modes of haptic/visual feedback in a simulated laparoscopic surgery task. It investigates localisation of an anatomical object to a spatially known location. Several studies, for example Jones, Bokinsky, Tretter, and Negishi (2005) and Moody, Baber, and Arvanitis (2001) investigate performance tasks with constant and continual visual feedback. This study investigates how performance of a task is affected as visual feedback is impeded slightly or removed.
- **Overview:** Subjects are given an opportunity to initially localise the instrument to the desired position using an active visual graphic position monitor. The active monitor is removed, and subjects must then rely on the modes listed below to relocate the instrument to the desired position. 10 male subjects aged 20-35 in total were tested.
- **Modes of visual/haptic feedback:**
  - None (limb localisation feedback only) (NF)
  - Fixed Viewpoint Visual Feedback (FVF)
  - Haptic Feedback (HF)
  - Fixed Viewpoint Visual & Haptic Feedback (FV&HF)
  - Varying Viewpoint Visual Feedback (VVF)
  - Varying Viewpoint Visual & Haptic Feedback (VV&HF)

  Visual feedback displays a virtual view of the instrument inside the virtual abdomen. The camera viewpoint is located to approximate the position of a real camera during surgery.

  The FVF displays the scene from a fixed viewpoint. Subjects can take advantage of this by visually lining up the instrument with tokens on the monitor.

  The VVF displays the scene from a camera randomly drifting in three axes. Observation of surgery suggests this is more realistic than a FV model. Position and angle drift is limited to approximately ±10% from the initial position, and can move between the limits in approximately 10 seconds.

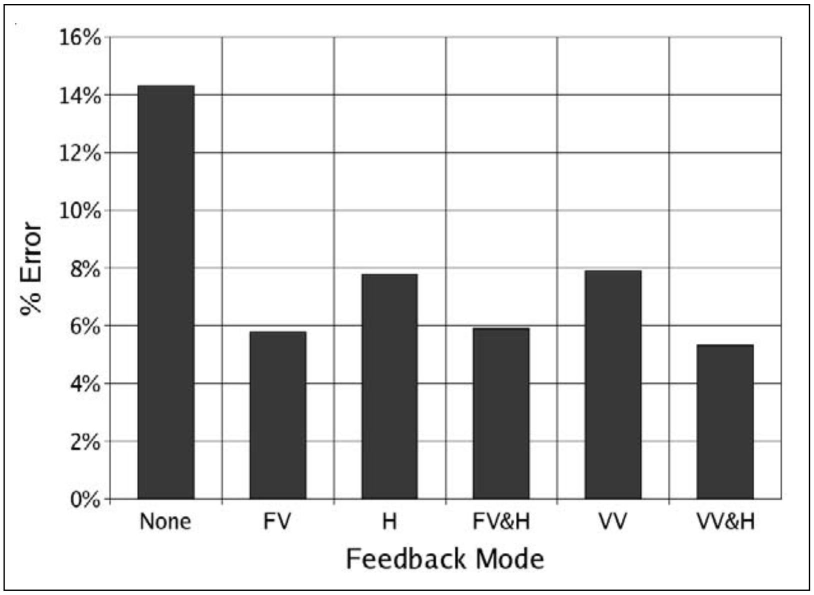
  HF displays a force to the user without any visual feedback. A simple elastic model is used for the object being stretched. The desired position represents a movement of 60mm from the initial position, generating a force of 2.5N.

  NF indicates no visual or haptic feedback. Subjects' eyes are covered, and haptic feedback is switched off. The ability to locate the instrument is based purely on the ability of the subject to localise themselves using the sensed angle of their shoulder, elbow, and wrist joints. This provides a benchmark for other modes.
- **Method:** Following familiarisation and a trial run, subjects perform the localisation task five times with each feedback mode. After the five attempts, subjects stand, walk around, then localise themselves again using the active position monitor under the new feedback mode conditions. The whole experiment is performed twice per subject.
- **Results:** The percentage error in locating to the desired position without visual or haptic feedback is approximately 15%. With FVF only the percentage error in locating is approximately 6%. With VVF, only the percentage error in locating is approximately 8%. The difference makes sense, as it is more difficult to locate something using vision if your frame of reference is changing. Haptics alone measured a percentage error in locating of approximately 8%.

The most interesting results combine visual and haptic feedback. With FV&HF the percentage error in locating is still approximately 6%. This suggests haptics neither detracts nor adds to the ability to locate under these circumstances when the visual feedback is fixed. With VV&HF the percentage error is approximately 6%, a 2% improvement on both VVF & HF alone. This suggests haptics aids in the ability to locate an object when the visual viewpoint is changing.

A plot of results can be found in Figure 5. To analyse the data, an ANOVA with three factors, Feedback(FB) Mode, Subject, and Trial, was performed. Subject was considered a random factor. Differences between FB-Modes and Trial were found to be highly significant ($p<0.001$ and $p=0.002$). Tukey's post-hoc test split the

Figure 5. Object localisation results



FBModes into three groups: NF; FV, FV&H, VV&H; and H, VV. (The assumptions of ANOVA were met.) Interaction plots suggested that the effect of Trial was chiefly due to the difference between Trials 1 and 2 for NF. When NF was removed, the analysis no longer found Trial significant, but Subject was now significant (p=0.012), because the MS error for Trials had diminished by a factor of 5. This suggests that even though each Subject had a different haptic ability, their comparative ability across FBModes showed significant trends. The groupings determined from Tukey's post-hoc test suggest that the addition of haptic feedback, when visual feedback is impeded, improves the performance of this task.

FUTURE TRENDS

The haptic community will continue to grow, providing more people with access to haptic devices. Surgery simulation will continue to be an area heavily involved in haptics. It appears that hospitals and staff are ready to take on new products, but difficulty of use, unreliability, nonrealistic haptic sensations, and pretraining requirements, will hinder their uptake.

More studies investigating how haptics effect performance will continue to generate knowledge on how the haptic sense works, and more importantly in this context, how to best develop training procedures or warm-up routines to best focus attention to the development of important skills required for surgery simulation.

Though several commercial devices exist, it is important that researchers continue work on all aspects of haptic systems. Commercialisation often limits common knowledge with black box components (Çavuşoğlu, Feygin, & Tendick, 2002, p. 556), closed source software and patents, hindering the ability for new users to learn how to best develop their own for a custom application.

CONCLUSION

Studies are required to validate new haptic hardware and software to ensure its suitability. Our mechanical interface has been validated using a virtual hemisphere navigation study, and a perception study measuring the JND of forces displayed to the user. Haptic attribute models operate at real-time, and provide measurable information to users. We believe our system is suitable for further studies in the context of surgery simulation.

A tissue localisation study was conducted, which compared performance using different modes of feedback. Results suggested that including haptic information to subjects improved their ability to locate tissue to a known position when visual feedback is impeded.

The development of haptic rendering hardware and software has identified a number of important engineering design challenges. Solutions to these challenges need to be both cost-effective and computationally efficient. Global physical modeling may produce a single virtual organ with realistic visual and haptic properties, but a multiorgan, multiinstrument, and multioperator simulation suggests a less global, more segmented, object-oriented approach. This approach is currently being investigated in relation to the haptic rendering of a virtual reality laparoscopic simulator.

KEY TERMS

Force Feedback or Kinesthetic Feedback: Refers to the information received via receptors in the limbs themselves. It is responsible for awareness of movement and position of one's limbs in space and time. Kinesthetic receptors are also responsible for the detection of size and weight of objects (Haans & Ijsselsteijn, 2006).

Haptic Attributes: All physical objects intrinsically display haptic attributes which feedback haptic information to humans interacting with them. The haptic attributes include texture, heat, mass, friction, stiction, elasticity, viscosity, temperature, vibrations, and more.

Haptic Attribute Decomposition: The overall haptic effect can be decomposed into a number of haptic attributes. The decomposition attaints to determine the method in which best to decompose the overall haptic effect. Once the decomposition has occurred, the individual attributes can be measured, compared, and recreated in a simulation.

Haptic Display or Force Display: Refers to the transfer of force information via the mechanical interface to the user. The case of a force display is analogous to that of a visual display, where visual information is passed to a user via a medium such as a computer monitor.

Haptic Rendering: Haptic rendering is the process of converting computer algorithms containing force information to a mechanical interface capable of displaying haptic information to a user (Salisbury et al., 2004). It is analogous to visual rendering, which converts graphics from a file into visual form, as on a video display. Haptic rendering is comprised of a hardware and a software component.

Haptics: From the Greek word *haptesthai*, meaning "to touch." Haptics broadly refers to touch interactions (physical contact) that occur for the purpose of perception or manipulation of objects (Salisbury, Conti, & Barbagli, 2004). This encapsulates both "Tactile" and "Force" information.

Tactile Feedback or Cutaneous Feedback: Encompasses all the information acquired through sensors in the skin, with particular reference to the spatial distribution of pressure, or more generally, tractions, across the contact area. Tactile Feedback is responsible for the detection of, but not limited to, roughness, temperature, and vibrations.

Visual Impedance: "Impedance" can be defined as something that impedes, such as an obstacle or hindrance. Therefore, a visual impedance is something that impedes vision.

Health Systems Simulation

INTRODUCTION

The health system is the culmination of organisations, institutions, and resources which work together for the purpose of providing health care and improvement in health (WHO, 2006). This system comprises a number of different levels (Proctor, Reid, Compton, Grossman, & Fanjiang, 2005) as shown in Figure 1. The highest level is the environment which provides the regulatory, policy, and funding frameworks in which the lower levels of the health system operate.

The health system is a *complex system* (Plsek & Greenhalgh, 2001) meaning that it is highly coupled and many outcomes are the result of the interactions that occur between many different parts (Plsek, 2003). Not only can interactions occur between different parts at the same level, but they can also interact across levels.

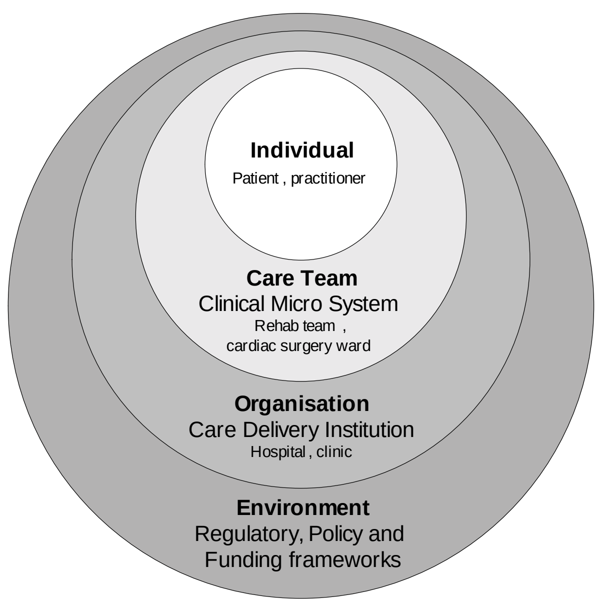
Adding to the complexity of the health system is that these interactions play out over time, often with effects being distant in both time and place to causes (Forrester, 1961). This *dynamic complexity* (Sterman, 2000) arises when systems change over time, are tightly coupled (characterised by strong interactions), are governed by feedback, and play out over time. Research has shown that people are very poor at understanding problems with dynamic complexity, with performance on tasks and outcomes declining as complexity or the strength of feedback increases (Paich & Sterman, 1993).

In this way, the health system is more than simply the sum of its parts because all aspects of the system need to function together in order to provide health care. One of the main difficulties in health care reform therefore is the systemic nature of health care. Reform to one area will undoubtedly affect other areas.

Most problems arising from the operation of the health system are studied and addressed using conventional reductionist methods, which reduce, isolate, and freeze aspects of the system at a given time. This fails to deal with the dynamic complexity inherent in the health system and which is often the source of the problem. The result is that all too often, well intentioned interventions make the original problem worse by failing to fully understand the complexities involved in the origin of a problem (Sterman, 2000).

In this article, we introduce *system simulation* as a means of exposing the underlying causes and systemic structures of problems within the health care system, as well as providing a tool for assessing the likely impact of new interventions. The following sections will examine the advantages of simulation, areas of application, how simulation experiments can overcome some of the limitations of randomised control trials (RCTs), and various simulation methodologies as well as the challenges of conducting simulation experiments.

Figure 1. Conceptual drawing of the 4 levels health care system (Adapted from Proctor et al., 2005)



HEALTH SYSTEM SIMULATION

Health system simulation is the application of modelling and computer simulation methods to study the interactions between individuals and/or components of a system and how these interactions over time produce the behaviour observed in the health care system.

There are both quantitative and qualitative modelling and simulation methods, however this article will focus exclusively on quantitative modelling and simulation. See Kuipers (1994) for a discussion on qualitative simulation methods.

Health system simulation helps develop an understanding of the dynamic relationships and systemic causes of problems. Interventions can be developed to address these problems and can be tested *in silico* to determine their suitability. This allows for risk free experimentation where stakeholders can try out *what if* scenarios and have the ability to play out the results of interventions over time.

Health care system simulation has been applied to a number of areas (Homer & Hirsch, 2006), including:

- Disease epidemiology: heart disease, diabetes, HIV/AIDS, cervical cancer, chlamydia infection, dengue fever, and drug resistant pneumococcal infections
- Substance abuse epidemiology: heroin addiction, cocaine prevalence, and tobacco reduction
- Patient flows through emergency and health care
- Health care capacity and delivery in areas such as population health planning, dental care, and mental health, as well as how the health system will be able to cope with natural disasters and terrorist incidents
- Interactions between health care and disease epidemiology
- Performance management
- Evaluation of the performance and impact of information and communications technology applications on health care (Anderson, 2002), including Computerised Physician Order Entry systems and electronic prescribing systems designed to reduce medical errors leading at adverse events.

The common characteristics of these areas are that they have features of dynamic complexity and involve large scale or multiple settings in which it would be difficult to conduct traditional experimental methods.

SYSTEM SIMULATION CAN OVERCOME SOME LIMITATIONS OF RANDOMISED CONTROL TRIALS

Randomised control trials (RCT) are often regarded in health care circles as the *gold standard* for evaluating the effectiveness and quality of health interventions (Muir Gray, 1997), with alternative research methods often judged by the degree to which they approximate RCT design.

While being recognised as the best way to evaluate new drug and treatment interventions, many problems which face the health system are complex, dynamic, and cannot be reduced to a single or linear cause and effect relationship. In these situations conducting RCT experiments may not be possible or ideal. When this occurs, system simulation can provide an alternative means of investigation.

For example, RCTs are not practical when the timeframe is too long (Black, 1996). Changes in population health, the management of chronic illness, and planning for future infrastructure will occur over years, decades, or even a lifetime. Aside from the impracticalities of conducting a study over such durations, in many cases decisions can not be put off that long. A computer simulation on the other hand can replicate many aspects of the experiment in a matter of minutes.

The scale of a study may also prohibit the use of RCTs (Black, 1996). This is especially the case in any study that deals with an entire population, such as epidemics or health delivery and capacity. The simulation researcher on the other hand can simulate the entire population.

Trials may be too expensive to conduct, as is the case with major implementations of information and communications technology or building new infrastructure. Simulation experiments overcome the cost barrier as these are tested *in silico* without the need for expensive purchases or capital investment. In a similar vein, this eliminates wasted money should simulation suggest that that a particular piece of new technology or infrastructure is not beneficial.

In certain circumstances an RCT may be unethical or too risky to conduct, especially when it may place the health and welfare of participants or other people at risk. This may arise from inherently risky experiments such as quarantine measures to isolate an outbreak of the H5N1 strain of avian influenza where the consequences of failure would be the deaths of many people, or an unanticipated and unexpected consequence of an experiment which could harm people involved. Again a simulation experiment eliminates the risk to participants and others.

Finally, an RCT is a very controlled and artificial process. It is not always possible to control all perceived and unknown extraneous variables (Black, 1996). Nor should it be desirable to be so controlling, as doing so would ignore that health care is a complex system with high levels of dynamic complexity. In an RCT, isolating the problem may mean removing it from its broader context which does not reflect how a problem behaves in the real world.

In contrast to a trial which attempts to control and limit variance from other sources, a system simulation aims to understand the interactions that produce the observed phenomenon under study. This may involve consideration of various factors that might be considered extraneous or confounding variables in an RCT. The difference is that system simulation focuses on the problem at hand, while RCTs concentrate on the causal relationship between an independent and dependant variable. A further advantage of system simulation is that it allows interventions to be tested prior to implementation, along with numerous other *what if* scenarios and all without additional expense in a risk free environment.

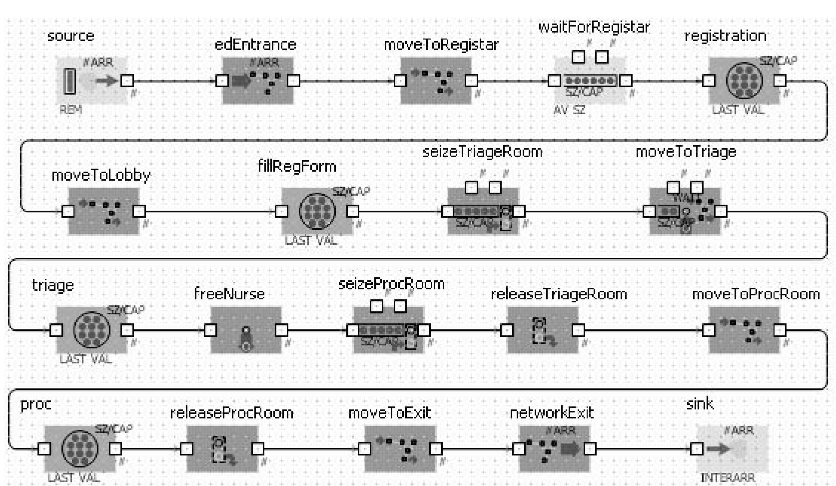
SYSTEM SIMULATION METHODS

Discrete Event Simulation

There are a number of simulation approaches which can be adopted. Discrete event simulation represents a system as a chronological sequence of events. A change of state in the system is marked by events that occur at a set of discrete points in time (Banks, Carson, Nelson, & Nicol, 2004).

Discrete event simulation is commonly associated with cost analysis, queue, inventory, and operation design and management problems. In the health care setting, it has been widely applied to patient scheduling, routing, and admissions, resource and staff allocation, and health services planning (Jun, Jacobson, & R., 1999). Its applications extend beyond the clinical setting and include the management of infection and communicable disease, costs of illness and economic evaluation, and screening (Fone et al., 2003). This can be seen in the assessment and design of health policies such as HIV intervention programs (Rauner, Brailsford, & Flessa, 2005), diabetic retinopathy screening policies (Brailsford, Davies, Canning, & Roderick, 1998), prevention and treatment strategies for coronary

Figure 2. A simple discrete event model of the emergency department in a hospital. Once patients enter the hospital they register and then wait to be seen by the triage nurse. Patients are seen in the order in which they arrive and must wait until a nurse and a triage room are available before being seen.



heart disease (Cooper, Brailsford, Davies, & Raftery, 2006), and resource requirements for renal treatment (Davies, 2006).

Agent Based Simulation

Agent based simulation reveals the global behaviour of a system as structures and patterns emerging as a result of repetitive and competitive local interactions between individuals, or "agents," and their environment (Axelrod & Tesfatsion, 2007; Bonabeau, 2002). The behaviour of each individual is defined by its encoded characteristics and rules for interactions which may be fixed or changed by an interaction with an agent or the external environment (Epstein & Axtell, 1996). This modelling technique also captures how a system learns, adapts, and self-organises itself to maintain order (Begun, Dooley, & Zimmerman, 2003). Agent based modelling is useful for describing systems that are open, complex, and with distributed control and resources. It is predominantly used for modelling epidemics and human social phenomena. Within the health arena, agent based modelling has been used to analyse the management of disease epidemics (Epstein & Axtell, 1996) like HIV epidemics (Teweldemedhin, Marwala, & Mueller, 2004), substance abuse (Perez, Dray, Ritter, Dietze, Moore, & Mazerolle, 2006), and health care and service delivery systems (Kanagarajah, Lindsay, Miller, & Parker, 2006).

System Dynamics

Developed by Jay Forrester at MIT in the 1950s, System Dynamics is a method that enhances understanding of the functioning of complex systems over time and in particularly dynamic complexity, by computing system interaction and taking into account nonlinear feedback (Sterman, 2000). System Dynamics uses a high level of aggregation, continuous flows, and focuses on the pattern of behaviour produced by a system, such as increasing costs, decreasing quality, and stagnating waiting times. System Dynamics modelling has been used to study policy interventions to reduce hospital waiting lists (Gonzalez-Busto & Garcia, 1999) and the care delivery capacity for chronic illness management (Hirsch & Homer, 2004) to name just a few.

Dynamical System Simulation

The precursor to System Dynamics, Dynamical Systems and System Dynamics share a number of similarities. Both model a phenomena whose state changes over time, both have continuous flows, and both do this using models of differential equations and other mathematically specified relationships, where the equations describe behaviours within the system (Willems, 1991).

However there are also some differences. Dynamical Systems simulation is usually limited to simulations

Figure 3. An agent based model, Acute Aged Care Interface (Adaptive Care Systems, 2007). This model tracks elderly people (the agents) in the community, where they stay overnight, and their level of disability and disease.

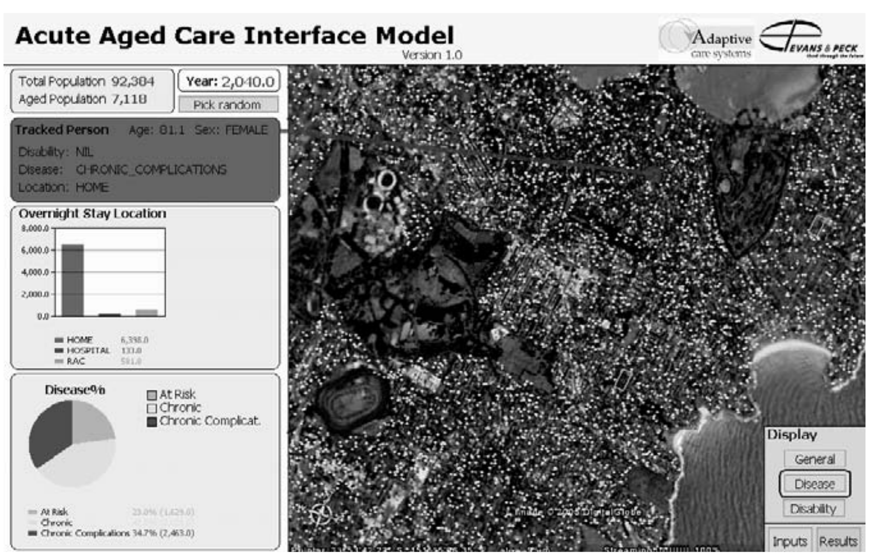


Figure 4. The SEIR model for disease outbreaks represented in a stock and flow diagram used by System Dynamics. The stocks (Susceptible, Exposed, Infectious, and Recovered) represent accumulations of people in each category. The flows (Infection, Incubation, and Recovery) represent the flow of people as they transition from one state to the next. The arrows show feedback, especially how the number of people exposed and infectious impact upon the number of people who become exposed, via infection.

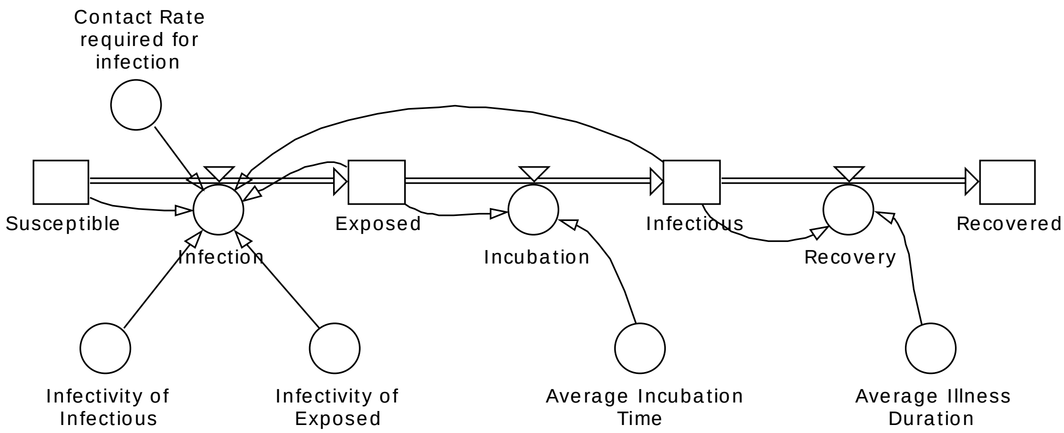

of physical and physiological systems (Borshchev & Filippov, 2004), such as heart beat or respiration. Dynamical Systems simulation is used in the natural sciences, especially physics and mathematics and in physiology modelling in health research.

In contrast, System Dynamics models work at a much higher level of abstraction and while able to model physical phenomena, it is also able to model more abstract policy concepts, such as quality of care and workforce morale.

Multi Method Modelling

Each modelling method is best suited to describe a particular level of abstraction of the problem. System Dynamics outlines the context of the problem making explicit the boundaries of the health system, its structure, and relationships. Discrete event models are process focused and agent based modelling can provide more detail at the individual level as well as a depicting the collective behaviour at the macro level.

Some problems can be elegantly described at one abstraction level by one modelling method however, health care problems span across a wide scale (Bar-Yam, 2006), from the patient, health professionals, and communities to the organisations, institutions, and resources whose primary purpose is to improve peoples' health (WHO, 2006). Multiple levels of abstraction of a health problem, described using multiple modelling paradigms, are required to capture the complexity within and across each level of the health system hierarchy at different time scales.

Multi method modelling, also referred to as hybrid modelling, combines more than one modelling method into one model. Multi method simulation is the execution of this multi method model over time. This process is made simpler with simulation platforms now capable of integrating and cooperating efficiently between different modelling paradigms (Borshchev & Filippov, 2004).

Multi method modelling can be used to develop multiscale simulations that bring together multiple scales of a problem in the one simulation. Multiscale simulation is yet to make its mark in the health industry, however its success in the environmental science discipline and applications to biological systems analysis (Bassingthwaighte, Chizeck, & Atlas, 2006) provide a promising future in health.

CHALLENGES OF SIMULATION

System simulation is not a solution to the problems of health care per se, but instead its value lies in its ability to enhance our understanding of the systemic causes of health system behaviour. This knowledge then becomes the basis for the development of interventions to improve the system, which can be tested on the simulation. The greatest barriers to the success of system simulation stem from barriers to learning.

A commonly used method of teaching the insights gained through system simulation is to allow stakeholders in a problem to “fly” the simulator themselves. They are able to run the simulation, pull the different policy levers, try each *what if* scenario, and observe the results. However, there is the potential danger with simulation gaming that participants will treat it as a video game where the goal is to win or beat the next person’s highest score. This *Video game syndrome* is a barrier to learning when participants instead of learning, play too much, and think too little (Isaacs & Senge, 1992).

Another risk is that participants will learn the insights of the simulation, but will fail to translate these lessons into the real world. Simulation is a distillation of the problem faced without the distractions of the real world. When participants return to their workplace after flying the simulator, it may be easy for them to get caught back up in treating the surface symptoms of the problem, rather than treating its root cause.

Both of these problems can be overcome with good facilitation of the simulation gaming. A good facilitator will draw attention to the specific purposes of the model, provide the conceptual background, and strongly tie the flight simulator to the real world problem. In this way the focus is on the real world problem, not on the simulation as a game or a concept that is removed from the real world.

There is also a risk that simulations and model can be seen as *black boxes* with people unsure of exactly what is occurring inside the computer to produce the results observed. When a simulation is seen as a black box, it is easy for sceptics to dismiss them, weakening the effectiveness of insights gained. This can especially be the case when the results or course of action the process reveals in counter intuitive.

Modellers can overcome the perception of simulations as a black box and improve the acceptance of the simulation by involving the stakeholders in the development of the simulation (Sterman, 2000). Stakeholders should be encouraged to ask questions, suggest changes, and challenge and test model assumptions. These people then become the champions of the simulation and increase the level of acceptance amongst their peers.

A systematic review of system simulation in population health and health care delivery (Fone et al., 2003) concluded that despite the potential of simulation to inform and improve policy development, there is little evidence of the value or impact of such studies and a lack of reporting on implementation. There is a need for more research to develop a larger evidence base for successful system simulation-based interventions in the field of health care.

Complex problems in health will inevitably affect multitudes of people, each of whom will have differing views on the causal relationships and structures which create the problem. If stakeholders in the problem feel that their perspective has not been adequately addressed in the simulation model, their perceived validity of the model will deteriorate, weakening the possibilities for learning and positive change.

SIMULATION VALIDITY

A system simulation is an abstraction of the real world, aiming to capture the relevant essence of the problem. In this way, a simulation model is a hypothesis of the causal relationships and structures that produce the system behaviour of interest. The usefulness of a simulation will depend on how well it represents the real world problem.

Just as a hypothesis can never truly be proven, a model can never be truly validated (Sterman, 2000). Instead there are a number of techniques that can be used to increase confidence in it. One of the most commonly used is behaviour replication, that is, how well does the simulator replicate historical data.

Testing the simulation with extreme values or conditions helps to ensure that the rules on which the model is built are robust and will respond plausibly when evaluating various policies or determine how the system will respond to shocks.

There needs to be an evaluation of the adequacy of the boundary of the simulation to ensure that concepts important to the functioning of the system are endogenous to the model. Failing to include important concepts may mean that important sources of interactions or feedback are being ignored.

Sensitivity analysis, which determines how sensitive the model is to parameter changes, should be performed on parameters where the initial conditions are not certain. If a model is very sensitive to an estimated parameter, then we need to carefully question why this is so.

Simulation models should also be tested to ensure the structure is correct, that it is a consistent representation of the real world problem.

FUTURE TRENDS

There are a number of developments within the system simulation field which are helping to expand its utilisation. It is pleasing to note that the use of systemic approaches for analysing the health system is increasing (Fone et al., 2003). We believe that a more complete view of the complexity of the health system across its varying levels along with multiscale analysis will be best achieved using a combination of modelling paradigms.

Another important trend concerns the incorporation of human factors in system simulation. Health care systems are influenced significantly by the behaviour of the people within them (Brailsford, Sykes, & Harper, 2006). Currently human behaviours are poorly represented or omitted in health system models causing observed behaviour to depart from the behaviour expected from the modelled system. The incorporation of human factors and behaviour in simulation models will be enhanced by the development of agent based modelling (Brailsford & Schmidt, 2003).

Advances in technology have made modelling and simulation a more practical tool for exploring, understanding, and presenting the behaviour of the health system. Innovative graphics used in simulation animations can create an emotionally engaging, immersive learning environment heightening the users' experience and encourages more relevant, applicable and realistic decisions to be made. Moreover, the use of parallel and distributed "grid" computing will allow the execution of large complex models to be completed in less time, assisting more effective and faster decision making. Simplifying the modelling process will increase the popularity of system simulation in the health industry. This can be achieved by formalising a project management process around model building and including the decision makers in the model design process, using simple-to-use modelling tools with engaging animations, increasing re-use and interoperability of simulation models with the development of model building standards, and a health modelling library comprising a collection of reusable health modelling building blocks. Multidisciplinary collaborative communities supported by dynamic software infrastructures for combining simulation with data online are emerging in systems biology (Swertz & Jansen, 2007) and in time they could extend to a range of health system problems.

Systems simulation has the potential to provide more realistic insights into the relationships and interactions between components within the health system and its resultant behaviour. Marrying real world data with health system models opens possibilities to accelerate the understanding of the systems actual patterns in behaviour and thus enable decisions for positive change to be made quicker and be more relevant. For example, calibrating a biological model, such as the Archimedes model, with data obtained from electronic medical records could facilitate the simulation of evaluation studies and clinical trials with outcomes made available remarkably sooner than studies performed in real time (Eddy, 2007).

CONCLUSION

Not only is health care a large, complex, and dynamic system, but it is also a critically important one. It is a system where the price of failure may be counted in lives needlessly lost. Learning by trial and error places too much at risk. RCTs may take too long to produce usable results, fail to consider key factors, cost too much, not cover sufficient scale, or be unethical or otherwise impractical to conduct.

Traditional methods of management seek to understand and solve complex problems by reducing, isolating, and freezing in time. As we have established, in a complex and highly coupled system such as health care, these approaches ignore dynamic complexity and the effects of feedback. There needs to be an understanding of the systemic structures and interactions that give rise to social issues and problems. It is only by addressing the systemic causes that they can be fully addressed.

System simulation is the term we give to a collection of simulation methodologies that focus on the interactions of systems which provide the means for gaining the understanding of system causes. They also provide the ability to test intervention *in silico* before they are implemented in the real world. In an ideal world, all health policy and reform would be extensively tested in computer simulations before any changes were made because in something as important as the public health system the price of policy failure is high.

KEY TERMS

Agent Based Simulation (AB): A method of simulation which focuses on the interaction of individual agents. In Agent Base simulations, agents are encoded with attributes and rules governing how they interact with other agents and what attributes may change as a result of the interaction.

Complex System: A highly coupled system where the outcomes of the system are the result of the interactions that occur between its different components.

Discrete Event Simulation (DES): A method of simulation that treats the operation of a system as a sequence of chronological events, with changes in the state of the system being triggered by a discrete event.

Dynamic Complexity: Occurs when systems are dynamic, tightly coupled, governed by feedback; plays out over time.

Dynamical System Simulation (DSS): A method of simulation that is similar to System Dynamics (SD). However in contrast to SD, Dynamical Systems simulation are usually limited to simulations of physical or physiological systems where the relationships are expressed as mathematical equations.

Health System Simulation: The application of quantitative modelling and computer simulation methods to study the interactions between individuals and/or components of the health care system and how these interactions over time produce the observed behaviour which is produced by the health care system.

Multi-Method Simulation: Asimulation which uses more than one simulation method.

System: A combination of parts which form a whole entity.

System Dynamics (SD): A method of simulation that focuses on system interactions over time, which considering feedback effects. System Dynamics models are made up of a series of differential equations and are continuous. They are highly aggregated, focus on patterns of behaviour, and can incorporate abstract concepts. It is a useful method for policy level analysis.

Healthcare Information Systems and the Semantic Web

David Parry
Auckland University of Technology, New Zealand

INTRODUCTION

The World Wide Web (WWW) is a critical source of information for health care. Because of this, systems for allowing increased efficiency and effectiveness of information retrieval and discovery are critical. Increased intelligence in Web pages will allow information sharing and discovery to become vastly more efficient .The semantic Web is an umbrella term for a series of standards and technologies that will support this development.

BACKGROUND

The Web and Healthcare Information Systems

The early development of the Internet, from ARPA developments and the Internet protocol in the 1960s and 1970s to increasing use of e-mail and text-based systems, led to the development of HTTP and HTML in the 1990s (Barry et al., 1997). The Web has become a critical source of information and communication among people in all domains. The world of medicine on the Web, including such concepts as eHealth, have become areas of great academic interest (Pagliari et al., 2005). Thus, the Web and health care are increasingly co-dependent.

Finding the required information in a search of HTML documents is difficult, as HTML is really a formatting language for humans rather than for indexing. Of course, Web-based systems such as search engines or digital libraries are available, but these rely on indexing either as a set of keywords drawn from a limited vocabulary or from sometimes unreliable parsing of the document. Knowing what information a Web page contains, whether it is a medical record, a clinical result, or an academic paper, is still difficult.

The Semantic Web

Tim Berners-Lee has coined the term "Semantic Web" (Berners-Lee, Hendler, & Lassila, 2001). This term has been enthusiastically adopted and generally includes any work intended to allow the meaning of data contained in Web resources to be made accessible to software agents or humans.

In essence, a semantic Web document is a collection of three parts:

- The document that contains the information, marked up in a suitable way
- A document that contains the rules for interpreting the markup (Namespace)
- A document that links the information with the namespace (i.e., which set of interpretation rules is being used).

There has been a great deal of work under the auspices of W3C to develop standards for the semantic Web, in particular representations using XML. Two of the major efforts are the Web ontology language (OWL) (Smith, Welty, & McGuinness, 2004) and the resource description framework (RDF). In terms of information retrieval, the semantic Web will allow a user to express what they mean to find and find objects that satisfy that request without regard to the language or syntax of the request. The semantic Web implies ways of representing the meaning of documents and constructing queries to discover that meaning. If possible, such a process will be as automatic as possible and incorporate the advances in computing power available to users on the desktop and at the server.

An example may make this system clearer. The example is taken from the W3C example page (http://www.w3.org/2000/10/rdf-tests/)

The original RDF document is:

```
<?xml version="1.0"?>
<rdf:RDF
  xmlns:a="http://description.org/schema/"
  xmlns:rdf="http://www.w3.org/1999/02/22-rdf-syntax-ns#"
  xmlns:oiled="http://img.cs.man.ac.uk/oil/oiled#"
  xmlns:xsd="http://www.w3.org/2001/XMLSchema#"
  xmlns:rdfs="http://www.w3.org/2000/01/rdf-schema#"
  xmlns:daml="http://www.daml.org/2001/03/daml+oil#"
  xml:base="file:/C:/downloads/RDF-Model-Syntax_1.0/ms_4.1_1.rdf">
 <rdf:Statement>
   <rdf:subject rdf:resource="http://www.w3.org/Home/Lassila"/>
 <rdf:predicate rdf:resource="http://description.org/schema/Creator"/>
  <a:attributedTo>Ralph Swick</a:attributedTo>
  <rdf:object>Ora Lassila</rdf:object>
 </rdf:Statement>
</rdf:RDF>
```

This can be displayed as shown in Figure 1.

This can be expressed in words as “Ralf Swick and Ora Lassila have the attributes of creators of RDF.”

The flexibility of this approach can be seen by the fact that the definitions of what RDF is and what “creator” means can be located in other files. Thus, agreed meanings can be used across multiple data files.

Often it may be useful to think of the meanings of items in documents as related to an ontology and that there is a standard for the expression of ontologies on the WWW. This standard—Ontology Web Language (OWL) (Smith, Welty, & McGuinness, 2004)—allows ontology relations to be coded in a machine and human readable form within files that can be located on the WWW.

An example of an OWL statement is shown in Figure 2 (the example is taken from Smith, Welty, & McGuinness, 2004.

This example shows the definition of an equivalent class—items that satisfy the conditions given in the equivalent class construction are regarded as equivalent. In this particular example, things from Texas are assigned to be “Texas things.” This project is still at a fairly early stage but obviously represents a potentially beneficial approach to standardization that may be useful for the deployment of the fuzzy ontology described later.

What both these approaches do is allow the page author to identify to agents or humans the intended meaning of various parts of the document. The RDF form does not need the existence of an underlying ontology, but in many cases, an ontology does exist, which makes consistent namespace creation easier. Of course, systems such as HL7 already have what are effectively namespaces, but the semantic Web approach means that the author provides the data, the possible values of the data, and the potential meaning of the data in a format that allows shared meanings. This

Figure 1. XML document construction

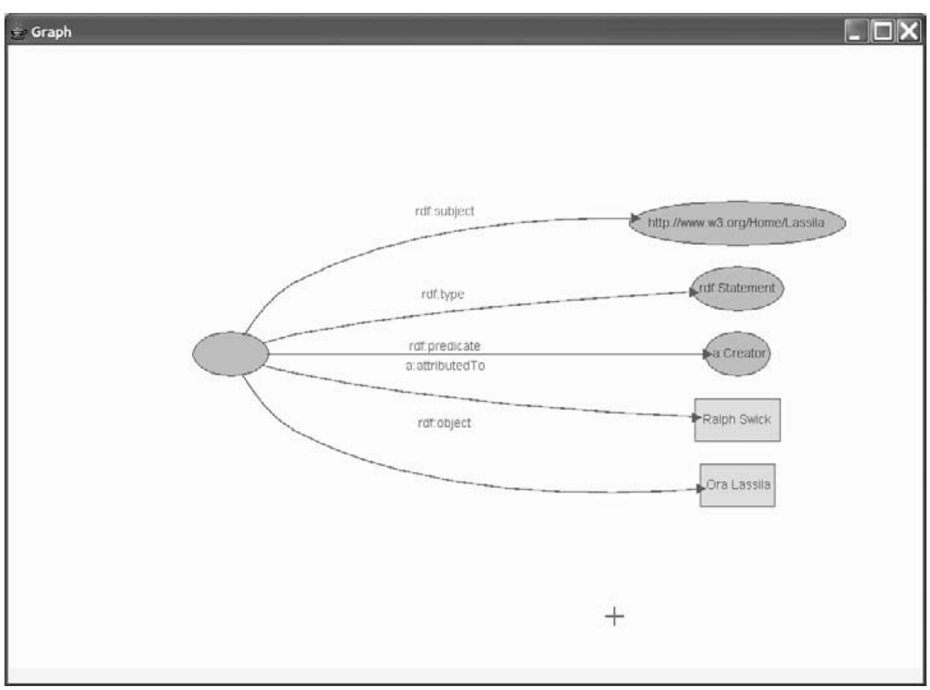

Figure 2. OWL example

```
<owl:Class rdf:ID="TexasThings">
 <owl:equivalentClass>
  <owl:Restriction>
   <owl:onProperty rdf:resource="#locatedIn" />
   <owl:someValuesFrom rdf:resource="#TexasRegion" />
  </owl:Restriction>
 </owl:equivalentClass>
</owl:Class>
```

makes the approach very powerful for semistructured information or approaches where only a subset of the information is needed.

Systems for encoding semantic information do not have to rely on XML or other general-purpose systems. An extremely general-purpose approach to adding semantic information to documents is the WorldNet approach described in Mihalcea and Mihalcea (2001). In WorldNet, there is a number of keywords, each of which has a large potential set of attributes such as synonyms, hyponyms, related terms, and so forth, which are used for searching. Documents have their own schema that includes information about the position of e-words within the document.

HEALTH INFORMATICS AND THE SEMANTIC WEB

The use of semantically meaningful XML structures is not new in medicine. The entrez database that is used to access PubMed has a standard XML output that allows users and agents such as the entrez e-search tools to identify elements of a document record. Similar systems are available for gene and protein libraries.

The use of Semantic Web technologies for a health database is described in AnhÃ¸j, 2003. In many cases, the use of ontologies has predated the implementation of Semantic Web formulation in the medical domain. In the previous terms, the reference to namespace is implicit, as the namespace is determined by the ontology that is being used. This approach is more powerful in some respects, as extremely complex relations and workflow can be encoded into complex ontologies, but less flexible in that all the documents have to refer back to the same namespace.

Web-based ontologies can be seen as a part of implementing the Semantic Web. The Stamford medical informatics group suggest their language—PROTÉGÉ-2000 (Noy, Sintek, Decker, Crubézy, Ferguson & Musen, 2001)—as a means of representing ontologies on the Web. The central role of ontologies in knowledge management is emphasized by Staab and Maedche (2001).

A number of systems have been designed to allow communication between ontologies; for example, XOL, an otology exchange language implemented in XML and developed from Ontolingua (Karp, Chaudhri, & Thomere, 2004). The Ontolingua server (Stanford University Knowledge Systems Laboratory, 2001) allows online collaborative editing of ontologies, and the knowledge system laboratory is also the home of a library of ontologies (e.g., the enterprise ontology and others).

The MeSH system also can be easily represented as an ontology, although in this case an object can be allowed to be a member of more than one leaf element at the lowest level. This is because a particular document can be "about" many different and closely related subjects. It is also possible to have the same leaf element incorporated in a number of different branches. This creates problems for some representation systems, and artificial distinctions have to be made between the same terms, depending on from which branch it has come.

A keyword or index term hierarchy can be seen as a particular class of ontology. At the same time, documents can be analyzed in terms of such ontologies. In this case, the attributes used to define a document are themselves divided by navigating the tree that represents possible classifiers. In the information retrieval case, it is highly likely that documents will possess many attributes, some of which may tend to place it in differing parts of the ontology. For example, a page produced by a sufferer's charity about a disease may have attributes such as brevity, low reading difficulty that indicates it would be located in a tree associated with public information, but it may have valuable links to research teams and means of getting funding that would make it suitable for researchers and located in that tree. An XML result from PubMed can be seen as an example of a Semantic Web document, where the namespace is not directly referenced but can be obtained from the publisher.

```
<?xml version="1.0"?>

   <Month>06</Month>
   <Day>18</Day>
```

Not only knowledge sources can be represented in this way. The Electronic Health Record (EHR) can use Semantic Web technologies, for example, by identifying regions that correspond to patient ID, date of birth, or diagnosis.

Current Research Projects in this Area

The National Library of Medicine (http://www.nlm.nih.gov/healthit.html) runs a number of large-scale projects in this area; in particular, the UMLS work mentioned earlier. This forms a basis for a great deal of work. Underlying the concept of a Semantic Web is that of ontology. The protégé research group at Stanford (http://protege.stanford.edu/) is continuing to develop interactive tools and ontology products.

The WWW consortium (W3C) has active programs developing and promoting OWL and RDF (http://www.w3c.org). Research in ontology development includes the use of fuzzy ontologies to better match uncertain classifications (Parry, 2004; Tho, Hui, Fong & Tru Hoang, 2006) and the development of ontologies for specific areas such as the gene ontology machine (http://www.**geneontology**.org). Applications of Semantic Web approaches to health care include drug safety (Stephens, Morales & Quinlan, 2006) and the investigation of e-health quality and reliability (Eysenbach, Lampe, Cross & Brickley, 2000). A particularly strong effort is being made to use semantically enhanced web services in the medical domain in the Artemis project (Asuman et al., 2006).

FUTURE TRENDS

The Bioinformatics community has a number of applications ready for Semantic Web approaches (Wang, Gorlitsky & Almeida, 2005). The wide variety of interfaces to the various databases in this area remains difficult, and a standardized semantic approach seems particularly likely to arrive. The latest release of HL7, version 3 (Dolin et al., 2001) is explicitly based around semantics of documents. Many applications are based around data-sharing via XML documents and Web services, and standards are emerging. Semantic standards—what a particular piece of information means—is intrinsically more complex for more sophisticated information, and it may be that hybrid approaches are used. That is, items such as name, patient number, drug therapy, and so forth are easily standardized, but more abstruse concepts such as prognosis or lesion appearance may not be so easily represented. The Semantic Web architecture will become more attractive for purely internal projects as tools for XML and RDF become more effective.

In business terms, there appears to be a role for brokers and intermediaries between systems. There are potential issues with privacy of medical data in that Semantic Web storage should be more comprehensible than proprietary formats, but health care systems always have had this problem. It seems likely that the open source movement will be particularly adept at adopting this approach, which will lead to increased use of the EHR (Middleton, Hammond, Brennan & Cooper, 2005). In terms of health knowledge and information retrieval, interoperability between systems seems the greatest possible benefit and, in particular, the development of intelligent browsers with agent technology that can vastly increase the power of search by personalizing it and putting it in context.

CONCLUSION

The Semantic Web is based around a number of fairly simple standards, but adoption of those standards in the health care domain is sometimes difficult. It is possible that Web publishers will generally adopt Semantic Web coding standards to allow their documents to be used by increasingly sophisticated agent-based systems. The vision presented in Shadbolt, Hall & Berners-Lee (2006) is attractive and is happening for particular domains. The huge bulk of Web pages that have not been revised for ease of semantic understanding seems to pose a problem. However, HTML coding was seen as difficult in 1996, so as more editors become available and the utility of Semantic Web applications becomes obvious, this may not be a vain hope. Undoubtedly, Semantic Web approaches to information publishing and sharing are likely to be a key aspect of work in health care information in the future.

KEY TERMS

Electronic Health Record: A system of storing information about a patient to assist in diagnosis and treatment.

HL7: A medical message system standard.

MeSH: Medical Subject Headings. Index terms used by NLM.

Ontology: A rigorous and exhaustive organization of some knowledge domain that is usually hierarchical and contains all the relevant entities and their relations.

Semantic: Of or relating to meaning or the study of meaning.

PubMed: Web portal to the National Library of Medicine Bibliographic Database.

W3C: The World Wide Web steering committee.

WWW: The World Wide Web. A system using data and program protocols that allow simple publishing and transfer of information.

XML: Extensible Markup Language. A standard set by W3C for documents that can include description of the meanings of items.

Healthcare Training for the Greek Municipalities' Citizens in the Program of "Home Help" with the Medical Educational Web Sites

Bill Ag Drougas
Higher Technological Institute of Epirus, Greece

INTRODUCTION

Today, the Internet is one of the most useful tools for information, education, business, and entertainment. It is one of the modern technology tools giving us many applications. One of the most important applications of the Internet is the health educational Web sites. These sites can be used not only by researchers but also by everyone easily taking important information for continuing self-training. In the division of public health, this part is very important. Medical Web sites give us access to information about our health or about prevention methods. In Greece today, there is a new 12-hour program offering home health help and care to citizens. This program is under the organization of the local municipalities and the affiliation of the Ministry of Health.

BACKGROUND

In Greece and especially in the agricultural municipalities, there are many old people who must have healthcare at their home. The Greek government established a serious program for public health. But still this program, after some years since the beginning of its application, continues with many problems. New technologies and the Internet may help local municipalities and their citizens.

The Home Help Care program was established by the ministry of Health in Greece to help people in Greece in their homes. For the application, there were about four to eight people working in the program with various levels of training but under the same direction in order to help people in their homes, giving them health and psychological help.

The administration, application, and recognition of the program Home Help is under the recognition of the Administration Work Group (AWG), which established it with the No.DY1d/oik. 10024/1.6.2001 recognition No. of the Government (FEK 726/τ.B/2001 paragraph 18 article 18 N. 2503/1997 (Government Newspaper FEK 107/rA/97) and still exists today (Moraiti, 2005).

This program offers a first-step healthcare to citizens, so it is important to help them use the contemporary technologies for self-training or for simple self-help and protection.

ABOUT THE RESEARCH

There is an enormous number of programs today in the Greek Kapodestrian Municipalities. One very important program with many positive applications is the Home Help Care program. Many individuals can help themselves along with the affiliation and the help of Home Help Care program employees in the municipality. This research recognized the problems from the application of this program.

This research took part in western Greece. The employees of the program asked to help giving the questions to the citizens and taking back the answers. Then all the answers were organized carefully. There were many results with an important statistical study and many different diagrams. We were able to understand what happens with the program of Home Help Care and what we must do in order for this program to work more efficiently. In this research, there were many statistical tables and many more statistical diagrams, but we will present only a few of them.

ISSUES

The existing Greek geographical status today makes more difficult the application of healthcare, especially at the municipalities far away from the big cities or to the villages where there are many climatic problems that continue for many months per year.

The traditional way to offer help to people in various places makes the application of this program very difficult. By using the periodical visits in every home and spending much time for this either in transportation or staying in the same house for a long time, the program cannot work fast for a simple or combined health problem. People working in the program today are not able to visit all the persons once or more times per week because the number of them is very big and the claim for psychological help is bigger every day with various problems, especially with older persons. Sometimes they must work with the same person more than one time and for many hours.

The effort of employees at time management gives them the probability for more dangers driving many kilometers to every village far from the center, which happens every day.

There are only a few persons working in the program, less 4 and maximum 7 persons, offering home help and care. So it is very difficult for them to work every day personally with every citizen (Moraiti, 2005) They are not able to visit all the persons in their home in different villages many kilometres away. Another problem is that the official number of inducted persons in the program asking for home help is very big in every municipality. This problem is bigger if someone works with people with different problems and more than three or four times per person. Especially if the people are over 60 years old, this is more difficult.

Sometimes they must visit and work with the same person for more than one time per week. This is what gives us the opportunity to claim that the IT technologies will help the program to continue with success. On the other hand, municipalities must work hard to induct new technologies and continue to the modern philosophy with many vital technical changes (Drougas, 2005b). Some of these changes are summarized in Table 1.

A network system will help people have access with the control center, even if they are many kilometers away from the center (Drougas, 2004). After searching the selected answers from the questions given to the people associated with the program, we can say that the most serious problems are summarized in Table 2.

All these results from the research give us the icon that the program today continues very slowly. Internet technologies and a self-training methodology program will help both employees and citizens in the next years with success. This will be a part of the applications of the contemporary network systems WAN and LAN, which will help citizens have local or national and

Table 1. Summary of the technical changes in telecommunications in the municipality

- New connections in affiliation with the local telecom organizations or companies
- ISDN Networks
- LANs Local Area Networks
- WANs Wide Area Networks
- MANs Metropolitan Area Networks
- Internet TCP/IP
- Intranet communications
- Extranet communications
- VPN Virtual Private Networks

Table 2. Summary of the vital problems from the application

- The low level of the citizens education
- The big number of the new Kapodistrian municipalities with many villages many kilometers far
- The small number of the employees in the program
- The big number of the citizens served in the program
- The personal visit in every person
- The difference of the health problems
- Geographical problems
- More persons are older than 60 years old
- Telecommunications problems
- Economical and other time problems

international access to Internet information using their home computers (Apostolakis, 2002).

It is time to train all citizens, the municipality's administration office employees, and the Ministry administration office employees in IT philosophy of network for the e-health education and applications (Drougas, 2005b).

Citizens are not able to use the Internet connections, and many of them are unable to search and use or understand the Internet medical information Web sites. Also, we must say that there are only a few Internet sites in the Greek language today with serious information about healthcare.

This study explains why the case of Greek agricultural municipalities are different than other central and how they can help families understand the use of the Internet medical resources for a self-training, rehabilitation, first aid, family health, and so forth.

The low level of education in the villages makes the work of the employees more difficult because sometimes there is much time to spend with only one person to help him or her for one or more problems. This is a phenomenon appearing in the agricultural areas in the same municipality today. Telecare and telecommunications can send information many kilometers from the control center with best quality, security, and in less time. We are able to repeat this many times per day or per week and for different places in the municipality and to different persons.

The following statistical analysis gives us the icon about the 300 citizens in the research. Searching the numbers in the following presented tables, it is easy

Table 3. Males and females

TABLE 3		Less than 450€		Over 450 €		Total	
Sex	Male	62	79,49%	16	20,51%	78	100%
	Female	198	89,19%	24	10,81%	222	100%
	Total	260	86,67%	40	13,33%	300	100%

For the Program		%	%
Less satisfaction	9,00	3,00	3,00
Much Satisfaction	152,00	50,67	50,67
Very Much Satisfaction	139,00	46,33	46,33
TOTAL	300,00	100,00	100,00

for someone to understand that the employees in the program must work very hard to serve all the people. The number of male and female persons in the program in our research are presented in Table 3. Forty people did not answer.

Their personal health problems are summarized in Table 4.

Table 5 includes data about the personal health and the economical level.

Table 6 presents general information about the satisfaction from the program's application with the divisions of less, much, and very much.

INTERNET SITES ENVIRONMENT IN THE PROGRAM

The program does not associate with any Internet connection and serves people only with personal visits. In the central office, there is not any technician or anyone working in the IT technologies professionally. The program does not use any database, and there is not any future plan to train citizens for a family or personal care via IT and other technologies (Sasiakos, Papastefanatos, & Lazakidou, 2006).

Personal visits are really a big problem in the program where simple problems can change everything very quickly. Using the experience from the past inductees in the program and the experience of the employees, establishing a database may induct always new data, and an effective program like this will continue as a contemporary telehome care program.

With this method of distance advice or with distance help applications, many people will have the opportunity to contact the database using information from this base together with other citizens at the same time and from different places in the municipality. After this, anyone may have answers for his problem directly using the electronic "Tele-Municipality Advisor" for any simple or combined problems. This will help anyone when the visit is not necessary to them personally spending much time.

USING THE HEALTH SITES

Searching the Internet sites, we are now able to say that all the Web sites that have been published by Academic Institutions and professional organizations were of higher quality than those published by any private practice groups or any profit organization, although they gave us much important information.

In Figure 1 the statistical results are shown for how the computer and the Internet were used for the health

Figure 1. The use of contemporary technologies from doctors nurses and hospitals

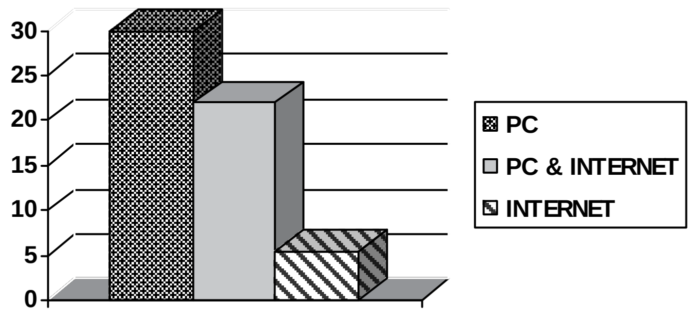

Figure 2. Types of Internet search by the health professionals

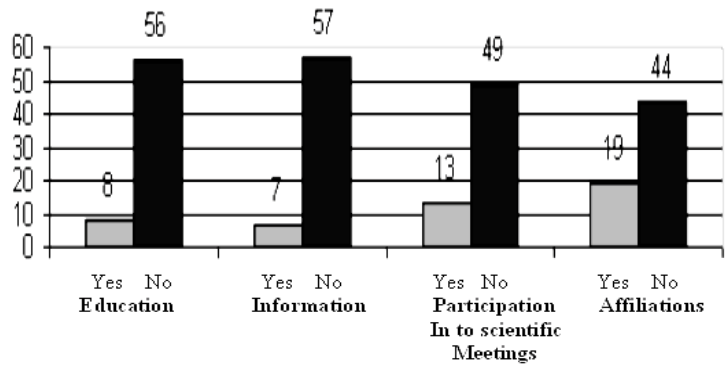


help from doctors, nurses, hospitals, and medical companies. 5.5% use the Internet, 30% use only a computer, 22% use both the computer and the Internet.

This statistical diagram shows the answers from health professionals of how the traditional methodologies help them in their work.

All this is recognized from an important research in 2003-2004 for the health professionals to recognize the existing problems in their work area the technological problems and the upcoming induction of the Telematics in medicine applications**.**

Searching the various problems of the affiliated people with the program (HHC), we found that many people today in Greece between 40 and 70 years old are not able to use the modern technologies, especially if they do not have a diploma. Also, many of them do not have a personal computer. There are also many problems with the connecting lines in Greece, and the Internet is still very expensive.

Serious problem were found when we asked them to read and understand information presented on important medical sites. Many of them were not able to organize this information. We must say that health information presented from various sites would be better to follow a video and graphics for self training, audio, or other video files for better education. This will help the old people in the program to better understand the practical application and also people with special needs.

AN IT MODEL FOR THE HHC PROGRAM

In the direction to help people read and train using correct medical information, the Ministry of Health in Greece must create a central database with simple and combined information in the Greek language selected from health professionals and medical bases or scientific magazines and laboratories.

Let's see the model for an Internet self-training from Web pages in the Home Help Care program. This model may help both employees and the people who are associated in the program.

The model is summarized in the next eight points:

- Scientific and medical Web pages selected from the Ministry of Health office
- A new central database will enclose all the medical information with access to other Web pages
- The Ministry of Health will establish a local administration office for the program in every municipality with a central administration
- The local office will have to refresh periodically the local database LDB with access to the central database CDB
- The local office will associate with the program's employees to give and select information about the application of the program
- Citizens who will be in affiliation with the program will have access to the central office and to the local database with a personal electronic address
- Citizens will have the opportunity for self-training and education in different levels and in different subjects periodically
- Citizens will have a dialogue with other persons from the program and scientists and participate in online seminars and information lessons

Table 7 summarizes the answers about IT.

Figure 3 presents the icon from the answers of Table 7.

There is an important machine today in the United States. This is a platform of double direction communication for the healthcare problems. The name of this is Motiva, which works between the TV canals. This program can help people in their homes as a virtual doctor for many health problems, giving information about different health problems. Motiva offers today the following applications:

- Information about one health problem and the vital steps for self-information.
- Personal help from the doctor and communication with the other family members.
- Reminder for medicines and care for personal health.

Table 7. Answers about the IT use

Question	Yes
Do not like computer technologies	20%
You know that it is a useful tool	62%
Do you have a PC in your home?	4%
You think that the HHP uses a computer	8%
Have you heard of the Internet?	70%
You like to ask a computer for your problem	45%
You like to ask a doctor something online	80%
You want to learn to use a computer	54%

HOME HEALTHCARE COMPANIES IN GREECE

Some of the most known companies in Greece offering medical machines and programs in the healthcare:

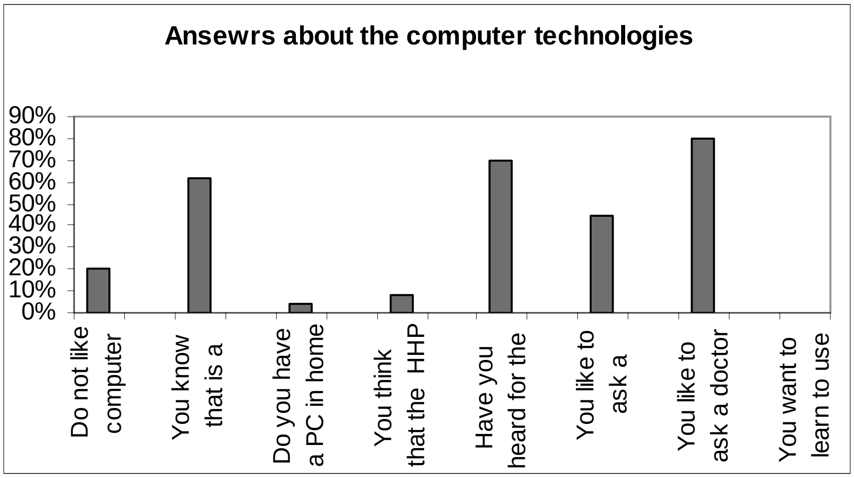
- Advance Products
- Akoustica Medica
- AlfaTech
- Anthos Hellas
- Bio-Spectrum
- BioChem Diagnostics
- Celestar
- Cip Hellas
- Ebedent A.E.
- Sigma Medical
- Sterile Hellas
- Ratio
- Nova Medica
- Nivaco

CONCLUSION

The official recognized program with the name Home Help Care from the Greek Health Ministry is a very important program helping people in every place in Greece. People can use very easily the applications offered from the program, but still there are many problems with the big number of the affiliated persons and the small number of the scientists and the employees who work in the program. The induction of the modern Information technologies will change this program in Greece and make it more efficient.

A personal training for everyone as a personal health information training program will give the information by distance, as personal help from the doctor and com-

Figure 3. Answers about the computer technologies



munication with the other family members or a reminder for medicines and care for the personal protection with the personal doctor.

Using the affiliations of the local companies and the administration of the central municipalities' offices, it is possible to induct new telecommunications technologies into the program's applications. IT technologies will help the program to continue with success and to save money and time. Employees and citizens must train in healthcare and protection electronic technologies and machines, which will help both to associate with success.

KEY TERMS

Healthcare: Care, services, or supplies related to the health of an individual. Healthcare includes but is not limited to the following: preventive, diagnostic, therapeutic, rehabilitative, maintenance, or palliative care; counselling, service, and assessment, as well as the sale or dispensing of a drug, device, equipment, or any other item in accordance with a prescription. (Lazakidou & Ilioudi, 2006)

Home Care Technologies: Any technology used to implement home-care telemedicine services; also any device or any instrument for patient monitoring, therapy, or environmental control (Mantas & Hasman 2002).

Home Help Care Program (HHC): The Home Help Care program established from the Ministry of Health in Greece to help people in Greece in their homes. The administration, application, and recognition of the program Home Help is under the recognition of the Administration Work Group (AWG), which is established with the No.DY1d/oik. 10024/1.6.2001 recognition No. of the Government (FEK 726/τ.B/2001 paragraph 18 article 18 N. 2503/1997 (Government Newspaper FEK 107/rA/97), and still exists today.

Kapodestrian Municipalities: The modern municipalities in Greece with the accreditation of the Greek government. The new local municipalities inducted many small or bigger villages under the same administration.

Network: Defined as a set of nodes and connecting lines to describe intricate structures (e.g., neuronal network, computer network, data network (Paraki, 2006).

Telehealth: The removal of time and distance barriers for delivery of healthcare services or related healthcare activities (American Nurses Association). The methodology of serving people by distance to various heath problems and care. This includes health information programs, self or group training, tele-education, and so forth.

Telehomecare: Uses telecommunication and videoconferencing technologies to enable a health-care provider at a clinical site to communicate with patients in their homes (Demiris, 2004).

WAN: Wide Area Network system of communications by information technologies.

World Wide Web: A system of Internet servers that support specially formatted documents in a language called HTML (Hyper Text Markup Language), which supports links to other documents as well as graphics, audio, and video files (Zvanut, 2006).

Heterogeneous Quality Information in Healthcare Marketplace

Kimberlee Schumacher
Northeastern University, USA

Yang W. Lee
Northeastern University, USA

INTRODUCTION

Contemporary healthcare systems are utilizing new information technology to digitize and share previously paper-based information among the legitimate but distributed participants in the healthcare marketplace. A critical stumbling block the participants face in this effort is the questionable quality of the information. Demands for quality information in the healthcare arena are dramatically increasing as information is being used as a basis for evidence-based medical care. Quality information is also critical for management decision-making and benefit design, but more importantly for providing decision choices for healthcare consumers: patients. Although everyone agrees on the critical need for quality information, there is a lack of agreement on what constitutes quality information for healthcare systems.

In this research, we use the classical stakeholder perspective (Butterfield, 2004; Freeman & Reed, 1983) and information quality research (Lee, Pipino, Funk & Wang, 2006) to examine what constitutes quality information among directly participating stakeholders in the healthcare marketplace. We argue that the role a stakeholder plays in the healthcare marketplace affects the nature of quality information each provides and uses, thus shaping the principles that dictate each stakeholder's view of quality information. Our findings, based on participatory observation and the analysis of research publications, provide a basis for a shared understanding of quality information in the healthcare market place.

BACKGROUND

The healthcare industry is at a crossroads. With healthcare costs continuing a trend of annual double-digit increases, employers are in the unenviable position of either absorbing these costs, passing them on to their employees, or dropping insurance all together. As a result, consumers are responsible for more of their overall healthcare costs and are challenging the healthcare system to become more consumer-driven. A virtual healthcare marketplace is developing in which consumers "shop" for their healthcare. As with any marketplace, consumers are becoming cost-conscious and therefore demand transparency of cost and quality information throughout the healthcare system. In this marketplace, five major groups—consumers (patients), physicians, government, healthcare plans, and employers—form the key stakeholders who play a critical role in shaping what constitutes quality information.

Issues and factors associated with technology acceptance, diffusion, and training (e.g., effective use of new systems by doctors and nurses) have been studied thoroughly (Aas, 2001; Bashshur, Reardon & Shannon, 2001; Cloutier, Godin, Gagne & Reiharz, 2005; Hu, Chau, Liu & Tam, 1999; Jayasuriya, 1998; Menon, Lee & Eldenburg, 2006; Raitoharju & Laine, 2006); the information shared, the contents of the systems, has not been studied adequately.

Guided by the stakeholder perspective (Butterfield, 2004; Freeman & Reed, 1983) and research on information quality (Lee, 2004; Strong, Lee & Wang, 1997; Wang, Lee, Pipino & Strong, 1998), this research asks the following question: What constitutes quality information by multiple stakeholders in the healthcare marketplace? This work further examines principles held by each stakeholder, which serve as the basis for different views on quality information.

This chapter contributes to the research in the healthcare arena for both research and practice. For research, the study will expand and deepen the research in healthcare systems by including the analysis on information that healthcare systems design and use. For practice, the research helps to design and use healthcare information considering all stakeholders' perspectives for an effective evidence-based practice of healthcare. Furthermore, the findings of this study will elevate the discussion on establishing measurements and a common definition of quality information for healthcare practice based on the goal of sharing useful and useable information.

QUALITY INFORMATION IN THE HEALTHCARE MARKET

Many recognize the importance of quality information through a crisis. For example, a CEO of a hospital received a letter with a fine for poor-quality information submitted to the state government (Davidson, Lee & Wang, 2004). An insurance provider paid mistaken claims due to its information quality problems, which resulted from its misaligned business and information processes (Katz-Hass & Lee, 2005). A hospital could not make a critical business decision on medical project initiatives due to inconsistent information (Lee & Pipino, 2004). Physicians resisted using the information from the hospital's data warehouse due to the inconsistent and not-believable service records shown on the report (Lee & Pipino, 2004). Worse yet, ad hoc reports on the news evidenced disasters from mistaken surgeries based on poor-quality information.

A crisis, errors, mishaps, financial loss, and an inability to make decisions are often the results of many cumulated and interdependent factors. A key common factor involved, however, is poor-quality information. Inconsistent data fed from various sources are aggregated to produce a report. Financial and medical information is often aggregated to support decision-making in medical care, medical service project prioritization, and physician compensation. Data collectors, those database professionals who store and maintain the data, and data consumers who use this data and further produce data for various medical and business purposes are all involved in designing, collecting, storing, maintaining, distributing, analyzing, and utilizing the same data. Therefore, various aspects of information quality have different impacts along the long value chain of information.

So what is "quality" information as it pertains to healthcare? Among the various dimensions of information quality (Wang & Strong, 1996)—free of error, timeliness, consistency, conciseness, privacy, accessibility, believability, reputation, ease of use, flexibility, security, value added, objectivity, amount of information—what the healthcare market is currently grappling with is accessibility of information. For example, consumers want to know which physicians and hospitals are the "best." The trouble is, who defines what is the best? Currently, the healthcare industry does not have a unified answer to this question. For example, ask a physician, "Who would you go to if you needed heart surgery?" The physicians would tell you that he or she would ask friends and colleagues to find out who the best heart surgeon is. Health plan providers would resort to statistical information that has measures of evidence of a good practice. Regardless of the fact that one answer may be better than others for a particular purpose, shouldn't this information be available to consumers, the patients? Until recently, this information has been placed in a virtual "black box" unavailable and inaccessible to consumers. Magazines such as *U.S. News and World Report* and *Boston Magazine* publish annual lists of the "best doctors," but critics will tell you that those lists are based on reputation and not actual evidential data, and often the doctors and surgeons on the lists are affiliated with the most well known and largest teaching institutions, not rated according to well-articulated objectives and measured outcomes.

The common definition of quality care needs to be acceptable to all stakeholders, and it needs to be practical enough in order to be usable and useful. Currently, there is a race to define healthcare quality and to provide the information. The quality information and the packaging of this information will be a key differentiator in the coming months and years, particularly for health plan providers.

The pivotal event for quality information in the healthcare arena goes back to 1999. In 1999, the Institute of Medicine (IOM) reported that as many as 98,000 people die annually as a result of medical errors, and they called for a national effort to make healthcare safe. The IOM's report, *To Err is Human: Building a Safer Health System* (Kohn, Corrigan & Donaldson, 1999), galvanized a dramatically expanded level of conversation and concern about patient injuries in healthcare, both in the United States and abroad (Leape & Berwick, 2005). The vision required by the IOM charged the Agency for Healthcare Research and Quality to bring together all stakeholders, including payers, to agree on a set of explicit goals for patient safety to be reached by 2010.

Evidence-based medicine is dependent on the collection, design, and use of quality information that is collectively agreed upon by key stakeholders. Emphasis is on the dissemination and accessibility of information so that the evidence can represent and reach clinical practice and thus service patients. Evidence-based medicine is also based on guidelines of how care should be delivered. The evidence is represented in information that reinforces healthcare guidelines and informs the healthcare practice and services delivered.

STAKEHOLDERS IN THE HEALTHCARE MARKETPLACE

The key stakeholders who are critical for defining quality healthcare information are physicians and care providers such as hospitals, health plans, employers, consumers, and the government. Now we turn to identifying each stakeholder and its underlying principles.

Physicians

Principles held by physicians:

- Physicians know what is best for their patients
- Health plans should be hassle free
- Financial compensation should be fair
- Physicians should be involved in defining quality information
- Evaluative information should be based on physician group level instead of at the individual physician level

In general, physicians are concerned about how information is collected and used and by whom, since the disseminated information can have an impact on their own reputation and future service and work. It is critical that information is consistent with what they perceive as good quality. Quality information for physicians, therefore, means that the use of collected information is well understood and known to the physicians in advance and that the information is collected from reputable sources.

A recent analysis on medical practice (Wennberg, 2006) identified that there is widespread variation in the ways physicians practice, which results in widespread variation in both outcomes and cost. Rochester Independent Physician Association (IPA), an organization of 3,000 clinicians including 900 primary care physicians, has developed a set of measures that they use to compare specialists within each specialty. The purpose is both to develop best practices that all of the specialists should follow by learning from top performers, and to work with the bottom outliers. We show the example of their measures, used for quality improvement purposes, below:

- ***Underused measures:*** Measures that the test or procedure is not being performed as often as it should be.
    - **Diabetes testing:** Did the physician perform glucose and cholesterol testing on diabetic patients?
    - **Colon cancer and breast cancer screenings:** Did the physician order or perform the appropriate cancer screening procedure based on the patient's age and gender?
- ***Misuse measures:*** Measures where inappropriate care is given.
    - Antibiotics for viral infections
- ***Overuse measures:*** Unnecessary care.
    - Antibiotics for sinusitis

The Rochester IPA systematically tries to identify overuse and misuse by reviewing treatments for conditions and analyzing local and regional variation by specialty. For example, the IPA found that carpal tunnel syndrome was treated by some physicians as an inpatient procedure and by other physicians as an outpatient procedure. The outcomes were the same, but it cost a lot more to have an inpatient procedure, so the IPA decided it should be treated as an outpatient procedure moving forward.

Evidence-based medicine is dependent on the use of randomized controlled trials and systematic review based on the collected information. Its emphasis is the dissemination of information so the evidence can influence clinical practice.

Evidence-based medicine is also based on guidelines of how healthcare should be delivered. The evidence is represented in information that reinforces healthcare guidelines and informs the healthcare practice delivered. For example, Bruce Bagley, M.D., Medical Director for Quality Improvement at the American Academy of Family Physicians, states that physicians must move from pedigree to performance and that medical board certification is necessary but not sufficient criteria (World Congress Conference, 2006). However, there is widespread recognition that although leading physicians and academics embrace the notion that quality metrics are important to improving quality care, physicians in the trenches have not all come to the same conclusion.

B. Dale Magee, President Elect of the Massachusetts Medical Society, urges the development of a national measurement set so that physicians are not measured according to different sets of measures that each health plan develops (World Congress Conference, 2006). In the interim, he recommends measurement information at the physician group level instead of individual physician level so the data are statistically more accurate. A concern is that health plans sharing this information with members will result in patients deciding who good doctors are based on aggregated and averaged information, despite the fact that the patient is seen by an individual doctor.

Health Plans

Healthcare plan providers want to achieve effective and profitable management of healthcare with minimum cost. Healthcare premiums continue to increase in double digits, which employers and employees cannot continue to absorb. In response to this difficulty, health plans are trying to develop alternative models. For example, some plans are focusing on paying for quality care that in the long run will keep costs down. The healthcare plan therefore needs to determine what quality care is. The Institute of Medicine Report (Kohn et. al., 1999) offers a working definition: "Quality care refers to the care that is based on evidence-based guidelines and seeks to address overuse, misuse and underuse of services."

Health plans have designed incentive mechanisms for improving the quality of care by physicians. The most common mechanisms are pay- for-performance programs, product design, and public reporting. Health plans have been experimenting with various ways to impact provider reimbursement in ways to promote quality care. The most common method is through the "pay-for-performance" program, which resembles a bonus system. If providers score well on quality metrics specified by the health plan, then they are eligible for an annual bonus that may equate to 2% to 15% of a provider's overall reimbursement. These pay-for- performance plans apply mostly to primary care physicians and hospitals and, in some cases, specialty care physicians.

Due to escalating healthcare costs, employers are looking for ways to pass on more of the cost to their employees. This has resulted in the term "consumer directed health plans." Now burdened with increasing financial responsibility, employees (the direct consumers of healthcare) are more involved in their healthcare decisions. Consequently, consumers need more information, and health plans need to provide this information to consumers, including who the highest quality physicians are and what the costs variance is across various physicians and hospitals.

Beginning in 2004, many of the larger health plans, including United, Aetna, Cigna, and some of the Blues, began to release performance information about physician groups and hospitals to their consumers. For example, these national plans worked with vendors, including Subimo and HealthShare Technologies (part of WebMD), to allow their members access to the software products that let consumers identify where they live and compare how hospitals stack up on certain common procedures so that consumers can compare rates for mortality, complications, average length of stay, and in some cases one to three dollar signs to indicate how costly the hospital is.

Principles held by health plans:

- Reduce costs
- Improve quality
- Get and retain profitable membership
- Keep healthcare providers satisfied enough that they remain in the Plan's network

QUALITY INFORMATION AS DEFINED BY HEALTH PLANS

Information on Efficiency

Efficiency can be measured as a per member per month cost based on care a physician or hospital provides, or by bundled costs of treatment categories. High-cost radiology and lab costs are also measured and closely monitored. Many plans work with a company called Symmetry to measure efficiency of providers through Episode Treatment Groups (ETGs) or aspects of a condition. As consumers share more of the financial burden, we may see a rise in their wanting to know who the most efficient providers are and a movement to those physicians. However, there is still a questionable perception that highest cost providers may be the best cost providers: if you pay more, you get more.

Information on Process

Most physician measures are process measures that are examples of medical underuse. Most plans utilize the national measurement set defined by the National Committee for Quality Assurance (NCQA). Examples of primary care physician measures that health plans use as part of physician reimbursement and reporting include cholesterol monitoring for patients with cardiovascular conditions; depression screening; and cervical cancer, breast cancer, and colon cancer screenings. There are also measures that reward providers for increased use of generic prescriptions as opposed to brand pharmaceuticals that are more expensive.

Quality Outcomes Measures

Ideally, health plans should want to measure, report, and pay based on quality outcomes alone (which physician improved his or her patients' health). However, there is no consensus as to how one would measure this practice. Each provider can claim that his or her patients are sicker and therefore cannot be compared to results with the rest of the population. Instead, focus measures for physicians are the process, efficiency, and technology measure. On the hospital side, there are some outcome measures that most health plans use to measure and reimburse hospitals based on their performance. The Agency for Healthcare Research & Quality (AHRQ) has a prominent role in establishing hospital measures that are based on administrative claims data that hospitals submit to the states in which they operate. AHRQ measures include rates of hospital-acquired pneumonia and obstetrical trauma during child delivery.

Technology Adoption

Health plans logically recognize that the use of technology such as electronic prescription, computer physician order entry, and electronic medical records should lead to safer care, better outcomes, and less medical errors. For this reason, health plans often offer bonus payments for technology adoption and will help to supplement payment for that technology based on the assumption that it will lower costs and improve quality outcomes.

Consumers

Principles held by consumers include:

- Stay healthy
- Affordable healthcare
- No hassles from insurer
- Choose doctors based on recommendations of family or friends
- Have trustworthy physicians
- Free from medical errors

Quality Information as Defined by Consumers

Consumers are increasingly using the Internet to look up symptoms, conditions, and treatment options; they often print this information and will use it as a basis for discussion with their physicians. They should also have information on how to compare and choose a physician or surgeon. They should be able to choose which physician is best for them based on quality outcomes. Consumers tend to care about the following criteria:

- **Information on access to care:** How close is the physician and hospital to where they live, and how long will they have to wait for an appointment?
- **Information on patient experience:** How satisfied are past patients, and therefore, what is the level of their satisfaction with this physician or hospital?
- **Information on value:** This is especially important for members who have to pay a significant portion of their care out of pocket. They need to decide if it is worth going to a particular physician and getting a particular treatment.
- **Information on similar experiences:** Patients want to know how the provider treated patients similar to them in terms of conditions and health status. Consumers also believe indicators of quality include the physician's training, age, gender, and nationality. As mentioned previously, there is very limited publicly available data on physicians, but more on the hospitals.

- **Information on lawsuits:** Patients want to know if a physician has any past or current malpractice suits.

Employers

Principles held by employers:

- Control costs
- Keep employees healthy and working (reduce absenteeism)
- Understand the medical needs by employees

Quality Information Defined by Employers

Large employers especially want to be able to track (within privacy restrictions) the conditions and diseases most prevalent among their workforce and devise how they should best be treated to keep these employees healthy and working, while keeping costs under control. Employers want to track absenteeism related to medical care to keep their employees as productive as possible.

In 1998, more than 170 large employers such as GE and Ford began to come together on the issue of hospital-patient safety. Members of Leapfrog Group, a coalition of employers, agreed to influence hospitals to institute programs and health plans to reward providers that meet patient safety standards. To further its mission, Leapfrog has developed an incentive program that it licenses to health plans to kick off their pay-for-performance programs. On the physician side, Bridges to Excellence, a coalition of employers, payers, and providers, licenses their physician incentive quality program to health plans such as United, Cigna, and Carefirst. Leapfrog Group and Bridges to Excellence have strong support in the employer community.

Government

Principles held by government:

- Control healthcare costs and spending
- Support electronic medical records
- Improve quality
- Pay for better quality (new)

Quality Information as Defined by Government

- Health outcomes. This includes volume of procedures, mortality, complications, and satisfaction
- Technology adoption, as it is assumed to lead to safer and more efficient care
- Cost efficiency

In 2004, the Center for Medicare Services (CMS) launched a voluntary reporting program for hospitals with a starter set of 10 quality measures related to three medical conditions: heart attack, heart failure, and pneumonia. The list of measures has since increased to 34 and includes measures for bypass surgery and hip and knee replacements. The program is still voluntary, but hospitals that do not report take a .4% reduction in CMS reimbursement. CMS is conducting a pilot financial bonus program that rewards the top 20% of participating pilot hospitals with a 1% to 2% bonus. Premier is one of the pilot sites and reports 10% improved patient care since beginning the program.

Some states have begun to require mandatory reporting to consumers on physicians and hospitals. Minnesota has passed a law requiring that physicians and hospitals are not reimbursed for "never events"—egregious medical errors like wrong side surgery or surgery on the wrong patient for the wrong reason. For now, each state is defining these "never events," and policies vary across states and payers.

FUTURE TRENDS

The healthcare marketplace is moving fast toward digitizing information. Software vendors provide enterprise versions of databases that can be used by physicians and nurses that are linked to patients' records. Claims data are also moving toward including more comprehensive clinical information and being accessible in a timely manner. Currently, there is up to a one- to two-year lag in the payment after the actual performance period occurrence. As more physicians and hospitals implement electronic medical records, there needs to be open discussion about what data need to be captured and what security interface mechanisms should be established so that relevant quality outcomes can be shared across the healthcare system without jeopardizing patient privacy and confidentiality. Electronic records improve the information collection time and information accessibility from its reusability. However, we also need to understand that poor quality information can spread even faster with electronic records.

Currently, numerous systems are being developed and deployed. Many systems are not well integrated to share data. Particularly, integrating financial data and medical data is an issue to resolve. Increasingly, the issues of privacy and confidentiality have become an important aspect of quality information that critically deserves a resolution.

CONCLUSION

Improving information quality is an idea-in-good-currency in the healthcare marketplace. Many hospitals and health plan providers are engaged in ways to provide quality information. The demand for quality information from the consumers pushed hospitals and health plan providers to spend more resources in restructuring their internal information quality managers and analysts to address the issue in a continuous and integrated way.

Quality of information in the healthcare marketplace is considered to be a critical determinant of the quality of medical service delivered. With the emphasis on evidence-based medicine, information is the asset for various analyses geared at finding out efficient and effective ways of using resources for quality care. With elevated discussion on quality information, the various concerns by patients, employers, physicians, hospitals, and health plan providers will have a better chance to be addressed. It is time to act on establishing information quality strategy (Lee et al., 2006) to provide quality healthcare information.

KEY TERMS

Quality Care: Care based on evidence-based guidelines that seeks to address overuse, misuse, and underuse services (Kohn, Corrigan & Donaldson, 1999).

Quality Information: Information that is fit for use by information consumers.

A Historical Overview of Health Disparities and the Potential of E-Health Solutions

Michael Christopher Gibbons
Johns Hopkins Urban Health Institute, USA

INTERNATIONAL ORIGINS

Over the past decade, a rapidly expanding body of scientific evidence has been put forth documenting differences in health status among U.S. racial and ethnic groups. Evidence has also mounted suggesting that these differences may be related to both medical and nonmedical determinants. Internationally, however, neither the evidence nor the realization of a link between nonmedical sociobehavioral factors and health outcomes is new. The earliest reported observation of a hypothesized association between socioenvironmental risk factors and health outcomes occurred in Italy over three centuries ago when Bernardino Ramazzini detailed an unusually high frequency of breast cancer in Catholic nuns (Wilson, Jones, Coussens, & Hanna, 2002). Not long thereafter, in 1775, British surgeon Sir Percival Pott reported a cluster of scrotal cancer cases among British chimney sweeps (Wilson et al., 2002).

By the mid-19th century, large-scale epidemiologic evidence began to corroborate these early observations. In 1840, Edwin Chadwick, British civil servant and statistician, demonstrated mortality differentials between the social classes living in Liverpool, England. Chadwick asserted that these differences were likely due to poverty and lifestyle factors common to the poorer working classes (Macintyre, 1997). German physician Rudolph Virchow went a step further when, in 1849, he asserted that because diseases of the populace are traceable to defects in society, the focus of medicine should shift from changing the individual to that of changing the society (Amick, Levine, Tarlov, & Walsh, 1995). Finally, in France, French physician Louis Villerme recommended improving school and working conditions as social interventions that would reduce class differences in mortality (Amick et al., 1995). Thus, in Europe, by the beginning of the 20th century, the existence of class variations in morbidity and mortality were clearly evident in the scientific literature (Macintyre, 1997).

Throughout the 20th century, the study of social class differences in health status continued across Europe, especially in Britain where epidemiologists began using decennial census data to evaluate national mortality trends. The insights gained from these analyses enabled them to construct an occupational social class grading system that correlated inversely with infant mortality. It also was the basis of the claim made by the Registrar General of Britain that at least 40% of British infant mortality was entirely preventable if the social conditions of poor infants could be elevated to that of upper-class infants (Macintyre, 1997).

Two British researchers, Titmuss and Logan, evaluated regional class-based mortality trends and documented that the disparity in infant mortality rates between upper- and lower-class infants continued to increase from 1910 to 1950 (Macintyre, 1997). This data, along with the Depression and World War II, encouraged the British government in 1942 to respond by instituting the welfare state and promoting several policy initiatives designed to address the "five giants of Want, Disease, Ignorance, Squalor and Idleness" (Acheson, 1998; Macintyre, 1997). Despite this government investment, however, problems attributable to social inequalities and inadequate access to health care persisted. In fact, by the mid-1970s, some 30 years later, the evidence seemed to indicate that the problems were still increasing and that the health of British citizens was slipping behind that of other industrialized nations (Acheson, 1998). Thus, in 1977, the British government formed the Research Working Group on Inequalities in Health and selected Sir Douglas Black as its chair. The committee's report, issued three years later in 1980, became known as the Black Report, and it represents the first attempt by a national government to systematically study, understand, and explain health inequalities (Acheson, 1998). In summary, the health improvement recommendations of the report emphasized the need to improve the physical and social environments in which the poor and lower classes lived (Acheson, 1998).

DOMESTIC RECOGNITION

Across the Atlantic in the United States, scientific evidence from several lines of inquiry examining outcomes and patterns of health care delivered to defined populations began to converge and suggest the importance of the socioenvironment in determining health outcomes. Researchers using small area analysis and geographic information systems analytic techniques demonstrated that a significant amount of nonrandom practice variability existed between clinical practices in different geographic locales, despite treating clinically similar patients (Barnes, O'Brien, Comstock, D'Arpa, & Donahue, 1985; McPherson, Wennberg, Hovind & Clifford, 1982). As public awareness grew, the U.S. government became involved. In 1984, the U.S. Department of Health and Human Services released a report on the health of the nation, titled *Health, United States, 1983* (NCHS, 1983). The report documented that while the overall health of the nation showed significant progress, major disparities existed in "the burden of death and illness experienced by blacks and other minority Americans as compared with the nation's population as a whole" (NCHS, 1983).

In response to the disparities identified in the report, the secretary of the Department of Health and Human Services established a task force on black and minority health—the first time that the U.S. government formed a group of experts to conduct a comprehensive study of minority health problems. In 1985, release of the "Report of the Secretary's Task Force on Black and Minority Health" significantly raised awareness of the disparate health of the country's minority groups compared to the white majority population (Mayberry, Mili, & Ofili, 2000).

Large epidemiologic studies like the Harvard Medical Practice Study emerged, documenting that a significant portion of practice variability could be classified as substandard care and that there was a correlation between substandard care and health care centers treating substantial numbers of poor and minority patients (Brennan, Leape, Laird, Localio & Hiatt, 1990; Brennan et al., 1991; Leape et al., 1991).

The emerging problems of differential outcomes and health status were not limited, however, to minorities and the poor. The Whitehall studies of a large cohort of British civil servants had convincingly demonstrated that a social class-based health gradient existed even among the well educated and employed (Marmot, Rose, Shipley & Hamilton, 1978). Additionally, it became increasingly recognized that certain community and societal level factors, including stress (Marmot, 1986; Sapolsky & Mott, 1987), early life experiences (Tager, Weiss, Munoz, Rosner, & Speizer, 1983), social capital (Coleman, 1988), and income inequality (Wilkinson, 1992a, 1992b) seemed to exert significant effects on health and disease outcomes independent of personal behavior (Amick et al., 1995; Brennan et al., 1990; Wilkinson, 1996). Soon, major philanthropic and advocacy organizations, including the Commonwealth Fund, the Kaiser Family Commission, the Kellogg Foundation, the Robert Wood Johnson Foundation, and the California Endowment began major initiatives designed to address issues related to disparities and health care quality (Compendium of Cultural Competence Initiatives in Healthcare, 2003a).

By the late 1990s, the scientific evidence seemed to indicate that issues of disparity, practice variation, substandard care, and socioenvironmental determinants of health may all be related to the quality of health care experienced by patients. Fiscella, Franks, Gold, and Clancy (2000) published a paper titled "Inequality in Quality," in which they called attention to issues of health care quality and health care disparities as related issues of health care organizational capacity. They further contended that national efforts to eliminate racial and ethnic disparities in health care and national health care quality improvement initiatives represented two inseparable components of providing high-quality health care for all citizens (Fiscella et al., 2000).

SYNTHESIZING THE SCIENTIFIC EVIDENCE ON HEALTH DISPARITIES

As the domestic evidence for population differences continued to accumulate, definitions of disparities were nonstandardized and racial categorizations became increasingly criticized as being imprecise and biologically meaningless (Anderson & Nickerson, 2005; Smedley & Smedley, 2005). While multiple definitions are still in current use, disparities are generally held to be population differences (Wilson et al., 2002) in environmental exposures (Macintyre, 1997) health care access, utilization, or quality, (Amick et al., 1995) health status (Acheson, 1998), or health outcomes (Carter-Pokras, & Baquet, 2002). As alluded to previously, within the U.S. health care system, these differences have most convincingly been demonstrated across racial and ethnic lines (whites vs. minorities); however, disparities based on other categorizations have also been described, including geography (urban vs. rural) (2005), gender (male vs. female) (McGrath & Puzan, 2004; Quinn & Overbaugh, 2005), socioeconomic status (poor vs. nonpoor) (Adler & Ostrove, 1999; Federico & Liu, 2003), and age (nonelderly vs. elderly) (Pyle & Stoller, 2003).

Health disparities are generally thought to be related to the health care system and other social factors. Several lines of investigation examining the socioenvironment and the clinical encounter give evidence of differences in the quality of care received by many racial and ethnic minorities. While these factors have been described as "causes" and are likely to be important in the genesis of disparities, scientifically validated evidence of definitive causal pathways and the underlying biologic mechanisms is largely lacking (Evans, Barer, & Marmor, 1994).

To help bring clarity to these issues, the Institute of Medicine released the first of several reports highlighting and summarizing the scientific evidence concerning issues of differential health status, culture, behavior, communication, substandard care/medical errors, and health care quality (2002; Smedley, Stith, & Nelson, 2003; 2001; IOM Committee on Quality of Healthcare in America, 2001; 2003b; Kohn, Corrigan, & Donaldson, 2000; Haynes & Smedley, 1999). The work of the IOM on disparity issues culminated with the 2003 release of a report titled "Unequal Treatment: Confronting Racial and Ethnic Disparities in Health Care" (Smedley et al., 2003). In this report, the IOM Committee on Understanding and Eliminating Racial and Ethnic Disparities in Health Care was charged with assessing the extent and potential sources of racial and ethnic disparities in health care that are not otherwise attributable to access to care, ability to pay, or insurance coverage. The committee was also to provide recommendations regarding potential interventions to eliminate health care disparities (Smedley et al., 2003). The committee found that within the United States, even among individuals with access to care, significant racial and ethnic disparities indeed existed and were related to historic and contemporary social and economic inequality, discrimination, and a fragmented U.S. system of health care (Smedley et al., 2003). While the release of this report has engendered significant public, media, and academic interest, likely ensuring that efforts to understand and eliminate disparities will continue at least into the foreseeable future, the magnitude and intransigence of the problem, the complexity of its causal pathways, and its resistance to intervention efforts are only beginning to be realized (2002).

DIGITAL DISPARITIES

Since the mid-1990s when the World Wide Web became a powerful part of America's communications and information culture, there has been great concern that the nation's racial minorities would be further disadvantaged because Internet access was not spreading as quickly in the African-American community as it was in the white community. Former Assistant Secretary of Commerce Larry Irving said the following in his introduction to "Falling Through the Net," the 1999 Department of Commerce Study on the digital divide (the divide between those with access to new information technologies and those without): "[The digital divide] is now one of America's leading economic and civil rights issues" (US Department of Commerce, 1999a). This report found that although overall the number of Americans connected to the nation's information infrastructure was soaring, a digital divide existed between whites and African-Americans in terms of their access to the Internet, and that in many cases, the divide was *widening* over time. A follow-up study revealed a persistent but substantially narrowed gap, with large increases in computer ownership and Internet use across most major demographic populations (Spooner & Rainie, 2005). The most recent survey, released in 2003, indicated a significant slowing in the growth of the number of Internet users since late 2001 (Lenhart, Horrigan, Allen, Boyce, Madden, & O'Grady, 2003). Overall, 42% of surveyed individuals did not use the Internet, and significant utilization differences remained according to race, education, income, and geography (urban vs. rural) (Lenhart et al., 2003). Generally, whites are more connected than African-Americans and Hispanics. Even at equivalent levels of income, African-Americans are less likely to be online than whites or Hispanics. In fact, over the period of this study (mid-2000 to mid-2002), the composition of the non-Internet user group did not change substantially (Lenhart et al., 2003). Interestingly, 56% of nonusers said they did not ever plan to go online and cited the cost of computers or Internet access, fear of fraud, credit card theft, or pornography as the major reasons for avoiding Internet use (Lenhart et al., 2003).

Recently, there has been a significant increase in the public availability of computers and Internet access at schools, public libraries, and workplaces (Office of Disease Prevention and Health Promotion, 2002). Thus, conclusions regarding the extent of a digital disparity based on data considering only home-based access may be limited. Despite this reality, Internet availability in the home is accepted as an important indicator of equitable access among population groups (Office of Disease Prevention and Health Promotion, 2002). In addition, access in public settings may be problematic because of computer monitoring in the workplace, privacy and confidentiality concerns, and the facilities' hours of operation. Because of the potentially sensitive nature of health-related uses of the Internet, access at home is thought to be essential (Office of Disease Prevention and Health Promotion, 2002).

Several studies have shown that access to the Internet correlates with income level and educational attainment (Office of Disease Prevention and Health Promotion, 2002; Spooner & Rainie, 2005; Lenhart et al., 2003; U.S. Department of Commerce, 1999a). As with racial and ethnic differences, Internet utilization is increasing in all income brackets. The largest increases are seen in the higher income categories. All things considered, household incomes above US$50,000 are positively associated with Internet utilization (Lenhart et al., 2003). Beyond socioeconomic issues, some researchers have speculated that African-Americans have had less access to the Internet because they participate to a greater degree in entertainment-oriented technologies like television rather than in information technologies. They argue that relatively high proportions of African-Americans use radio and television, but a relatively low proportion read newspapers (Spooner & Rainie, 2005). As already suggested, the primary reasons why some groups have less access to information technology and resources are related to geography, literacy, disability, local infrastructure requirements, and cultural differences (Eng, Maxfield, Patrick, Deering, Ratzan, & Gustafson, 1998), some of which are not easily overcome simply by increasing personal computer ownership. Even if equity in personal computer and Internet access were achieved, emerging evidence suggests that online habits may vary by race and ethnicity. For example, online African-Americans are more likely than online whites to have (1) searched for information about major life issues such as researching new jobs and finding places to live, (2) used entertainment online, (3) used the Internet to obtain health information, and (4) searched for religious or spiritual information [40]. On the other hand, African-Americans with access to the Internet do not go online as often on a typical day as whites do, and they do not participate on a daily basis in most Web activities at the same level as online whites (Spooner & Rainie, 2005).

As information technology plays an ever-increasing role in Americans' economic and social lives, the potential health implications of these findings need to be more clearly evaluated because the prospect that some people will be left behind in the information age may have serious repercussions (U.S. Department of Commerce, 1999b). Persistent digital disparities in access or utilization could leave some groups less able to take advantage of cutting edge innovations in population health technologies that enhance disease surveillance, environmental monitoring, food safety, emergency planning, disaster management, and geographic information systems-based tracking of environmental hazards (Eng, 2004).

THE ROLE OF INFORMATION TECHNOLOGY IN OVERCOMING HEALTH DISPARITIES

One major domain of eHealth focuses on improving health communication through the use of technology. This notion of enhancing communication and understanding is a fundamental component of addressing health disparities. Among other things, the recommendations of the Institute of Medicine report call for initiatives designed to enhance patient-provider communication, trust, and cultural appropriateness of delivered care (Smedley et al., 2003). Similar goals are the basis for the Healthy People 2010 objective to increase the number of individuals with Internet access in the home. Providers, health care organizations, and public health agencies are increasingly using the Internet as a main source of information dissemination and communication (Office of Disease Prevention and Health Promotion, 2002). This need for innovative improvements in communication should represent a significant opportunity for eHealth technologies, researchers, and interventionists, with many important implications for overcoming disparities in health and health care. Given that eHealth is currently understood as attempting to facilitate the utilization of information technologies, the Internet, and communication technology in order to facilitate behavior change, improve health care, and enhance health outcomes (Eng, 2002), eHealth researchers may become the catalysts needed to spur the development of transdisciplinary interventions to effectively address disparities in health and health care.

Recent advances in the computer sciences and information technology fields have spawned several methodological advances in the biological and molecular sciences (e.g., DNA chip technology and microarray analysis), enabled quantum leaps in molecular and submolecular medicine, and catalyzed the emergence of whole new fields of study such as proteomics, phenomics, nutrigenomics, and pharmacogenetics. Perhaps in like manner with the emergence of eHealth, the behavioral and population sciences may be on the verge of a similar information technology-based scientific revolution. New eHealth solutions may soon permit real-time integrative utilization of vast amounts of behavioral-, biological-, and community-level information in ways not previously possible. Behavioral algorithms and decision support tools for scientists could facilitate the analysis and interpretation of population level data to enable the development of "community (population) arrays" or communitywide risk profiles, which in turn could form the foundation of a new "populomics." This population-level risk characterization could potentially go beyond the limitations of typical geographic analyses and yield insights distinctly different from risk stratification based on current methodologies. Generically, these emerging technologies have been termed population health technologies and are believed to offer significant promise (Eng, 2004).

These assertions are not based on mere speculation. Encouraging early evidence suggests that multimedia health communication and behavior change efforts that include the use of computers and other eHealth technologies can improve health outcomes (Neuhauser & Kreps, 2003). Among other factors, the evidence suggests that applications that are tailored to the individual, participatory, personally relevant, and contextually situated will be more likely to promote behavior change (Neuhauser & Kreps, 2003). On the other hand, the Internet has been implicated in the causation or persistence of disparities because of the relative lack of access of some groups and because of its current inability to deliver content that is dynamically tailored to meet the cultural, language, or literacy needs of the individual user (Cashen, Dykes, & Gerber, 2004). This may be particularly true of eHealth applications that are Internet-enabled, requiring access to the Internet to provide the interventional content. It is conceivably possible, however, to conceptually divide eHealth applications into at least two genres: those that rely on the Internet to deliver the interventional content directly to patients (Internet-enabled), and those that only employ the Internet to facilitate transfer and utilization of data for or about content that is delivered to patients by an alternate approach. The content or interventions themselves can actually function without the Internet, but when used in the context of the Internet, they are potentially much more efficacious and far-reaching. These types of technologies could be termed "Internet-enhanced" eHealth solutions. Here, the Internet would facilitate the transfer of data and information, but the tailored content could be delivered by trusted people from the user's own culture or community. The actual intervention could also be administered to patients by print or multimedia applications. Thus, in terms of overcoming health disparities, issues of guaranteeing Internet access for every individual may prove to be less important than attempting to address health disparities via interventions and methodologies that lack cultural relevance. Indeed, those interventions and strategies that integrate behavioral interventions with emerging information technologies will likely be the interventions capable of cost-effectively enabling mass customization, interactivity, and convenience. Ultimately, though, the health disparities challenge for eHealth researchers remains to harness the technical capabilities of emerging information technologies in ways that support the social and cultural realities in which people work and live (Neuhauser & Kreps, 2003), while enhancing our ability to address the health needs of every patient (Safran, 2003).

KEY TERMS

Access to Information: Ability to get the right information at the right place at the right time.

Digital Disparities: Differences in groups of populations due to impact of technology.

E-Health: Health care information or services provided using Web-based technologies.

Internet: Web-based technologies.

Socioeconomic Factors: Social and economic factors that impact the ability to get needed health care solutions.

How Can Human Technology Improve the Scheduling of Unplanned Surgical Cases?

Janna Anneke Fitzgerald
University of Western Sydney, Australia

Martin Lum
Department of Human Services, Australia

Ann Dadich
University of Western Sydney, Australia

INTRODUCTION

Human technology in health care includes managerial knowledge required to marshal a health care workforce, operate hospitals and equipment, obtain and administer funds, and, increasingly, identify and establish markets. In this article, the authors focus on human technology and improvement of decision-making processes in the context of operating theatre scheduling of unplanned surgical cases.

Unplanned surgery refers to unscheduled and unexpected surgical procedures in distinction to planned, *elective* surgery. The management of unplanned surgery is a strategic function in hospitals with potential clinical, administrative, economical, social, and political implications. Making health care management decisions is complex due to the multidisciplinary and the multifocussed nature of decision-making processes. The complexity of multidisciplinary and multifocussed decision-making is further exacerbated by perceived professional identity differences.

This article presents findings from interviews with doctors and nurses about the scheduling of unplanned surgical cases. The interviews focused on current decision-making determinants, the acceptability of using a model to guide decision-making, and enablers and barriers to implementing the model. The key finding was the limited practicality of a model to guide the scheduling of unplanned surgery. While it could guide decisions around clinical determinants, logistical determinants, and ideal timeframes, it would have difficulty reshaping inter- and intra-professional dynamics.

LITERATURE REVIEW

The scheduling of unplanned surgery typically involves negotiating (and renegotiating) established surgery lists, whereby patients requiring nonelective surgery are attended to before those requiring elective surgery (Gabel, Kulli, Lee, Spratt, & Ward, 1999). However, delayed patient access to unplanned surgery can inflate economic costs (Jestin, Nilsson, Heurgren, Påhlman, Glimelius, & Gunnarsson, 2005; Pollicino, Haywood, & Hall, 2002). Poor patient health necessitates more health care services, including prolonged hospital stays, ongoing access to health care professionals, and medication. The tension between *health care cost containment* and the *high cost of surgical operations* is a powerful incentive for health care organisations to improve the management of the surgical suite (Gabel et al., 1999). Thus, an investigation of current scheduling practices of unplanned surgical cases is well-justified.

Empirical research on the scheduling of unplanned surgery is limited. This is somewhat reflected in the *ad hoc* practices found in some operating rooms when organising surgical queues (Fitzgerald, Lum, & Kippist, 2004). In Canada for instance, it was found that the waiting times for elective surgery were not only determined by the number of patients on the waiting list, or by how urgently they required treatment, but also by the *management* of the waiting list (Western Canada Waiting List Project, 2001). To ensure consistent practice, criteria were developed to guide decision-making processes. However, clinicians who managed the waiting lists were somewhat reluctant to change their management practices, preferring to adhere to less-standardised, conventional methods (Martin & Singer, 2003).

In the United Kingdom, surgical lists are typically compiled in an unplanned manner, and the negotiations and modifications that follow are also extemporised (Hadley & Forster, 1993). Even when theatre lists *are* established, they are seldom observed, often because of the need to accommodate patients who require unplanned surgery (Ferrera, Colucciello, Marx, Verdile, & Gibbs, 2001). This gives rise to extended surgery delays. Given such inconsistencies, the National Health Strategy (NHS) Executive circulated a national directive to guide good practice (Churchill, 1994). The directive emphasised the significance of operating room services, the prominence of patient care, the effective management and supervision of operating room use, staff morale, and communication, efficient transportation for patients, and dependable activity and cost information.

A standardised approach to manage operating room lists is also lacking in New South Wales (NSW), Australia (NSW Health, 2002a). This is not to suggest that NSW public hospitals lack direction for scheduling unplanned cases. Many have adopted priority codes to guide these decisions (NSW Health, 2002b). These help health care professionals to classify patients from highest to lowest priority based clinical need and/or timeframes.

However, research in NSW suggests that, in addition to clinical determinants, other factors influence the scheduling of unplanned surgery (Fitzgerald et al., 2004; King, Kerridge, & Cansdell, 2004); notably, logistics and inter- and intra-professional dynamics between staff involved in the process. Current policies for scheduling surgery, particularly unplanned surgery, fail to acknowledge these, providing little direction for accepted practice.

A review of literature on surgical decision-making practices suggests that the normative model of decision-making is *decision theory* (Gordon, Paul, Lyles, & Fountain, 1998; Magerlein & Martin, 1978; Parmigiani, 2002; Wright, Kooperberg, Bonar, & Bashein, 1996). Its ability to comprehensively consider information from diverse sources, especially in situations of great uncertainty, makes it particularly valuable.

Decision theory in operating theatres manifests through several models, including *queuing theory* (NSW Health, 1998) and the *Poisson distribution model* (Kim & Horowitz, 2002). Queuing theory commonly operates on a *first-come-first-served* basis, whereby priority is determined by chronology. However, in the case of unplanned surgery, where patient health outcomes are at-risk, this is illogical; and in the absence of explicit queuing rules, the theory causes confusion (Fitzgerald et al., 2004). In contrast, the Poisson distribution model operates with greater autonomy and is able to represent occurrences of a particular event—like unplanned surgery—over time or space. Using the Poisson distribution model for unplanned surgery would allow for the random arrival of patients, for assuming independence from other patient arrivals, and it supposes independence from the state of the hospital system (Clemen & Reilly, 2001). However, the model does not account for the multifactorial nature of clinical determinants and their relationship with time. Nor does it guide decisions in an environment where logistics and professional dynamics influence efficiency. Therefore, research into decision-making practices is needed to explore the tensions affecting the applicability of different queuing models.

Clinical Determinants and Time

Most operating rooms classify unplanned surgery according their relative urgency (Gabel et al., 1999). Although formalised classification systems are often lacking (NSW Health, 2002a), hospitals typically use a triage system to consider clinical determinants when scheduling both planned and unplanned surgery. Clinical decision-making practices therefore involve elements of rational choice theory (Johnson, 2000). It is deductive, based on evidenced-based practices that maximise patient health, and is therefore judicious.

However, there is no consistent system to allocate priority *between* unplanned cases (King et al., 2004). Furthermore, there is little quality auditing of the way clinical priorities are assigned. It is therefore possible that other factors determine the scheduling of unplanned surgery; critics of decision theory allude to this (Kahneman & Tversky, 1979; Redelmeier, Rozin, & Kahneman, 1993).

The unpredicted and often urgent nature of unplanned surgery suggests that *time* is an important factor when scheduling such surgery. Indeed some triage guidelines are entirely time-based, whereby certain clinical conditions must be done within a certain timeframe to prevent further loss of quality of life; there are thus serious time pressures within the operating room (Gabel et al., 1999) that may have direct consequence for clinical decision-making.

Logistical Determinants

Logistical determinants can further complicate the scheduling of unplanned surgery. A report concerning two public hospitals in Sydney, Australia, recognises the difficulties caused by limited resources and the ineffective management of operating theatres (King et al., 2004). For instance, it explains that while middle management personnel perform the executive management of the operating theatres, they are often absent or involved with other duties, leaving direct decision-making responsibilities to other, variably qualified staff. The report also mentions the physical fragmentation of operating theatre space; the management of large emergency and semi-urgent caseloads; and the inadequacy of systems to ensure that trauma patients are scheduled and prepared efficiently.

There are many more logistical determinants, including the availability of expert and support staff, specialist instruments, and theatre time and space. Therefore, despite the presenting *clinical* needs of the surgical patient, other factors can delay timely surgical intervention (Lebowitz, 2003). These in turn, have considerable economic implications (Bogner, 1997).

Professional Identity

Ineffective management is also partly consequent to surgeon desire to retain professional discretion (Buchanan & Wilson, 1996). Sociological literature has long recognised the domination of the medical profession (Freidson, 1970; Illich, 1977; Olesen, 2001). It is a profession characterised by *authority*, *autonomy*, and *sovereignty* (Bogner, 1997).

However, these attributes are not created and maintained by the medical profession in isolation; they are also influenced by the perceptions others have of the medical profession (Fitzgerald, 2002). These perceptions help to create strongly-defined professional boundaries that can divide different professional paradigms. Some of these boundary constructs include power, status, scientific educational background, clarity of task, and reward. The professional boundary between doctors and nurses is crystallised on each of these constructs.

Additionally, communication difficulties within and between professions are exacerbated by the lack of clear power structure between surgeons, anaesthetists, and nurse-managers within the operating theatre. This is particularly the case between surgeons and anaesthetists (Bogner, 1997; King et al., 2004).

Most operating room logistics are managed by the operating theatre manager, who is typically a nurse. This person is frequently the decision-maker who has a managerial perspective, incorporating the availability of beds and human resources with economic restraints, such as the staff-overtime budget. Together, these circumstances can create a climate of tension (Gabel et al., 1999). For those managers who use finesse and compromise to pursue a goal, confrontational behaviour from colleagues who demand perfectionism maybe difficult to manage. They may find themselves struggling to communicate appropriately, which, in turn, stifles the facilitation of effective management within the operating theatre.

Summary

A number of factors affect the scheduling of unplanned surgery. These include clinical determinants and time, logistical determinants and the dynamics between professionals. Because the complex nature of scheduling unplanned surgery can increase workplace frustration (Creswell, 2003; Stake, 1995), it is important to identify a framework that will facilitate effective decision-making practices in this area (Myers, 1997; Wilson, 2005). However, the implementation of this framework may pose difficulties.

To examine this possibility, this article presents findings from interviews with doctors and nurses, all of whom were presented with a decision-making model for scheduling unplanned surgical cases. The model was informed by previous research, which identified the clinical determinants, logistical determinants and ideal timeframes for scheduling unplanned surgical cases, according to doctors and nurses (Fitzgerald, Lum, & Dadich, 2006). Because the value of the model was largely unknown, it was crucial that its practicability be examined by those at the coalface.

METHOD

To recruit interviewees, the research team attended a statewide workshop at which 71 NSW operating rooms were represented. Operating room managers were invited to nominate their hospital as a possible research site. From the nominations, the researchers selected four metropolitan and four rural hospitals, each from different Area Health Services to limit geographical bias. Approval to conduct the research was gained from the university and Area Health Service ethics committees.

Hospital site coordinators were appointed for each participating hospital to assist with data collection. Hospital Site Coordinators were asked to recruit decision-makers in operating rooms, including surgeons, anaesthetists, nurse-managers, floor-managers, and administrators. Coordinators were then asked to invite interviewees to voluntarily contribute to the study.

A semistructured interview schedule was devised (and piloted) to explore the following themes:

- Current practices in the scheduling of unplanned surgery;
- The influence of clinical and time determinants;
- The influence of logistical determinants;
- The role of inter- and intra-professional dynamics when scheduling unplanned surgery;
- Methods to improve decision-making around the scheduling of unplanned surgery; and
- Thoughts about the proposed model (Fitzgerald et al., 2006).

Each interview was audio-taped and transcribed verbatim. QSR N-Vivo® software was used to aid detailed analysis of the data, facilitating the interpretation process (Creswell, 1998). This facilitated the emergence of core themes. To ensure consistency within each theme, codebooks were developed that included detailed descriptors of each theme, inclusion and exclusion criteria as well as exemplars from the research material.

RESULTS

Interviewees included surgeons (n=17), anaesthetists (n=9), and nurse- and nonclinical managers (n=12). There was much diversity in managerial qualifications—two (7%) doctors had undertaken internal management courses, while nine managers (83%) held qualifications ranging from certification to master degrees in management.

Corresponding with the literature review and the preceding discussion of clinical determinants and time, logistical determinants, and professional identity, the following section presents research findings that verify the influence of these factors on the scheduling of unplanned surgery. However, unlike existing literature, the findings suggest that the speed and efficiency of decision-making processes are mostly influenced by inter- and intra-professional dynamics.

Clinical Determinants and Time

Presented with the proposed model, the interviewees were asked to consider a taxonomy in which three clinical states were labelled *urgency 1*, *urgency 2,* and *urgency 3*. Collectively, they agreed that these categories represented conditions of *extreme urgency*, *intermediate urgency*, and *no urgency*. Within each category, there was recognition that specific physiological states were associated with different timeframes for surgical treatment:

The things that matter most are the urgency one and no one need a protocol to work out what's an urgency one… I have never seen an argument about that, everyone's in total agreement about its uniformity (surgeon).

It was evident that for categories other than *extreme urgency*, intuition was used to order the cases and times of surgery:

we got to feel it…. how things are likely to flow and give them our best guess (surgeon).

Although the three categories were statistically distinct, variations in acceptable responsiveness produces overlap and some ambiguity between the categories. Interviewees agreed that the overlap and ambiguity contributed to a "grey-zone":

when you got two cases that are very close, they probably would all come within more than one of these type of the categories (clinical care coordinator).

Although there was clear distinction between *extreme urgency*, *intermediate urgency*, and *no urgency*, there was ambiguity around the boundaries that separated each entity. Thus, five categories of clinical urgency might have the scope to accommodate individual case variation and overlap. A five-category model may help clinicians accept the need for dynamic decision-making. It also makes more explicit the clinical reasoning process for more transparent inputs, and provides common ground for reaching inter- and intra-professional agreement.

Logistical Determinants

Several logistical determinants influence the scheduling of unplanned surgery within NSW public hospitals, including the availability of space, theatre time, and staff, particularly surgeons. Because these are highlighted in relevant literature (Bogner, 1997; King et al., 2004; Lebowitz, 2003), focus will be given to findings seldom noted in the literature.

Inter- and Intra-Professional Dynamics

Most interviewees suggested that inter- and intra-professional dynamics influence the scheduling of unplanned surgery. These suggestions were often couched in observations about communication between personnel, which was sometimes cantankerous. This in turn, created clear distinctions between professions that are typically involved in the decision-making process—surgeons, anaesthetists and nurses. Furthermore, the comments suggest a strong hierarchy that sees surgeons having most decision-making power, followed by anaesthetists and nurses:

Some [surgeons] get very impatient and make a lot of noise… and we have used the anaesthetic department sometimes to adjudicate (nurse).

the consultant on-call has a power to veto [the decision to continue with planned surgery] and if you aren't happy with that decision, you call the consultant anaesthetist and see whether they'll… open an extra operating theatre… I guess… it comes down to… how hard the surgeon is prepared to push for the continuation of planned surgery, verses how hard the anaesthetic people are prepared to push for an extra theatre (anaesthetic registrar).

it's basically a situation where the nursing staff are really not making any decisions about patients; it's purely related to the medical team (surgeon).

Explicating these professional divisions, some interviewees noted the personal agendas that personnel bring to the decision-making process. Medical terms that lack an irrefutable definition are used to further individual interests:

surgeons tell fibs about what might be an emergency to suit themselves. That makes decisions difficult because they don't care if they categorise something a little bit differently, because they might have something to do elsewhere. They actually come out and admit that, but then they stick to their guns, that, "Yes this is an emergency" (nurse).

The hierarchical divisions between the three professions suggest concord *within* the professions. However, some interviewees recognised times of limited consensus among members of the *same* profession when attempting to schedule unplanned surgery.

I've seen conflict occur… There might be 100 surgeons of high-standing and ask them to assess the patient and you will get 100 different opinions about the diagnosis, let alone the urgency of treatment! (surgeon)

Occasionally, intra-professional disharmony was due to the different roles assumed by individual professionals. Some surgeons, anaesthetists, and nurses have accepted managerial roles within the hospital. With added responsibilities, they often bring an organisational perspective to the decision-making process. In the scheduling of unplanned surgery, they adopt a system-approach, ensuring the efficient use of existing resources:

We get caught up by nursing intensive care patients in recovery because there was no thought given to the aftercare the patient might require (manager).

Thus, a multifaceted decision-making process becomes more complex by managerial responsibilities that can (or should) constrain decisions.

The dual-identity of clinician-*cum*-managers can also generate intra-professional dissension. Non-managerial personnel are seen to "lack insight"; they are believed to have a limited understanding of the way decision-making processes affect the hospital as an organisation:

It is all very well to keep on providing services at all hours, at all costs. But we can't continue to do this in that way (manager).

Complex inter- and intra-professional dynamics suggest that models to guide decision-making practices can only be successful when there is opportunity to enhance these interactions.

DISCUSSION

This article demonstrates that while clinical state, time, and logistics influence the scheduling of unplanned surgical cases, equally important are inter- and intra-professional dynamics. Divergent views about the role of different professions depict an individualistic view of a context that requires collaborative decision-making. Surgeons in particular portray clear jurisdictions for clinical decision-making when scheduling unplanned surgery.

Nevertheless, there was some consensus between the different professions. Those interviewed recognised value in a model that guided the scheduling of unplanned surgery. The example presented to them resonated well, reflecting internal processes that are used intuitively (Fitzgerald et al., 2006). While some doctors and nurses warned against prescriptive and mechanistic protocols, surgeons, anaesthetists, and nurse-managers generally accepted a tool that provides common dialogue and facilitates effective decision-making.

The proposed model is thus a framework to bridge gaps in professional positioning. It allows dialogue to be redirected from individualistic drivers to greater collaboration.

Reflecting existing literature, the interviewees highlighted key determinants that influenced the scheduling of unplanned surgery; namely, clinical determinants and time (Gabel et al., 1999; Johnson, 2000), logistical determinants (Bogner, 1997; King et al., 2004; Lebowitz, 2003), and inter- and intra-professional dynamics (Buchanan & Wilson, 1996; Fitzgerald, 2002).

With regard to clinical determinants, the interviewees made clear distinctions between cases that are of *extreme urgency*, *intermediate urgency*, and *no urgency*. However, there was little agreement about where the boundaries lie that separate each category. Making decisions around the parameters of these three urgency classification may be assisted by a risk assessment model that incorporates reflection about *likelihood* and *consequence* of adverse events when delaying unplanned surgery.

Logistical determinants were also regarded as significant. The interviewees highlighted the availability of space, theatre time, and staff, particularly surgeons.

The intensity and volume of discussion on workplace interactions suggests that inter- and intra-professional dynamics impact more on the scheduling of unplanned surgery than current literature suggests. Dynamics between *and* within professions involved in this process can hinder the effective prioritisation of cases. Factors that thwart communication include the hierarchy that divides surgeons, anaesthetists, and nurses, personal agendas, difference of medical opinion *within* a profession, and the hybridity of roles assumed by clinician-*cum*-managers.

However, a number of methodological limitations must be considered. The cross-sectional nature of this study indicates that the interviewees provide a snapshot of the decision-making practices around the scheduling of unplanned cases within NSW public hospitals. Furthermore, qualitative research is limited by time, context, and the nature of individual perspectives (both the interviewee's and the researcher's interpretation). The use of convenience sampling to recruit interviewees may have also biased the findings.

FUTURE RESEARCH

Despite these limitations, the findings are consistent with those found in the existing body of relevant literature. However, most of this literature focuses on concrete triage determinants and little is published on inter- and intra-professional dynamics. Therefore, these findings pave the way for future research, particularly on the changing nature of professional jurisdictions in a climate where inter- and intra-professional decision-making is expected, as well as the organisational effects of hybrid roles.

CONCLUSION

In conclusion, this article confirms the dynamic and complex nature of decision-making around the prioritisation of unplanned surgery. It also suggests variability in the way unplanned cases are scheduled. In light of this, efforts to develop standardised practices through policy development may be somewhat futile, for they fail to appreciate the contextual differences of each hospital setting. Nonetheless, a decision-making tool, such as was presented to the interviewees, can improve decision making practices by acting as a catalyst for dialogue between and within professions when scheduling unplanned surgery.

KEY TERMS

Clinical Determinants: Physical or physiological patient characteristics that influence the priority assigned to a surgical case, and in turn, influence patient health and economic outcomes. These include (but are not limited to) degree of risk to life, limb or senses, type of wound or injury, degree of haemodynamic stability, extent of pain, patient age, and diagnostic procedure required.

Emergency Surgery: Emergency surgery is required by a patient whose poor health requires urgent attention; this is most evident when there is risk to life, limb, or organ. An *emergency* is commonly understood to be an unforeseen combination of circumstances that demands immediate action, or an urgent need for assistance or relief. In the medical setting, it implies an injury or illness that poses an immediate threat to a person's health or life. In the clinical context, however, determining the immediacy and urgency of interventions becomes the ground for discourse between health care providers within the hospital setting. Each stakeholder offers different understandings of the term, *emergency* (Lum & Fitzgerald, 2007).

Human Technology: The body of information, skills, and experience developed for the production and use of goods and services.

Logistical Determinants: Practical or operational factors that influence the priority assigned to a surgical case, and in turn, influence patient health and economic outcomes. These include (but are not limited to) the availability of beds, hospital equipment, specialist instruments, surgery schedules, theatre time and space, as well as expert and support staff.

Non-Elective Surgery: See *emergency surgery*.

Professional Identity: An ongoing concern of the professional involving the practice of his or her work, social interactions with colleagues and patients, and his or her place within the professional institution and the professional discourse. It is thus socially bestowed, socially sustained, and socially transformed.

Scheduling: "A complex activity where human schedulers tend to make use of a wide range of knowledge, heuristics, and intuition" (Bharadwaj, Sen, & Vinze, 1999, p. 322).

Unplanned Surgery: Any surgical procedure that is not scheduled and thus, unexpected. While typically referred to as *emergency surgery*, the term *unplanned surgery* is preferred because of the variable understandings associated with the term *emergency surgery*.

INTRODUCTION

Radio Frequency Identification (RFID) technology has been considered the "next revolution in supply chain management" (Srivastava, 2004, p. 60). Current research and development related to RFID focuses on the manufacturing and retail sectors with the aim of improving supply chain efficiency. After the manufacturing and retail sectors, health care is considered to be the next sector for RFID (Ericson, 2004). RFID technology's potential to improve asset management in the health sector is considerable, especially with respect to asset management optimization.

In fact, health expenses have increased substantially in Organisation for Economic Co-operation and Development (OECD) countries in recent years. In Canada, the public health budget amounted to $91.4 billion (CAD) for the year 2005–2006 compared to $79.9 billion in 2003–2004 (CIHI, 2005). Moreover, the health care industry has been the focus of intense public policy attention. In order to curb this upward trend, the public heath sector in Canada is subject to strict budget constraints. Among the different alternatives for reducing expenditures, the improvement of asset management within the different health institutions appears to be worthwhile. RFID technology seems to be a viable alternative to help hospitals effectively manage and locate medical equipment and other assets, track files, capture charges, detect and deter counterfeit products, and maintain and manage materials. In other words, health care organizations would benefit particularly from RFID applications.

The main objective of this study is to investigate the potential for RFID technology within one specific supply chain in the health care sector. Based on a field study conducted in a large nonprofit hospital, this article tests some scenarios for integrating RFID technology in the context of two warehousing activities.

We will first introduce the context of the health care sector and the current applications of RFID technology in that sector. The next section presents the methodological approach that was used in the study. The research findings and their implications are then discussed. Finally, some closing remarks are made.

CURRENT CONTEXT OF THE HEALTH CARE SECTOR

The health care sector has been investing ever more money in information technology (IT) to reduce operating costs and improve patient safety and medical services, and RFID is expected to become critical to health care organizations in achieving these goals.

The IT implementation trend in health care works toward common IT platforms, which allow patient and product information to be exchanged. For many observers, the adoption and use of IT-related technologies, especially RFID, by health care organizations could boost the effectiveness and efficiency of this information-intensive sector. However, the health care sector has been relatively slow to embrace the full potential of IT initiatives. In general, the implementation of IT in hospitals has not been particularly successful (Aarts, Doorewaard, & Berg, 2004; Hersh, 2004; Pare, 2002). The major impediments appear to be linked more to organizational issues than to technological problems (Southon, Sauer, & Dampney, 1997). Among the many factors slowing down the implementation of IT initiatives, previous studies have identified the complexity of health care organizations (Glouberman & Mintzberg, 2001; Glouberman & Zimmerman, 2002), their inappropriate organizational structure (Mintzberg, 1979), and integration issues (Christensen, Bohmer, & Kenagy, 2000; Kumar, Subramanian, & Strandholm, 2002).

Characteristics of the Health Care Supply Chain

In response to all those constraints, some visionaries understand and are already taking action to rectify supply chain processes as a key strategic factor supporting patient service. A study within certain hospital departments made it possible to identify the priorities (Landry & Beaulieu, 1999). The priorities of administrative departments are generally the review and improvement of the supply chain process, IT system modernization, and system integration on a common platform used by other health care organizations.

In fact, Beaulieu, Duhamel, and Martin (2004) state that the integration of procurement activities would improve efficiency by eliminating nonvalue-added activities; this would allow health care organizations to concentrate on more strategic activities (Landry & Beaulieu, 1999). According to some researchers, better resource monitoring and allocation will reduce costs throughout the restocking chain (Blouin, Beaulieu, & Landry, 2001; Perrin, 1994). In addition, the procurement activities represent a large proportion of health expenses. In a hospital, for instance, they range from 30% to 46% of all expenses (Bourgeon et al., 2001; Poulin, 2004). Moreover, the health sector currently loses up to 15% of its assets due to inappropriate and inefficient monitoring procedures (Nabelsi, 2007). The larger the hospital, the bigger these problems are (Nabelsi, 2007).

RFID APPLICATIONS IN HEALTH CARE ORGANIZATIONS

The market potential is interesting: according to a recent study, the worldwide market for RFID tags (active, passive and semi-active) and systems in the health sector will rise from $90 million in 2006 to $2.1 billion in 2016 (Harrop & Das, 2006). The sale and implementation of a complete RFID platform solution would obviously represent much higher revenues for the participating solution providers.

The application of RFID in hospitals has received a great deal of attention over the last few years, with a "boom" in early 2003 due to the rapid spread of Severe Acute Respiratory Syndrome (SARS) in Taiwan (Li, Liu, Chen, Wu, Huang, & Chen, 2004; Wang, Chen, Ong, Liu, & Chuang, 2006). This emergent technology plays a significant role in the global fight to contain SARS; some hospitals have tested an RFID infrastructure system that tracks the movement of patients, medical professionals, and visitors in order to trace and identify when and where people may have been in contact with patients infected by SARS (Li et al., 2004; Wang et al., 2006). The real-time information can be received from this system to trace detailed patient medical records and read bio-information such as pulse, temperature, and respiratory rate (Li et al., 2004).

A number of hospitals have announced new projects including several that will use RFID for supply chain management applications. Tracking assets has become a potential area for improving hospitals' performance (Anonymous, 2006a). In addition, the use of RFID technology for equipment tracking in the health care supply chain can lead to a tremendous reduction in inventory levels and better collaboration among supply chain players. For example, RFID can reduce the time staff members spend looking for equipment they need, thereby improving the utilization rate of equipment and cutting down on missing equipment (Ostbye et al., 2003). Furthermore, the greatest use of RFID in the health care sector will be for labels on medical equipment, drugs, and other products at the item level and the infrastructure and services to support this throughout the supply chain. It will also be used in health care facilities to protect products against counterfeiting. The primary purpose will be to prevent counterfeiting by establishing the full history of a given package at all times—known as its pedigree.

Furthermore, RFID technology can trace patients and materials in hospitals in order not only to optimize the health care process but to minimize human errors. The Food and Drug Administration (FDA) is paying increasing attention to RFID, especially to avoid mistakes because errors involving medication and drug administration are very expensive for the health care sector. A number of studies state that about 7% of patients (Bates, Cullen, & Laird, 1995) in the USA experience an adverse drug experience (ADE) and that the costs of these amount to about US$80 billion annually (Johnson & Bootman, 1995). In addition, clinical studies suggest that Bar Code Medication Administration (BCMA) might significantly decrease ADEs by up to 58% (Jensen, Merry, Webster, Weller, & Larsson, 2004). Another use that has been suggested is cross-checking of blood transfusions (Anonymous, 2006b). A pilot study in Massachusetts General Hospital used the technology to reduce blood transfusion errors by using RFID tags in patient wristbands (Anonymous, 2005). As in many studies, patients were fitted with RFID bracelets containing patient information, including blood type, allergies, and more. Overall, RFID initiatives in the health care sector are driven by the desire to enhance patient safety and improve quality assurance.

METHODOLOGY

Our study builds on previous work (Strassner & Schoch, 2004; Subirana et al., 2003) and focuses on a large nonprofit hospital supply chain which is considering implementing RFID technology.

Research Design

Since the main objective of this case study is to gain a better understanding of the potential for RFID technology in the context of warehousing activities in one specific supply chain, the research design corresponds to an exploratory research initiative. This appears appropriate since it enables researchers to examine a new interest. Moreover, a "case study is a research strategy which focuses on understanding the dynamics present within single settings" (Eisenhardt, 1989, p. 534). This research strategy is consistent with the goal of our study. The field research was conducted in 12 consecutives steps. This methodology was developed at the ePoly research center (see Figure 1, adapted from Lefebvre, Lefebvre, Bendavid, Fosso Wamba, & Boeck, 2005).

The first six steps correspond to an initial phase which can be broadly termed as the "opportunity-seeking phase."

- **Step 1:** All health care organizations are highly motivated to find the best alternatives to give patients better care and reduce time-consuming human administrative activities.
- **Steps 2 and 3:** Benefits are observed in several areas of opportunity related to product information which is to be exchanged with partners and/or departments within the same organization.
- **Steps 4 and 5:** Reflect the current context in terms of supply chain structures and dynamics, and existing intra- and inter-organizational business processes. The implementation of integrated IT platforms allows systems to be integrated and facilitates the exchange of information.

The second phase constitutes "scenario building" to evaluate RFID opportunities; this phase incorporates steps 6 to 10.

- **Steps 6 and 7:** Several scenarios are evaluated regarding the implementation of RFID in applications such as tracking patients, equipment, and errors.
- **Step 8:** Business and technological concerns are evaluated. RFID implementation provides increased integration with suppliers as information is captured in the RFID tags. This minimizes documentation exchanges, dramatically improves the quality of information transferred and reduces the need for internal control or manual activities to zero.
- **Step 9:** Business processes are redesigned to integrate RFID technology. By including enterprise resource planning (ERP) and middleware integration, steps are taken toward process automation; some of those steps have already been accomplished in some health care organizations. A free flow of information, the identification of impacts on human resources and supply chain alignment are assets in redesigning and simplifying the business process activities.
- **Step 10:** Several scenarios are simulated. Suggestions are received from supply chain departments, regarding replenishment needs in the ER, product validation at the time of receipt, tracking mobile beds and chairs, and so forth.

The final phase is to "validate the scenarios" retained from the second phase in a controlled environment (Proof of Concept or PoC; step 11) and then in a real-life setting (step 12).

- **Step 11:** PoC in laboratory. Product receiving and/or replenishment are reproduced in a similar physical and technological environment to that found in the health care organization. The main goal is to demonstrate the feasibility of RFID technology and assess the ERP and middleware integration, process automation, information flow, and human resources impact for all supply chain members. The equipment is acquired, calibrated, and configured, and the business rules are identified and configured in various middleware applications and integrated with the ERP engine. Finally, dry-run tests are conducted to validate

Figure 1. Steps undertaken in the field study

Detailed activities	
Phase 1: Intra- and inter-firm opportunity seeking	
Step 1	**Determination of the primary motivation** towards the use of RFID and the EPC network **(WHY?)**
Step 2	**Analysis of the product value chain** (PVC) activities specific to a given product **(WHAT?)**
Step 3	**Identification of the critical activities in the PVC**, (**WHICH** activities to select and **WHY?)**
Step 4	**Mapping of the network of firms supporting the PVC** to understand the relationships between the firms supporting the product **(WHO** and **WITH WHOM?)**
Step 5	**Mapping of intra- and inter-business processes** for critical activities **(«As is»)** (**HOW** within and between organisations?).
	Time and motion data capture and analysis
Phase 2: Intra- and inter-firm scenario building integrating RFID and the EPC network	
Step 6	**Evaluation of RFID and the EPC network opportunities** with respect to the product (level of granularity), to the firms involved in the SC and to the specific PVC activities
Step 7	**Evaluation of RFID and the EPC network potential applications** including scenario building and process optimization («As could be») (**HOW** within and between organisations?)
Step 8	**Mapping of intra- and inter-organizational processes integrating RFID and the EPC network**
Step 9	**Validating business processes and technological solutions integrating RFID and the EPC network** with key respondents. Feasibility analysis and evaluation of the challenges **including ERP and middleware integration**, **process automation, information flow, huma**
Step 10	**Simulating several scenarios** for final choice of proof of concept
Phase 3: Scenario validation and demonstration	
Step 11	**Proof of Concept (PoC) in laboratory** simulating physical and technological environments, and, interfaces between SC players. Feasibility demonstration of RFID technology and evaluation assessment (ERP and middleware integration, process automation, inform a. Laboratory set-up -Equipment acquisition -Equipment set-up, calibration and configuration -Business rules define and configure in various Middleware -IS integration (e.g. Middleware with ERP) -Dry-run to test IT integration and process integration at all the SC members' level -Business rule refine and IT adjustment b. PoC, post-analysis and decision to go for the beta test replicating PoC scenarios in a real-life setting
Step 12	**Beta Test in real life setting.** Deployment of application and its appropriation by the different organizations involved and their staff

the IT and process integration at the level of all supply chain members.

- **Step 12:** Based on the analysis of PoC results, the decision to run beta tests in a real-life setting is made; the application is deployed in the health care organization and appropriated by the staff involved.

Research Sites

One hospital was involved in the research design. This hospital is briefly described in the following paragraph.

Hospital Profile

The nonprofit hospital is a regional health care facility and is one of the major hospitals affiliated with the Université de Montréal; it is one of the largest hospitals in Quebec (North America). The hospital, which employs 4,000 persons currently, has 554 beds. It has an operating budget totaling $231 million and $66 million of charges associated with supply chain activities. The hospital is a university center that provides specialized and ultraspecialized services to a regional and supraregional clientele. The hospital uses the systems, applications, products (SAP) platform to integrate and centralize patients' personal data such as patient indices from different sources, scheduling and visit information, patient movements (admission, transfer, and discharge information) and gather activity volumes related to clinical data from various sources, all of which are valuable for the management of finances and controls. The supply chain activity is a target for integration with external suppliers using the global healthcare exchange (GHX) platform through an e-supply chain, by automating the ordering process and electronic invoices. Probably the most complex IT integration process will start with the exchange of a single "Electronic Patient File" with health care organizations all over Canada.

Data Collection

The case study methodology allowed us to employ multiple data collection methods to gather information from one or a few entities (Benbasat, Goldstein, & Mead, 1987). Data collection for the case study approach was based on:

1. Various focus groups were conducted in the university-based research center with health care professionals (5) and IT experts (3). The main objective of these focus groups was to reach a consensus on strategic intent with respect to the use of RFID technology in one product value chain (steps 1, 2, and 3), and to evaluate different scenarios and retain the "preferred" or "as could be" scenario (steps 7, 8, and 9). Each consecutive step of the methodology illustrated in Figure 1 was evaluated and validated and agreed upon with members of the focus groups.
2. On-site observations at the research site were performed in order to carry out the process mapping required for Steps 5, 6, and 9. The analysis of the current inter-organizational business processes allows the researchers to understand the supply chain dynamic and its business environment.
3. Semistructured interviews were conducted with seven participants at the research site. The participants in the case study were the department head responsible for the logistics and distribution division (1) and some warehousemen (6). The purpose was to document and obtain more detailed information, resolve potential inaccuracies in the mapping of existing business processes, and ensure that our observations and the results of the mapping were valid and representative of the normal flow of operations (Steps 5 and 6).

The researchers acted as observers, interviewers, and facilitators (for focus groups). They also formulated and presented the detailed scenarios that were developed from the empirical evidence gathered in the nonprofit hospital.

RESULTS AND DISCUSSION

The health care professionals involved in this study are aware of the potential advantages derived from the implementation of RFID technology. Their initial motivations were focused on the reduction of manual interventions by employees for the overall "receiving" and "verifying" processes and the increased accuracy of validation of controls such as validate delivery order (DO) against purchase order (PO), and quantities of items received vs. ordered.

Within the scope of this article, our discussion will mainly focus on the empirical results obtained from steps 5, 6, and 9 (Figure 2). These three steps correspond to the mapping of current business processes and redesigned processes integrating RFID technology. Proponents of the process-based approach believe that the process view is "a more dynamic description of how an organization acts" (Magal, Feng, & Essex, 2001, pp. 2). Moreover, this process view provides a structured approach which allows one to focus on value creation. The process view is also used increasingly often to evaluate the impact of information technologies (Subramaniam & Shaw, 2004).

Current Business Processes

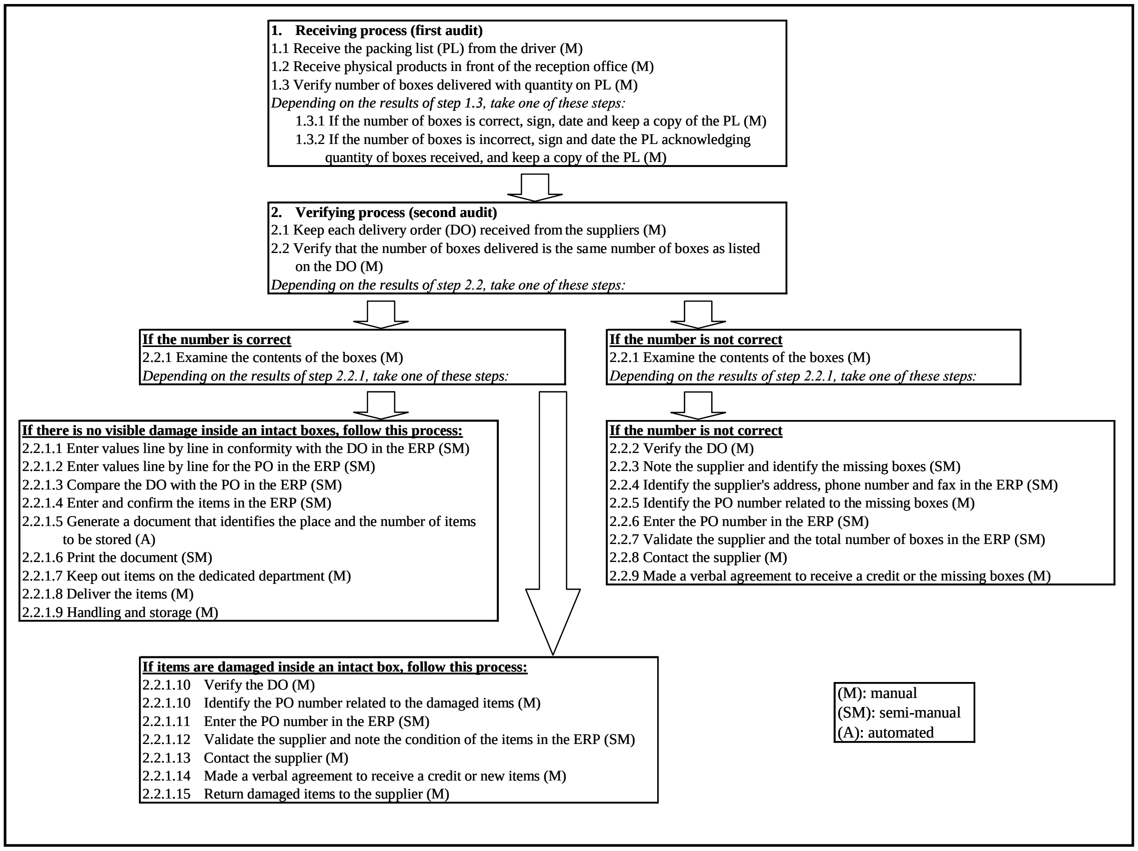
In Figure 2, processes are drilled down from the more general to the more detailed. Based on the analysis of the current inter-organizational processes in that figure, the following observations can be made: (a) the overall "receiving" and "verifying" processes require time-consuming human interventions by the warehousemen (they depend on manual resources); (b) time is devoted to several audit levels (receiving and verifying); (c) validation is error-prone due to of the numerous visual checks and repetitive manual activities when the DO is compared line by line against the packing slip (PS).

Based on the analysis of these processes, the process flow of receiving and verifying contains several steps to be completed in a semi-manual verification of 15 to 17 steps, depending on the following situations:

a) The best case scenario reveals no anomalies in the receiving and verification processes, which mean that the products and their quantities are as ordered. However, the audit processes require manual verification of all 17 processes: 11 manually and 5 semimanually. Only one is automatically created by SAP (2.2.1.5), a document that identifies the place and the number of items to be stored. We can observe that even in this best-case situation, all those steps need to be performed in order to meet this expectation.

b) If the second audit reveals inadequate quantities inside boxes or products are damaged for any reason, 15 or 16 other manual or semimanual steps must be completed to expose those anomalies.

Figure 2. Current interorganizational processes



In general, all receiving and verifying steps seem to fall into two categories (manual and semimanual).

Retained Scenario Integrating RFID Technology

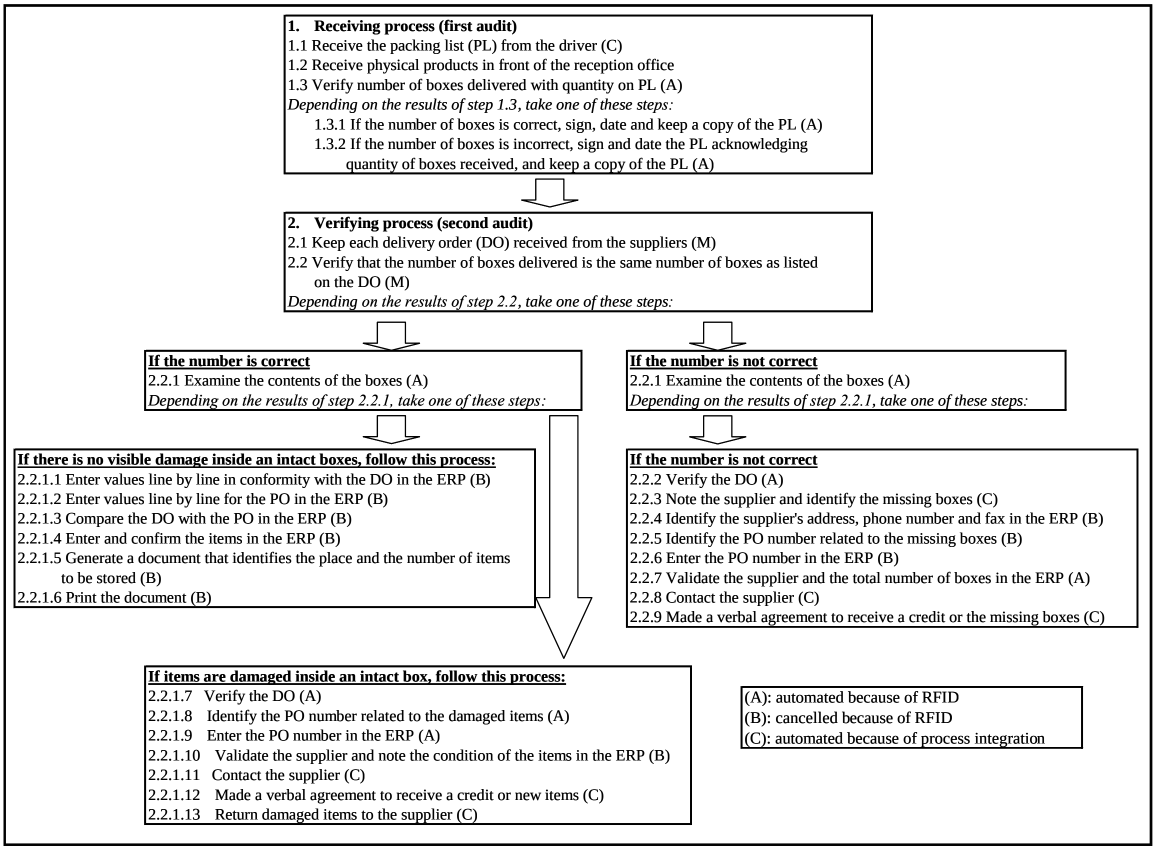
The retained scenario integrating RFID technology (steps 8 and 9) was validated with the focus groups in a nonprofit hospital scenario. By contrasting the existing business processes (Figure 2) with those integrating RFID technology (Figure 3), it is possible to explore some of the impacts of RFID technology on the receiving and verifying processes.

When one integrates RFID (tags on boxes or, even better, tags on products inside boxes) new categories of business process emerge.

Automated processes will reduce human interventions, and therefore will protect against human error and assure consistency of data. Some of the manual processes described in Figure 1 will be eliminated because of automation, others reduced because processes are integrated with the SAP supply chain. In the first situation in the described current process, the number of observed processes will be reduced by 14 (six processes will be automated, six will be eliminated, and two will be reduced because of automated integration with the existing SAP system).

For the second situation, a substantial number of steps will be automated either because of RFID or because of the integration of the RFID and SAP systems (seven processes) or will no longer be necessary (two processes eliminated). All information-based processes are now automatically performed at the receiving point, providing a high level of accuracy of information at a high level of granularity. With RFID technology, approximately 80% of the processes will therefore be replaced or automated, resulting in a proportional human intervention time.

Figure 3. The impact of RFID on selected business processes



FUTURE TRENDS

Increased operating profits and greater customer satisfaction are the objectives that health care organizations strive for. The main objectives are better tracking in real time of patients' presence and patient records, tracking patients in case of contagion, avoiding medical errors such as patient misidentification, reducing medical errors by increasing the accuracy of reads, assuring better arrangement and distribution of products especially for emergency interventions, avoiding confusion during emergencies by quickly tracking the availability and location of a specific blood group, tracking equipment to avoid theft of equipment and supplies, and combating the growth of counterfeit medicine. Reverse logistics and recall management (returning shipments because they are out of date or stocking conditions are inadequate) are new requirements for increased supply chain cost efficiencies.

For health care organizations, RFID is the inevitable next step towards the new generation of health care service operations. It should provide new efficiencies, improved services, and greater productivity by reducing the time health care professionals spend in locating misplaced equipment. It will also allow cost avoidance by preventing spending on redundant equipment, enhance health care workflows and increase patient care in organizations seeking a competitive advantage.

CONCLUSION

This article assesses the impacts of RFID technology on information flows within one health care supply chain in a large nonprofit hospital. Our study shows that RFID technology could enhance information flows within a supply chain by automating all information-based activities, reducing inventory and warehousing costs, reducing human errors, and managing real-time product information throughout the supply chain.

The synchronization of information and material flows in a given supply chain is the principle upon which supply chain integration is based. However, in the health care sector, supply chain integration cannot rely on traditional logistical information to become more efficient. In health care delivery, the unpredictable fluctuations in the demand for services, but also the need to meet shorter lead times and very high service levels, are leading health care organizations to develop volume-flexible strategies (Jack & Powers, 2004). RFID is one technology that has been proven to provide benefits in the hospital environment.

KEY TERMS

Active RFID Tags: Active tags contain a battery that powers the microchip and allows it to transmit a signal to the reader.

Passive RFID Tags: Passive tags rely heavily on the magnetic field of radio waves to generate a current which can be received by their antenna.

Receiving Process: Handling products that arrive at the receiving office and acknowledging receipt and unpacking supplies.

RFID: RFID, which belongs to the large landscape of Automatic Identification and Data Capture technologies (AIDC), uses radio waves to automatically identify in real-time individual objects, items, or products. An RFID system is basically composed of three major layers: a tag containing a chip, a reader and its antennas, and a computer.

Semi-Active RFID Tags: Semi-active tags draw power from the magnetic field created for reader-to-reader communication.

Verifying Process: The function encompasses the physical receipt of material, the inspection of the shipment for conformance with the purchase order including quantity, quality and damage, the identification of the destination and delivery there, and the preparation of receiving reports.

Volume Flexibility: In health care, this represents a means to improve service delivery and it allows organizations to leverage their scarce resources for optimal utilization in response to fluctuations in patient demand.

Implementing RFID Technology in Hospital Environments

Marlyn Kemper Littman
Nova Southeastern University, USA

INTRODUCTION

A promising approach for facilitating cost containment and reducing the need for complex manual processes in the healthcare space, RFID (Radio Frequency Identification) technology enables data transport via radio waves to support the automatic detection, monitoring, and electronic tracking of objects ranging from physicians, nurses, patients, and clinical staff to walkers, wheelchairs, syringes, heart valves, laboratory samples, stents, intravenous pumps, catheters, test tubes, and surgical instruments (Karthikeyan & Nesterenko, 2005). RFID implementations streamline hospital applications and work in concert with WLANs (wireless local area networks) and mobile devices such as cellular phones and personal digital assistants (PDAs). RFID technology also safeguards the integrity of the drug supply by automatically tracing the movement of medications from the manufacturer to the hospital patient.

This article begins with a discussion of RFID development and RFID technical fundamentals. In the sections that follow, the work of standards organizations in the RFID space is introduced, and capabilities of RFID solutions in reducing costs and improving the quality of healthcare are described. Descriptions of RFID initiatives and security and privacy challenges associated with RFID initiatives, are explored. Finally, trends in the use of RFID-augmented wireless sensor networks (WSNs) in the healthcare sector are introduced.

BACKGROUND

RFID technology traces its origins to 1891 when Guglielmo Marconi first transmitted radio signals across the Atlantic Ocean, and demonstrated the potential of radio waves in facilitating data transport via the wireless telegraph. During the 1930s, Alexander Watson Watt discovered radar, and illustrated the use of radio waves in locating physical objects. Initially used in World War II in military aircraft in what is now called the first passive RFID system, radar technology enabled identification of incoming aircraft by sending out pulses of radio energy and detecting echoes (Want, 2004). Libraries have used RFID technology for electronic surveillance and theft control since the 1960s.

Present-day RFID solutions track objects ranging from tools at construction sites and airline baggage, to dental molds and dental implants. RFID systems monitor the temperature of perishable fruit, meat, and dairy products in transit, in order to ensure that these goods are safe for consumption, and facilitate the detection of package tampering and product recalls (Want, 2005). The U.S. Department of Defense (DoD) mandates the use of RFID tags as replacements for barcodes for tracking goods (Ho, Moh, Walker, Hamada, & Su, 2005), and requires suppliers to use RFID tags in equipment and clothing shipped to military personnel. RFID technology is widely used by major retailers that include Home Depot and Wal-Mart in the U.S., and Marks and Spencer in the United Kingdom to track inventory. In the transportation and education sectors, credit cards that incorporate RFID technology enable automatic transactions at gas stations and toll plazas and at university bookstores, libraries, and cafeterias. RFID systems also facilitate building access, port security, vehicle registration, and supply chain management; verification of the identity of pre-authorized vehicles and their drivers at security checkpoints; and reduction in the circulation of counterfeit goods and paper currency (Garfinkel, Jules, & Pappu, 2005).

Developed by the U.S. Department of Energy Oak Ridge National Laboratory (ORNL), the RFID-enabled Protected Asset Tracking System is the first instance of RFID technology installed at the National Nuclear Security Administration site (Oak Ridge National Laboratory, 2007). Capabilities of the ORNL-sponsored RFID accountability system (RAS) in accurately tracking assets and monitoring the location of personnel were validated in a pilot test conducted in a large-sized facility at the Washington Navy Yard. This initiative also demonstrated the role of RFID technology in facilitating the safety of rescue workers responding to crisis situations and national emergencies in federal facilities, and the importance of using RFID tags on miners, firefighters, and other workers in hazardous occupations, so their location and safety can be monitored as well.

RFID TECHNICAL FUNDAMENTALS

RFID systems consist of RFID tags or transponders, and interrogators or readers. Classified as passive, semiactive, or active, a RFID tag is an extremely small device containing a microchip, also called a silicon chip or integrated circuit that, at a minimum, holds digital data in the form of an EPC (Electronic Product Code). RFID tags are affixed to or incorporated into objects, such as persons or products (Weinstein, 2005).

A RFID tag is also equipped with an antenna for enabling automatic receipt of and response to a query from an RFID interrogator, via radio waves (Myung & Lee, 2006). The RFID communications process involves the exchange of an electromagnetic query and response, thereby eliminating RFID dependency on direct line-of-sight connections. Subsequent to transmission of the EPC from the RFID tag to the RFID interrogator, the tagged object can be monitored and traced.

Passive RFID tags are inexpensive and limited, in terms of functions supported (Weinstein, 2005). In terms of transmission, a passive nonbattery operated RFID tag makes use of incoming radio waves when it is within range of a RFID interrogator to transmit a response. A passive RFID tag contains the EPC in the form of eight-bit data strings associated with a distinct object and several bits of memory for storing data describing the tagged object. When multiple passive RFID tags transmit EPCs concurrently in response to RFID interrogators, collisions occur, thereby disrupting information flow. Designed to support passive RFID tag operations, the adaptive binary splitting (ABS) collision arbitration protocol diminishes the occurrence of collisions, thereby significantly reducing delay and communications overhead in the transmission process (Myung & Lee, 2006).

As with passive tags, semiactive and active RFID tags also feature EPCs or unique identifiers, and utilize the RF spectrum for data transmission. Batteries in semiactive RFID tags remain dormant until signals are received from interrogators. When sufficient power is available, semiactive tags initiate data transmissions in response to interrogator queries.

An active RFID tag features an onboard battery that serves as its own power source for performing operations, and transmitting the EPC and related data on-demand in response to interrogator queries. An active tag also supports security functions, and can contain an environmental sensor (Karygiannis, Eydt, Barber, Bunn, & Phillips, 2006). Moreover, an active tag enables transmissions over longer distances than passive and semiactive tags. However, an active tag is limited in sustaining continuous operations as a consequence of battery constraints. Since active tags are larger and more costly to implement than passive and semiactive tags, these tags typically monitor large items.

Classified as active RFID systems, wireless sensor networks (WSNs) contain sensors for monitoring the environment (Philipose, Smith, Jiang, Mamishev, Roy, & Sundara-Rajan, 2005). To conserve available power and provision efficient operations, active RFID tags that are part of WSNs are also equipped with battery-powered four-byte or eight-byte processors, and employ cryptographic algorithms to facilitate secure transmissions. Next-generation sensors are expected to operate without batteries by harvesting power from ambient sources.

RFID operations are typically carried out in the unlicensed portion of the RF spectrum, and are dependent on the availability of suitable frequencies and bandwidth at affordable costs. Generally, active RFID tags operate in allocated spectrum in the UHF (ultra high frequency range) between the 300 MHz (megahertz) and 3000 MHz frequencies, and the SHF (super high frequency) between the 3 GHz (gigahertz) and 30 GHz frequencies. These tags carry more data, and support operations over longer distances than passive RFID tags operating in allocated spectrum in the LF (low frequency) between the 30 kHz (kilohertz) and 300 kHz frequencies, and the HF (high frequency) between 3 MHz and 30 MHz frequencies (Littman, 2002). It is important to note that while increased transmission rates and operating range are advantageous in the UHF and SHF spectrum, data transmitted via RFID systems in these frequencies are also vulnerable to interception. Spectrum allocation for RFID utilization differs between countries and regions, and between member states in the European Union.

RFID SPECIFICATIONS

Developed by EPCglobal, the Electronic Product Code (EPC) replaced barcodes developed during the 1970s. An EPC is a unique number that corresponds to an individual product or a container of products. EPCs are embedded in RFID tags that are affixed to or incorporated into an object. As a consequence, the terms EPC tag and RFID tag are used interchangeably. With an EPC and access to the EPC network, detailed information about a product, item, or package, such as dates of manufacture and expiration, can be determined. Designed for companies using RFID technology for supply chain management, the EPC network provisions real-time access to RFID data via the Internet. The EPC network also enables product authentication and exchange of product information among authenticated participants (Staake, Thiesse, & Fleisch, 2005).

EPCglobal is a participant in GS1, an organization with members in more than 100 countries that supports the design and implementation of global technologies and supply chain standards. The GSI HUG (Healthcare User Group) supports development of automatic product identification specifications for EPC-compliant RFID devices to enhance patient safety and facilitate efficiencies in supply chain management. In addition to EPCglobal, entities active in establishing RFID standards include the European Telecommunications Standards Institute (ETSI) and the International Telecommunications Union—Telecommunications Standards Sector (ITU-T).

RFID INITIATIVES IN THE HEALTHCARE SPACE

RFID initiatives in the healthcare sector vary in scope and complexity, and support a broad array of applications. For instance, RFID systems consisting of ultra-low power RFID tags monitor patients with medical implantations such as pacemakers, insulin pumps, and defibrillators. The medical identifier embedded in the medical implantation also provides access to the medical history and relevant data including the name of nonverbal or unconscious patients. Hospitals increasingly mandate the use of wristbands embedded with RFID tags for verification of a patient's identity. RFID tags for surgical patients contain additional data including the type of procedure and the name of the surgeon to ensure optimal outcomes.

RFID systems reduce medical errors including incidents of drug over dosage by ensuring the accurate administration of medications given to hospitalized patients. RFID technology also effectively monitors the location and movement of patients, hospital staff, and resources in the triage area in hospital emergency departments, and facilitates data collection and analysis.

At U.S. hospitals and medical centers—such as Massachusetts General Hospital, New York-Presbyterian Hospital, Georgetown University Hospital, Beth Israel Deaconess Medical Center, and Stanford University Medical Center—RFID solutions track patients and their physical medical records and monitor expiration dates of time-sensitive products including medications. In Korea, Won Ju Christian Hospital employs password-protected PDAs (personal digital assistants) as interrogators that work in concert with RFID tags embedded in wrist bracelets for mothers, and ankle bracelets for their infants, for securing newborns and eliminating mother and baby mix-ups at discharge (Dalton, Kim, & Lim, 2005).

To contain the outbreak of SARS (severe acute respiratory syndrome), RFID technology was used by health officials in Singapore to monitor the movements of every person entering and leaving Singapore General Hospital (Gopalakrishna, Choo, Leo, Tay, Lim, Khan, et al., 2004). Staff and visitors were required to wear credit card-sized RFD tags that transmitted their locations to sensors placed in hospital ceilings. As a consequence of the SARS outbreak, Singapore General Hospital also implemented an online physiotherapy program for enabling physical therapists to remotely monitor their patients, and teach them new exercises at their homes.

RFID tags on birds are used to contain outbreaks of avian flu. RFID tags on herds of cattle stem the spread of mad cow disease. The United States Department of Agriculture (USDA) supports a national registry that contains RFID data on infected livestock, such ad deer and bison. This information serves as a foundation for establishing quarantines to prevent widespread epidemics. Developed by the USDA, the National Animal Identification System (NAIS) also enables animal health officials to respond to emergencies and reduce disease spread.

PRIVACY AND SECURITY CONSIDERATIONS

RFID technology plays a vital role in monitoring the health and safety of patients in hospitals and medical centers. Nonetheless, the ability to obtain real-time detailed information as a consequence of RFID deployment also raises concerns about security (Nath, Reynolds, & Want, 2006). Possible abuse of RFID tracking capabilities also raises questions about potential violations of personal privacy (Ohkubo, Suzuki, & Kinoshita, 2005).

Generally, patient-related information collected by RFID systems in the healthcare space is extremely sensitive, and contains personal information that is protected by the Health Insurance Portability and Accountability ACT (HIPAA), and requires the enforcement of strict privacy controls (Karygiannis et al., 2006). Data obtained from RFID tags embedded in medical implantations and patients' wristbands for one purpose may be covertly used for monitoring individuals without their knowledge or consent. Data obtained from RFID tags embedded in consumer items such as shoes and clothing can potentially be used by employers to monitor surreptitiously the work of employees and terrorists to target attacks against specific political and ethnic groups. As a consequence of RFID system abuse and its potentially adverse impact on data confidentiality and privacy, groups such as CASPIAN (Consumers Against Supermarket Privacy Invasion and Numbers) have launched protest campaigns against manufacturers and retailers worldwide.

To counter these concerns, government entities such as Japan's Ministry of Economy, Trade, and Privacy, and consumer advocate organizations—including the Electronics Frontier Foundation and Electronic Privacy Information Center—have issued RFID privacy and security guidelines to safeguard the integrity of data collection. In California, legislation to impose limits on the use of RFID technology statewide has been proposed. According to the RFID Bill of Rights drafted by consumer advocates, consumers should be informed if products they purchase contain RFID tags, and be able to remove, deactivate, and/or destroy these tags and the data they contain. (Garfinkel, 2004). RFID privacy protection is also supported by encryption, key-exchange protocols and security specifications, such as the ITU X.509 standard.

Methods for disabling RFID tags to prevent responses to queries from interrogators are in development. A promising approach involves the use of clipped RFID tags that can be used by consumers to separate the RFID microchip from the RFID antenna, thereby deactivating RFID operations (Karjoth & Moskowitz, 2005). According to Juels, Rivest, and Szydlo (2003), utilization of selective blocking tags provides another option for addressing privacy concerns associated with the widespread use of RFID technology in consumer products. Selective blocking tags simulate ordinary RFID tags, but prevent RFID interrogators from reading RFID patient and consumer data. To address public opposition to RFID utilization, EPCglobal has also passed a standard that requires RFID tags to be equipped with a kill command, so that consumers can disable RFID functions. This specification is incorporated into the EPCglobal standard titled Class 1 Generation 2 UHF-Air Interface Protocol (Gen2). Additionally, the kill command also prevents utilization of the RFID tag after a product with a killed tag is resold or recycled (Ohkubo, Suzuki, & Kinoshita, 2005).

RECENT TRENDS

Healthcare advances that contribute to longevity also have resulted in the increase of debilitating age-related diseases including dementia and Alzheimer's. A new approach for enabling the elderly to remain at home involves utilization of sensor-augmented wireless sensor networks (WSNs) (Ho et al., 2005). In WSNs, self-powered sensors embedded into active and semiactive RFID tags are called sensor RFIDs. WSNs operate in the HF and UHF spectral frequencies and support a range of applications in the healthcare space, including the intake of medications by the elderly at regular intervals. By querying RFID tags placed on each pill container, WSNs detect changes in the amount of medicine available, and alert seniors to take their medications via blinking lights and beeping sounds. WSNs consisting of RFID tags affixed to everyday objects such as clothing, shoes, chairs, and beds can also track the daily living activities of the elderly at home and in independent living facilities. With the worldwide population expected to reach 761 million in 2025, WSNs are expected to play an increasingly important role in supporting elder healthcare solutions.

At Shin-chon Severance Hospital in Seoul, Korea, RFID-augmented WSNs monitor the temperature of blood bank refrigeration to ensure that this blood is safe to use in transfusions. RFID tags at Shin-chon Severance Hospital also track the location of blood bags in transit, so that the intended patient receives the assigned transfusion, thereby reducing the mortality risk for transfused patients and safeguarding the transfusion process (Brooks, 2005).

CONCLUSION

In the healthcare space, RFID technology is distinguished by its effectiveness in enabling patient identification, data collection, asset tracking, and real-time monitoring of the elderly at home and in independent living facilities (Philipose, Fishkin, Perkowitz, Patterson, Fox, Kautz, et al., 2005). In hospital environments, RFID implementations contribute to patient safety by eliminating incorrectly labeled medications, vials holding blood samples and laboratory specimen, and enable innovative application-specific services for treating infectious diseases such as SARS. RFID technology presents new options for healthcare enhancement, as well as new and ongoing security and privacy challenges that are not yet fully addressed.

KEY TERMS

Active RFID Tag: Features an onboard battery that serves as its own power source for performing operations.

Application-Specific Service: Service that satisfies the performance and functional requirements of either an application or class of applications.

Barcode: Consists of lines of different widths that identify an item. Works with a scanner.

Passive RFID Tag: Lacks an onboard power source. Makes use of incoming radio waves broadcast by an interrogator to power its response.

Radio Frequency Identification (RFID): Wireless identification and data capture technology that consists of a tag or transponder and an interrogator or reader to support applications ranging from airport baggage handling to supply chain management.

RFID System: Consists of the RFID tag, the RFID reader, and the communications between them.

Improving Consumer Health Literacy with Information Technology

Gondy Leroy
Claremont Graduate University, USA

INTRODUCTION

Before the Internet became popular as a device for distributing and sharing information, people turned to friends, books, and their doctors when they had medical questions. Today, many more options exist (Figure 1). Hundreds of Web sites provide health information and opportunities for interaction among patients, doctors, and caregivers. Estimates differ, but all surveys show that millions of people search online for health information. A Pew survey estimates that 80% of adult Internet users, about 93 million Americans, searched online for at least one of 16 major health topics (Fox & Fallows, 2003). Baker, Wagner, Signer, and Bundorf (2003) estimate that 20% of the U.S. population uses the Internet to find health information. A larger proportion (71%) of older people (50 to 64 years old) compared to 53% of younger people (18 to 29 years old) turn to the Internet for health information (Fox & Rainie, 2002). Although there is a digital divide, use of information technology is not simply decided by race or social class. Safran (2003) found that Medicaid families, who are believed not to use these new technologies, accessed their online Baby CareLink from the hospital, work, library, or other public access points. Gustafson et al. (2002) point out that poverty is the prime indicator for lack of technology use.

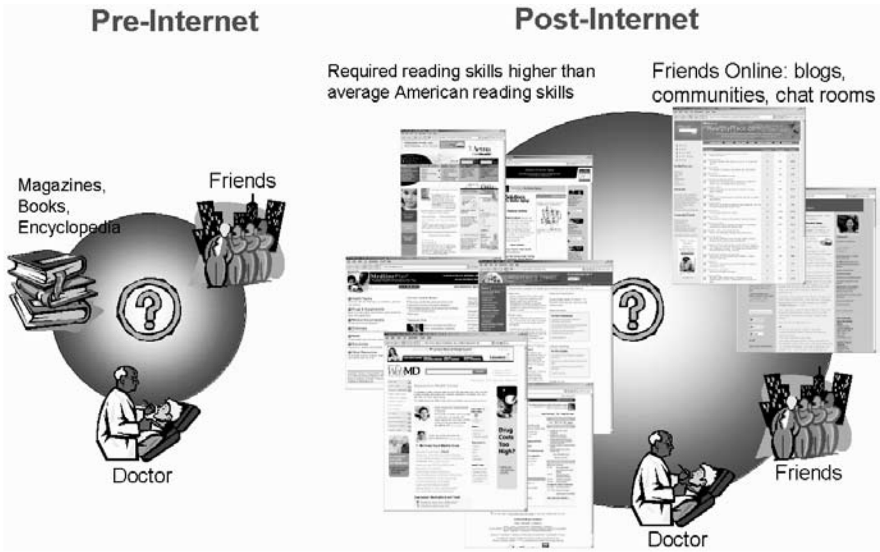
The problem we address in this chapter is consumers' lack of understanding of the available information. This is extremely important since for at least a third of these consumers, the information affects decisions about their health, health care, and visits to a health care provider (Baker et al., 2003). Warner and Procaccino (2004) found a much higher percentage in his interviews with women; more than 80% responded that the information they found online affected their decisions about treatments.

BACKGROUND

Thousands of Web sites provide information and additional opportunities to share information in an interactive format. The information can be targeted at the general public or a specific subgroup, and there are several advantages to this trend. Foremost, consumers will be more informed. This is a benefit because it empowers them to ask more informed questions when seeing their caregivers and lessens their fears of the unknown (Fox & Fallows, 2003). Often, physicians want to refer their patients to Web sites and printed patient educational material for additional information (Brawn, 2005). The online information is especially beneficial for consumers who need more detailed information than their health care provider can give in a limited amount of time. For example, Rosmovits and Ziebland (2004) conducted in-depth interviews with cancer patients and found that they have complex information needs that were not met by their health care providers. They felt they received incomplete and sometimes contradictory information from their caregivers. Consumers also interact with each other online to provide information and support. There are many support groups where members share advice or provide support in difficult times (e.g., multiple sclerosis patients supporting each other during painful self-injections) (Johnson & Ambrose, 2006).

Unfortunately, there are also disadvantages associated with health information as it is currently provided online. The disadvantages can be classified into two groups related to incorrect information and incorrect understanding of information. Since the Internet is not regulated, there is no guarantee that the information provided is correct and trustworthy. The general public should be educated in the usage of this information. Murray, et al. (2003) questioned physicians and found that 75% of the respondents felt that health information on the Internet was a good thing. However, the quality

Figure 1. Information sources for consumers

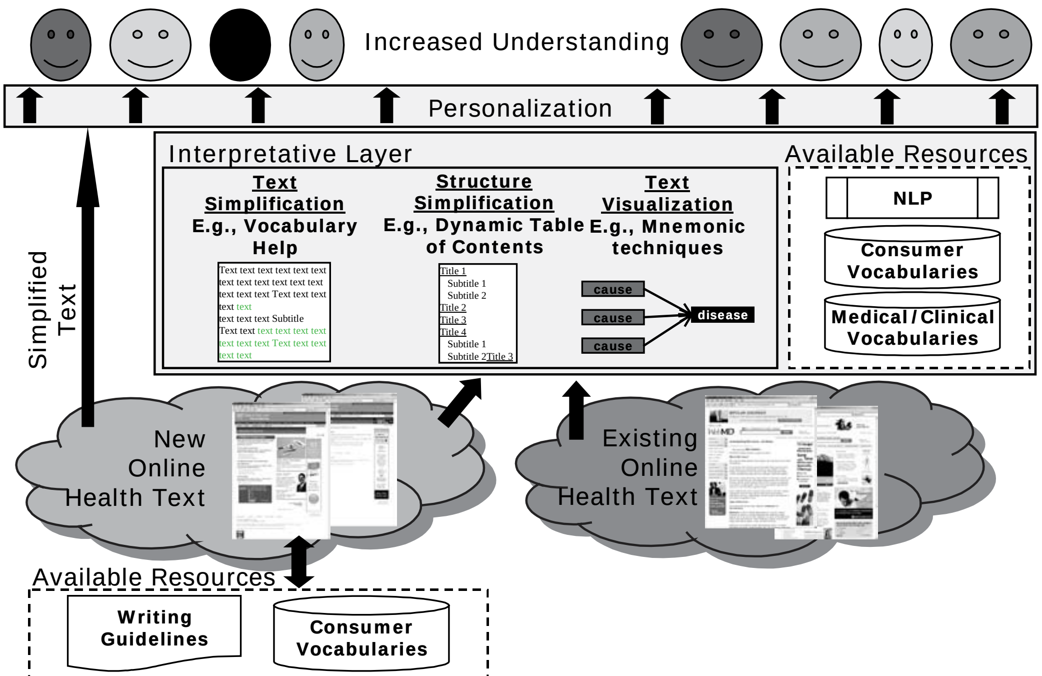


of online information affected the health care outcome and the patient-physician relationship. Accurate and relevant information had a beneficial effect on both. In addition, the outcome and relationship were also influenced by the physician's perceived threat to his or her authority, especially when the patient wanted something inappropriate. The second group of problems centers on health consumers' lack of understanding of this information (Berland et al., 2001; D'Alessandro, Kingsley, & Johnson-West, 2001; Root & Stableford, 1999) and has consequences for health care at large. The Ad Hoc Committee on Health Literacy for the Council on Scientific Affairs (1999) found that misunderstandings in health information increase the risk of making unwise health decisions leading to poorer health and higher health care costs. For example, Garbers and Chiasson (2004) showed that Latinas with low health literacy were significantly less likely to have preventive cervical cancer screening. Kalichman, Benotsch, Suarez, Catz, Miller, and Rompa (2000) found that HIV/AIDS patients with low literacy levels were more likely to (incorrectly) believe that antiviral drugs would help prevent transmitting HIV during unprotected sex.

Figure 2 shows how technology can help improve understanding of health information. Current research is still in the early stages and has not advanced much beyond measuring reading levels and describing these in numerous studies of consent forms and patient leaflets for a variety of afflictions. Existing interventions focus on tailoring information to specific groups (tailored information) or individual people (targeted intervention) (McCray, 2005). In general, newly written text should take writing guidelines into account, and simple versions of the material should be available where possible. There are several guidelines that can be consulted: MedlinePlus (http://www.nlm.nih.gov/medlineplus/etr.html) provides guidelines for writing easy-to-read versions of documents; the National Institutes of Health (NIH) provide the Plain Language Initiative (http://execsec.od.nih.gov/plainlang/index.html); the state of California provides the California Health Literacy initiative (http://cahealthliteracy.org/); and the Health & Literacy Special Collection (http://lincs.worlded.org/) also provides advice. Regrettably, it is impossible to provide simplified versions of all information because the content itself may be too complex. It is also infeasible to rewrite all existing text even if one were to limit it to English. Automated tools need to be developed to help consumers understand text.

Three approaches can be followed and combined to help increase understanding of the information. First, the language and grammar used in the text can be simplified (text simplification). Second, the structure of the text can be visualized and simplified so the document is easier to follow (structure simplification). Finally, important information can be simplified, visualized, and emphasized (text visualization). These techniques

Figure 2. Making health information understandable for consumers



should be partially or completely automated and optimized for various consumer groups.

In the following, an overview is provided of current research that fits into this framework. The focus is on English language Web sites. Then, key consumer groups who would benefit most are discussed. Finally, future trends are described.

INTERPRETATIVE LAYER

Text Simplification

Several formulas are commonly used to measure readability (Berland et al., 2001; D'Alessandro et al., 2001; Root & Stableford, 1999), and all studies using them show that a significant portion of information is too difficult for average adults to read. Most evaluation studies use the Flesch readability scores or the Flesch-Kincaid grade levels to evaluate text. These formulas use syntax, word counts, and word length to assign readability levels and are easily available with Microsoft Word. An additional popular measure is the SMOG measure (McLaughlin, 1969), which is based on syllable count. Freda (2005), however, found the SMOG measure assigned reading levels 2 or 3 grades higher than the Flesch-Kincaid grade levels. Most English sites require at least a 10th grade (Flesch) reading level, and more than half present information at college level. This is perhaps a partial explanation of the fact that Internet usage for health information is strongly associated with higher education (Baker et al., 2003; Fox & Fallows, 2003).

Additional metrics exist to approach the problem from the consumer side and focus on a person's health literacy level instead of the difficulty of the text. For example, the Test of Functional Health Literacy in Adults (TOFHLA), its shortened version STOFHLA (Parker, Baker, Williams & Nurss, 1995) and the Cloze procedure (Taylor, 1953) are often used. The Rapid Estimate of Adult Literacy in Medicine (REALM) (Davis et al., 1993) is one of the most popular measures (Pignone, DeWalt, Sheridan, Berkman, & Lohr, 2005). These metrics provide a common method to evaluate consumer understanding of common medical and health terminology and have led to surprising findings. For example, Zun, Sadoun, and Downey (2006) found that nurses and doctors overestimate written English competency in their Hispanic patients when compared to test results with the REALM and STOFHLA. Although these measures are commonly used, few studies directly compare performance of individuals (health literacy) with different text reading levels (readability measures). A recent exception is the work by Trifiletti, Shields, McDonald, Walker, and Gielen (in press) who evaluated text of different grade levels and performed the Cloze test on these texts. The Cloze test removes the n^{th} word from a text and then requires people to fill in the blanks. They found that more people performed at an acceptable level with lower grade level texts. Similarly, Pignone, et al. (2005) provide a review of studies focusing on text simplification and showed improved understanding in the low literacy group when texts were simplified.

There are two components that can be focused on to automatically simplify texts and lessen the aforementioned difficulties. The first is grammar; the second is vocabulary. Grammar and sentence structure simplification would lower the readability grade levels. For example, using active instead of passive sentences or right branching instead of embedded or left branching sentences increases readability. However, simply lowering the required reading level will be insufficient. Leroy, Eryilmaz, and Laroya (2006) found that difficult documents measured with the Flesch readability formulas not only use more complex sentence structures but also use more complex vocabulary and often discuss more difficult topics. These results correspond with Boulos' (2005) conclusion that some documents will remain difficult, and other means of user support will be needed.

Structure Simplification

Most research has concentrated on visualizing large collections of entire documents or visualizing information extracted from all those documents. Little research focuses on facilitating content access for a single document and even less on medical or health text. However, previews of single documents have been found to expedite review of documents (Greene, Marchionini, Plaisant & Shneiderman, 2000; Marchionini, Plaisant & Komlodi, 1998). A preview extracted from the original document acts as a surrogate. It is effective when it communicates sufficient information to the user about individual information items. For example, most search engines provide an excerpt of text called a "snippet." Some simply show the first few lines of text; others display the text surrounding keywords, use heuristics to select sections of documents (Amitay & Paris, 2000), or provide a document summary.

The previews can be textual, graphical, or a combination of both. Woodruff, Rosenholtz, Morrison, Faulring, and Pirolli (2002) compared textual and graphical (thumbnail) summaries and found the best results with a combination of both types. Manber (1997) combined color with the original text and proposes highlighting as a preview for documents. By keeping a personal list of keywords and highlighting these in a document, users can rapidly determine their interest in it. Hornbæk & Frøkjær (2001, 2003, 2004) studied linear, fisheye, and overview+detail interfaces to facilitate reading of electronic documents. They compared their subjects' essay, question-answer task performance, and user satisfaction. They manipulated how much text was visible to users at any time but did not extract any text or information from the text. Even so, the overview+detail interface helped their subjects understand main ideas better, and the fisheye interface helped them answer questions faster. The linear text interface was worse than the other two in most aspects. This approach is rarely evaluated for health information, with a few exceptions. Ogozalek (1994) used text and multimedia interfaces to provide prescription drug information to the elderly and found that the subjects answered questions better with the multimedia interface. There was no effect on retention of the information. Miller, Leroy, and Wood (2006) are working on dynamically generating tables of contents for WebMD documents using UMLS semantic types as entry points.

Text Visualization

More advanced approaches extract and visualize pertinent information from individual documents. This approach is being tested for biomedical text and biomedical researchers. For example, in Genescene (Leroy & Chen, 2005), an interactive graph visualization of biomedical relationships is shown. Researchers can browse the graphs and drill down to the underlying text. A simpler approach is used by Beier and Tesche (2001), who provide an overview of a metasearch based on the origin of the results, such as Internet sites or journals. However, no such tools are currently tested for or made available to health information consumers.

HEALTH INFORMATION CONSUMER GROUPS

Improved access, understanding, and retention of health information would benefit the general population. However, three groups in particular deserve special attention: non-native English speakers, the elderly, and patients. These three groups have special health information needs, which we will discuss in more detail, and are a growing group online. For example, Gustafson et al. (2002) focused on underserved African Americans, the elderly, and HIV patients, and found that these three groups tend to use mostly information and analysis services and not so much communication technology such as the discussion boards. As such, increasing their understanding of online health texts should be a key focus.

Many online readers who do not speak English as their native language still read information in English. To fully appreciate the problem, think about a second or third language you speak and how difficult it would be to understand the health information in that language. This is problematic and affects health care outcomes. The effect will be stronger when information is only available in English. In addition to the text, several other factors, such as cultural differences, structure of pamphlets, difficult images, and lack of definitions, affect health literacy (Hunter, 2005). Few realistic and feasible approaches are proposed in the literature. Popular advice is to provide translations of all text. However, Becker (2004) found that only 10% of state sites in the United States provide Spanish translations, and many buttons and links are never translated. Moreover, Parker and Kreps (2005) illustrated that translating all texts is not a scalable solution since health care organizations may need translations in 40 or more languages. Translations will not be available for everyone, and so this multilingual consumer group will benefit most from text simplification.

A second growing online group is the elderly. There have been large survey-based studies that looked at the relationship between Internet usage and demographic variables, such as race, gender, and age. Ito, O'Day, Adler, Linde, and Mynatt (2001) studied SeniorNet, an online community with more than 20,000 members and 4,000 volunteers. They found that seniors do not see themselves as different or technologically challenged. Even so, with increasing age, people encounter problems that may interfere with optimal Internet usage. Vision deteriorates, requiring bigger font sizes and more contrasting colors. Mouse and keyboard skills are often lower due to physical problems such as arthritis, tremors, or lack of experience with computers in general. Learning becomes slower and more difficult with longer training times and more attention problems (Hanson, 2001; Nielsen, 2000). This group may benefit especially from improved text structure since they perform as well as younger adults in recalling stories when events are in canonical order (Wingfield & Stine-Morrow, 2000). Although elder users do not see themselves as less experienced, Chadwick-Dias, Tedesco, and Tullis (2004) demonstrate that self-reported Web experience is not the same as actual Web expertise. Older users received lower scores on an expertise quiz, even when controlled for self-reported Web experience. The quiz consisted of a list of images and their possible meanings (e.g., a back button).

Patients are a third growing online group. This group is very diverse, and different types of patients have different needs. Most representative of this group are individuals who need information on a recently diagnosed disease. Depending on the seriousness of the illness, these patients are more or less stressed, tired, and fearful. All these factors may affect how well they grasp health information. For example, Van Servellen, Brown, Lombardi, and Herrera (2003) found that increased stress was significantly correlated with poorer recognition of HIV terms in their group of low-income Latinos. Most patients in this group will not understand all the vocabulary and information presented online. In contrast, there is an additional group of expert patients who have different needs. Although there are different opinions on what an expert patient is (Shaw & Baker, 2006), in the best scenario, these are patients with chronic diseases who are involved in the management of their disease and who collaborate with health care providers for the best outcome (Badcott, 2005). This expert patient group will have more background knowledge, use a much more advanced vocabulary, and understand more complicated documents.

FUTURE TRENDS

In the future, two broad trends can be expected. The first will be studies that focus mainly on user groups. There will be an increasingly sophisticated knowledge base that can distinguish between various user groups and their ability to learn and remember information in interaction with various types of technology. Both cognitive science and educational methodologies will play a significant role. Although this chapter focused on adults, children will become a much more important consumer group.

The second trend will be complementary and will comprise various types of technology and media and their interaction with various consumer groups. Computational linguistics and computer and information science will drive these trends. For example, text simplification will benefit consumers directly, but may also lead to better machine translation. Visualization can be used to visualize the structure of text, but also for treatments and interventions. Text visualization may be adapted and act as summaries or previews. PDA or Smartphone users with smaller screens would particularly benefit from previews. Such previews may also become relevant for medical professionals in the field when dealing with emergencies that require them to find new information. Voice recognition combined with wireless search engine technology to retrieve information and show this on small displays (e.g., watches, glasses) will also become available. More advanced visualization such as automated translation from text to graphical novels or movies and animation would be especially beneficial for low literacy groups and children.

CONCLUSION

Understanding health information is an important aspect of our health care. It leads to more informed and more comfortable patients and better adherence to therapies. Many studies show that the general public does not understand the information from which they would benefit. Current research to facilitate this understanding is in the early stages. Most research has focused on demonstrating the problem. Some are now evaluating how to simplify the information, but approaches are manual. To tackle the problem in an efficient manner, automated approaches are needed that can scale up. This research is in its infancy, but the benefits will be enormous as it matures. More and better-informed health consumers from all walks of life will benefit. And research which focuses on related problems such as summarization, visualization, or even machine translation may also be affected.

KEY TERMS

Cloze Procedure: A procedure to measure readability of text by deleting the n^{th} word and asking readers to fill in the blanks. This procedure was originally developed by Taylor (1953).

Consumer Health Informatics: Research that focuses on health information, the consumers who read the information, and the interaction between the two.

Flesch Reading Ease: A readability measure that provides an estimate of the readability of a text and the required grade level to understand the text. It is based on syntactic and word level considerations.

Health Literacy: The ability to understand health and medical information and act upon that information correctly.

Readability: The difficulty level of a text, usually measured by formulas such as the Flesch Reading Ease.

REALM: Rapid Estimate of Adult Literacy in Medicine.

STOHFLA: Short Test of Functional Health Literacy in Adults (Davis et al., 1993).

TOFHLA: Test of Functional Health Literacy in Adults (Parker et al., 1995).

Incremental Neural Network Training for Medical Diagnosis

INTRODUCTION

Artificial intelligence has attracted many researchers in recent years for its usefulness in the medical field. With the increase in research interest, artificial intelligence systems have found widespread usage in the medical domain (Remzi & Djavan, 2004; Tsakonas, Dounias & Jantzen, 2004). These applications arise as medical datasets usually contain a high volume of data, and it is very costly for human manual analysis and handling. The intelligent systems posses the ability to process datasets, extract useful information from them, and interpret the data at a much lower cost (Raymer, Doom, Kuhn & Punch, 2003) as compared to the manual handling. Intelligent systems like evolutionary computing, fuzzy logic, and neural networks are just some that many researchers have recently looked into.

Neural network has been used in the medical field to a great extent (Hayashi & Setiono, 2002) and more noticeably for classification problems (Abbass, 2002), since more frequently the outcome of the medical diagnosis is to categorize the patient into the different classes. The conventional method of neural network training for medical diagnosis is to present all the input attributes together as a batch at the same time to the neural network. However, some input attributes are more important and contain a higher consideration factor than others, and the criteria that each attribute uses for classification is also different. If all inputs are presented as a batch at the same time, trouble arises easily if there is interference among them. Thus, if all the input attributes are trained together in a batch, each attribute will interfere in the decision-making of others.

The input feature space and architecture of the output layer has proved to be a factor affecting the performance of neural network (Guan & Li, 2002a; Guan & Li, 2002b; Guan & Li, 2004; Guan, Li, & Qi, 2004). Input data space clustering techniques were applied in neural networks studies (Plikynas, 2004; Sun & Peterson, 1999). Sun and Peterson (1999) partitioned the input space into different regions and applied differential weighting for different regions so they have different agents that specialize in local regions. However, to date, little work has been reported to investigate the interference of the input attributes and, inferring from the information, to devise a carefully designed feature-partitioning algorithm.

This chapter proposes a novel method of incremental interference-free neural network training (IIFNNT) for medical datasets, which takes into consideration the interference each attribute has on the others. A specially designed network is used to determine if two attributes interfere with each other, after which the attributes are partitioned using some partitioning algorithms. These algorithms make sure that attributes beneficial to each other are trained in the same batch, thus sharing the same subnetwork while interfering attributes are separated to reduce interference. There are several incremental neural networks available in literature (Guan & Li, 2001; Su, Guan & Yeo, 2001). The architecture of IIFNNT employed some incremental algorithm: the ILIA1 and ILIA2 (incremental learning with respect to new incoming attributes) (Guan & Li, 2001).

This chapter is divided into five sections. The next section describes the incremental neural networks used in the IIFNNT. In Section 3, the method to evaluate interference between two attributes and the interference-free attribute partitioning algorithm is presented. The results of experiments on a diabetes medical dataset are given and analyzed in Section 4, together with a comparison to other related work in literature. The conclusion of our research, together with suggestions for future work, is given in Section 5.

Incremental Neural Networks Used

As mentioned earlier, the architecture of IIFNNT is based on the incremental algorithm ILIA (Guan & Li, 2001). When additional input attributes are considered, the ILIA expands its input space to accommodate these new attributes. The architecture of the ILIA algorithms from Guan and Li (2001) is described here.

ILIA1

The existing available attributes are first presented to the network, as shown in Figure 1. Network consists of direct connections from all the input units to all the output units. All input units are connected to all the hidden units. All the hidden units are also connected to all output units. The ILIA used the Constructive Backpropagation Learning algorithm (Lehtokangas, 1999) to train the weights and to determine the number of hidden neurons needed for its network. After the weights of the network have been trained, they are fixed and no longer changed.

When there are new attributes to be considered, increase the input dimension to accommodate the new attributes and a new subnetwork (in terms of new direct connections and new hidden units) is added to the existing network. The newly formed neural network architecture is shown in Figure 2. The process of adjusting the weights and installing new hidden units is done only for the new subnetwork.

ILIA2

An extension to ILIA1 is also given in Guan and Li (2001). In ILIA2 (Figure 3), new output units are added to the neural network obtained in ILIA1. The number of new output units is equal to the number of output units in ILIA1. Thus, with new output units being added to the neural network obtained in ILIA1, the output units in ILIA1 are being collapsed and have effectively become a new hidden layer.

INTERFERENCE-FREE NEURAL NETWORK

There are several steps needed to form the interference-free neural network. The steps will be broken down and the major ones presented in the following subsections. An example using the diabetes dataset will also be used along the way to illustrate the method.

Figure 1. Initial network

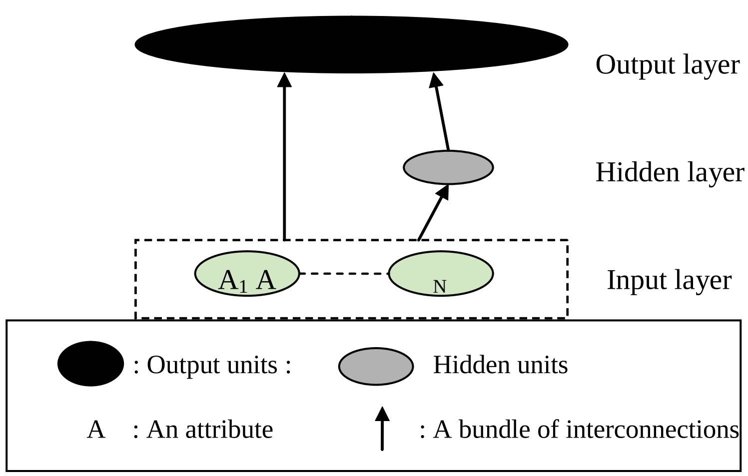

Figure 2. Architecture of ILIA1

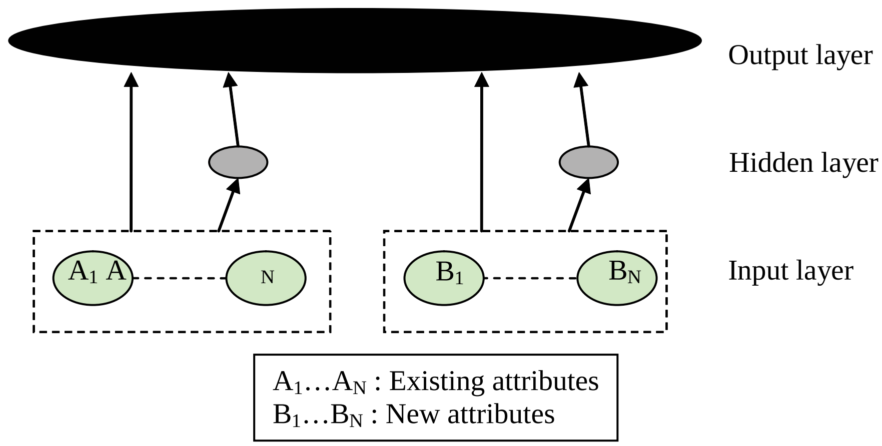

Figure 3. Architecture of ILIA2

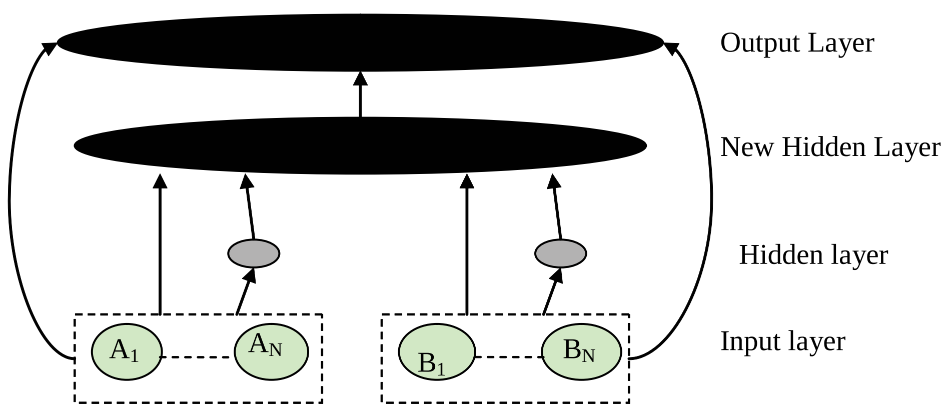

Formulating the Interference Table

The interference-free partitioning method is inferred from the Interference Table. The Interference Table consists of individual attribute discrimination ability (Guan & Li, 2004) and the discrimination ability of any two attributes when trained together.

Evaluating Individual Attribute Discrimination Ability

Guan & Li (2004) state an attribute's individual discrimination ability as the ability of each individual input attribute to correctly classify a given problem. The assessment of such ability is by having just an attribute (the attribute to be tested for its discrimination ability) in the input space of the neural network for training. This is done in the absence of other attributes. The network used here is similar to the network in Figure 1; the difference is that there is only one input attribute in this case, whereas the network in Figure 1 can take any number of attributes.

When training this network, all the patterns in the training dataset are used to train the neural network. There is only one attribute available in the training dataset, which is the attribute to be tested. The ILIA (Guan & Li, 2001) referred to Prechelt's (1994) work and used the method of *early stopping* for the Constructive

Backpropagation Learning Algorithm (Lehtokangas, 1999). The validation set is used here for evaluating the quality of the network during training and to prevent overfitting.

The error produced on the validation set at the end of the training will be a measurement of the individual attribute discrimination ability. The error is tabulated in Table 1.

Evaluating Discrimination Ability of Two Attributes When Trained Together

The neural network architecture shown in Figure 4 is used to evaluate the discrimination ability when any two attributes are trained together. At any one time, there are only two input attributes in the input layer. Once again, this network is similar to the network, as shown in Figure 1. The difference is that there can only be two input attributes (the two attributes to be tested) in the input layer.

There will be two attributes available in the training and validation set, and all the patterns in the training and validation set will be used for the training process. Output of the network will be decided by these two attributes trained in batch (both input attributes have connections to the same hidden units), and consequently, the percentage of error produced on the validation set is noted down and tabulated in the Interference Table.

The Interference Table

Formulation of this table is able to illustrate whether there exists interference between any two attributes. Table 1 gives an example of how an Interference Table looks. By comparing the error produced from training the two attributes together, I_{ij} with error produced by each attribute when trained alone, IDA_i or IDA_j it will be able to show if interference exists among these attributes. Two attributes are said to be interfering with each other if the error derived from training both the attributes in batch is higher than the error resulted from training either attribute alone (i.e., $I_{ij} > IDA_i$ or $I_{ij} > IDA_j$). Two attributes are not interfering if the error derived from training both the attributes in batch is lower or equal than the error resulted from training either attribute alone (i.e., $I_{ij} < IDA_i$ and $I_{ij} < IDA_j$). If error does not increase or decrease when two attributes are trained in batch compared to training them alone (i.e., $I_{ij} = IDA_i$ and $I_{ij} = IDA_j$), these two attributes most likely do not have an effect on one another.

For clarity, the interference table of the diabetes set is given in Table 2. For example, the individual discrimination ability of attribute 2 will produce an error of 17.08%, and the individual discrimination ability of attribute 4 will produce an error of 23.14%. When both of them are trained together, the error produced is 17.14, which is higher than the error when training

Figure 4. Architecture of neural network used to evaluate interference

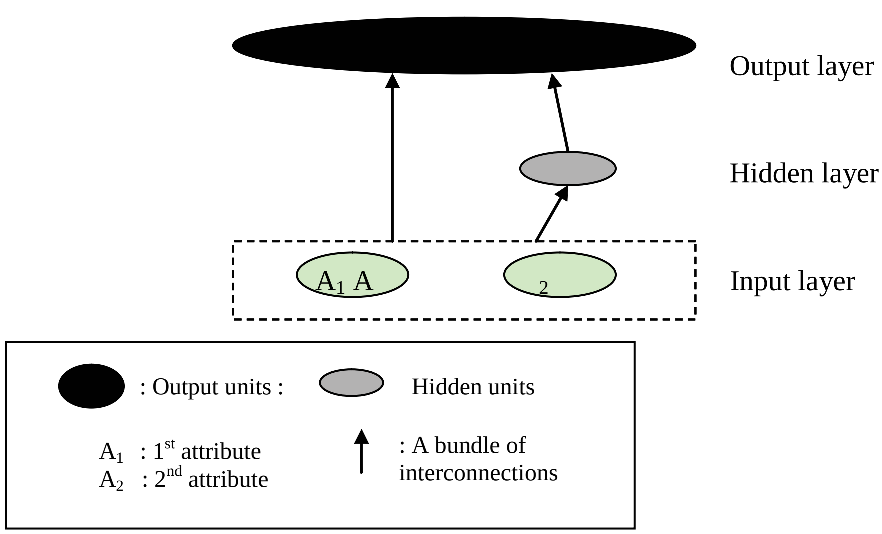

Table 1. Interference table

Attribute	1	2	3	4	5	6	……………..	N
1	IDA_1							
2	I_{12}	IDA_2						
3	I_{13}	I_{23}	IDA_3					
4	I_{14}	I_{24}	I_{34}	IDA_4				
5	I_{15}	I_{25}	I_{35}	I_{45}	IDA_5			
6	I_{16}	I_{26}	I_{36}	I_{46}	I_{56}	IDA_6		
							……………..	
N	I_{1N}	I_{2N}	I_{3N}	I_{4N}	I_{5N}	I_{6N}	……………..	IDA_N

Note : IDA_i - Individual Discrimination Ability of attribute i
I_{ij} - Classification performance of network when attribute i and attribute j are trained together

Table 2. Interference table—diabetes

% error	1	2	3	4	5	6	7	8
1	21.74							
2	16.25	17.08						
3	21.73	16.90	23.27					
4	21.64	17.14	23.09	23.14				
5	21.12	17.01	22.87	22.95	22.92			
6	20.50	16.84	21.51	21.72	21.49	21.68		
7	21.18	17.09	22.67	22.57	22.49	21.27	22.73	
8	19.61	15.04	19.85	20.05	20.11	19.37	20.20	20.02

attribute 2 alone. This means that these two attributes are interfering. The individual discrimination ability of attribute 7 will produce an error of 22.73%. When both attribute 4 and 7 are trained together, the error is 22.57, which is lower than the error produced by both the attributes' individual discriminating ability.

An overview of the Interference Table summarizing which are the interfering attributes to a particular attribute is given in Table 3. With this overview, the partitioning algorithm can proceed easily.

Interference-Free Partitioning Algorithm

The proposed interference-free partitioning method is inferred from the Interference Table. The main objective of this partitioning is to separate attributes that have interference with one another and group those attributes that are beneficial to each. The major steps involved in the algorithm are explained next.

Table 3. Overview of interference table—diabetes

Attribute	Do not interfere with	Interfere with
1	2 3 4 5 6 7 8	
2	1 3 5 6 8	4 7
3	1 2 4 5 6 7 8

7	1 3 4 5 6	2 8
8	1 2 3 6	4 5 7

Note: The column 'Do not Interfere with' contains attributes that have no interference with the attribute in the 'Attribute' field. The column 'Interfere with' contains attributes that interfere with the attribute in the 'Attribute' field.

Partitioning Algorithm

The major steps are:

A. Assign an attribute as the default attribute, start partitioning the attributes into two batches with reference to the default attribute. One batch contains all the attributes that interfere with the default attribute, and the other batch contains those attributes that do not interfere and the default attribute itself. The assignment of the default attribute can be done randomly or in numerical order, as it is not important. Ultimately, all the attributes should be treated as the default attribute once for the whole run.

B. The next partitioning will depend on the attribute next in line to the one that has just been used for partitioning. For example, previously the partition was done using attribute 4, then the next partitioning will depend on attribute 5. If there is a total of eight attributes and the default attribute is attribute 6, and the third partitioning has been done on attribute 8, then the next partitioning will depend on attribute 1, which is next in line. Identify the batch that the reference attribute belongs to, and split the batch according to the following guideline:

   1. If none of the attributes interfere with the reference attribute within the batch, nothing is to be done. All the attributes within the batch can co-exist with each other. Also, if there is only one attribute in the batch, nothing is to be done.
   2. If the number of attributes that interfere with the reference attribute is less than or equal to the number of attributes that does not interfere within the batch, take out those interfering attributes and form a new batch. This means that within the batch, there are more attributes that can be trained with the reference attribute than those that interfere. In order to form the largest possible group, we let the reference attribute stay in the batch and take out those that interfere.
   3. If the number of attributes that interfere with the reference attribute is more than none of the interfering attributes, then take out the reference attribute from the batch.

C. Repeat Step B until the all attributes have been considered.

Steps (A) to (C) will be repeated until all attributes have been considered as the default attribute. As we try to achieve comprehensive partitioning, all attributes will take their turn to be the default attribute.

ARCHITECTURE OF IIFNNT

The network used in IIFNNT is extended from the ILIA1 and ILIA2 (Guan & Li, 2001). IIFNNT partitions the input space into different batches, and each can contain any number of attributes. Attributes within each batch are grouped together because they have no interference among each other. IIFNNT makes sure that attributes beneficial to each other are trained in the same batch, thus sharing the same subnetwork, while interfering attributes are separated and trained in different batches to reduce interference. Growing of the IIFNNT1 structure is described in the following steps:

- **Step 1.** From the grouping obtained using the interference partitioning algorithm, introduce the first batch of attributes into the neural network for training. Order of batches to be introduced into the neural network is determined by the first attribute within the batches and is done in ascending order.
  Training of the network is based on the training and validation set, which will contain only attributes that are present in the first batch. When the training is done, all the weights of the network are fixed and no longer changed.
- **Step 2.** Introduce the next batch of attributes by forming a new subnetwork. Weights and connections are only adjusted for this new subnetwork. Once the training for this new subnetwork is done, fix all the trained weights.
- **Step 3.** While there are still batches of attributes not yet introduced to the network, repeat step 2.

The IIFNNT1 is shown in Figure 5. With respect to the diabetes problem, the partitioning algorithm gives the following partition: (1 3 5 6 7) (2) (4) (8). Thus, in this case, there are four batches (i.e., four subnetworks). The first batch of attributes to be introduced into the neural network is (1 3 5 6 7) followed by a second batch that consists of attribute 2, a third batch that contains attribute 4, and last, the final batch that contains attribute 8. Figure 7 shows the IIFNNT1 for the diabetes problem.

When all the batches of attributes have been introduced into the network and the network has been fully trained, all the weights are fixed. The network is then presented with the testing set to evaluate its generalization accuracy.

Given a medical dataset for a two-class problem, there will be two output neurons in the IIFNNT architecture. The decided class of the neural networks is determined by the winner-take-all strategy. The first output neuron is assigned class 0, and the second output neuron is assigned class 1.

IIFNNT2 (Figure 6) adds more hidden units to the IIFNNT1 architecture. IIFNNT 2 hopes to obtain more information from IIFNNT1 and improve the existing network to achieve better generalization performance.

IIFNNT IN MEDICAL DIAGNOSIS

The Medical Diagnosis Datasets

The medical dataset used in our experiments is a real-world problem—the diabetes1 problem, taken from PROBEN1 benchmark collection (Prechelt, 1994). The details of the dataset are given next:

Figure 5. IIFNNT1 (ILIA1) architecture

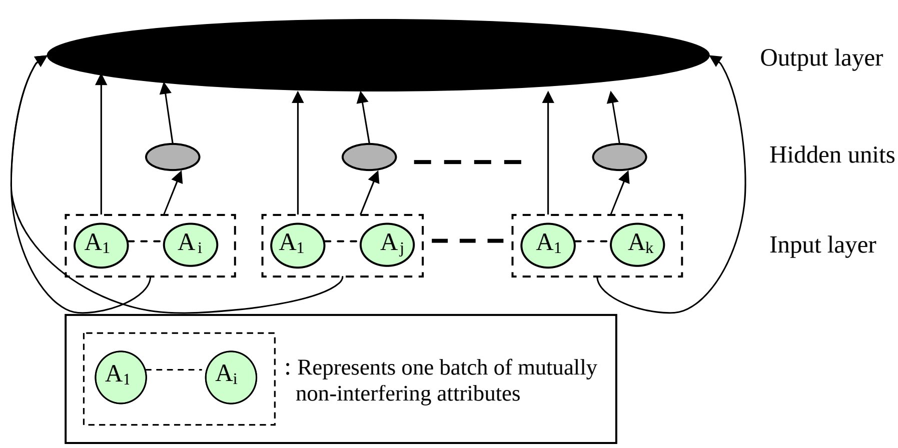

Figure 6. IIFNNT2 (ILIA2) architecture

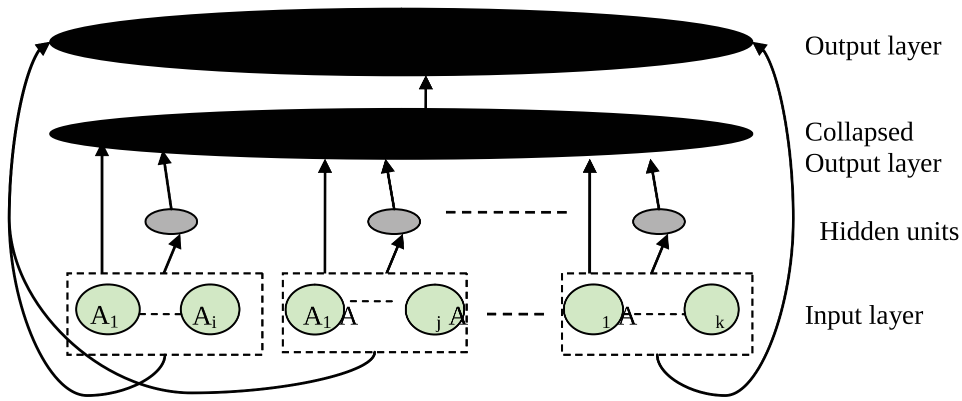

Figure 7. IIFNNT for the diabetes problem

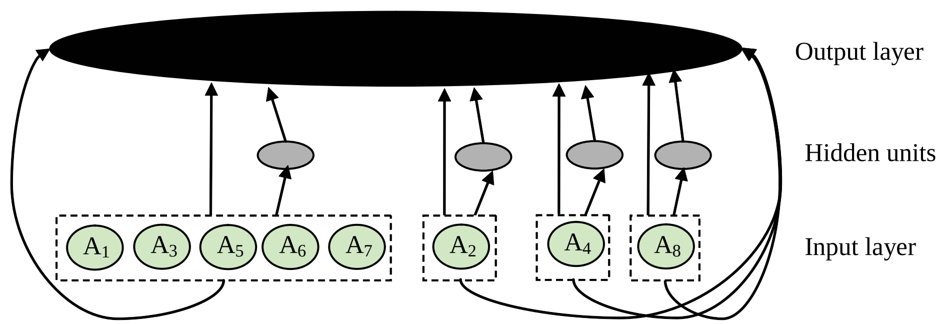

- **Diabetes Dataset:** The "Prima Indians Diabetes" problem dataset from the UCI repository of machine learning databases was used to create this dataset. This problem diagnoses diabetes of a Prima Indian individual is based on personal data and medical examination. All the values are being encoded into continuous values in the range of 0 to 1 in PROBEN1. The class output is such that a 0 output shows no diabetes, and a 1 output shows diabetes.

Experimental Settings

All the results were taken over an average of 20 trials, and the initial assignment of weights for the neural network are from -0.25…0.25 randomly. The percentage of total examples in the dataset used for training set is 50%, validation set is 25%, and test set is 25%.

- The total number of examples used for the training set is 384; the total number of examples used for the validation set is 192; and the total number of examples used for the test set is 192.

Training of network is done using the training set; the validation set is used as a guide for stopping criteria; and the test set is used to evaluate networks generalization accuracy based on unseen data.

Experimental Results and Analysis

There are several interferences detected among the attributes of the diabetes dataset, as given in Table 2 and Table 3. The resulting partitioning by the algorithm that uses different attributes as the default attribute is shown in Table 4.

Random Ordering for Partitioning

The partitioning of the attributes by the algorithm is based on attributes being presented to it in a sequential order. If there is a high degree of interference among the input attributes, the partitioning algorithm is also able to produce different partitioning if the attributes are presented to it in a different order. Two cases of randomly ordering the attributes being presenting it to the algorithm for partitioning is investigated. Table 5 shows the diabetes dataset partitioning obtained when attributes ordering is randomized.

Best Results

Each neural network with different partitioning is being trained using the training and validation set; the resultant networks are then being evaluated for their generalization accuracy. The result from the network that gives the highest generalization accuracy is being presented in Table 7. The network with the grouping (1 2 3 6 8) (4 7) (5) gives the best results for the diabetes problem, as shown in Table 6. The standard deviation is also given in Table 7 as a guideline to the consistency of the algorithm. For the diabetes dataset, IIFNNT1 achieved better results than IIFNNT2 for the same partitioning.

Results Comparison

Our results are compared with several algorithms in literature. Not only do we compare our algorithms with neural networks used for medical dataset analysis, but we also compare them with other intelligent systems for medical diagnosis. Before we could carry out the incremental interference-free neural network training, we had to compute the Interference Table and apply the partitioning algorithm to find out the different grouping of attributes in the input space. The calculation of parameters, like the total number of hidden units and time taken for the computation of the Interference Table, is hard to materialize. Therefore, only generalization accuracy that is the major concern in this chapter is being compared.

Diabetes Dataset

The diabetes dataset results were compared with the results obtained using the conventional method of training, IFGP (Oltean & Grosan, 2003) and EFNN (Tsakonas & Dounias, 2002). The evolution of feed-forward neural networks using BNF-Grammar driven

Minimum (%)	21.354
Mean (%)	22.344
S.D. (%)	0.674

genetic programming (EFNN) (Tsakonas & Dounias, 2002) uses genetic programming in an attempt to automatically define feedforward neural networks.

For this problem, in terms of mean error, IIFNNT has outperformed the conventional method, IFGP and EFNN, with its low classification error of 22.344%. This is a 7%, 12%, and 3% error reduction over the conventional method, IFGP and the EFNN, respectively. Among all the algorithms mentioned previously, IIFNNT produced the smallest standard deviation. No results were presented for the maximum error and minimum error of EFNN; therefore, comparison can only be made to mean error. With our method having much better performance than the conventional method of training, it should be noted that it is important to have a partitioning algorithm in the input space to reduce the interference among input attributes. As can be seen from Table 2 and Table 3, there is a considerable amount of interference among the attributes. Maximum error produced by IIFNNT is also much lower than the maximum error (26.04%) produced by the conventional method of training the neural network. For a medical dataset, one would like to have low standard deviation in order to achieve consistent and reliable results.

FUTURE TRENDS

In the future, we will see more and more attempts to hybridize different intelligent systems to improve their overall performance in medical applications, including health care practice and delivery. For future work on the proposed approach, more research effort would be needed to find out if there exist other partitioning algorithms that could be used together with the Interference Table. It would be interesting to discover other alternative partitioning algorithms that can further improve generalization accuracy and reduce cost in medical diagnosis.

CONCLUSION

This chapter proposed input space partitioning by taking into consideration the interference among attributes to improve the accuracy in medical diagnosis. IIFNNT worked out the interference between any two attributes and separated the input data space into different

Table 8. Comparison of IIFNNT results with other algorithms—diabetes dataset

Algorithm	Mean Error (%)	Maximum Error (%)	Minimum Error (%)	Std. Dev.
IIFNNT	22.344	23.438	21.354	0.674
Conventional	23.932	26.042	21.875	1.152
IFGP	25.34	-	21.87	2.08
EFNN	23.04	-	-	-

batches, each trained with a subnetwork. By having different subnetworks for different batches, it is able to reduce the interference between the attributes. Attributes within each batch do not interfere with each other, while interfering attributes are separated. The algorithm is tested with one real world problem: the diabetes problem. The results from the experiments showed that generalization accuracy has improved with reduced interference. Neural networks are able to perform better if the correct partitioning and grouping method is applied and it increases the efficiency of network training. The cost of our method is the computation of the Interference Table. However, it should be noted that the computation of the Interference Table is a one-time cost.

KEY TERMS

Artificial Intelligence: A branch of computer science that studies human intelligence and aims at embedding intelligent behavior, learning, and adaptation capabilities into machines.

Discrimination Ability: The ability of that particular attribute in classification performance when all the other attributes are absent from the neural network training.

Interference: Interference or cross-talking arises during the process of deciding the output value for a particular output attribute, the influence from two or more input attributes are conflicting.

Neural Network: A network of interconnecting neurons working together to produce some output function. The working of a neural network relies on the cooperation of the individual neurons within the network.

Overfitting: Refers to fitting a model (e.g., neural network) with too many samples or parameters.

Training: Refers to the process of adjusting or updating neural network weights to deliver the desired output function.

Validation: The process of checking whether overfitting (overlearning) is reached during neural network training.

Information Systems Resource Contribution in Strategic Alliance by Small Healthcare Centers

Yu-An Huang
National Chi Nan University, Taiwan

Chad Lin
Curtin University of Technology, Australia

INTRODUCTION

Alliance is defined as the "collaborative efforts between two or more firms in which the firms pool their resources in an effort to achieve mutually compatible goals that they could not achieve easily alone" (Lambe, Spekman & Hunt, 2002, p. 141). Cooperative alliances allow firms to explore new information technology, enhance a firm's knowledge foundation, lower development costs, and reduce the capital requirements and risks involved in development of new products and services (Das & Teng, 2000; Scotten, Shirin & Absher, 2006). This approach is often adopted by small and medium-sized enterprises (SMEs) as a competitive strategy to obtain necessary information systems resources in the rapidly changing and high-pressure healthcare industry (Nelson, Galvin, Essien & Levine, 1999; Scotten et al., 2006). However, according to Das and Teng (2000), around 60% of alliances between partners resulted in failure. Hence, the choice of partners and resource fit of alliance partners are of great importance for SMEs (Grant, Preece & Baetz, 1999). For those SMEs without much information systems (IS) resources, the formation process of alliance can be viewed partly as a process to increase both their tangible and intangible IS resources. Value generated from alliances is enhanced when partners have different IS resource profiles and contribute these IS resources to the alliance. These partner characteristics are important since they help in the evaluation of optimum allocations of IS resources for potential alliances to achieve suitable alliance resource alignments.

Thus, the objective of this chapter is to examine how different types of IS resource alignments affect the performance of alliances via the contribution of dissimilar and similar IS resources. The focus of this study is small healthcare centers in Taiwan. These small healthcare centers have formed alliances to confront the fierce competition as well as to absorb the regulatory pressure from the government. Most of these small healthcare centers in recent years have realized that they can only compete with major healthcare service providers through cooperative alliances, as most of the patients prefer to go to big service providers for long-term treatments. The literature on interorganizational collaborations has been criticized for its relatively narrow concentration on large firms and for ignoring SMEs' alliances where large firms do not operate in similar ways (Prater & Ghosh, 2005). These cost pressures, together with the general dynamic nature of the healthcare industry, require a significant change in approaches to utilize IS resources by these small healthcare centers. Therefore, these small healthcare centers must form alliances to obtain scarce IS resources. Unlike large firms that own a lot of IS resources to be able to form alliances with many partners, these small healthcare centers tend to form alliances with only a small number of partners, and therefore, their dependence on these partners is higher than large firms (Mambula, 2002). In this regard, these small Taiwanese healthcare centers offer an appropriate context for research.

BACKGROUND

Similar Resource Contribution

SMEs are particularly in need of finding suitable partners with dissimilar or similar resources due to their insufficient slack resources (Huang, Lin & Lin, 2005; Lin, Lin & Tsao, 2005; Srinivasan, Rangaswamy & Lilien, 2005). Formation of alliances is one way for firms that have possessed similar resources to decrease interfirm rivalry. Chen (1996) has defined resource similarity as "the degree to which two partner firms contribute resources compatible, in terms of both type and amount, to an alliance" (p. 107). The understanding of resource similarity is very important because the firms that have possessed similar resources can potentially be the fierce rivals (Chen, 1996). Moreover, resource similarity can also assist in interorganizational learning among alliance partners. For example, according to Pitts and Lei (1997), alliances formed to learn and absorb tacit knowledge are more difficult to manage among partners that come from different cultural backgrounds than partners from a similar cultural background. In addition, Inkpen (2000) has proposed that the relatedness between interpartners' knowledge base supported the acquisition of alliance knowledge. Therefore, we argue that IS resource similarity represents smaller knowledge distance and higher cultural similarity between alliance partners. These similarities are likely to assist alliance partners in developing a thorough understanding of their own knowledge and culture, and these can also enhance mutual learning and coordination and ultimately lead to increased alliance performance.

Dissimilar Resource Contribution

On the other hand, the uniquely dissimilar resource contribution is particularly critical to SMEs in their partner selection processes. SMEs are particularly in need of finding suitable partners with dissimilar resources, since it is difficult to produce alliance synergy without dissimilar resource contribution (Harrison, Hitt, Hoskisson & Ireland, 2001). Although potential competitors can easily imitate the research-based synergy from an alliance where the interpartners have strong research orientations, it will be much more difficult for them to acquire the synergy derived from dissimilar resource contribution (Harrison et al., 2001). Therefore, they are less likely to be interested in forming an alliance with firms who are only able to contribute similar IS resources. It is proposed that there is a negative correlation between interpartners on the contribution of similar IS resources. This implies that one party does not require the contribution by the other party on the IS resources they already own. On the other hand, there is a positive correlation between interpartners on the contribution of dissimilar IS resources. Interpartners that possess dissimilar IS resources are able to complement each other within an alliance. Therefore, the following hypotheses are proposed:

- **H1:** There is a negative correlation between the focal firm and the partner firm on the contribution of the similar IS resources.
- **H2:** There is a positive correlation between the focal firm and the partner firm on the contribution of the dissimilar IS resources.
- **H3:** Higher dissimilar IS resource contribution leads to higher alliance sustainable commitment.
- **H4:** Higher dissimilar IS resource contribution leads to higher alliance performance.

RESEARCH METHODOLOGY

Data Collection

In order to test the proposed hypotheses, five in-depth semistructured interviews lasting one hour each and a pilot survey of 10 industry executives were conducted to get insights into industry dynamics and to develop and refine the survey scales. Then, the main survey targeted small healthcare centers, which were classified to have formed alliances with others. This questionnaire asked the owners/directors or persons who were capable of representing their views to complete and return the questionnaire. The respondents were asked to answer the questions in relation to the cooperative relationship with their most important alliance partner.

A total of 69 questionnaires were received from the small healthcare centers that have formed alliances with others in Taiwan. The sample size is comparable to many other similar studies conducted in the last few years. For example, Sarkar, Echambadi, Cavusgil, and Aulakh (2001) collected 68 responses from 561 large international contractors sent (a net response rate of 12.1%) in their study of alliance on the role of dissimilar resource contribution, compatibility, and relationship capital on alliance performance. Nonresponse bias was tested by comparing the early and late responders on all constructs, and no significant difference between the two groups was found.

Measurement

This study has defined the interorganizational IS resource cooperation among the healthcare centers as the unique and valuable IS resources contribution by both the focal and partner firms. According to the resource-based viewpoint, IS resources (for a healthcare center) can be categorized as specialized IS support, medical IS support services, and IS management systems (Short, Palmer & Ketchen, 2002). There were 20 questions within the questionnaire, and respondents were asked to indicate their agreement on a seven-point Likert scale (1 for strongly disagree and 7 for strongly agree) with statements concerning four main constructs: (1) alliance sustainable commitment; (2) alliance performance; (3) focal firm's IS resource contribution—intangible resource, physical resource, and organizational capabilities; and (4) partner firm's IS resource contribution—intangible resource, physical resource, and organizational capabilities. In addition, we have used focal firm's perceptual sustainable commitment and performance to represent alliance sustainable commitment and performance in accordance with the finding by Geringer and Hebert (1991), in which they found that subjective performance is positively related to the objective measures of international joint venture (IJV) performance (i.e., survival, stability, and duration).

Factor analysis was performed on these measurement items to ensure that all scales were unidimensional and to assess reliability. A factor analysis was then performed to examine question items in each construct, and questions with an item loading below 0.5 were deleted without losing the representation of each of the constructs. Cronbach's alphas for all constructs are all above 0.80, indicating an acceptable reliability of the measures.

The *sustainable commitment* scale was derived from Sarkar, et al. (2001). We revised the scale into a four-item scale, and the alpha value for this scale was 0.94, indicating acceptable values of internal consistency (Nunnally, 1978). This scale measured the focal firm's willingness to invest required IS resources into the alliance.

The *performance* scale was based on Sarkar, et al.'s (2001) perceptual measure of assessing performance with both the relationship and performance between IJV partners. In this survey, performance was used as an indicator for alliance performance and measured on a seven-point Likert-type scale. Moreover, four items on healthcare characteristics were used as control variables. These included individual rating and size of healthcare centers, length of cooperative alliance, and type of cooperative institution (i.e., hospital or other healthcare service provider).

According to Johnson, Cullen, Sakano, and Takenouchi (1996), the resource contributions from both the focal and partner firms are part of the formative measurements, and as such, traditional associational-based validation procedures do not apply. Therefore, the measures for *sustainable commitment* and *performance* were analyzed for reliability and validity in accordance with the guidelines set out by Agarwal and Karahanna (2000). The reliability of the research constructs for sustainable commitment and performance was evaluated using Cronbach's coefficient alpha (α). The α values for *sustainable commitment* and *performance* in the sample were 0.94 and 0.84, respectively.

FINDINGS AND DISCUSSION

Most small healthcare centers surveyed (61%) operated independently within small and medium-sized hospitals, while the remaining small healthcare centers (39%) operated as local medical clinics. In terms of the number of hospital beds, 36% of small healthcare centers had fewer than 19 beds, while the other 39% had between 21 and 30 beds. The remaining 25% small healthcare centers had more than 30 beds. In terms of the alliance age, 38% of the respondents had less than three years, and 36% had between 3 and 5 years. The remaining 26% had more than six years.

Table 1 presents the descriptive statistics and Pearson correlation for the variables used in this study. The statistical software, SPSS 13, was used to analyze the data. Although there were few slightly stronger correlations among some independent variables, the maximum variance inflation factor (VIF) for the independent variables in all models was less than 2.766, and the average VIF was less than 1.754. This indicated that multicollinearity was not unduly influencing the least squares estimates (Neter, Wasserman & Kutner, 1985). Therefore, there was no evidence of multicollinearity in the data.

Table 2 presents the correlation matrix to highlight the relationships between the focal firms and the partner firms within interorganizational IS resources cooperation. The items shown in Table 2 are the types of resources that can be contributed by the partners. The results in Table 2 demonstrated that between the focal firm and the partner firm, there was a negative correlation on the contribution of similar IS resources. On the other hand, there was a positive correlation on

the contribution of dissimilar IS resources between interpartners. This supported the initial concept of similar/dissimilar IS resource contribution mentioned earlier in the chapter, since most of correlation coefficients were found to be significant. Thus, *H1* and *H2* were supported.

Models 1 and 2 in Table 3 analyzed the relationship between the individual IS resource contribution by both parties and the alliance sustainable commitment. The regression analysis results in Table 3 indicated that the contribution of specialized IS support items and medical IS support services items by the focal firms had significant positive effect on the alliance sustainable commitment. In addition, the results also showed that the contribution of IS management systems items by the partner firms had a positive impact on the alliance sustainable commitment. From these findings, it can be concluded that the contribution of dissimilar IS resources by both the focal and partner firms had a significant positive impact on the alliance sustainable commitment. Thus, *H3* was also supported.

Models 3 and 4 in Table 3 analyzed the relationship between the individual IS resource contribution by both parties and the alliance performance. The regression analysis results in Table 3 showed that the contribution of these three items (i.e., specialized IS support, medical IS support services, and IS management systems) by the focal firms had no significant relationship with the alliance performance. However, there was a positive relationship between the contribution of specialized IS support by the partner firms and the alliance performance. Therefore, as long as the partner firms were able to make significant contributions on other IS resource items, it can still have a positive effect on the alliance performance. Thus, *H4* was supported.

CONCLUSION

These findings have shown the dissimilar nature of IS resources contributed by all partners in the healthcare industry. The fact that there was a negative correlation between the similar IS resources provided by both the focal and partner firms indicates that the focal firms do not need similar IS resources provided by the partner firms. In terms of dissimilar IS resources, there was a positive correlation between the resources contributed by both the focal and partner firms. This has shown that the partner firms were able to provide necessary IS resources to satisfy needs of the focal firms. Moreover, there was a positive relationship between the IS resources contributed by both the focal and partner firms and the alliance sustainable commitment and performance. There are two approaches to establish the relationship between dissimilar IS resource contribution and alliance performance in the healthcare industry. One approach is that as long as the partner firms were able to make significant contributions on some IS resource categories, even when the focal firms failed to contribute significant unique IS resources, it could still have a positive effect on the alliance performance. The other approach to establishing a successful relationship was through both the focal and partner firms contributing unique dissimilar IS resources into the alliance. The implication of the findings is that symmetrically dissimilar IS resource contributions by interpartners within the healthcare industry can increase alliance sustainable commitment. Therefore, it can be said that successful alliance depends on partners' willingness to contribute a symmetric share of the requisite IS resources. Focal SMEs are only willing to fully commit themselves

to the alliance when they perceive fair dealing; that is, each partner has to provide equal or symmetric IS resource contributions in its alliance.

In addition, we further confirm that alliance performance could only be achieved when an interpartner contributed dissimilar IS resources to the alliance in the healthcare industry. Moreover, from the four models in Table 3, we fail to establish a positive relationship between the alliance performance and the overlapping similar IS resources contributed by both the focal and partner firms. Therefore, the results demonstrate that similar IS resource contribution had no impact on alliance performance. Furthermore, Table 3 has shown that the most characteristics of both the focal and partner firms had no direct effect on the alliance performance. Therefore, the dissimilar IS resources contribution was the key success factor for establishing alliances in the healthcare industry. Finally, the measurement proposed by this research had provided the means to evaluate both similar and dissimilar IS resources in the healthcare industry. The measurement could potentially be applied to both large firms and SMEs in other industries in the future.

FUTURE TRENDS

The future of strategic alliance in the healthcare industry will be based on the quality of the alliance relationships among partners and what they can contribute to the alliances. The results from this study suggest that SMEs should be careful in selecting their alliance partners as well as in evaluating the type and amount of dissimilar IS resources the partners are prepared to contribute to the alliance. Insufficient contribution of dissimilar IS resources to the alliance can potentially lead to failure. In addition, SMEs in the healthcare industry should prepare for the future by engaging in activities that make it a more attractive potential alliance partner. Moreover, the dedication to the growth and development of the strategic alliance can only be sustained if partners have trust and confidence in each other. Furthermore, there needs to be more than the desire to cooperate within alliances. The alliance partners should not only exchange information but also should share resources, risks, responsibilities, and rewards. Finally, the other two factors that should not be neglected are the strength of the leadership and knowledge of the healthcare industry by the alliance partners.

KEY TERMS

Alliance: The collaborative efforts between two or more firms in which the firms pool their resources in an effort to achieve mutually compatible goals that they could not achieve easily alone.

Alliance Sustainable Commitment: The maximum effort involved in maintaining and prolonging an ongoing relationship between alliance partners.

Resource Dissimilarity: The degree to which two partner firms contribute complementary resources in terms of both type and amount to an alliance.

Resource Similarity: The degree to which two partner firms contribute compatible resources in terms of both type and amount to an alliance.

SMEs: Small to medium-sized enterprises. The European Commission has defined SMEs as organizations that employ fewer than 250 people.

SPSS: A statistical and data management software package for analyzing collected questionnaire data.

Survey Research: A research method using questionnaires to obtain the required information.

Information Technology in Brain Intensive Therapy

Diego Liberati
Italian National Research Council, Italy

INTRODUCTION

In order to control a process, especially in a computer and instrumented assisted way, as in Brain Intensive Therapy (IT), a model of its behavior is needed. In order to do that, one must first be able to select the best set of a few (thus understandable and manageable) truly relevant variables.

In manufactured systems, also used in Brain IT, physics is in fact often quite known, with a manageable number of degrees of freedom; for instance, in robot kinematics, natural state variables may be (angular) positions and velocities.

Some natural systems are also easily characterized by state variables with physical meaning: for instance reservoirs (e.g., lakes), but also body organs with respect to soluble substances may be characterized by volumes, concentrations, fluxes, and gradients among compartments (Liberati & Turkheimer, 1999).

In other cases, the "natural" variables of the systems are not the best ones for identifying and control a process. A transformation of some of them may be needed; for instance, in the autonomous nervous control of the hearth system, the differential interbeat measure is the one that almost linearly interacts with baroreflex in the feedback control loop (Baselli et al., 1986).

In many cases, mainly for natural, especially neural processes, it is not easy to formulate a model based on variables whose physical meaning is a priori known; for instance, the electroencephalogram (EEG) is a very far field shielded measure of the interacting activity of billions of neurons. Many actors are thus playing, each one with many meaningful state variables, also depending on the investigated level, but with high reciprocal correlation. It would not be efficient to model every single variable for global monitoring such that it is not useful to take into account the kinetics of every single molecule of a gas when only global effects of pressure are of interest. A quest of some higher-level variables, even without a direct physical meaning, is thus natural in order to easily manage the complexity of the problem. Once such salient variables are found, the problem often arises to correlate in logical and/or mathematical sense their dynamics in order to properly model, forecast, and control the patient features.

Such interrelated problems will be addressed briefly in the present contribution, where Intensive Therapy is chosen as a paradigmatic application because of its critical conditions, while the approaches described whose rationale is better analyzed in the referred bibliography are of a quite general use in health information systems.

BACKGROUND

When data are in a time series (e.g., when a continuous process is properly sampled in time by an analog-to-digital converter at a sufficient frequency over the considered span of measured variables), a quite general approach is to express the measured sample x(t) of each variable x as a (linear) combination of:

- The recent past x(t-i) of itself;
- Possible other measured variables (which are simply taken into account in mathematical notation by considering x(t) as a vector of all the considered variables);
- A superposed noise w(t).

The EEG, for instance, is in fact well modeled by an autoregressive model of low order n:

$$x(t)=a(1)x(t-1)+a(2)x(t-2)+ \ldots +a(n)x(t-n)+w(t)$$

The set of parameters a(i), possibly varying in time, may be identified from the data time series and describes the changes in the system expressing the measured signal, whose spectrum is also easily computed from the a(i) themselves.

Such a simple black box model does allow a signal identification, useful, for instance, to monitor the effects of the control procedure; EEG may then be used in order to monitor control of drug infusion (e.g., in anesthesia) and their effects (e.g., hypotension) even in neurosurgery (Cerutti, Liberati & Mascellani, 1985) or Brain IT. Image fluxes can be treated as a set of pixel (Liberati, DiCorrado & Mandelli, 1992) or voxel (Maieron et al., 2002) streams taking into account their correlations.

In that respect, EEG, while summarizing the behavior of the complex system from which it is derived, may be quite simply modeled, processed, and identified in order to assist control. Extraction of its salient characteristics via parametric identification and/or neural networks makes the task of classifying brain states easier; even the decision to perform may be detected (Babiloni et al., 2000) toward Brain Computer Interfacing (among the 10 emerging technologies that will change the world, according to the *MIT Technical Review* of January 19, 2004). Besides being one of the most important and complex signals to be monitored in intensive therapy, and being itself the discriminant one among life and death even on legal ground, EEG thus can be reasonably assumed as the paradigmatic example of our approach to Brain IT, even involving other signals, as described in the next section.

INFORMATION PROCESSING IN BRAIN IT

When a model describing the system has been identified (e.g., in the black box way described in the background for the EEG), a direct convolution with a known input is able to render a "clean" filtered emulation of the expected output, making easier the clinical inspection. This is interesting, for instance, for single trial-evoked and event-related brain potentials (Liberati, Bedarida, Brandazza, & Cerutti, 1991a) and useful for objective assessment of possibly noncooperating subjects.

On the contrary, when only the noisy output is measurable (e.g., in hormone blood concentration), the inverse deconvolution provides an estimate of the not directly accessible variable; for instance, pituitary secretion (De Nicolao, Liberati, & Sartorio, 2000), whose little quantity as well as its little accessibility make it of unreachable direct measure.

Correlation and coherence, even partial (Liberati, Cursi, Locatelli, Comi & Cerutti, 1997), among subsystems may be usefully identified from multiple signals, discovering, for instance:

- The cardiovascular effects of the psycho-physiological stress through neural regulation (Pagani et al., 1991)
- The integrity of even nonlinear interactions between somato-sensory and visual cortex when stimulated together (Liberati et al., 1991a)
- Brain decay in degenerative pathologies (Locatelli, Cursi, Liberati, Franceschi, & Comi, 1998), or on the opposite side, hypercorrelations such as epilepsy that could, for instance, take relief by a sort of implanted defibrillator.

Time varying coefficients may be identified via Kalman filtering (Liberati, Bertolini, & Colombo, 1991b). Higher order spectral correlation also may be identified through a parametric approach, leading, for instance, to identify nonlinear effects as in muscle contraction (Orizio, Liberati, Locatelli, DeGrandis, & Veicsteinas, 1996) or in neural plasticity (Locatelli et al., 1986).

Nonetheless, linear, time invariant, and even multivariable modeling do allow much easier theory and algorithms, and thus more understandable results than nonlinear and time varying approaches. A natural quest is thus to approximate nonlinear models to linear ones in different regions. The problem is that it is not easy to a priori know-how to partition such regions. A possible solution (Ferrari-Trecate, Muselli, Liberati, & Morari, 2003) automatically clusters data in regions, without imposing continuity even in the variables at the borders, within the framework of the dynamic-logical "hybrid" models. In such a way, a linear regression is then jointly estimated in each region. Switching and nonlinear models thus may be simply identified via such Piece Wise Affine identification approach obtained by complementing a modified version of the cited stochastic parametric identification algorithm with a slightly modified *k-means* clustering. Most of the previously cited results can thus be revisited with such an approach. For instance, hormone pulses during secretion may be detected as belonging to one of the two identified states, the other being quiescent. In the same way, brain states can be discriminated, as in sleep staging.

When time course is not of paramount relevance to the data set, clustering becomes the only focus of the processing toward selecting salient variables and possibly identifying logical relationships among them. When many variables, even not homogeneous, are available, as in Brain IT, a simple hierarchy according to their interstate variance does not seem the best approach, not taking into account, besides scaling factors, correlation among them.

A Principal Components hierarchy does seem more appropriate, at least for the subset of homogeneous variables, in order to capture co-variances and to select a little number of co-factors describing a complex process, as in Garatti, Bittanti, Liberati, and Maffezzoli. (2007), where two kinds of leukemia are accurately discriminated from micro-arrays data.

A viable alternative is a Minimum Description Length hierarchy; the original variables are ranked accordingly to their decreasing ability to minimally (in terms of number of bits) codify, each alone, both the model and the observed probability distribution (Bosin, Dessi, Liberati & Pes, 2006a). Consequently, an Adaptive Bayesian Network provides a logical description of the (possibly nonlinear) interaction among them.

Such nonlinear interactions among variables also may be captured via Logical Networks (Muselli & Liberati, 2002), able to infer logical relationships among binary variables, in the form:

“if (V4 and V2) or (V3 and not V2), then....”

Their computational burden is only quadratic and, moreover, in terms of logical operations. They proved to be successful in identifying prognostic factors in oncology (Paoli, Muselli, Bellazzi, Corvó, Liberati & Foppiano, 2000). Nonlinear interrelations are detected, pointing out the relevance of the co-factor interaction, not instead provided via the widely spread, well-known powerful artificial neural networks approach (Drago, Setti, Licitra, & Liberati, 2002).

All such approaches can be fruitfully combined when identifying the salient variables among the measured ones, in order to keep directly monitoring only a little group of easily manageable size, and to identify their relationships in order also to easily understand of the underlying processes.

FUTURE TRENDS

The described approaches are not yet fully implemented everywhere, not even to some of the most critical problems in health systems such as the ones briefly introduced in the present contribution, but they are penetrating various contexts, helping to face a variety of problems even beyond those briefly addressed here for the sake of space.

Besides improvements and spreading of the introduced methodologies, a further trend should be mentioned; namely, the technological availability of Web services possibly over grid technology, able to ease cooperation among different competences even at different locations, which is now transforming forefront science as a distributed enterprise (Bosin, Dessi, Fugini, Liberati & Pes, 2006b) and will probably also penetrate health systems, as almost all useful technologies have already proved ever since.

CONCLUSION

In summary, the recalled advanced techniques of data and signal analysis, together with other more or less typical approach in health system context, may be of great help in both:

- Selecting really salient variables in discriminating classes of subjects; and
- Providing a first model describing their logical and/or dynamic interaction

Then the identified model can be used as the basis of real time processing, providing assistance also to Brain IT control, but generally useful in most applications, even beyond health systems. Interestingly, the recalled techniques, presented in the crucial framework of Brain IT, are of such a general purpose application that they are able to benefit many other applications even beyond health care.

KEY TERMS

Adaptive Bayesian Networks: Conditional tree of probabilistic dependence among features discriminating salient classes of data.

Autoregressive Model: Simple description of the time course of a variable in terms of the recent past of the variable itself.

Brain Computer Interfacing: Direct command of computers or instruments via brain waves processing without need of usual actuators (e.g., fingers and keypads, or voice and microphones).

Clustering: Partition of a set of data in groups (clusters) in such a way that each datum is maximally close in some defined metric to all the others belonging to the same cluster and maximally far from every other datum belonging to different clusters.

Coherence: Phase synchrony among pairs of variables, even with a fixed delay.

Evoked Brain Potentials: Brain activity directly related to the execution of a peculiar task.

Information Technology: The set of approaches related to the processing of information through both electronic hardware and mathematical software.

Intensive Therapy: One of the most demanding divisions in health care, where a patient's life is at risk and then where ultimate approaches (e.g., the ones presented in this chapter) may be more effective, even if they are also useful in other contexts beyond health systems.

Piece-Wise Affine Identification: Decomposition of a multivariable sampling of a possible nonlinearly related and/or time varying set of variables in linearly related sections, with automatic identification of the optimal borders among sections through joint clustering and autoregressive identification.

INTRODUCTION

Before 1980, the majority of patients with urolithiasis and nephrolithiasis needed surgery (Kerbl, Rehman, Landman, Lee, Sundaram, & Clayman, 2002; Soucie et al., 1994). Fortunately, percutaneous nephrolithotomy, ureteroscopic intrarenal surgery, laparoscopic surgery, and extracorporeal shock wave lithotripsy (SWL) now allow almost any calculus to be removed without open surgery. SWL refers to the use of high intensity pressure pulses, generated outside the body, to break up kidney stones (Chaussy, Brendel, & Schmiedt, 1980; Loske, 2007). It has become the standard treatment for the majority of patients and an alternative in the management of gallbladder stones, pancreatic concrements, and salivary gland stones. Even though initial studies concluded that shock waves had no damaging effect on renal tissue, later several authors reported that shock waves may cause tissue trauma (Evan, Willis, Connors, McAteer, & Lingeman, 1991; Evan, Willis, & Lingeman, 2003 Willis et al., 1999). Fortunately, techniques and devices are still evolving and improvements to increase stone fragmentation efficiency and reduce tissue trauma are being constantly sought.

BACKGROUND

The apparatus to perform SWL, called lithotripters, are composed of a shock wave generator, a focusing unit, an imaging system, a coupling device, and a treatment table (Lingeman, 2007; Loske, 2007). If the patient is properly positioned, shock waves enter the body, become focused on the calculus, and fracture it. Shock wave targeting is performed by fluoroscopy or ultrasound imaging systems. Several hundred shock waves may be needed to comminute a kidney stone. Fragments pass spontaneously through the urinary tract, and most patients are free of stones a few days after treatment. Three shock wave generation techniques are in use: piezoelectric, electrohydraulic, and electromagnetic (Loske, 2007). Many lithotripters use a focusing system to concentrate the shock wave energy onto the stone; others are self-focusing. Only piezoelectric shock wave generation will be discussed here.

Piezoelectric lithotripters generate shock waves by a high voltage discharge applied across an array of up to 3000 piezoelectric crystals mounted on a hemispherical bowl-shaped aluminum backing (Figure 1). Other systems only use a few crystals or one large spherically shaped ceramic plate. Each high voltage discharge causes rapid expansion of each crystal, producing a pressure wave. The pressure pulse arriving at the center (F) is generated by superposition of the pulse produced by each crystal (Loske, 2007). The shock wave generator is contained inside a cavity filled with water and closed with a rubber membrane placed in contact with the skin of the patient. Piezoelectric crystals are insulated from water with a flexible polymer. These lithotripters produce a focal zone in the shape of a cigar measuring about 17 × 3 mm. The shock wave pulse rate and the discharge voltage can be varied. The pressure in the focal region (Figure 2) consists of a compression pulse with a peak between 30 and 150 MPa and a phase duration of 0.5 to 3 μs, followed by a decompression pulse, sometimes referred to as the "negative" pressure pulse, with a tensile peak of up to - 20 MPa, and a phase duration between 2 and 20 μs. Pressure rise time is about 300 ns.

Cavitation is one of the main stone comminution mechanisms. Calculi also fracture due to spalling, squeezing, superfocusing, and fatigue (Eisenmenger,

Figure 1. Schematic of a standard piezoelectric shock wave generator. The power supply P charges a capacitor C, which remains charged until the switch S is fired by the trigger T. Shock wave rate can be adjusted with the pulse generator G.

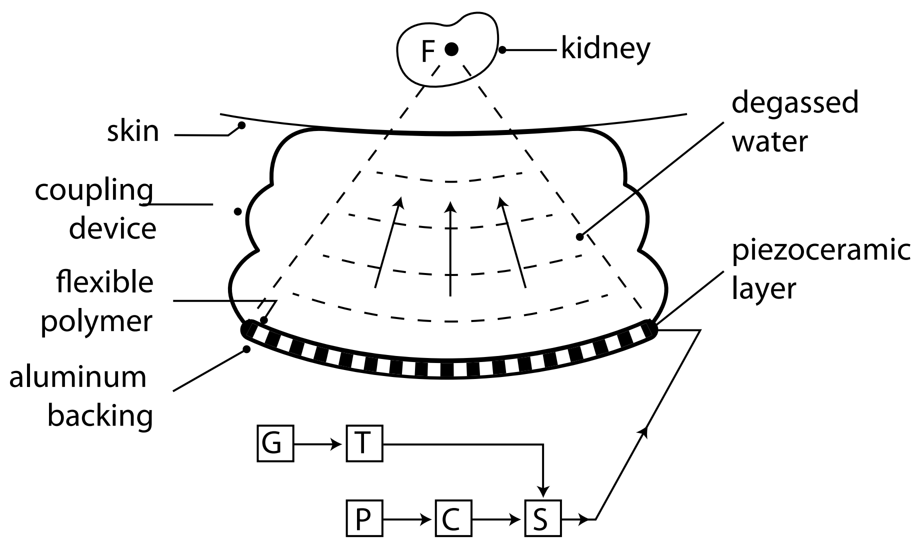

Figure 2. Pressure record obtained with a fiber optic hydrophone (FOPH 2000, RP Acoustics, Leutenbach, Germany), positioned at the focus of a standard piezoelectric lithotripter.

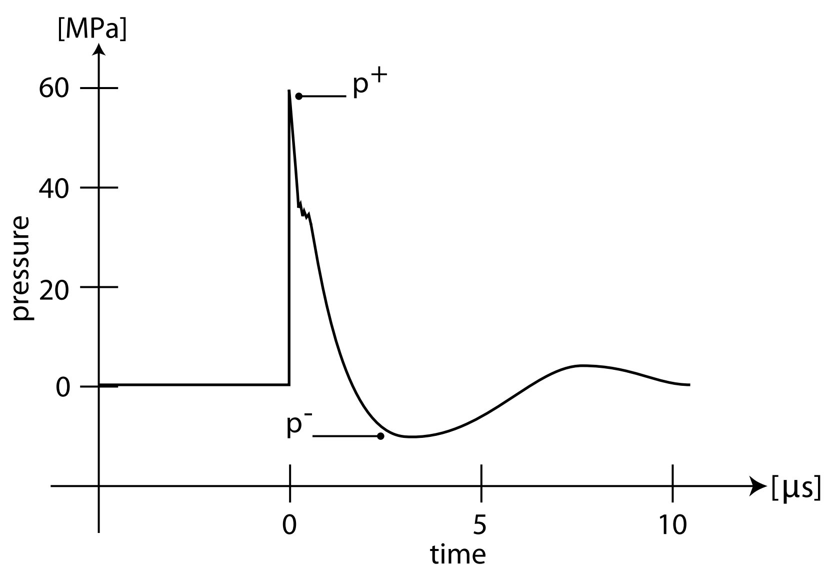

2001; Lokhandwalla, & Sturtevant, 2000; Loske, 2007). During SWL, all microbubbles contained in the fluid near the calculus are compressed by the positive peak (Figure 3). Their volume increases about 50 to 100 µs after shock wave passage. This occurs due to the action of the tensile part of the shock wave (Bailey et al., 2005). Lithotripter generated bubbles expand, stabilize, and collapse violently after approximately 250 to 500 µs, producing high-speed microjets (Crum, 1988), capable of damaging the calculus.

Enhanced fragmentation can be obtained if a second shock wave arrives during or shortly after their stable phase (Figure 4). This has been demonstrated with twin pulses generated from two identical shock

Figure 3. Representation of the pressure variation at the focus of a standard lithotripter and its influence on a bubble. The bubble is compressed as the positive pulse arrives (0 µs). Its volume increases a few microseconds later due to the tensile phase of the shock wave, stabilizes, and finally collapses after about 330 µs.

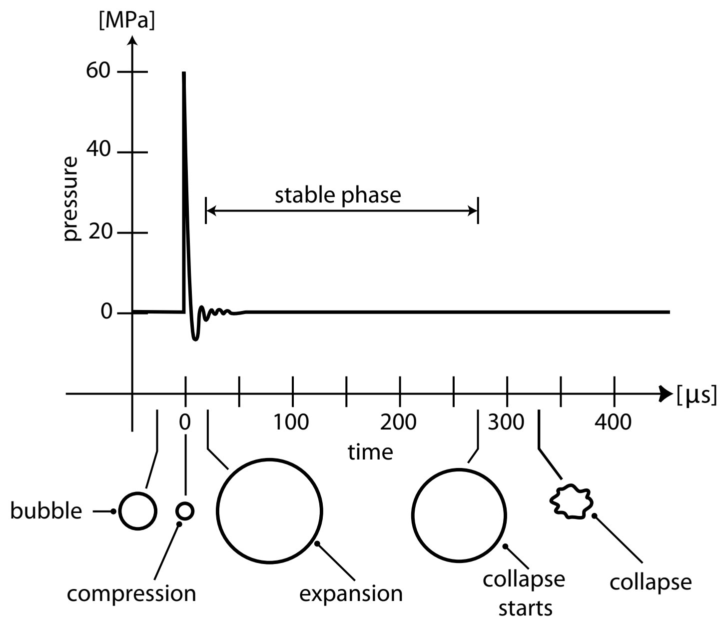

Figure 4. Representation of the pressure variation at the focus of the novel lithotripter and its influence on a bubble. The collapse of a bubble expanded by the first shock wave can be intensified if a second shock wave arrives shortly after the collapse starts.

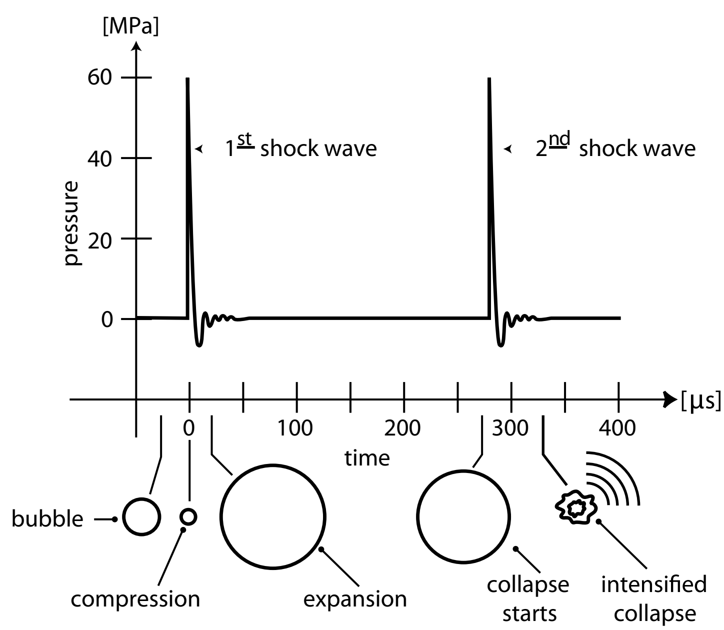
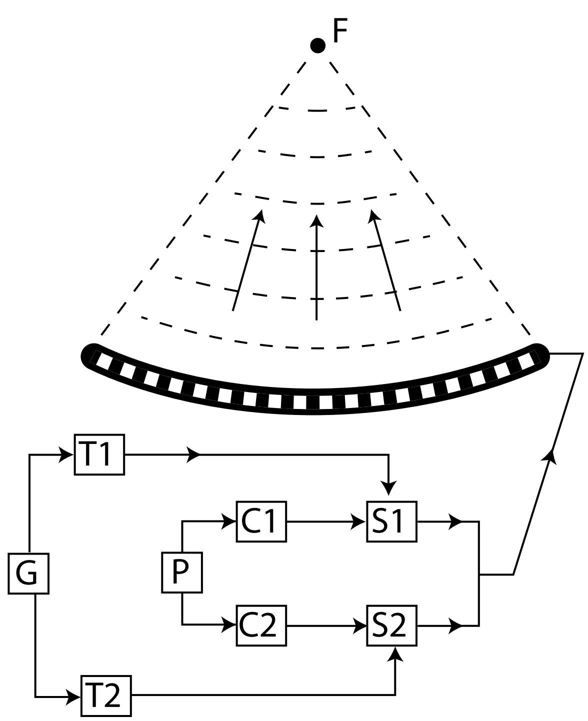


wave sources or using electrohydraulic shock wave generators with hybrid-ellipsoidal reflectors (Bailey, 1997; Loske & Prieto, 1996; Loske, Prieto, Gutiérrez, Zendejas, Saita, & Vélez, 2004; Prieto & Loske, 1999; Sheir, El-Diasty, & Ismail, 2005; Sokolov, Bailey, & Crum, 2000; Sokolov, Bailey, & Crum, 2001; Zhong et al., 1997; Zhong et al., 1999). Other authors (Xi & Zhong, 2000) proposed a combined electrohydraulic and piezoelectric shock wave generator.

Disadvantages of the above-mentioned systems are the need for two shock wave generators or the construction of a different composite reflector for each desired time delay between the first and the second shock wave. As a solution to this, we developed a novel piezoelectric lithotripter that generates two successive shock waves with an adjustable time delay between them (Loske, Fernández, & Gutiérrez, 2005; Loske, Prieto, Fernández, & van Cauwelaert, 2002). We named the device "tandem" shock wave generator, because of the extremely short delay between first and second shock wave.

Figure 5. Schematic of the new piezoelectric shock wave generator. The power supply P charges two capacitors. C1 remains charged until the switch S1 is fired by the trigger T1. C2 is discharged through S2 after a delay. The shock wave rate and the delay may be adjusted with the pulse generator G.



THE NOVEL LITHOTRIPTER

The first successful experiments with the tandem shock wave generator were performed during 2000 and 2001 (Fernández, Loske, van Cauwelaert, & Prieto, 2001; Fernández, Loske, van Cauwelaert, & Prieto, 2004; Loske, Prieto, van Cauwelaert, & Fernandez, 2001). A *Piezolith 2300* lithotripter (Richard Wolf GmbH) was converted into a tandem lithotripter by duplicating its energy discharge system (Figure 5). Both high voltage outputs were connected in parallel to the piezoelectric crystal array. A specially designed pulse generator triggers both systems with an adjustable time delay between 50 and 950 μs. The delay can be varied in steps of 10 μs.

Stone comminution obtained with the standard lithotripter was compared in vitro with that produced by the novel lithotripter at delay times between 100 and 900 μs using rectangular and spherical artificial kidney stones (High Medical Technologies). The delay was increased in steps of 50 μs. Stones were placed, one by one, inside a small polyethylene bag, and centered at F using the imaging system of the lithotripter. Six rectangular stones were exposed to 1200 standard shock waves and the same number of stones was treated with 600 tandem pulses. Additionally, a set of 6 spherical stones received 1000 standard, and an equal set received 500 tandem shock waves. Fragments were strained through a 1.0 x 1.0 mm nylon mesh after shock wave exposure, dried in an oven, and weighed on a precision scale. The discharge frequency of the system was fixed at 1 Hz. Results were encouraging (Figure 6). The best fragmentation coefficient (FC) was obtained at a delay of about 240 and 400 μs with spherical and rectangular stones, respectively.

In vivo tissue damage to rabbit kidneys obtained with the tandem lithotripter was compared with that of the standard lithotripter. Our results revealed that the tandem shock wave generator did not produce more tissue damage than the standard system (Loske, Fernández, Zendejas, Paredes, & Castaño-Tostado, 2005). Considering that less shock waves are needed when using the novel lithotripter, SWL tissue damage could be reduced.

To study the influence of cavitation during tandem lithotripsy, 7-mm long, 5-mm in diameter cylindrical artificial kidney stones, obtained from rectangular AST stones (High Medical Technologies), were implanted into the renal pelvis of 180 g pig kidneys, and exposed

Figure 6. In vitro fragmentation coefficient obtained with spherical (FC-S), and rectangular (FC-R) kidney stone models, exposed to tandem shock waves at different delays. The units on both vertical axes differ, because the rectangular stones are much larger than the spherical stones. Nonparametric smoothing was used to obtain both graphs.

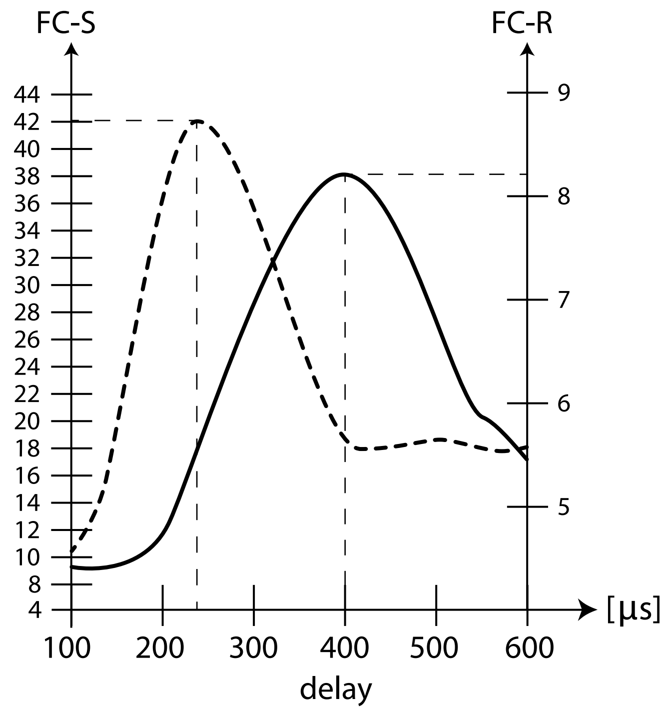


Figure 7. The innovation presented here has been used in the Piezolith 3000 and the Piezoson 100 plus (Richard Wolf GmbH). Two piezoceramic layers are activated through separate circuits. Pulses generated by both layers superpose additively, because the crystals on the inner side are fired with a delay D after the outer layer. Tandem shock waves can be generated by increasing the delay a few hundred microseconds.

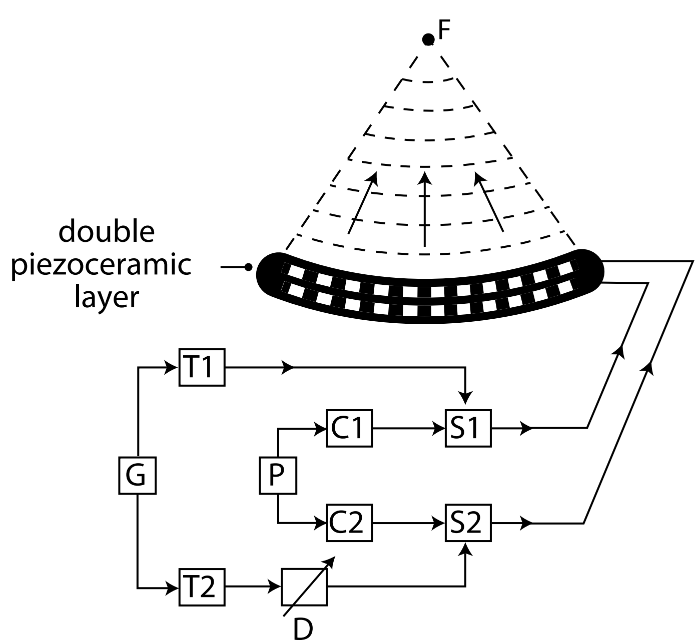

in vitro to 200 (100) single (tandem) shock waves. Delays between shock waves in the tandem mode were 250, 300, 350, and 400 μs. All stones were hydrated and placed at F using the ultrasound scanners. The kidneys were placed on a specially designed holder, inside the water tank of the lithotripter. In the first part, all stones were directly inserted into the kidney. In the second part, each stone was placed inside the tip of a finger of a latex glove, filled with saline solution, so that each stone was surrounded by about one millimeter of fluid, providing an "expansion chamber." The diameter of these balloons was about 8 mm. Each balloon was inserted inside the renal pelvis of a kidney. Again, single and tandem shock waves were used (7.5 kV, 1 Hz). The whole experiment was repeated five times. As shown in Table 1, tandem shock waves did not significantly improve fragmentation efficiency in those cases where the stone was inserted into the renal pelvis without an expansion chamber; however, the novel system enhanced stone fragmentation in stones surrounded by saline solution. The existence of an expansion chamber increased the FC by about 20% when using the lithotripter in the standard mode, and 34% with the tandem mode (delay = 350 μs).

Our results demonstrate two important issues: (a) acoustic cavitation significantly contributes to stone fragmentation during SWL, and (b) tandem shock wave lithotripsy is more efficient than standard single pulse lithotripsy only if the stone is surrounded by fluid. The optimal delay for tandem shock wave lithotripsy is between 250 and 400 μs; however this will depend on the geometry, size, composition, and location of the stone.

Table 1. In vitro fragmentation coefficients (FC) of artificial kidney stones exposed to 200 standard single-pulse (delay = 0 μs), or 100 tandem-pulse shock waves inside the renal pelvis of pig kidneys. FC_1 corresponds to stones implanted into the kidney without an expansion chamber, and FC_2 to stones placed into the kidney inside a saline solution-filled latex balloon.

Delay [μs]	FC_1 [%]	FC_2 [%]
0	20.2	40.6
250	17.9	47.4
300	15.4	54.3
350	21.9	56.1
400	14.3	54.7

A concern about the new lithotripter could be increased tissue damage. Fortunately, most mammalian tissue has few cavitation nuclei (Carstensen, Gracewski, & Daleki, 2000). Furthermore, cavitation bubbles in tissue have a different behavior from that observed in liquid. Since bubble expansion in vivo is constrained by the tissue, collapse is less violent than in urine.

FUTURE TRENDS

Shock wave generators having two layers of crystals mounted on a spherical dish are already on the market (Riedlinger, Dreyer, & Krauss, 2002). In order to compensate for the difference in path to the focus, the piezoelectric crystals on the convex side are fired before those on the concave (radiating) side. Both waves superimpose at the surface of the front layer (Figure 7). In this case, the modification required to produce our tandem shock waves is easier, since these piezoelectric-crystal arrays are already excited with delay.

All piezoelectric lithotripters can be converted into tandem lithotripters at relatively low cost. Our innovation (Loske et al., 2002) has already been used by other authors (Arora, Junge, & Ohl, 2005) and was recently installed into the Piezolith 3000 and the Piezoson 100 plus (Richard Wolf GmbH, Germany) shock wave generators (Ginter & Krauss, 2005). Since preliminary clinical results did not improve with the double layer technology (Ng et al., 2003), the manufacturer expects better results using our tandem system. No clinical results have been reported so far.

Due to its flexibility, appropriate tandem shock wave delay may also be useful to improve the efficiency of shock wave mediated macromolecule delivery (Armenta, Varela, Martínez de la Escalera, & Loske, 2006) and exposure of isolated cells and microorganisms (Álvarez et al., 2004).

CONCLUSION

Shock wave-induced cavitation is one of the main fragmentation mechanisms during SWL; however, it will only be efficient if the urinary stone is surrounded by fluid. Because of this, urologists are encouraged to try to produce an expansion chamber for the calculus before starting SWL. Furthermore, if the urinary stone is surrounded by saline solution or urine, enhanced fragmentation can be obtained using the novel tandem lithotripter described here. Tandem shock wave sources could be installed in clinical devices to improve fragmentation and reduce the number of shock waves used per treatment.

KEY TERMS

Acoustic Cavitation: Growth and collapse of vapor bubbles because of a fast change of positive pressure into tensile stress, produced by a shock wave.

Dual-Pulse Shock Waves: Shock waves generated with a dual-head lithotripter. Dual-pulse shock waves are not necessarily equivalent to tandem shock waves.

Focal Zone: Volume in which the pressure at any point is equal to or higher than 50% of the maximum peak positive pressure.

Fragmentation Coefficient: For in vitro kidney stone fragmentation, the fragmentation coefficient is defined as $FC = (W_i - W_f)100/W_i$. In this equation, W_i and W_f stand for the weights of the initial (intact) stone and final stone fragments.

Lithotripter: A device to perform SWL, composed of a shock wave generator, a focusing unit, an imaging system, a coupling device, and a patient treatment table.

Peak Negative Pressure: Maximum pressure amplitude of the negative pulse of a shock wave, that is, the difference between the minimum pressure and the ambient pressure.

Peak Positive Pressure: Maximum pressure amplitude of the positive pulse of a shock wave, that is, the difference between the maximum pressure and the ambient pressure.

Rise Time: Time needed for the pressure peak to rise from 10% to 90% of its final value.

Shock Wave: Mechanical wave of high amplitude that arises when any elastic medium is subjected to a rapid compression.

Tandem Shock Wave: Consecutive shock waves having a delay of up to several hundred microseconds, used in SWL to enhance cavitation bubble collapse and, as a result, increase fragmentation efficiency.

Insulin Metabolism Models for Children with Type 1 Diabetes

INTRODUCTION

Diabetes Mellitus (DM) is a chronic metabolic disease resulted from insufficient secretion of hormone insulin. DM is mainly classified into Type 1 (or insulin dependent diabetes), which is characterized by absence of insulin secretion, due to destruction of the β-cells of pancreas, and Type 2 (or insulin independent diabetes), which is characterized by reduced action of insulin. This dysfunction of insulin results in many short- (hypoglycaemia, hyperglycaemia) and long-term (like neuropathies, nephropathies, retinopathies, and so on) complications. The result of the Diabetes Control and Complications Trial (DCCT) (DCCT Research Group, 1993) and the U.K. Prospective Diabetes Study (UKPDS) (UKPDS Group, 1998) indicate that the intensive glucaemic control reduces many short- and long-term complications of DM.

The ultimate goal in management of DM is the development of an automatic "closed-loop" system, well known as "artificial pancreas," able to simulate accurately the glucose-insulin metabolism and maintain glucose levels of a diabetes patient into physiological levels (70–110 mg/dl for a healthy person). A "closed-loop" system for DM comprises three primary components: (i) an accurate frequent or continuous glucose measurement system, (ii) an insulin delivery system, and (iii) a control system able to change the dose of delivered insulin, with respect to the requirement of glucose levels in desired range. Currently, individuals with Type 1 Diabetes Mellitus (T1DM) measure their glucose levels using either conventional finger-stick glucose meters (three to four times per day), or continuous glucose monitoring systems (CGMS), and choose their insulin delivery method between multiple daily injection (MDI), and continuous subcutaneous insulin infusion (CSII). The most appropriate algorithms to close the loop seems to be those based on model predictive control—MPC (Bequette, 2005). In a MPC controller, a model is used for the prediction of current and future insulin delivery parameters based on estimation on future glucose concentrations, while an optimizer finds the optimum insulin delivery parameter values in order to maintain future glucose values inside the desired range.

The models for the predictions of glucose values simulate the glucose-insulin metabolic system, which is characterized by high complexity and nonlinearity. Several mathematical models (MMs) have been proposed for the simulation of glucose -insulin metabolism for T1DM patients taking into consideration previous glucose measurements, type, and dose of insulin intake, and food intake, while recently, artificial neural networks (NN) have been proposed for simulation of glucose—insulin metabolism.

The aim of this article is to describe how NN have been applied for the simulation of glucose—insulin metabolism, and to present two NN based personalized models for children with T1DM. The models, which are able to make short-term glucose predictions, are based on the combined use of MMs and NNs. The models are comparatively assessed using data about glucose levels, insulin intake, and diet during previous time periods, from four children with T1DM.

BACKGROUND

Many computer-based simulations of glucose-insulin metabolism systems have been proposed in order to predict short-term glucose levels, and avoid hypoglycaemic and hyperglycaemic events. Usually, these systems, using among others glucose data from finger-stick glucose meters, are based on Compartmental Models (CMs). CMs represent a type of MMs commonly used for modeling complex dynamics systems, such as the physiological systems (Brown & Rothery, 1993; Cobelli & Foster, 1998). CMs have been used in order to estimate the way in which changes in insulin dosage affect blood glucose levels (Puckett & Lightfoot, 1995). Furthermore, a pharmacokinetic model has been developed by Berger and Rodbard (1989) for the simulation of plasma insulin and glucose dynamics after subcutaneous injection of insulin for the prediction of the expected time course of plasma glucose in response to a change in the insulin dose, timing or regime. This model has been improved by Lehmann and Deutsch (1992), by taking into consideration the absorption, in quantitative terms, of carbohydrates contained in the food. The widespread use of the resulted physiological model, known as AIDA, though being one of the most popular physiological models of glucose-insulin interaction for T1DM patients, it has been limited, due to uncertainties associated with the estimation of blood glucose profiles. These uncertainties have been addressed by Andreassen, Benn, Hovorka, Olesen, and Carson (1994) using causal probabilistic networks, for both the hourly prediction of blood glucose levels and the insulin dose adjustment. The obtained results have shown that this approach is able to identify and predict nocturnal hypoglucaemia (Cavan, Hovorka, Hejlesen, Andreassen, & Sönksen, 1996).

The acceptance of the aforementioned models was limited, because these systems take into account only a confined number of the factors associated with glucose metabolism, and they are not easily individualized to accurately simulate metabolic processes for a specific T1DM patient. In order to overcome the aforementioned difficulties, the use of NNs for the simulation of glucose-insulin metabolism has been proposed. NNs are a powerful tool in handling complex, nonlinear problems, due to their ability to be trained in order to handle unknown information hidden in the data (Haykin, 1999). Specifically, the information about blood glucose levels, insulin intake, and observed hypoglycemia symptoms have been used as input to a system consisting of two NN models in a chained scheme (Mougiakakou & Nikita, 2000; Mougiakakou, Nikita, Protonotarios, & Matsopoulos, 1998). The output of the first NN provides estimation for the insulin regime, while the output of the second NN estimate the appropriate insulin doses. Furthermore, inputs related to the insulin type and time of injection, carbohydrate and time of meal, exercise, blood glucose measurements, and special events (stress, pregnancy, and so on) from a T1DM patient have been fed to a NN resulting in a satisfactory accuracy in the prediction of blood glucose levels (Sandham, Hamilton, Japp, & Patterson, 1998). A comparative study of different NN approaches for the prediction of short-term blood glucose levels for T1DM patients has shown that the use of NNs is promising for the simulation of glucose metabolism (Tresp, Briegel, & Moody, 1999). Moreover, a hybrid system combining the principal component method with a NN has been proposed for the prediction of blood glucose levels in diabetic patients (Liszka-Hackzell, 1999). Recently, the use of a NN trained by the Levenberg-Marquardt (LM) algorithm has been presented, in order to predict the blood glucose concentration in T1DM patients (Zitar, 2003), with promising results. Finally, a hybrid model based on the combined use of MMs and NNs has been proposed for the short-term prediction of glucose levels in T1DM patients based on measured blood glucose levels, insulin intake, and description of food intake, along with the corresponding time (Mougiakakou, Prountzou, & Nikita, 2005).

MODELING OF GLUCOSE: INSULIN METABOLISM FOR CHILDREN WITH TYPE 1 DIABETES MELLITUS

In this article, two glucose-insulin metabolism models for children with T1DM are presented. The models, which are personalized and able to make short-term glucose predictions, are based on the combined use of CMs and NNs. The outline of the proposed models is shown in Figure 1. The models consist of a mathematical model (MM) module and a NN module. The MM module incorporates five CMs. The first four estimate plasma insulin concentration, due to quick acting (QA), short acting (SA), intermediate acting (IA), and long acting (LA) insulin intake, while the fifth the glucose absorption from the gut in response to carbohydrate intake. The outputs of the MM module along with the most recent glucose measurement are passed to the NN module, which provides prediction of short-term glucose levels.

Data Collection

Data from four children with T1DM have been used for the development and testing of the personalized glucose-insulin metabolism models. The characteristics of the patients are summarized in Table 1. Glucose data are collected using a CGMS (Continuous Glucose Monitoring Sensor, Medtronic MiniMed), which allow the measurement of interstitial glucose every five (5) minutes. The statistic of the glucose data is also given in Table I. The patients were monitored for a period between three to five days. For this period, the children recorded the time of insulin injection, the insulin type (QA, SA, IA, and LA) and dose, and the amount of carbohydrate ingested.

Mathematical Model Module

As aforementioned, the MM module consists of five CMs.

1. **Compartmental Models for Insulin Kinetics (CM-I, …, CM-V):** After the injection of D (U) units of insulin, the change in plasma insulin concentration $I(mU/lt)$ is given (Lehmann & Deutsch, 1992) as:

$$\frac{dI}{dt} = \frac{st^s (T_{50})^s D}{V_i[(T_{50})^s + t^s]t} - k_e I \qquad (1)$$

$$T_{50} = aD + b \qquad (2)$$

where $k_e = 5.4\ lt/h$ is the first-order rate constant of insulin elimination, $V_i = 9.94\ lt$ is the volume of insulin distribution, and T_{50} is the half- time insulin dose absorption. The constant parameters a, b, and s characterize insulin absorption patterns of the different insulin types entered in the model,

Figure 1. General architecture of the proposed artificial intelligent based glucose – insulin metabolism models

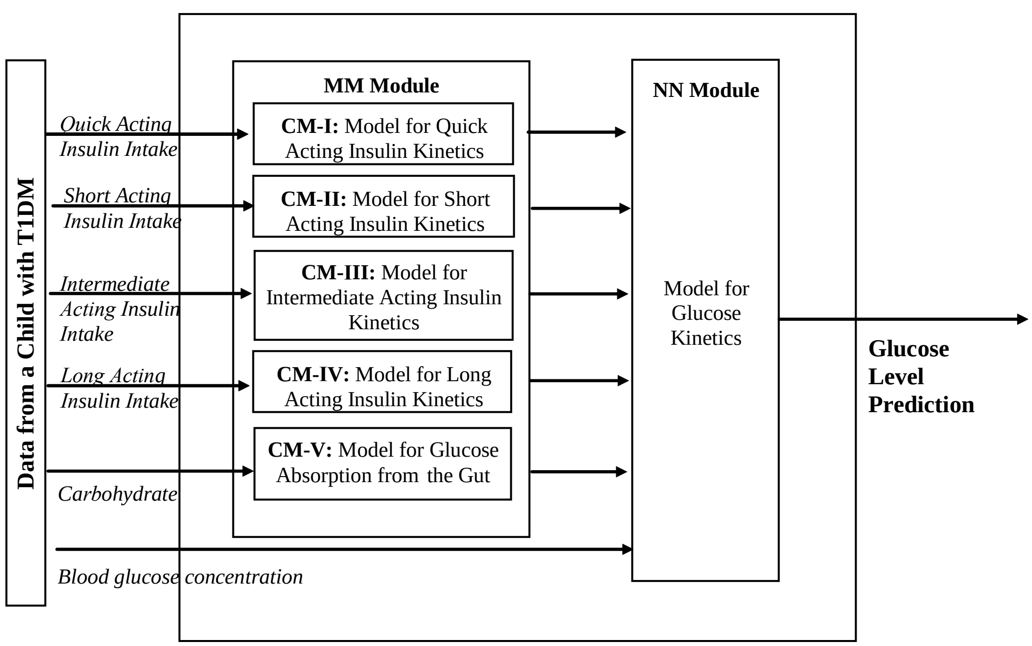

Table 1. Characteristics of the children with type 1 diabetes and statistics of the available glucose data (meas: measurements, SD: standard deviation)

Patient #	*Age (years)*	*Sex*	*Diabetes Duration (years)*	*BMI (kg/m^2)*	*Hba1c*	*# meas*	*Glucose levels (mg/dl)*		
							Min	*Max*	*Mean (SD)*
Patient 1	15	F	06	23.3	6.7	1311	44	400	157.07 (71.88)
Patient 2	15	F	13	29.5	7.5	1392	40	395	196.01 (94.53)
Patient 3	13	M	11	18.6	8.5	863	40	400	233.75 (96.61)
Patient 4	22	M	02	18.6	6.8	1069	57	228	123.03 (39.53)

and are given in (Lehmann, 1992). The differential equation (1) is solved using the fourth order Runge-Kutta method with a five-minute step.

2. **Compartmental model for glucose absorption from the Gut (CM-V):** After food intake, the glucose amount in the gut G_{gut} can be estimated by the equation:

$$\frac{dG_{gut}}{dt} = G_{empt} - k_{gabs} G_{gut} \qquad (3)$$

where $k_{gabs} = 1h^{-1}$ is the rate constant of glucose absorption from the gut into systemic circulation, and G_{empt} (mg / h) is the gastric emptying function given by a trapezoidal or triangular function, according to (Lehmann & Deutsch, 1996). Then, the glucose input into the blood from the gut wall is given by:

$$G_{in} = k_{gabs} \cdot G_{gut} \qquad (4)$$

Neural Network Module

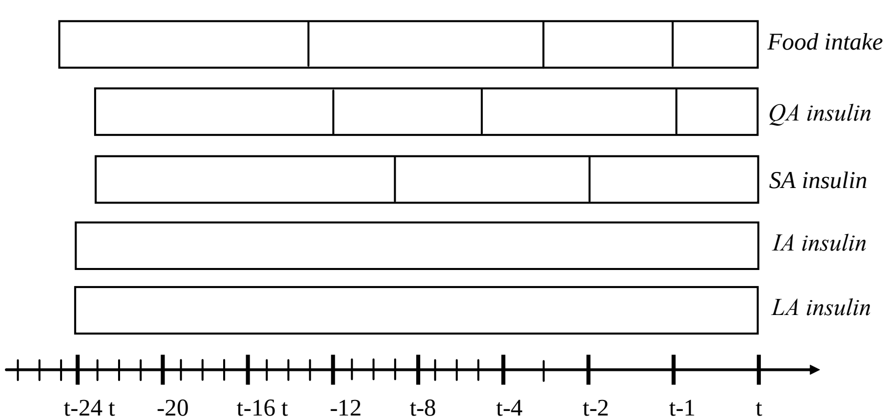
In order to predict the glucose level G (mg / dl) at a time instant t, the most recently measured blood glucose concentration along with parameters reflecting the effects of taken insulin and food are applied to the NN module. For comparative reasons, two different NN architectures have been developed and tested: a Feed-Forward NN (FFNN), and a Recurrent NN (RNN).

1. **Feed forward neural network:** The output of the FFNN is the glucose level G (mg / dl) prediction at time t, given by:

$$G(t) = \mathrm{FFNN}(G_{\mathrm{meas}}, \mathbf{G}_{\mathrm{in}}, \mathbf{I}_1, \mathbf{I}_2, \mathbf{I}_3, \mathbf{I}_4) \qquad (5)$$

where G_{meas} corresponds to the most recent glucose measurements, $\mathbf{G}_{\mathrm{in}} = \{G_{\mathrm{in},t-t_1}, G_{\mathrm{in},t-t_2}, G_{\mathrm{in},t-t_3}, G_{\mathrm{in},t-t_4}\}$ is a vector describing the effect of food intake in

Figure 2. Time windows (h) used for the description of insulin and food intake effects associated with blood glucose measurement at time t



the time-windows $t - t_i$ with i = 1, 2, 3, 4, $\mathbf{I}_1 = \{I_{1,t-t'_1}, I_{1,t-t'_2}, I_{1,t-t'_3}, I_{1,t-t'_4}\}$, is a vector describing the effect of taken QA insulin in the time-windows $t - t'_i$, $\mathbf{I}_2 = \{I_{2,t-t''_1}, I_{2,t-t''_2}, I_{2,t-t''_3}\}$, is a vector describing the effect of taken SA insulin in the time-windows $t - t''_i$ with i = 1, 2, 3, $\mathbf{I}_3 = I_{3,t-t'''_1}$ is a vector describing the effect of taken IA insulin in the time-window $t - t''_i$, and $\mathbf{I}_4 = I_{4,t-t''''_1}$ is a vector describing the effect of taken LA insulin in the time-window $t - t''''$. Each element of the above vectors is estimated as the sum of the prediction in the corresponding time windows. The used time-windows are indicated in Figure 2, and have been selected according to the expertise of physicians (Tresp et al., 1999). If in a time-window more than one event of the same type occurs, then the combined effect of the events is taken into account.

In Equation 5, the symbol FFNN denotes the nonlinear transformation of the data according to the used NN architecture. A fully connected feed-forward NN, trained by the batched back-propagation algorithm with adaptive learning rate and momentum (Haykin, 1999), has been used. The NN consists of three layers: input, hidden, and output layer. The input layer is formed by a number of neurons equal to the number of parameters used for the description of previous blood glucose measurements, insulin, and food intake. The hidden layer consists of a variable number of neurons ranging from three to 25. The output layer consists of one neuron, providing prediction of the subsequent blood glucose level. The tan-sigmoid function has been used for both hidden and output layers. In order to define the optimal number of neurons, the momentum term, and the initial value of learning rate, a trial-and-error process has been followed until no further improvement in glucose prediction could be obtained.

2. **Recurrent neural network:** In the case of RNN, the outputs of the MM module provide exogenous input to the RNN, which is a second-order RNN with one state variable. The output of the RNN is the glucose level G (gm / dl) prediction at time t, given by:

$$G(t) = G(t-1) + \mathrm{RNN}(G(t-1), G(t-2), G_{in}, I_1, I_2, I_3, I_4) \tag{6}$$

where $G(t-1)$, $G(t-2)$ are the current and previous blood glucose predictions, respectively, G_{in} is the glucose input into the blood from the gut, I_1 is the plasma insulin concentration due to QA insulin intake, and I_2 is the plasma insulin concentration due to SA insulin intake, I_3 is the plasma insulin concentration due to IA insulin intake, and I_4 is the plasma insulin concentration due to LA insulin intake.

The RNN is a fully connected NN trained with the online Real Time Recurrent Learning (RTRL) algorithm (Haykin, 1999). The used training algorithm has the ability to update online the RNN weights. As long as the RNN is provided with new inputs (external and internal), it adapts the weights accordingly, trying to simulate the dynamic system at real time. For comparative reasons, two strategies have been applied: the Free-Run (FR), and the Teacher-Forcing (TF). In the case of FR (online RTRL–FR), the RNN ignores the available glucose measurement, while in the case of TF (online RTRL–TF) strategy, the RNN replace the actual output, during training, with the corresponding available glucose measurement.

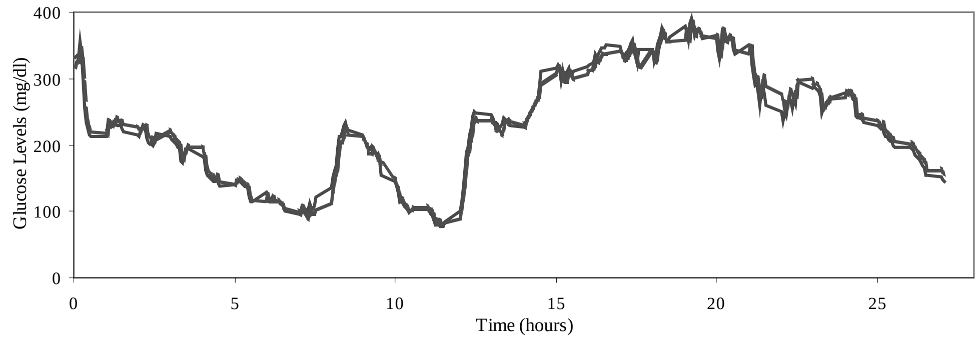
The RNN consists of three layers: the input layer formed by five external neurons, the hidden layer with a number of neurons ranging from five to 15, and the output layer with one neuron, providing prediction of the change of blood glucose level at next time step. The tan-sigmoid and linear activation functions have been used for the hidden and the output layer, respectively. The optimal configuration of RNN is defined following the same procedure as for FFNN.

Results and Discussion

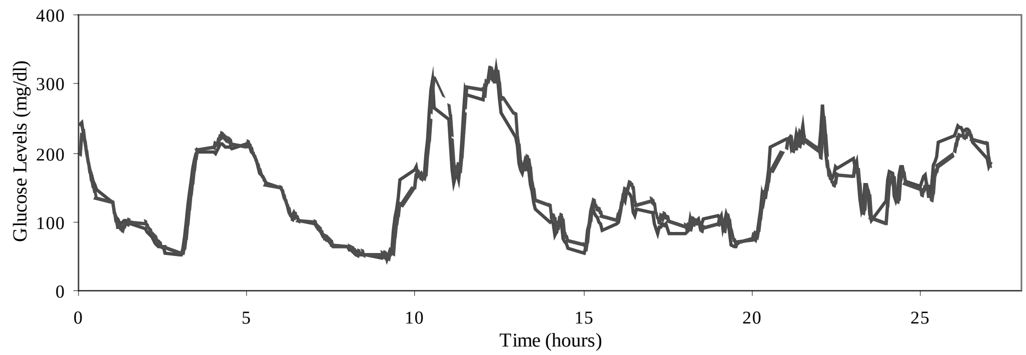
Aiming at the minimization of overtraining risk, and at the maximization of the models ability to predict glucose levels, the recorded days have been divided into two disjoint datasets: training, and testing sets. For each patient, the data of the first days (minimum three days) using CGMS have formed the training set, and the data of the last day using CGMS the testing set.

In order to assess the performance of the developed models, the Root Mean Square Error (RMSE) and the correlation coefficient (cc) have been calculated for both data sets. In Table 2, the RMSE, and the cc are given for each model.

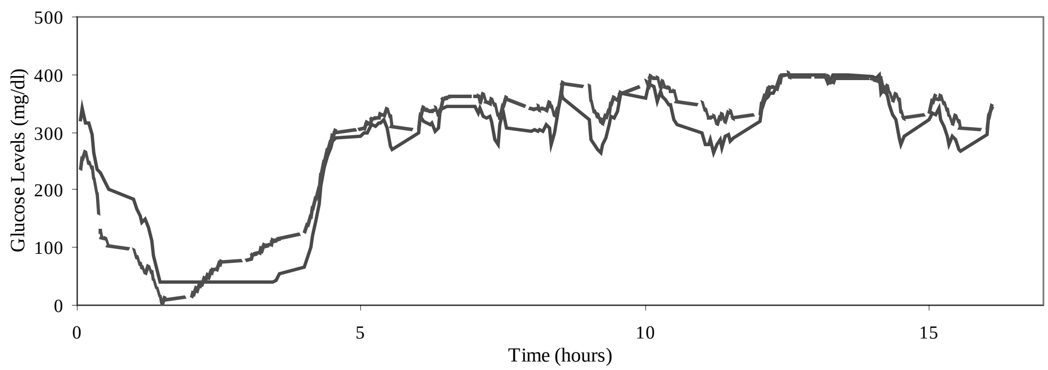
Figure 3. Comparison between estimated by the model using the online RTRL – TF trained RNN (-) and the measured (-) glucose levels for the testing set, in case of (a) patient 1, (b) patient 2, (c) patient 3, and (d) patient 4



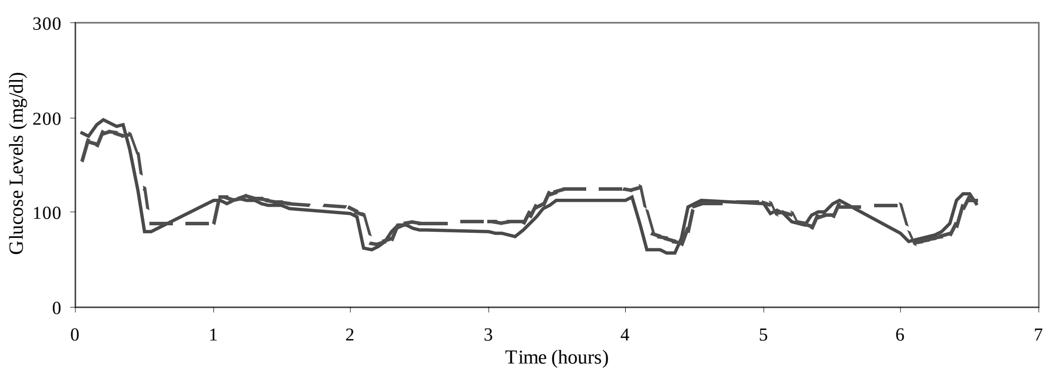
(a)



(b)



(c)



(d)

From Table 2, it can be shown that the results obtained from the FFNN and the RNN trained with the online RTRL-TF are superior to those obtained by the online RTRL-FR trained RNN for all diabetes patients. Furthermore, it can be observed that the performance of FFNN is slightly better, as compared to the online RTRL-TF trained RNN. Despite this, the online RTRL-TF trained RNN is preferable, due to its ability to adapt the weights whenever a new input is applied.

Finally, in Figure 3, the measured and the estimated blood glucose levels vs. time are presented for the testing set of all patients, using online RTRL-TF trained RNN. From the above results, it is obvious that further studies need to be performed, including a greater number of T1DM patients in order to improve the significance of the results.

FUTURE TRENDS

Future direction of the current research includes the development of an automatic advisor, which can make recommendations about the appropriate (i) time and the doses of insulin for patient using MDI, and (ii) insulin pumps settings for patient using CSII is in progress. The system will be part of an integrated platform for the monitoring and management of T1DM patients. The platform will be based on the combined use of insulin pumps, blood glucose measurement devices, internet technology, Wireless Personal Area Networks (WPAN), mobile communication networks, and tools for the intelligent processing of diabetes information.

The ultimate goal is the development of an autonomous closed-loop system able to mimic accurately the glucose-insulin metabolism, and maintain the glucose levels into physiological range.

Table 2. Root mean square errors (RMSE), along with correlation coefficients (cc) between measured and estimated by the models glucose levels for the testing set

Patient #	*Model*	*RMSE*	*cc*
Patient 1	*FFNN*	27.82	0.94
	RNN/FR	39.32	0.80
	RNN/TR	15.13	0.97
Patient 2	*FFNN*	7.19	0.99
	RNN/FR	38.11	0.91
	RNN/TR	11.58	0.99
Patient 3	*FFNN*	41.34	0.98
	RNN/FR	71.69	0.79
	RNN/TR	55.38	0.90
Patient 4	*FFNN*	12.31	0.92
	RNN/FR	33.47	0.62
	RNN/TR	14.25	0.91

CONCLUSION

Advancements in information technology and software engineering permit the design and development of computational models able to simulate accurately complex, nonlinear biological, and physiological processes. In this article, the application of NNs for the design and development of glucose–insulin metabolism models for T1DM patients has been presented. Furthermore, two glucose-insulin metabolism models for children with T1DM have been described. The models, which are based on the combined use of CMs and NNs, provide individualized, accurate, short-term predictions of glucose levels.

ACKNOWLEDGMENT

This work is being supported in part by the General Secretariat of Research and Technology/Ministry of Development (Greece) under the R&D project "SMART-DIAB: Insulin Infusion Intelligent System."

KEY TERMS

Artificial Neural Networks: Neural networks that include artificial intelligence.

Compartmental Models: Models that have distinct sections.

Continuous Glucose Monitoring Systems: Systems that monitor glucose levels at all times.

Personalized Models: Models that are individualised.

Type 1 Diabetes Mellitus: A condition characterized by disordered metabolism and inappropriately high blood sugar resulting from either low levels of the hormone insulin, or from abnormal resistance to insulin's effects, coupled with inadequate levels of insulin secretion to compensate.

Integrating Medication and Health Monitoring Systems

Burges Karkaria
Intel Corporation, USA

Vincent Zimmer
Intel Corporation, USA

INTRODUCTION

Current health care providers (medical practitioners, insurance companies, pharmacies) have disjointed proprietary systems. This makes data sharing and collaboration very difficult. Furthermore, consumers (patients) have no abilities to interact directly with these systems. This chapter discusses an ecosystem for patient medication and health monitoring called the patient medication and health monitoring system (PMHMS). PMHMS proposes global and ongoing collaboration of data between the patient, various medical practitioners, and pharmacies. Existence of this ecosystem helps to enable some of the following scenarios:

- Medical practitioners can view the patient's current medication (from other medical practitioners as well) to ensure that the current prescription will not conflict with other medications.
- The medical practitioner's office can monitor if chronic patient is skipping medication (e.g., no refills ordered). The medical practitioner's office can also monitor patient's stats (patient uses PC to upload, for instance, blood sugar levels, blood pressure, and so forth).
- Pharmacies will be able to automatically send refills to patients.
- Patients can get a quick off-site consultation from the medical practitioner's office (using video conferencing to show some visual symptoms as needed by the medical practitioner)
- Patients get automated dosage reminders.

BACKGROUND

A consumer facing commerce model generally consists of the consumer, main and ancillary services, and a financial broker or approver. As an example, we look at some sample models. Figure 1 shows the constituents and associated transactions of a consumer electronics store, while Figure 2 shows the same for a travel agency. Both of these depict seamless end-consumer experience.

In comparison, Figure 3 shows an example model of today's health care systems. While this example is more relevant to certain geographies like North America and Europe, it does highlight the lack of integration in the health care system constituents. The PMHMS system is a sample implementation aiming to rectify some of these issues.

PATIENT MEDICATION AND HEALTH MONITORING SYSTEM (PMHMS)

Overview

PMHMS is an ecosystem for patient medication and health monitoring. There is global and ongoing collaboration of data between the patient, various medical practitioners, and pharmacies. Existence of this ecosystem helps to enable some of the following scenarios (for a complete list of PMHMS possibilities, see Use Cases in Figure 4):

- Medical practitioners can view the patient's current medication (from other medical practitioners as well) to ensure that the current prescription will not conflict with other medications.
- The medical practitioner's office can monitor if chronic patient is skipping medication (e.g., no refills ordered). The medical practitioner's office can also monitor patient's stats (patient uses PC to upload, for instance, blood sugar levels, blood pressure, and so forth).

Figure 1. Consumer store economic model constituents

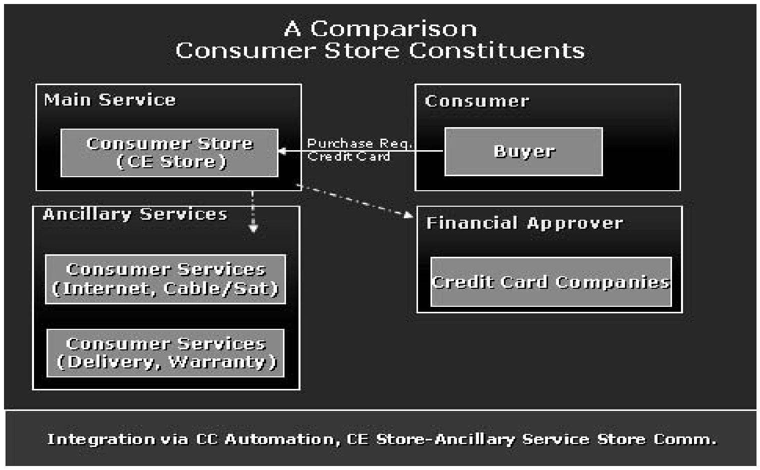

Figure 2. Travel agency economic model constituents

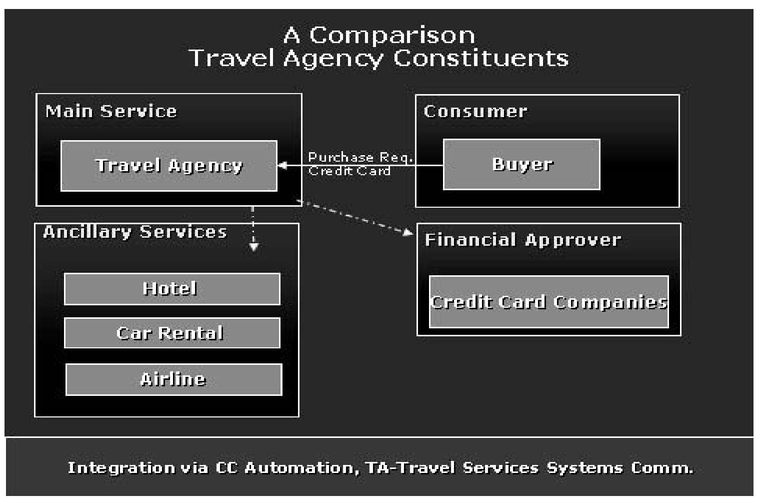

- Pharmacies will be able to automatically send refills to patients.
- Patients can get a quick off-site consultation from the medical practitioner's office (using video conferencing to show some visual symptoms as needed by the medical practitioner)
- Patients get automated dosage reminders

PMHMS Subsystems

PMHMS consists of the subsystems as shown in Figure 5.

Central Patient Repository (CPR)

CPR is a centrally available database of the medication history of the patient. (This repository also can be upgraded later to include a patient's medical records (e.g., previous diagnosis, X-ray scans, blood reports, etc.). CPR is run as a commercial service. Multiple vendors may be offering CPR services, and the insurance provider may choose to use its vendor of choice based on factors such as cost, features, security, and so forth. The system is built on an established set of open standards (e.g., HL7 [Std1]).

Figure 3. Health care system constituents

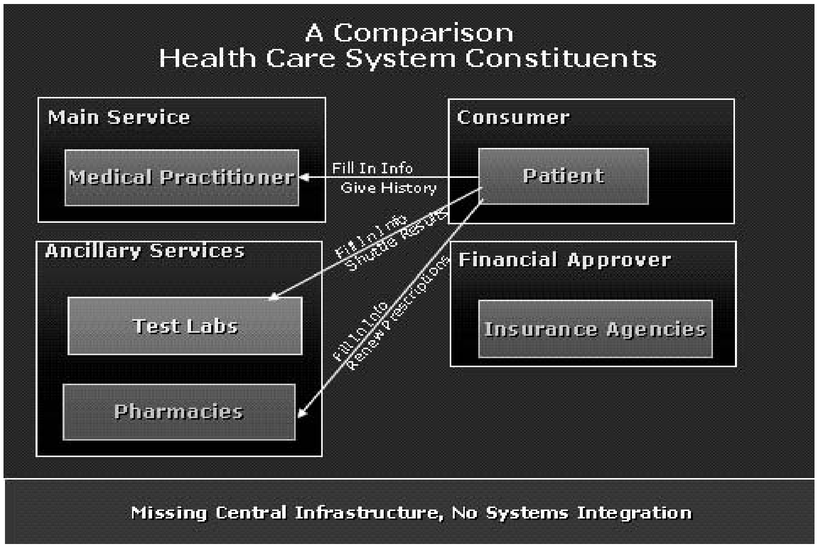

Figure 4. PMHMS possibilities/use cases

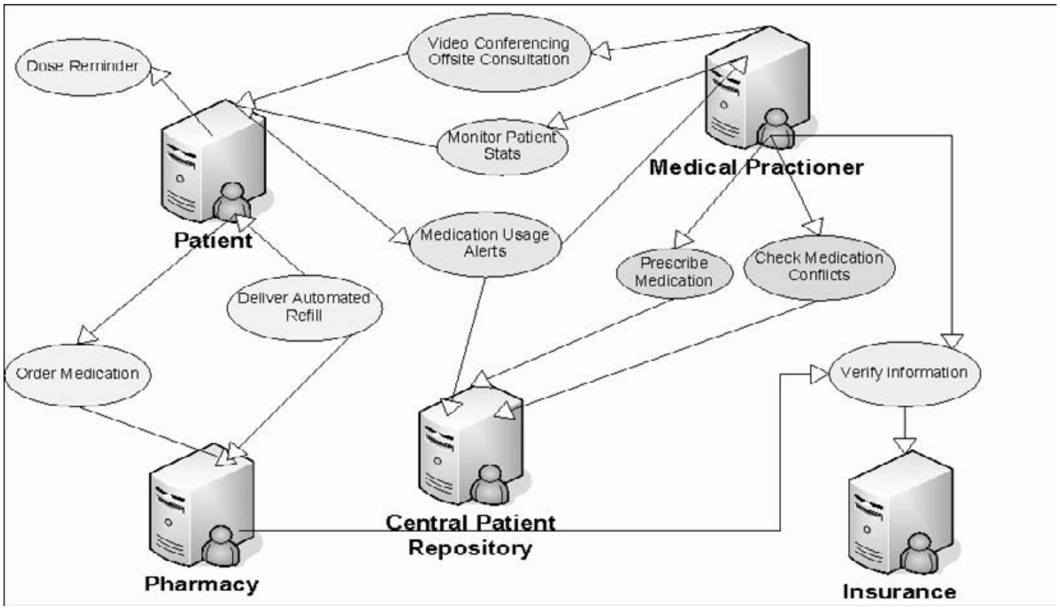
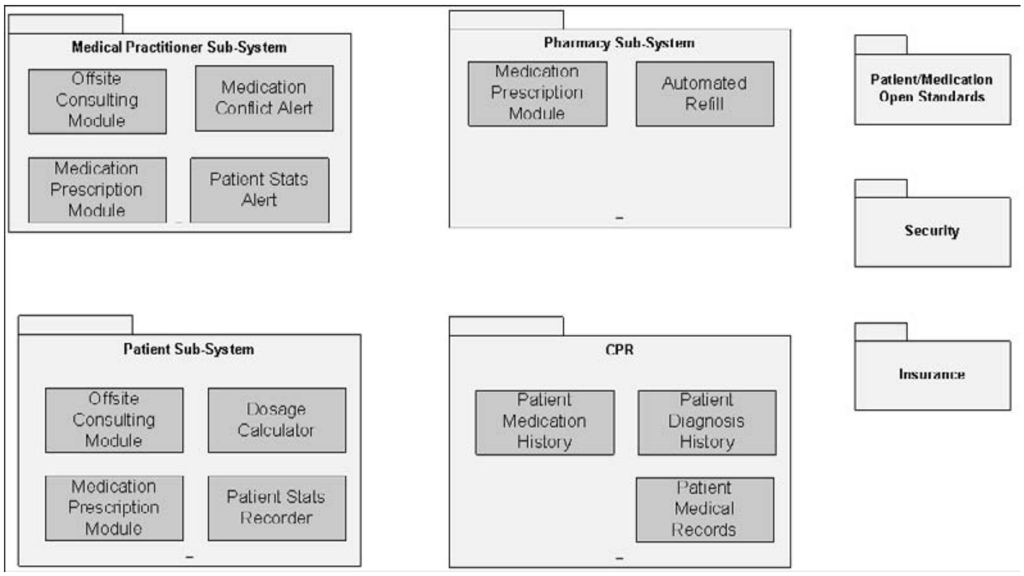


Medical Practitioner's Subsystem

The Medical Practitioner's Subsystem is a local app installed in the medical practitioner's office. The medical practitioner can use this subsystem to view the patient's medication history (using CPR). The medical practitioner also uses this to log prescriptions into the CPR. This subsystem also has the ability to detect potentially conflicting drugs. If the Medical Practitioner is prescribing some medication that may conflict with another prescribed drug, the system will alert the medical practitioner, and the medical practitioner has the ability to change the prescription.

Figure 5. PMHMS subsystems



Pharmacy Subsystem

The Pharmacy Subsystem takes medication orders, gets refills sent out automatically as applicable, and so forth.

Insurance Subsystem

The Insurance Subsystem lets medical practitioners and pharmacies verify patient information

Patient Subsystem

The Patient Subsystem is a local app installed on the patient's local PC. Using the Patient Subsystem, the consumer can do some of the following:

- **Ordering medication:** PMHMS allows the user to order prescription drugs from pharmacies. The user can have a preferred pharmacist (in which case new prescriptions automatically get delivered). It automatically notifies the pharmacy for refills when one is needed.
- **Medication intake and health monitoring:** This system also prompts the user about what dosage needs to be taken next. The system also allows users to log into their statistics such as blood sugar levels or blood pressure (using approved devices that connect to the PC). If the statistics show an undesirable spike, then an alert goes out to the relevant medical practitioner, and the medical practitioner's office can follow up to ensure the patient's well-being.

Finally, the patient can have small off-site consultation sessions directly with the medical practitioner's office by starting video conferencing and VOIP sessions.

Use of Standards

The reason various subsystems can communicate with each other is due to the use of standards. The standards are applied via the following:

- **Data standards:** Medication, diseases, patient, and so forth are well defined (we could use existing standards such as HL7 (health Level 7) [Std1] or DICOM.
- **Service standards:** The services that need to be exposed by the subsystems need to be standardized as well. There could be internal differentiation in the implementation of the service. For example, all CPR service providers should offer a service such as GetPatientCurrentMedication (Patient, MedicationColl).
- **Privacy standards:** Going to a more automated electronic system of medical records handling

raises concerns about patient privacy. The Health Insurance Portability and Accountability Act of 1996 [Std3] was intended to provide guidelines to avoid fraud, waste, and other information abuses. This is key to assuage customer concerns for this medical information automation.

FUTURE TRENDS

The evolution of standards is going to continue due to focused government and industry initiatives. If certain health care providers start providing some of the automation depicted previously, it will be a huge differentiating factor enhancing their basic service offerings. This in turn would fuel a competitive race to provide equivalent customer service via integration. The end result would be a highly automated model facilitating myriad advances in patient health care via specialized appliances and services.

CONCLUSION

Health care systems today are plagued by lack of integration. This causes huge end-user disadvantages such as redundant information filling, increase in stress, and so forth. It can also be the cause of critical and costly mistakes such as medication conflicts as a result of incorrect medication history disclosure. An integrated ecosystem built with an end-consumer centric focus can eliminate these issues. The enabling of Health Care Systems Integration can be caused by the use of existing and evolving standards.

INTRODUCTION

Computer aided medical diagnosis is one of the most important research fields in biomedical engineering. Most of the efforts made focus on diagnosis based on clinical features. The latest breakthroughs of the technology in the biomolecular sciences are a direct cause of the explosive growth of biological data available to the scientific community. New technologies allow for high volume affordable production and collection of information on biological sequences, gene expression levels and proteins structure on almost every aspect of the molecular architecture of living organisms. For this reason, bioinformatics is asked to provide tools for biological information processing, representing today's key in understanding the molecular basis of physiological and pathological genotypes. The exploitation of bioinformatics for medical diagnosis appears as an emerging field for the integration of clinical and genomic features, maximizing the information regarding the patient's health status and the quality of the computer aided diagnosis.

Cancer is one of the prominent domains where this integration is expected to bring significant achievements. As genetic features play a significant role in the metabolism and the function of the cells, the integration of genetic information (proteomics-genomics) to cancer-related decision support is now perceived by many not as a future trend but rather as a demanding need. The usual patient management in cancer treatment involves several, usually iterative, steps consisting of diagnosis, staging, treatment selection, and prognosis. As the patient is usually asked to perform new examinations, diagnosis and staging status can change over time. On the other hand, treatment selection and prognosis depend on the available findings, response to previous treatment plan and, of course, clinical guidelines. The integration of these evolving and changing data into clinical decision is a hard task which makes fully personalised treatment plan almost impossible. The use of clinical decision support systems (CDSSs) can assist in the processing of the available information and provide accurate staging, personalised treatment selection, and prognosis. The development of electronic patient records and of technologies that produce and collect biological information have led to a plethora of data characterizing a specific patient. Although this might seem beneficial, it can lead to confusion and weakness concerning the data management. The integration of the patient data (quantitative) that are hard to be processed by a human decision maker (the clinician) further imposes the use of CDSSs in personalized medical care (Louie, Mork, Martin-Sanchez, Halevy, & Tarczy-Hornoch, 2007). The future vision—but current need—will not include generic treatment plans according to some naive reasoning, but totally personalised treatment based on the clinicogenomic profile of the patient.

In this article, we address decision support for cancer by exploiting clinical data and identifying mutations on tumour suppressor genes. The goal is to perform data integration between medicine and molecular biology by developing a framework where clinical and genomic features are appropriately combined in order to handle cancer diseases. The constitution of such a decision support system is based on (a) cancer clinical data and (b) biological information that is derived from genomic sources. Through this integration, real time conclusions can be drawn for early diagnosis, staging and more effective cancer treatment.

BACKGROUND

Clinical Decision Support Systems are active knowledge systems which use two or more items of patient data to generate case-specific advice (Fotiadis, Goletsis, Likas, & Papadopoulos, 2006). CDSSs are used to enhance diagnostic efforts and include computer based programs that, based on information entered by the clinician, provide extensive differential diagnosis, staging (if possible), treatment, follow-up, and so forth. CDSSs consist of an inference engine that is used to associate the input variables with the target outcome. This inference engine can be developed based either on explicit medical knowledge, expressed in a set of rules (knowledge based systems) or on data driven techniques, such as machine learning (Mitchel, 2006) and data mining (intelligent systems) (Tan, Steinbach, & Kumar, 2005). CDSSs require the input of patient-specific clinical variables (medical data) and as a result provide patient specific recommendation.

Medical data are observations regarding a patient, including demographic details (i.e., age, sex), medical history (i.e., diabetes, obesity), laboratory examinations (e.g., creatinine, triglyceride), biomedical signals (ECG, EMG), medical images (i.e., MRI, CT), and so forth. Demographic details, medical history, and laboratory data are the most easily obtained and recorded and, therefore, most commonly included in electronic patient records. On the other hand, biomedical signals and medical images require more effort in order to be acquired in a digital format and must be processed for useful feature extraction. Apart from these, several types of genomic data can be generated from laboratory examinations, that is, gene DNA or protein sequences, gene expression data, microarray images, and so forth. Genomic data can also be used for medical diagnosis, disease prevention, and population genetics studies. Although medical data are sufficient for the diagnosis of several diseases, recent studies have demonstrated the high information value of genomic data, especially in specific types of diseases, such as cancer diseases.

The great amount and the complexity of the available genetic data complicates their analysis from conventional data analysis methods and requires higher order analysis methods such as data mining techniques. Lately, data mining has received much attention in bioinformatics and molecular biology (Cook, Lawrence, Su, Maglothin, & Jonyer, 2001). Data mining methods are usually applied in the analysis of data coming from DNA microarrays or mass spectrometry. Over the last few years, several scientific reports have shown the potential of data mining to infer clinically relevant models from molecular data and thus provide clinical decision support. The majority of papers published in the area of data mining for genomic medicine deals with the analysis of gene expression data coming from DNA microarrays (Jiang & Gruenwald, 2005; Shah & Kusiak, 2007; Walker et al., 2004) consisting of thousands of genes for each patient, with the aim to diagnose types of diseases and to obtain a prognosis which may lead to therapeutic decisions. Most of the research works are related to oncology (Louie et al., 2007), where there is a strong need for defining individualized therapeutic strategies. Another area where data mining has been applied is the analysis of genes or proteins, represented as sequences (Exarchos, Papaloukas, Lampros, & Fotiadis, 2006); sequential pattern mining techniques are suitable for analyzing these types of data (Zaki, 2000).

Several CDSSs for cancer have been proposed in the literature. Most of the approaches are based solely on clinical data and a few methods exist that provide cancer decision support using microarray gene expression data. The cancer CDSSs concern several different types of cancer and employ various techniques for their development. The majority of systems are still in a research level and only a few are being used in clinical practice. A CDSS which is already in clinical use is PAPNET (Boon & Kok, 2001) which deals with cervical cancer. PAPNET uses ANNs to extract abnormal cell appearances from vaginal smear slides and describe them in histological terms. Other CDSSs for cervical cancer concentrate on the evaluation of the benefits of the PAPNET system (Doornewaard, 1999; Nieminen, Hakama, Viikki, Tarkkanen, & Anttila, 2003). Colon cancer has also been studied using clinical data and fuzzy classification trees (Chiang, Shieh, Hsu, & Wong, 2005) or pattern analysis of gene expression levels

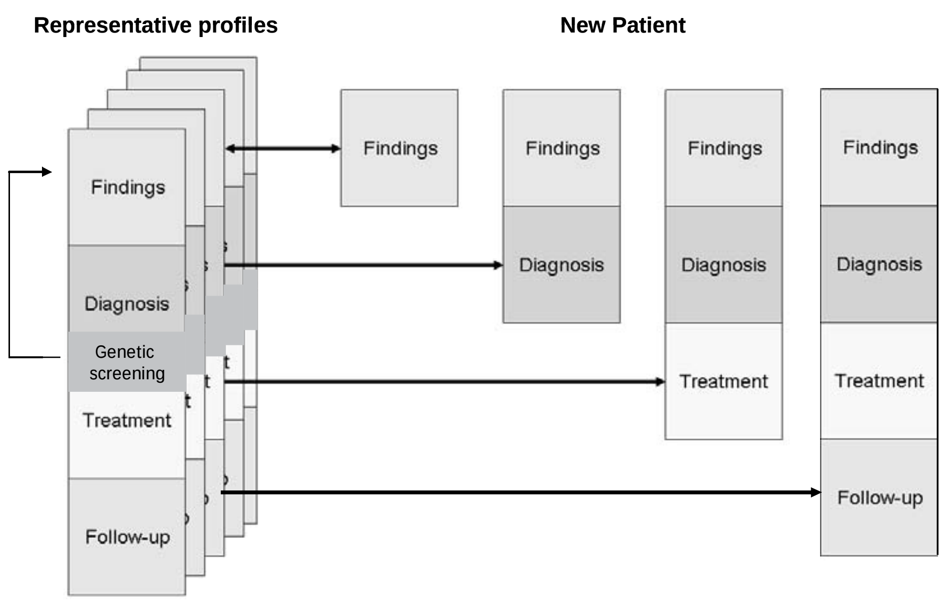
(Alon et al., 1999). A CDSS that combines imaging data with pathology data for colon cancer has also been proposed (Slaymaker, 2006). CDSSs proposed for prostate cancer, employ prostate specific antigen (PSA) serum marker, digital rectal examination, Gleason sum, age, and race (Remzi et al., 2003). Another approach for decision support in prostate cancer is based on gene expression profiles (Singh et al., 2002). Regarding bladder cancer, a CDSS has been developed based on proteomic data (Parekattil, Fisher, & Kogan, 2003). Concerning breast cancer, the potential of microarray data has been analysed (Van't Veer et al., 2002). Also, a recent CDSS has been developed that integrates data mining with clinical guidelines towards breast cancer decision support (Skevofilakas, Nikita, Templakesis, Birbas, Kaklamanos, & Bonatsos, 2005). It should be noted that all CDSSs mentioned above are just research attempts and only PAPNET is in clinical use.

CLINICAL DECISION SUPPORT USING CLINICOGENOMIC PROFILES

Methodology

Conventional approaches for CDSS focus on a single outcome regarding their domain of application. A different approach is to generate profiles associating the input data (e.g., findings) with several different types of outcomes. These profiles include clinical and genomic data along with specific diagnosis, treatment and follow-up recommendations. The idea of profile-based CDSS is based on the fact that patients sharing similar findings are most likely to share the same diagnosis and should have the same treatment and follow-up; the higher this similarity is, the more probable this hypothesis holds. The profiles are created from an initial dataset including several patient cases using a clustering method. Health records of diagnosed and (successfully or unsuccessfully) treated patients, with clear follow-up description, are used to create the profiles. These profiles constitute the core of the CDSSs; each new case that is inserted is related with one (or more) of these profiles. More specifically, an individual health record containing only findings (and maybe the diagnosis) is matched to the centroids. The matching centroids are examined in order to indicate potential diagnosis (the term diagnosis here refers mainly to the identification of cancer subtype). If the diagnosis is confirmed, genetic screening may be proposed to the subject and then, the clusters are further examined, in order to make a decision regarding the preferred treatment and follow-up. The above decision support idea is shown schematically in Figure 1.

Figure 1. Decision support based on profiles extraction. Unknown features of patient are derived by known features of similar cases.



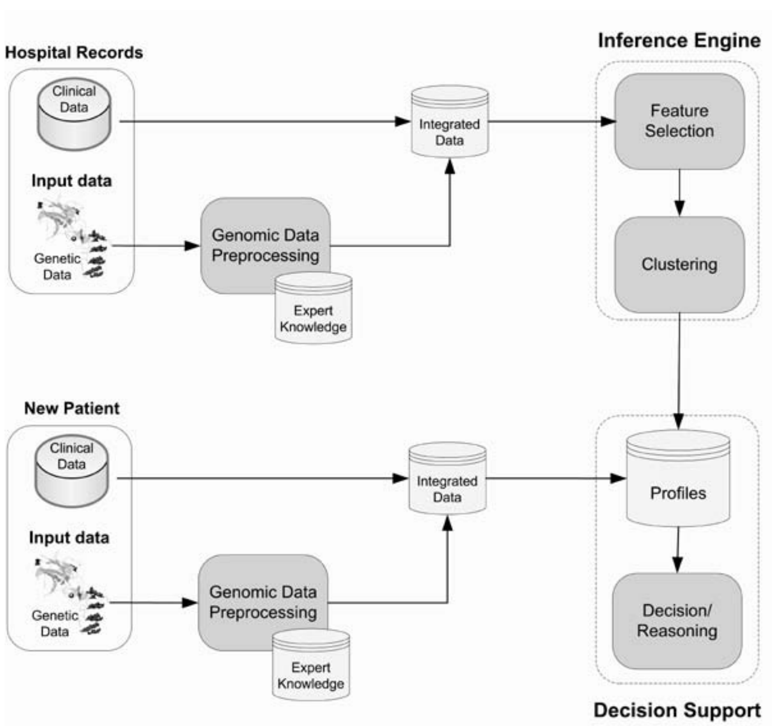
General Description of the System

Known approaches for the creation of CDSSs are based on the analysis of clinical data using machine learning techniques. This scheme can be expanded to include genomic information, as well. In order to extract a set of profiles, the integration of clinical and genomic data is first required. Then data analysis is realized in order to discover useful knowledge in the form of profiles. Several techniques and algorithms can be used for data analysis such as neural approaches, statistical analysis, data mining, clustering and others. Data analysis is a two stage procedure: (i) creation of an inference engine (training stage) and (ii) use of this engine for decision support. The type of analysis to be used greatly depends on the available information and the desired outcome. Clustering algorithms can be employed in order to extract patient clinico-genomic profiles. An initial set of records, including clinical and genomic data along with all diagnosis/treatment/follow-up information, must be available for the creation of the inference engine. The records are used for clustering and the centroids of the generated clusters constitute the profiles. These profiles are then used for decision support; new patients with similar clinical and genomic data are assigned to the same cluster, that is, they share the same profile. Thus, a probable diagnosis, treatment, and follow-up is selected. Both, the creation of the inference engine and the decision support procedure are presented in Figure 2.

Types of Data

Clinical data that are contained in electronic patient records (i.e., demographic details, medical history, and laboratory data) are usually presented in a simple and structured format, thus simplifying the analysis. On the other hand, genomic data are not structured and, therefore, appropriate preprocessing is needed in order to transform them into a more structured format. Three different kinds of biological data may be available to clinicians: (i) genomic data, often represented by a collection of single nucleotide polymorphisms (SNPs), DNA sequence variations that occur when a single nucleotide in the genome sequence is altered and since each individual has many SNPs, their sequence forms a unique DNA pattern for that person; (ii) gene expression data, which can be measured with DNA microarrays to obtain a snapshot of the activity of all genes in one tissue at a given time or with techniques

Figure 2. Representation of a general scheme for a CDSS, integrating clinical and genomic information



that rely on a polymerase chain reaction (PCR) and real-time PCR when the expression of only a few genes needs to be measured with better precision; (iii) protein expression data, which can include a complete set of protein profiles obtained with mass spectra technologies, or a few protein markers which can be measured with ad hoc essays.

Data Processing

Depending on the type of the available biological data, different preprocessing steps should be performed in order to derive structured biological information, while expert knowledge could favor the preprocessing steps. The processing stage is necessary in order to transform the genomic data into a more easy-to-analyse form, allowing their integration along with the clinical data into the data analysis stage. Also, the genomic data processing might take advantage of expert knowledge, that is, known genomic abnormalities. Finally, the integrated data (clinical and genomic) are analysed in order to discover useful knowledge that can be used for decision support purposes. This knowledge can be in the form of associations between clinical and genomic data, differential diagnosis, treatment, and so forth.

The initial dataset (clinical or genomic) is defined by the experts and includes all features that according to their opinion are highly related with the domain at hand (clinical disease). After acquiring the integrated data, a feature selection technique is applied in order to reduce the number of features and remove irrelevant or redundant ones. Finally, the reduced set of features is used by a clustering algorithm. K-means (MacQueen, 1967), fuzzy k-means (Bezdek, 1981), and expectation maximization (Dempster, Laird, & Rubin, 1977) are known approaches for clustering and can be involved for profile extraction. The profiles are the output of the clustering procedure (centroids). A deficiency of several clustering algorithms is that the number of centroids (profiles) must be predefined; this is not always feasible. Thus, in order to fully automate the profile extraction process, a meta-analysis technique is employed, which automatically calculates the optimal number of profiles.

Application to Colon Cancer

Colon cancer includes cancerous growths in the colon, rectum, and appendix. It is the third most common form of cancer and the second leading cause of death among cancers in the developed countries. There are many different factors involved in colon carcinogenesis. The association of these factors represents the base of the diagnostic process performed by medics which can obtain a general clinical profile integrating patient information using his scientific knowledge. Available clinical parameters are stored together with genomic information for each patient to create (as much as possible) a complete electronic health record.

Several clinical data that are contained in the electronic health records are related to colon cancer (Read & Kodner, 1999): age, diet, obesity, diabetes, physical inactivity, smoking, heavy alcohol consumption, previous colon cancer or other cancers, adenomatous polyps which are the small growths on the inner wall of the colon and rectum; in most cases, the colon polyp is benign (harmless). Also, other diseases or syndromes such as inflammatory bowel disease, Zollinger-Ellison syndrome, and Gardner's syndrome are related to colon cancer.

In the context of genomic data related with colon cancer, malignant changes of the large bowel epithelium are caused by mutations of specific genes among which we can differentiate (Houlston & Tomlinson, 1997):

- **Protooncogenes.** The most popular mutated protooncogenes in colon cancer are: K-RAS, HER-2, EGFR and c-MYC.
- **Suppressor genes-anticogenes.** In colorectal cancer the most important are DCC, TP53 and APC.
- **Mutator genes.** So far, six repair genes of incorrectly paired up bases were cloned from humans. Four are related to Hereditary Nonpolyposis Colon Cancer (HNPCC). These are: the hMSH2- homolog of yeast gene MutS, the hMLH1 - homolog of bacterial MutL, the hPMS1 and hPMS2 - from yeast equivalent.

An efficient way to process the above gene sequences is to detect Single Nucleotide Polymorphisms (SNPs) (Sielinski, 2005). SNPs data are qualitative data providing information about the genomic at a specific locus of a gene. An SNP is a point mutation present in at least 1% of a population. A point mutation is a substitution of one base pair or a deletion, which means the respective base pair is missing or an addition of one base pair. Though several different sequence variants may occur at each considered locus, usually one specific variant of the most common sequence is found, an exchange from adenine (A) to guanine (G), for instance. Thus, information is basically given in the form of categories denoting the combinations of base pairs for the two chromosomes, for example, A/A, A/G, G/G, if the most frequent variant is adenine and the single nucleotide polymorphism is an exchange from adenine to guanine.

According to previous medical knowledge, there are several SNPs with known relation to colon cancer. Some indicative SNPs already related to colon cancer, according to several sources in the literature, identified in TP53 gene, are presented in Table 1. The expert knowledge contains information about the position of the SNPs in the gene sequence (i.e., exon, codon position and amino acid position), the transition of the nucleotides and the translation of the mRNA to protein. Based on the list of known SNPs related to colon cancer, appropriate genomic information is derived, revealing the existence, or not, of these SNPs in the patient's genes.

Some of the described genes are acquired from the subjects and based on the SNP information regarding every acquired gene, such as SNPs in Table 1 for TP53 gene, new features are derived. These new features contain information regarding the existence or not of these SNPs in the patient's gene sequence. The derived features along with the aforementioned clinical data that are related to colon cancer are the input to the methodology and, after following the above described inference engine creation methodology, clinicogenomic profiles are generated. These profiles are able to provide advanced cancer decision support to new patients.

FUTURE TRENDS

There should be no doubt that several challenges remain regarding clinical and genomic data integration

Table 1. Indicative SNPs transitions and positions in the TP53 gene, related with colon cancer

Region	mRNA pos.	Codon pos.	Amino acid pos.	Function	Transition	Protein residue transition
exon_10	1347	1	366	nonsynonymous	G/T	Ala [A]/Ser [S]

exon_2	314	3	21	synonymous	T/C	Asp [D]/Asp [D]

to facilitate clinical decision support. The opportunities of combining these two types of data are obvious, as they allow obtaining new insights concerning diagnosis, prognosis, and treatment. According to this, medical informatics are combined with bioinformatics towards biomedical informatics. Biomedical Informatics is the emerging discipline that aims to put these two worlds together so that the discovery and creation of novel diagnostic and therapeutic methods is fostered. A limitation of this combination is that although data exist, usually their enormous volume and their heterogeneity constitute their analysis and association a very difficult task. Another challenge is the lack of terminological and ontological compatibility, which could be solved by means of a uniformed representation. Besides new data models, ontologies are/have to be developed in order to link genomic and clinical data. Furthermore, standards are required to ensure interoperability between disparate data sources.

CONCLUSION

Advances in genome technology are playing a growing role in medicine and health care. With the development of new technologies and opportunities for large-scale analysis of the genome, genomic data have a clear impact on medicine. Cancer prognostics and therapeutics are among the first major test cases for genomic medicine, given that all types of cancer are related with genomic instability. The integration of clinical and genomic data makes the prospect for developing personalized health care ever more realistic.

KEY TERMS

Cancer Staging: Knowledge of the extent of the cancer at the time of diagnosis. It is based on three components: the size or depth of penetration of the tumour (T), the involvement of lymph nodes (N), and the presence or absence of metastases (M).

Clinical Decision Support Systems (CDSS): Entities that intend to support clinical personnel in medical decision-making tasks. In more technical terms, CDSSs are active knowledge systems that use two or more items of patient data to generate case-specific advice.

Cluster analysis: The task of decomposing or partitioning a dataset into groups so that the points in one group are similar to each other and are as different as possible from the points in other groups.

Data Integration: The problem of combining data residing at different sources and providing the user with a unified view of these data. This important problem emerges in several scientific domains, for example, combining results from different bioinformatics repositories.

Data Mining: The analysis of observational datasets to find unsuspected relationships and to summarize the data in novel ways that are both understandable and useful to the data owner.

Mutation: A change in the genetic material (usually DNA or RNA) of a living being. Mutations can happen for a lot of different reasons. They can happen because of errors during cell division, because of radiation, chemicals, and so forth.

Single Nucleotide Polymorphism (SNP): A DNA sequence variation occurring when a single nucleotide—A, T, C, or G—in the genome differs between members of a species or between paired chromosomes in an individual.

Tumour Suppressor Gene: A gene that reduces the probability that a cell in a multicellular organism will turn into a tumor cell. A mutation or deletion of such a gene will increase the probability of the formation of a tumor.

An Intelligent Wearable Platform for Real Time Pilot's Health Telemonitoring

INTRODUCTION

Aviators engage in a variety of outdoor activities where their health status, the environment, and the degree of workload and fatigue affect their performance. An innovative tool has been developed, which supports the real-time health monitoring of pilots using new algorithms based on intelligent clustering techniques for the recognition of possible health problems in flight. The Smart Profiler and the Intelligent Advisor modules of this system exploit the use of knowledge based expert systems and intelligent classification techniques. Coupled with the Portal, which also exploits the use of intelligent clustering techniques, it estimates the pilot's performance in unknown environments. The new system targets recognizing possible problems at the time of flying, but it can also be used for the monitoring of the pilot performance and progress throughout a period of time, as it stores information from different flying sessions. The system was applied in 20 private pilots during the flight of a Cessna 152 aerobatic. The device was reliable and user-friendly, enabling us to monitor real-time health status of aviators in order to detect possible problems caused by the actual environmental conditions to which individuals are exposed, thus contributing to their health and safety in their working environments.

Despite the automation and increasing technological complexity of modern aircrafts, the human operator still plays an important role in controlling those demanding systems. Piloting an aircraft is a highly complex task that requires the pilot to be proficient in numerous skills (Wilson & Eggemeier, 1991) in a hostile environment of cabin pressure changes and circadian rhythm disturbances particularly in long duration flights. The resulting overload of the pilots mandates the need for real time health telemonitoring (Charles, Winget, Charles, DeRoshia, Markley, & Holley, 1984; Denison, Ledwith, & Poulton, 1966; U.S. National Research Council, 2002; Ustinavičienė, Obelenis, & Ereminas, 2004). Real time health telemonitoring would be crucial to early detect and prevent conditions affecting aviator's vital signs and cognitive performance.

BACKGROUND

A series of technologically advanced devices has been gradually proposed in order to detect pilot performance decrement, but most of the methods referred to pre or post flight data analysis and basically in simulation flights. Most of the commercially available wearable or portable devices measuring health parameters were mainly developed in sports activities for athletes. Initially those products did not support wireless transmission of data for long distances. Long-distance measurements were made possible due to newer products such as Cardiosport (6), FitSense (7), Polar S-Series Monitors (8), and FS-1 speedometer; which share the drawbacks of limited storing capacity; only one parameter monitoring and no wireless data transmission support (or when provided, only for very short distances). Newer products as MySportTraining (9), WebCoach (10), CrossTrak 2.0 and CoachConnect (11) and the Virtual Coach (12) offered the possibility of calculating personalized indicators, but none of these products, however, record or use information related to the environmental conditions of the training place. Recently a product in the form of life shirt was presented by VivoMetrics™-LifeShirt (13) embedded with tiny wires and electrodes which continuously monitor 40 physiological signs of sickness and health. The problem with this device included high cost and the insufficient adaptability to individual's body features. Additionally, it did not incorporate capabilities of Computer Aided Diagnosis so the continuous presence of a doctor was mandatory. In all those products, environmental parameters were not included as it is recommended in the case of pilot's activities.

AN INTELLIGENT WEARABLE PLATFORM

The goal of the present study was to assist in the implementation and the application of an innovative device for real time health telemonitoring to early recognise potential hazards and alert the pilot or the supervising personnel, using a neural network technique, which enables the system to incorporate adaptations of the real environment, and estimate possible future events that may occur during an intended flight in similar environment.

The proposed system consists of two architectures designed, one for monitoring a group of pilots and the other for a pilot alone (standalone). The difference between those architectures is that for the standalone version, the wearable unit is embedded inside the Monitoring Station while for a group of pilots it is separate and on the ground.

The system for a group of pilots is more complicated and will be analysed here. This system is composed of a set of sensors distributed on the body via a wearable comfortable vest, underneath the pilots clothes, connected to a portable wearing device where the communication module is incorporated receiving information from three sources: the environment and the medical and training profile of the pilots. Through a SIM card which contains a microprocessor chip which stores unique information about an account and identifies that to the network, all the data are transmitted online to the monitoring station where the processing and analysis is accomplished until the final recognition of the problem when the appropriate alert will appear on the screen of the monitoring personnel. Independently of this system, another external monitoring system, the portal, is used to keep a record of the pilot performance in each flight and through the intelligent clustering mechanism. This is compared to similar situations. This whole process is succeeded by seven subsystems: more analytically

Figure 1. The system overview

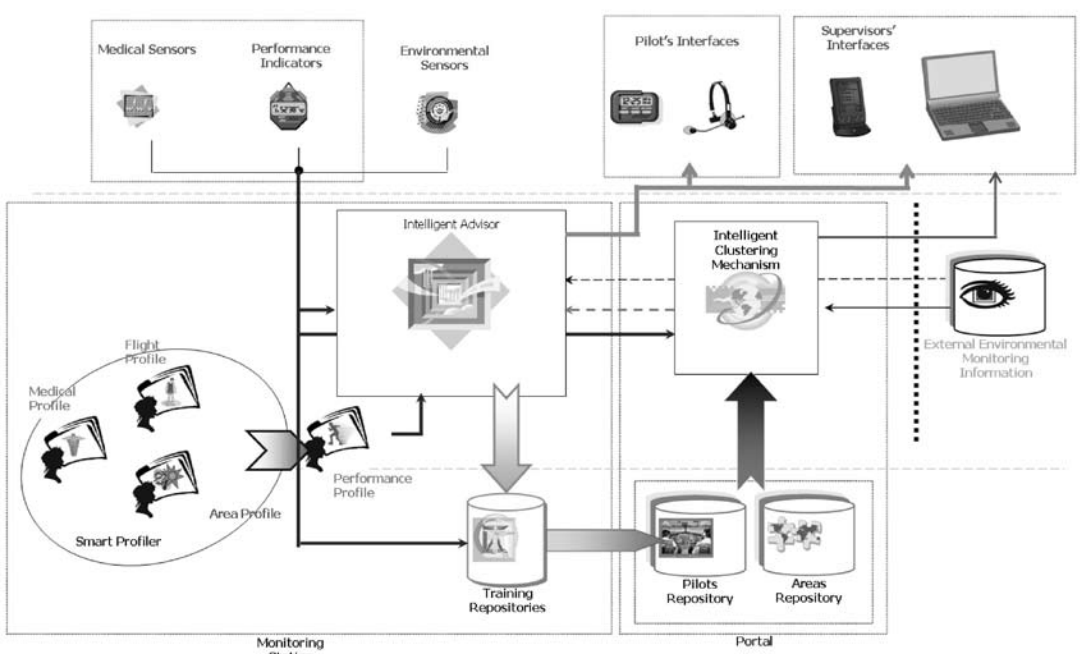

Figure 2. The architecture of the full functionality Configuration PREVENTIVE system

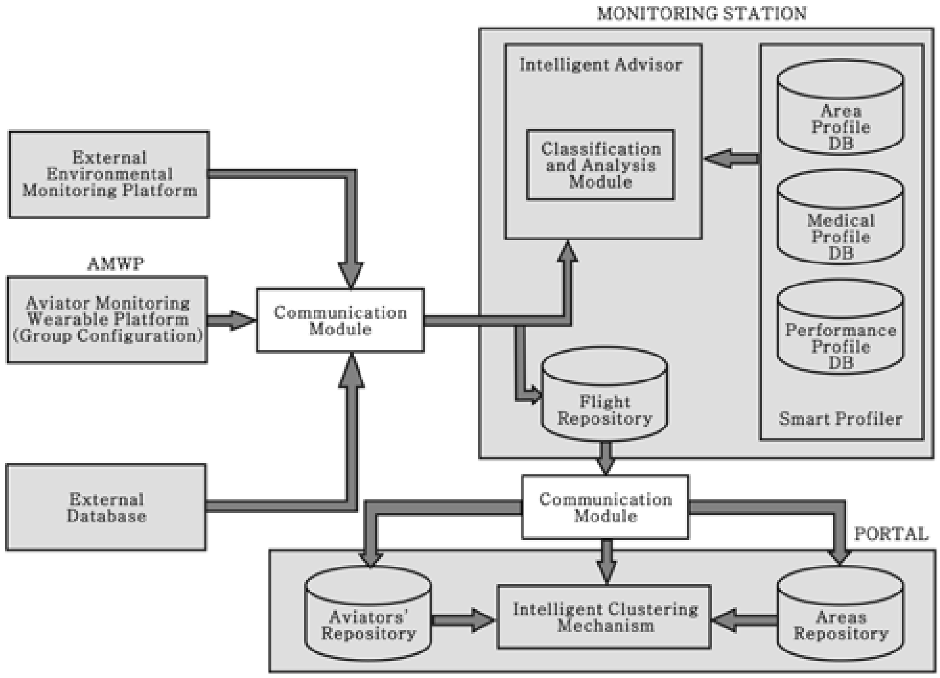

the Aviator Monitoring Wearable Platform (AMWP), the Monitoring Station, the Portal, the Interface to external Environmental Monitoring System, the Interface to external Training Database, the Communication Module, and the Security Module.

More specifically, the AMWP, which is physically attached on the aviator's body with a set of sensors, is composed of the following modules: medical sensing system, which acquires and digitizes medical measurements, performance sensing system, which acquires and digitizes performance measurements, and integrator, which synchronizes measurements from both the medical and performance sensing systems. The hardware part of the WAD unit consists of all the internal circuitry and the communication interfaces. Figure 3 depicts the block diagram of the WAD.

For the sensing systems, the sensors are distributed as follows: two for respiration, one for temperature, one for pulse oximeter (NONIN 8000J, Nonin Medical Inc.), one for wrist blood pressure meter (OMRON 637IT, Omron Healthcare Europe), one for 5-lead ECG, one for accelerometer, and all were embedded in the WAD unit. The signals were acquired using analogue interface for ECG, respiratory, temperature, and acceleration sensors and digital for the pulse oximeter (P-OX) and blood pressure meter (BPM). Each portable unit was supplied with a preconfigured GPRS-enabled wearable device and any data collected were transmitted via a GPRS network to a Gateway server with an IP address publicly accessible. In turn, the Gateway server stored the data to a database server where all data reside and a visualization subsystem which typically includes a PDA for viewing the results of the performed tests through wireless connection to the Web server, enabling specialized personnel to real time monitor the aviator through the Monitoring Station.

The Monitoring Station is a portable computer consisting of three software modules to process all incoming data: the Smart Profiler to generate the performance profile, using information from the medical profile, area, and flight profile which are processed, analyzed, and calcified by the intelligent advisor and stored in the Training Repository. The Smart Profiler works by using personalized information to specify each pilot's performance profile, which expresses the pilot's capacity for the specific environmental conditions, medical history, current health status, and flight requirements. It is formulated from the intelligent incorporation of the pilot's Medical Profile, the Flight Profile, and the Area Profile. The three profiles can either be created automatically, or manually. The medical profile changes as pilots are submitted to frequent medical examinations,

Figure 3. The Smart Profiler Expert System

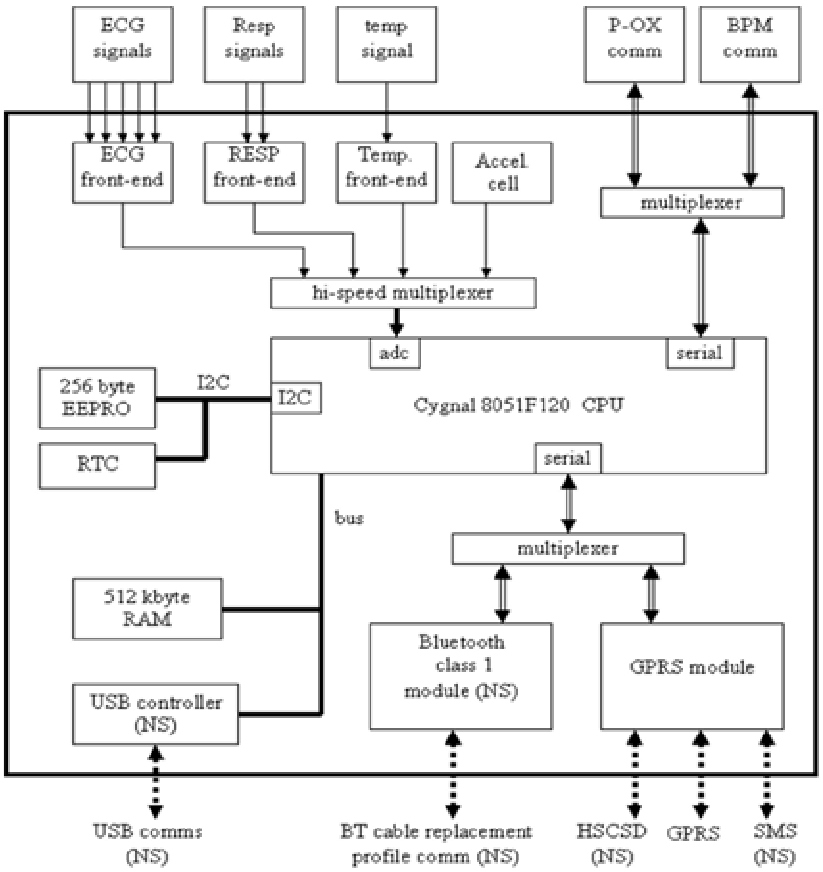

Figure 4. Block diagram of the WAD unit

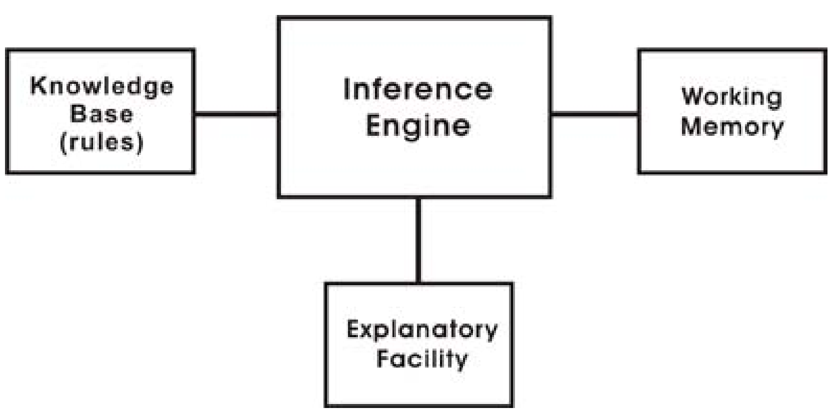

I

which provide new information on their health status. Flight profiles record the existing knowledge on how the body reacts to certain types of flight. Area profiles exploit the recorded environmental monitoring parameters for a region. They are strongly time-dependant and change dynamically as more monitoring measurements and data become available. The Smart Profiler, which is actually a knowledge-based expert system through one of its components, the working memory, receives the three basic profiles of a pilot who is about to fly in a specific location, and uses the already recorded knowledge from previous similar training sessions to provide an estimation of the pilot's performance and his vital response during this specific flying session. In order to achieve this, a knowledge base is used which is actually a set of rules which apply to the facts of the expert system and can be seen as the codification of the experts' knowledge from the medical and flight domain. Then a managing mechanism is used, called inference engine, which is capable of deciding which rules are satisfied by facts, prioritizing the satisfied rules, and executing the rule with the highest priority. Finally, the explanatory facility explains the reasoning of the final result (the performance profile) to the end users.

Besides the smart profiler, the second component of the Monitoring Station is the Intelligent Advisor, which processes real-time monitoring data from the medical, environmental, and performance sensors, combining them with the smart profiles in order to classify the aviator's status according to the significance of a possible abnormality. An innovative technique that the system is using is the clustering algorithm in order to process data by classifying flight areas in terms of both performance capabilities and associated health risks. Those areas are represented in high-dimensional spaces and hence the inherent similarities are hard to recognize and to illustrate. In order to facilitate this process, a neural network model that is capable of visualizing these similarities was built, based on the Self Organising Map (SOM) algorithm. The Intelligent Clustering Mechanism, by using the SOM algorithm, creates clusters of areas according to the similarities that the areas present and for each area two different estimations are provided, one for the performance and one for the aviator's health response. The SOM algorithm, in order to create the clusters of areas, needs as input the estimated importance factor of each of the above parameters, which is subjected to changes according to the type of flight. The estimation for the possible health problems that may appear in the aviator's health is also provided for every flight area that belongs to a specific cluster.

The third component of the Monitoring Station is the Flight Training Repository, which stores information about a flight session for each aviator (environmental conditions of the flight area, as well as medical and performance parameters); and provides diagnosis and advices generated from the Intelligent Advisor. Information from the Flight Repository is send through the communication module to another external monitoring system, the Portal.

The Portal is an independent part of the system, the purpose of which is to provide the long-term service of gathering results from a large number of training sessions throughout different locations and time periods, and extract conclusions and predictions on the future course of a pilot. Consequently, it is a self-learning and maintenance mechanism that gets improved as time goes by: the more the training sessions in a specific area are, the more accurate the produced area similarity maps become. Therefore, its results and usefulness can be evaluated only after a long period of time and after the insertion of a great number of a data. Another advantage that the portal adds to the platform is centralization. Having a head repository that keeps all training area data to the portal, we offer/ we present a unified system

Table 1. The importance factor of each environmental parameter according to the flight requirements

Areas clustering with SOM algorithm							
Altitude	Importance factors of each parameter						
	WBGT	O_3	CO	SO_2	NO_2	Pm	Altitude
Height<= 500 m	80		5	5	5	5	
500 m < Height <= 1000 m	15	5					80
Height >1000 m	5	5					90

that prevents duplication of records in the monitoring stations. All area attributes are kept inside one repository and training information about an area can be gathered from multiple resources independently, without confusing instances. The Preventive Portal user interfaces are implemented in simple HTML, in conjunction with ASP.NET Server Controls, and VB.NET programming for the site's dynamic parts.

The data from the environmental conditions are entered through an external subsystem, the Interface to an External Environmental Monitoring System which is used to obtain environmental measurements and import them to the platform through the communication module in order to form the profile of the training area over time and to evaluate how this may affect the aviator's performance. The communication model is also receiving training information from another subsystem, the Interface to an External Training Database, which provides the platform with medical and training data for an aviator in order to form his medical and training profile over time.

Overall, the Communication Module is the medium for transferring data between the subsystems and consists of a serial communication between the Configurator application and the WAD unit, communication of the sensors with the WAD unit, and a wireless communication consisting of GPRS connection between the WAD unit and the Gateway application.

In order to configure all the three submodules, the wireless communication with a remote Monitoring Station and the set-up of a training session the software component of the Wearable Platform, the WTA Suite, was used. The applications included in the software were the Training Assistant:, the Configurator, and the Gateway.

The Training Assistant is a .NET application allowing a user to remotely connect to a wearable device, to set all the acquisition session parameters, to start/stop an acquisition session, and to view and record all of the acquired data in realtime through a series of graphs and fields.

The Configurator is a .NET application suitable to configure a wearable device through a serial cable attached to a serial port, through which all communication and security related parameters of the wearable device can be entered. The WAD unit includes a subscriber identity module (SIM) card with activated general packet radio service (GPRS) communication subsystem, which is a connectivity solution based on Internet Protocols, that transmits the acquired measurements to a Web server, and a visualization subsystem which typically includes a personal digital assistant (PDA), which is a handheld device that combines computing, telephone/fax, Internet, and networking features and is used for viewing the results of the performed tests.

Because of the personal information transmitted through the communication module, the existence of a Security Module ensures the overall security within the platform and stores personal data of the user related to demographics, medical condition, and medical history. Security is implemented along the communication paths between servers and other devices. Servers security refers to the protection of devices hosting PREVENTIVE's applications, basic set-up security which refers to basic software configuration that is almost standard when implementing a security policy, and application security which refers to the security mechanisms employed in the application code or which are specific to the PREVENTIVE application apart from those applied to the communication channels.

In case of emergency situations, the advice or alert is communicated either to the aviator through optical or acoustic messages or to the supervising personnel, or both if requested. The form of the messages is simple and easily recognizable, without distracting the pilot from the engaged activity.

The completed system was tested in 20 private pilots of approximately 150 flying hours experience (16 men with a mean body weight of 78.6±9.6 kg, and 4 women with a mean body weight of 72±14.1 kg)

Table 2. The mean values of the parameters compared before and during flight

Measurements	Before Flight	During Flight
Systolic Blood Pressure (mmHg)	122.6 ± 10.6	139.4 ± 12.2
Diastolic Blood Pressure (mmHg)	72.0 ± 6.8	72.7 ± 6.7
Heart rate	75.3 ± 7.5	91.3 ± 10.1
Oxygen Saturation (SaO_2)	97.5 ± 1.0	87.7 ± 0.9

during a baseline session and during flight manoeuvres in an altitude of 0 – 10000 feet. Pilots mean age was 34.8±14.2 years for men and 37.5±11.7 years for women. They all signed an informed consent form. The airplane used was a Cessna 152 aerobatic. The flight profile was start up engine, taxiing, take off, climb, level flight, stall manoeuvre at 5.000 feet, an ascent to 10.000 feet with a negative g maneuver , and then a positive g maneuver to descend in forced landing with no touch procedure but go around for a final landing to the airport. The total session lasted 1 hour and 30 minutes. It was repeated once a week for 4 consecutive weeks.

The data flow was continuous with a delay of a few seconds. After each testing session, a measurements datasheet was filled by the medical doctor with the pilot's data. Questionnaires and interviews were also used for the system ergonomics, usability, friendliness, and so forth. Final comments and useful feedback was gathered from doctors, medical professionals, and pilots.

The first measurements were taken right after the vest was applied and connected to the server. Those measurements served as rest data. After the pilot was settled in the airplane the second measurement was taken as baseline data. Continuous measurements were taken during taxiing, take off, actual flight, and landing. From the actual measurements, generally we revealed differences in heart rate, oxygen saturation, and systolic blood pressure during hypoxia and stress in flight.

There was a considerable inter and intra subject variability in response to different parts of flight which imposes the need for a larger number of subjects. The interest at this stage was given from the scientists to the functionality of the system and the successful recording of the vital signs and performance of the pilots in various flying conditions, and their correlations with advanced algorithms in order to be clustered.

The advantages of the PREVENTIVE device are the monitoring of a wide range of physiological signs, coupled with performance indicators and on-site, environmental parameters, providing real-time, continuous monitoring and online feedback, supporting both individual pilots and groups of pilots, capable of being "packaged" in an unobtrusive, user-friendly wearable device.

The questions asked mainly referred to clinical functionality and more specifically to the operability of the preventive system in a realistic environment, which involves ease of use in a cockpit environment and evaluation of feedback methods. The clinical evaluation was also included in the questionnaire, referring to the evaluation and assessment of the diagnosis module, whether the system was functional, and finally the users were asked to provide comments and suggestions on issues related to usability as comfort, feedback, and incentive for use, overall functionality on best and worst things about the system. Doctors and instructors found both software and hardware of the system very useful and easy to operate with some suggestions for improvement. More specifically the general opinion was that the preventive system contributes to increase the benefit of pilots' health and potential risks during flying.

FUTURE TRENDS

Further investigation is necessary for the development of a wearable platform for real time pilots' health telemonitoring. There is a further plan to improve this product in order to resolve small problems that appeared during the study. One of the problems was the oximeter finger sensor which was annoying, especially during the maneuvers. It was placed to the left hand and attached with a tape. It was suggested that the sensor be replaced by an ear lobe sensor. Artifacts in ECG signal due to body movement, hairy chest, and body sweat seen in the majority of pilots during their first flight, were faced with new patches firmly attached to the skin (that was previously thoroughly cleaned and prepared by soft soap and alcoholic solution). There were suggestions from the users to make the wearable device lighter and smaller in size. In a future version of the product, it may be considered the use of other wireless communication means, memorization of larger amount of data on small modules, acquisition extended to other biomedical signals, implementation of a simple alerting system onboard, upgrades of the software applications, upgrades of the user interface on the WAD unit, and upgrades on the biomedical t-shirt, as well as new accelerometer modules capable of acquiring real time three-axial acceleration measurements.

CONCLUSION

Real time health telemonitoring is crucial for the early detection and prevention of conditions affecting aviators' vital signs and cognitive performance. PREVENTIVE system allows the on-board real time pilot's health telemonitoring, though further improvements are necessary.

KEY TERMS

Health Telemonitoring System: A system that gives the ability to monitor healthy individuals or chronically ill patients by distance.

Hypoxia: A pathological condition in which the body as a whole or region of the body is deprived of adequate oxygen supply.

Neural Network: A computing solution that is loosely modeled after cortical structures of the brain. It consists of interconnected processing elements called nodes or neurons that work together to produce an output function.

Personal Digital Assistant (PDA): Handheld computers that were originally designed as personal organizers, but which have become much more versatile over the years.

Portal: A site on the World Wide Web that typically provides personalized capabilities to its visitors, providing a pathway to other content.

Subscriber Identity Module (SIM) Card: A removable digital smart card that can store securely the key identifying a mobile phone service subscriber.

Workload: The relationship between a group or individual human operator and task demands.

Interactive Video Game-Based Tool for Dynamic Rehabilitation Movements

INTRODUCTION

In being seated, standing, and walking, many uncontrollable factors contribute to the degradation of our balance system. The maintenance of balance involves many essential sensory (visual, vestibular, and somatosensory) and motor processes. Each sensory input provides unique internal and external reference frame information to the central nervous system (CNS). The CNS interprets the sensory information, from which preplanned and/or preventative (feedforward controls) and corrective (feedback controls) actions can be taken and conflicting sensory information can be mediated (Peterka, 2002). In the absence of a sensory input, balance can still be maintained; however, the compensatory actions become larger and different balance strategies may be employed.

Serious problems facing older adults and many people with neurological disorders (e.g., stroke, traumatic head injuries, incomplete spinal cord injuries, Parkinson's, multiple sclerosis, diabetic peripheral neuropathy, and osteoarthritis) are balance impairment, mobility restriction, and falling (Gill et al., 2001; Harris, Eng, Marigold, Tokuno, & Louis, 2005). In these cases, even small disturbances may result in a fall and injuries are very likely to occur. This increased risk of falling combined with mobility limitations precipitates patient dependency in instrumental and basic activities of daily living; in turn, this results in reduced levels of physical activity.

Due to the many problems associated with reduced balance and mobility, providing an effective rehabilitation regime is essential to progress recovery from impairments and to help prevent further degradation of motor skills. Thus, we developed a tool which uses a computer-based gaming system to facilitate the rehabilitation process for restoration of weight bearing and balance control, for persons with neurological or musculo-skeletal disorders.

BACKGROUND

There are many aspects to consider when developing therapy programs for balance impairments and mobility limitations. Rehabilitation regimes often include cycling, standing activities, steppers, and over-ground and treadmill walking. Dependent on the type of disorder, these exercises will be performed at a given difficulty level (e.g., rate, tension, or incline settings) for a specified duration (Carr & Shepherd, 1998). The effectiveness of these regimes is proportional to the: (1) instensity and volume of training; and (2) task specificity of the exercises (Carr & Shepherd, 1998; Kwakkel, 2006). Constraint-induced movement therapy (CIMT) is a program that directly addresses these two issues (Marklund & Klassbo, 2006). For example, Marklund and Klassbo (2006) applied CIMT to chronic stroke patients, targeting the lower limb. The knee of the less-affected limb was restricted, requiring the tasks to be performed with the affected limb. Results demonstrated that the subjects showed improved dynamic balance and motor ability. While results of these studies are encouraging, repetitive, time-intensive therapies can become tedious, causing a lack of motivation; in turn, the patient may not complete the rehabilitation program. Thus, an important factor of a successful exercise program is maintaining the patient's interest and motivation (Betker, Szturm, Moussavi, & Nett, 2006; Cogan, Madey, Kaufman, Holmlund, & Bach-y-Rita, 1977).

One method to add motivation is through the selection of exercise tasks that are in themselves fun. For example, Tsang and Hui-Chan (2004) found that learning both Tai Chi and golf improved dynamic standing balance control. However, as these are complex tasks, not all patient populations will be capable of participating; thus, methods must be found which will allow even severely disabled individuals to play and be competitive. A promising example is the incorporation of biofeedback into virtual environments or video games, which are based on conventional therapies (Back-y-Rita et al., 2002; O'Connor et al., 2000; Sveistrup, 2004). Biofeedback augmented training presents a functional, task-oriented signal to the subject in a simplified format in order to enhance movement, weight bearing status, or balance awareness (De Weerdt & Harrison, 1985; Glanz, Klawansky, & Chalmers, 1997; Huang, Wolf, & He, 2006). Both virtual environments and video games cognitively engage the patient when they are training, in fun and challenging tasks; in turn, this can increase practice time, volume, and recovery (Bach-y-Rita et al., 2002; Cunningham & Krishack, 1999). In general, video games have been employed less than virtual environments, as the input systems are less developed (e.g., converting center of pressure signal into a mouse signal).

Another consideration is the availability of the system. In order for the tools to be available to a wide range of clinics (for example low and moderately funded clinics) and for at-home use, the equipment should be easy to use, should not incur a large cost, and should be portable. Another aspect, essential for at-home use, is a method to embed the assessment into the treatment regime. Embedded assessment will also remove performance pressure from the patient and automatically log their practice time and performance. Our interactive video game based tool, which adopts the aforementioned ideas, is described in the following section.

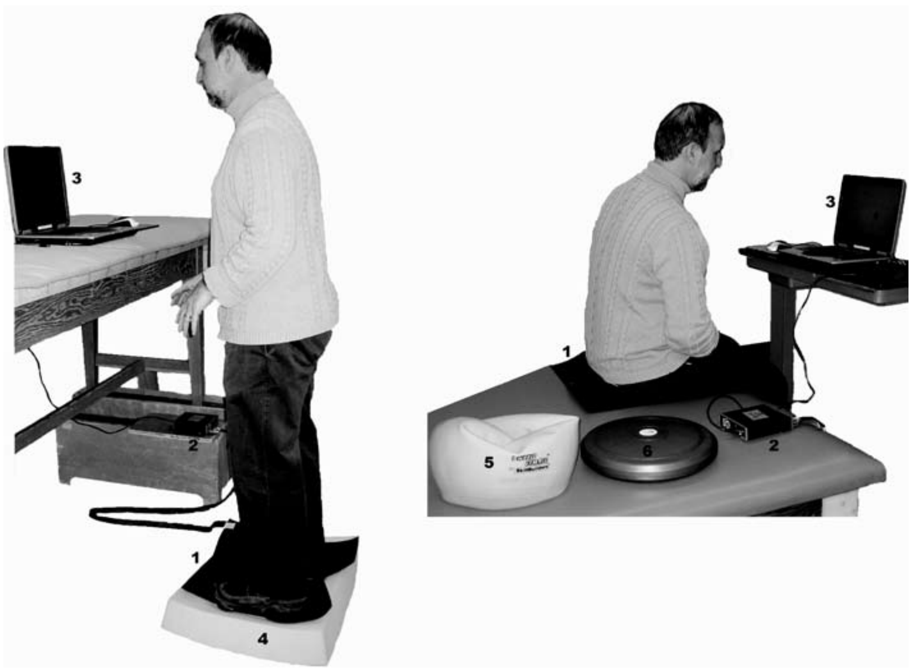
VIDEO GAME-BASED EXERCISE TOOL

Biofeedback Signal Selection and Presentation

The center of pressure (COP) was selected as the biofeedback signal and outcome measure, as it reflects global instabilities of both balance disturbances and reactions (Cheng, Wu, Liaw, Wong, & Tang, 2001; Lee, Wong, & Tang, 1996). For example, in Zambarbieri, Schmid, Magnaghi, Verni, Macellari, and Fadda (1998), insoles were used to determine the COP trajectory; a tactile stimulation device was then used to inform the subject when their COP fell outside an accepted normal range. The amount of load for each leg was displayed on an LED (Cheng et al., 2001; Lee et al., 1996), with a line indicating whether the weight was equally balanced or towards which leg the balance was skewed. In Femery, Moretto, Hespel, and Lensel (2001), a visual display of the footprint sensors was given, with a sound being played if the amount of pressure exceeded a predefined threshold. Similarly, in Urhan and Dincer (2001), the force at the heels was displayed on an LCD, with an audio tone indicating if the correct force is being applied. In Rougier (2004), anterior-posterior (AP) and medial-lateral (ML) displacements of the COP were displayed; different delays were also added to the display to determine their effects on balance. These functional associations between the COP and biofeedback strengthened and created the awareness of the tasks and performance levels, for both the patient and clinician.

As previously mentioned, the COP biofeedback is incorporated into video game-based exercises. A flexible pressure mat (Verg Inc., Winnipeg, MB, Canada) is used to determine the user's COP, which the video game software acquires from the pressure mat's interface box (Figure 1). The COP coordinate acts as the game cursor, emulating either a mouse (analog input) or a joystick (digital input). This is done by mapping the physical COP position signal into a corresponding on-screen pixel coordinate. In order to ensure that the games fully exercise the user's full range of movement, a method is provided to dynamically determine the user's movement range. First, the center point coordinate is determined, that is, the user's overall pressure center point. Next, the peaks of self-induced oscillatory movements are found. These ranges are then displayed on the screen, indicating the portion of the pressure mat which can be activated by the user. As appropriate, the maximal range values can be scaled by a percentage value and the center point coordinates may be offset. For example, if a user's stance was asymmetric, the center value could be offset to try and bias the pressure towards the paretic leg. In order to allow individuals with even small movement ranges to play, only the physical COP positions within the determined move-

Figure 1. System setup: (1) subject stands/sits on the pressure mat, which is connected via (2) the interface box to (3) the laptop. The laptop currently displays the game balloon burst. Example surfaces the pressure mat may be placed on top of are (4) a foam pad, (5) a PhysioGymnic ball, or (6) a SwisDisk



ment range are scaled to the on-screen COP values. As the physical positions are scaled, the resulting on-screen movements may appear jittery; thus, the on-screen coordinates can be smoothed over a given number of samples to reduce this effect.

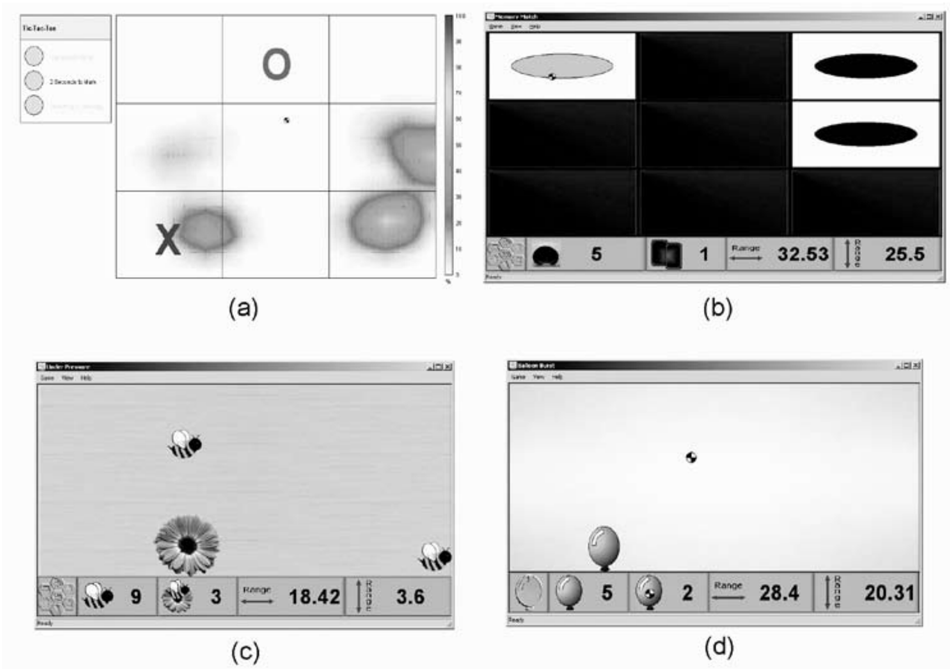
Video Game-Based Tool

The following paragraphs describe game play for each of the four games, Tic-Tac-Toe, Memory Match, Under Pressure, and Balloon Burst (Figure 2).

In Tic-Tac-Toe, the COP coordinate emulates a joystick controller. The screen is divided into nine squares and the user must shift their weight in order to move the on-screen COP cursor to the desired square. The goal is to create a line, with the computer serving as the opponent. The user is instructed what to do via a display panel: (Red) the user may rest, as it is the computer's turn; (Yellow) the user should move the on-screen COP cursor to the desired square they wish to occupy. The user has a limited number of seconds with which to mark the square. This value is configurable, allowing the user/physiotherapist to select the appropriate exercise protocol (e.g., can focus on quick or sustained movements). The remaining number of seconds the user has left to move the cursor is indicated to the user. A sound is played for each elapsed second while the user is selecting a square; and (Green) the square marked by the on-screen COP cursor is now marked. If the user selects a square that has previously been marked, the game returns to the Yellow state.

In Memory Match, the COP coordinate emulates a joystick controller. The screen is divided into squares and the user must shift their weight in order to move the on-screen COP cursor to the desired square. The goal is to select two matching cards from a 3-by-3 or 4-by-4 array of squares. Once the COP is held still in a square for a user selected duration, the card is revealed. The second card is then selected in a similar manner; if the cards match, they remain face up. This process is repeated until all of the card pairs are selected. The Memory Match display is similar to that for Tic-Tac-Toe, showing the number of pairs found and the indicators for what stage the game is at: (Red) the two selected cards are checked for a match. When a pair is found, a sound plays and the score is updated; (Yellow) the user should move the COP cursor to the card they would like to turn over. The number of seconds they have left to move the cursor is also indicated. A sound is played for each elapsed second while the user

Figure 2. Screenshots: (a) Tic-Tac-Toe: the user has 2 more seconds to select their square, as indicated by the yellow light; (b) Memory Match: the number of pairs found and the ranges are displayed; (c)Under Pressure: the total number of bees, number of bees caught, and ranges are displayed; and (d) Balloon Burst: the total number of balloons, number of balloons popped, and ranges are displayed



is selecting a card; and (Green) the card that the COP cursor is on is turned face up. If the user selects a card that has previously been selected, the game returns to the Yellow state. Difficulty levels are configurable through: (1) the number of seconds the user has to select a card; and (2) the number of cards displayed: 9 or 16. A cognitive difficulty is added when 9 squares is selected, as 1 card will be without a pair. When the number of cards is 16, the area the COP must be in to select the card is smaller and thus the COP movement must be more precise.

In Under Pressure, the COP coordinate emulates a mouse. The user shifts their weight to move a receptacle in order to catch an object, in one of three modes: (1) horizontal: the user must shift weight side to side; (2) vertical: the user must shift weight back and forth; and (3) both: the user is required to shift weight in all directions. Difficulty levels are configurable through: (1) the receptacle size; (2) the object speed; (3) the number of objects; and (4) the option of multiple objects appearing at a specified interval. The number of objects caught and the total number of objects that have appeared are displayed to the user. The game is over when the number of objects reaches a prespecified maximum number.

In Balloon Burst, the COP coordinate emulates a mouse. The user must shift weight in order to move the on-screen COP cursor over the balloon, with the goal being to pop the balloon. The stationary balloons appear at random or predetermined locations. Difficulty levels are configurable through: (1) the size of the balloon; (2) the duration of the balloon appearance; and (3) a rotation of the on-screen COP cursor, which forces the user to adapt a new motor program (Jones, Wessberg, & Vallbo, 2001). In addition, Balloon Burst includes an embedded assessment feature. When the game is played, an assessment file will be automatically generated and named using an ID and the date and time when the game was played. The assessment file contains the positions of the on-screen COP coordinate, the balloon coordinate, and whether the balloon was popped. From these values, the following parameters can be calculated: (1) the COP's trajectory profile; (2) the time taken to pop the balloon; (3) the trajectory of the COP cursor from the time the balloon appears until when the balloon is popped. This will provide an account of spatial accuracy, indicating endpoint undershoot error and its absolute magnitude and endpoint overshoot error and its absolute magnitude.

System Benefits

Our interactive video game-based exercises offer the following benefits: (1) the elicited COP movements are goal directed, to random or predetermined target locations; (2) the ability to map small movement ranges onto on-screen pixel locations, allowing even severely disabled individuals to play and be competitive; (3) user selected game speeds elicit various movement speeds; (4) configurable game difficulty levels; (5) the games require the users to multitask gaze control (head and smooth pursuit), attention to game play strategy (target motion and predicting final location), and balance control; (6) rewarding goal achievement and positive reinforcement; (7) using the flexible pressure mat allows the games to be performed on firm, fixed surfaces or compliant/irregular surfaces. This adds increased balance requirements as appropriate; and (8) embedded assessment with the game Balloon Burst. In addition, results from case studies with seated and standing subjects indicated that our video-game based exercises were enjoyable and improved participants fall rate performance post-therapy (Betker, Szturm, Moussavi, & Nett, 2006).

A similar approach was taken by NeuroCom NeuroGames, which provides three games that are used to enhance practice and motivation. The center of gravity (COG) is used as the control variable and is measured via a custom strain-gauge force plate. In comparison to NeuroGames, our system offer several advantages. First, any required item selection is done independently of external aids, through a configurable time duration parameter. In NeruoGames Puzzle Master and Solitaire, the user is required to use a mouse must be used to select the desired object. The use of a mouse is undesired; in some cases the user may not be able to operate a mouse; the operation of a mouse provides an unwanted additional tactile input, which could reduce sway variance (Pai & Patton, 1997). Second, the NeuroCom system has an increased cost compared to the pressure mat used in our system. Therefore, our system is available to a wider range of clinics and for at-home use. Last, the pressure mat used in our system is flexible, allowing it to be placed on different surfaces, characteristic of outdoor conditions.

FUTURE TRENDS

Primary trends in this area concern successful rehabilitation program completion. There are two main ways to achieve this: (1) further motivation by increasing the number and variety of games available to the user. One way to do this is through the development of an input device that will allow the COP signal from the pressure mat to play commercially available video games. In turn, this will keep the users motivated and interested and eliminate the need to develop new games; and (2) the progression of the exercise regime to an at-home program. The ability to customize our system to each subject's needs, the system's portability, and the embedded assessment file affords its use in monitored at-home programs. Additional work is required to communicate the assessment files to the clinician and allow the clinician to reconfigure the patient's game settings.

CONCLUSION

In this research, the need for and requirements of an effective rehabilitation regime were addressed. Of primary importance was motivating the patient to perform their exercises, using methods which are task-specific. Based on these requirements, an interactive video game based tool was developed to aid individuals with balance disorders and motivate them to complete their exercise program.

KEY TERMS

Balance: The maintenance total body equilibrium.

Biofeedback: A biological signal which is recorded and presented to a person in real-time. In most cases, a visual or auditory feedback representation of the input signal intensity is used.

Center of Pressure: The directional sum of the vertical load exerted by the body.

Exercise: An activity performed in order to increase motor control.

Pressure Mat: A tool used to measure the load exerted by an object.

Rehabilitation: A therapy program used to improve motor control and balance.

Video Games: A game which is played on a personal computer.

Issues, Claims, and Concerns of Different Stakeholders of Healthcare Systems

INTRODUCTION

Adopting a holistic sociotechnical perspective, healthcare systems do not merely exhibit complex structures and functionalities but are also affected by the differing expectations, claims, and concerns of the systems' stakeholders (Guba & Lincoln, 1989; Haux, Winter, & Ammenwerth, 2004). Furthermore, the issues addressed at healthcare systems are not limited to the concerns and requirements of health service providers, whose primary and most fundamental concerns in general terms represent the assurance of their own economic well-being and ability to proactively operate as well as the development of sustainable strategies in order to realize their own interests whatever they may be (Carsten, Hankeln, & Lohmann, 2004; Kappler, 1994). Furthermore, the objectives of other health systems stakeholders such as hospital operators and financiers as well as (health) politicians, which may well be in contradiction to the objectives of mere health service providers, have to be incorporated when systematically analyzing healthcare systems (Horev & Babad, 2005; Peltier, Kleimenhagen, & Neidu, 1996; Staudinger, 2004a).

If one now considers the capability of various stakeholders to implement their varying concerns, one may first assume that the political sphere in conjunction with hospital as well as healthcare operators and financiers has exclusive rights on organizing the system because of the common aptitude for developing and executing norms and directives in a way that allows the system's functionality to correspond to their own objectives. However, it has to be noted that in the case of health service providers delivering respective services within these system specifications, the subsequent adoption mechanism may have a reversing effect as compared to the original intentions and objectives of, for example, the legislators (Lim, Lee, & Taehun, 2005; Puxty, 1994).

In this context of potentially competing (and even conflicting) stakeholders' interests, the quality and availability of process data is of particular importance for all affected system participants. When considering the questions of system transparency and functionality, process data which are valid and, more importantly, able to be evaluated, provide the basis for judging whether certain system objectives are actually able to be implemented and have been implemented and whether deviations have taken place or not . However, as the process data is again acquired by different stakeholders themselves, conflicts may arise with regard to different perceived levels of process support and data management may well become an essential part of the conflict due to different data management objectives of the system's participants (Lim et al., 2005; Power, 1999).

BACKGROUND

The challenges involved with the potential conflict of competing issues, claims, and concerns of healthcare systems' stakeholders are currently being analyzed and observed on an international scale with a substantial amount of research focusing on the concept that participative models contribute to the solving of this conflict (Byrne & Sahay, 2007; Chaulagai et al., 2005). However, opposing this popular presumption of participative models are the health service providers' fundamental interests in being involved in the—particularly financial—health resource allocation processes in a manner which is conducive to allowing the greatest range of possible actions as well as reactive capability for themselves (Robinson, 2000; Robinson, 2004).

Playing an important role here is the fact that it is not only the health service providers, operators, financiers, and politicians striving for the realization of their concerns. Patients as well as tax payers also have an important say in this potential conflict and wish to incorporate their interests, too. Moreover, conflict-laden moments may also take place within different groups of stakeholders themselves. If one regards the general public, for instance, one may well realize competing multistakeholder interests when taking the stance of tax payers, where people may be less inclined to pay higher taxes on the one hand, and considering the interests of tax paying patients, who expect an adequately financed healthcare system, on the other (Staudinger, 2004a).

Hence, this resource-based approach to the implementation and evaluation of healthcare systems outlined above may serve as an appropriate tool for maintaining an overview of the development of the cost-service ratio (Webster, 2006; WHO, 2000). This approach, however, appears to be fairly inadequate because of two reasons: First, and more generally, healthcare systems do not necessarily adhere to market economy criteria. Second, the resource-based approach only considers non-monetary phenomena such as the local provision of healthcare structures when actual services are provided at this level and parameters such as service-quality ratio as well as the necessity for the provision of certain medical services can be taken into account (Berger, Honig, & Spatz, 2006). This problem of incorporating relevant phenomena is more intensified by the fact that, through the formation of (virtual) medical networks, the analysis of the individual health service providers from a strategic perspective is no longer sufficient (Waitzkin, Jasso-Aguilar, Landwehr, & Mountain, 2005).

Beyond pure cost considerations, analyses of the effectiveness of medical facilities and national healthcare systems therefore have to be carried out on the basis of input and output analyses, quality analyses , and associated process analyses. This in turn has to be done on the basis of process data which are (1) comparable and hence able to be analyzed on the one hand and (2) represent an integrative part of data management within the healthcare system on the other (Kaushal, Bates, Poon, Jha, & Blumenthal, 2005).

The challenges involved with the incorporation (and sometimes also unilateral resolution) of different stakeholders' issues, claims, and concerns into health systems shall be presented using the example of healthcare reforms in Austria.

ISSUES, CLAIMS, AND CONCERNS OF DIFFERENT STAKEHOLDERS OF HEALTHCARE SYSTEMS

Trade-Offs between Interdependent Stakeholders' Objectives in Austria

The Austrian healthcare systems can be first and foremost characterized by its decentralized and mostly federal nature in terms of decision-making as well as service-provision (Hofmarcher & Rack, 2006). As in other social insurance countries, virtually the entire national population is obliged to be health insured (save for a few exceptions such as soldiers, claimers of social benefits or prisoners) and people are bound by legislation to membership of a particular insurance association depending on the individual profession. The financing of hospitals and doctors, again, is in principle thought to be provided by social insurance associations too, even though the members' insurance premiums are not sufficient to finance the entire system. For this reason, federal government taxes are also incorporated in order to maintain a stable system (Hofmarcher & Rack, 2006).

In principle, each insured person is able to freely choose his or her hospital and physicians irrespective of whether these healthcare providers have contracts with the relevant insurance association or not. Financial compensation between different (in particular federal) insurance associations is only granted up to a certain extent, and in the past this has led to strong competition between the healthcare providers—and also between the insurance associations themselves (Hofmarcher & Rack, 2006).

Currently, the Austrian healthcare system is still lacking a reasonable amount of data exchange between healthcare providers as well as financiers, and neither central patient records nor process requirements or instruments for quality assurance exist (Pfeifer, 2001). Well aware of these shortcomings, the Austrian government had already decided upon a multilevel reform concept in 1997 in order to ensure the financing of healthcare and maintain cost-service transparency. Within this concept of reform, special attention was paid to the visionary objective of establishing a national network of communicating healthcare institutions for decentralized regional service provision. When devising the healthcare reform of 2005, this objective of networking healthcare providers of all different levels was determined in more precise terms and finally led to the concept of regional hospitals representing the vital nodal points of the intended networks (BMGF, 2006; Hofmarcher, 2006).

An important requirement in association with local (and also federal) integrative care structures featuring a hierarchical differentiation in terms of its functionalities is the challenge of reaching an agreement upon a common and minimally realizable set of objectives. Put in other words, by negatively limiting the task, healthcare systems planning consequently has to exclude contradictory interests of different stakeholders due to their inhibitory nature in order to guarantee a goal-orientated interdisciplinary service provision within a given care structure. (Bradley, Williams, Brownsell, & Levy, 2002; Ulrich & Wille, 1997).

As in other social insurance countries, the provision of healthcare services is regarded as an essentially public task in Austria, which is for the sphere of public healthcare subject to the principle of central healthcare planning and which is, at least in theory, free of market economy mechanisms. This implies that the organizational structure of public healthcare is based on the premise that a particular demand for healthcare provision has to be satisfied by a particular range of service offers and over- as well as under-capacities cannot or should not arise in the first place (Republik Österreich, 1990; Rosenbrock & Gerlinger, 2004).

However, this state-directed and essentially planned economic approach to organizing and maintaining the national public healthcare provision is prone to be challenged by a hardly controllable increase of healthcare institutions and providers of all levels which attempt to gain competitive advantages in the "health market" according to market economic principles. In the context of hospital and health systems planning, health politicians as well as civil servants of the health departments first have to consider that a multitude of adjustable and controllable elements of health systems is most commonly opposes the same multitude of freely operating health services providers. Moreover, the group of health system financiers is not congruent with the one of healthcare providers, which in turn are not identical to those politically responsible (Hofmarcher, 2006; Staudinger, 2004a).

In order to be able to correctly appraise and understand this basic framework of potential interests which interferes with healthcare planning, it appears rational to make the effort to re-examine what controls the actions and reactions of the system stakeholders on a more abstract level (Guba & Lincoln, 1989; Horev & Babad, 2005).

In Austrian healthcare, one can clearly identify a conflict of interest between hospitals providing health services on the one hand and the Federal Government, the *Länder,* and social insurance institutions representing interest groups involved in health politics and financing on the other (Staudinger, 2001). Here two different levels of conflict can be distinguished: service and cost (Table 1).

Regarding the service-level, the Federal Govern-

Table 1. Focuses of interest

Level of conflict	Federal Government, *Länder*, and Social Insurance Institutions	Hospitals
Service-level	<u>service optimization</u>	<u>service maximization</u>
	subsidiary principle	capacity principle
	appropriateness principle	availability principle
	minimal principle	optimal principle
Cost-level	<u>cost minimization</u>	<u>cost optimization</u>
	principle of structural diversification	principle of structural monopolization
	principle of statics	principle of dynamics

ment, the *Länder,* and social insurance institutions strive for the optimization of healthcare services in the sense of each individual patient receiving those healthcare services which are similarly optimal in terms of medical progress as well as business aspects. Hospitals and other healthcare providers are likely to take a different position in this respect as they are prone to incentives leading to the quantitative maximization of healthcare services provided. An example of this may be that in case of doubt, a patient will be taken in as an in-patient as long as there are beds free, even if out-patient treatment could well be sufficient under certain circumstances (Laimböck, 2001).

Moreover, the tenet of service optimization pursued by the Federal Government, the *Länder,* and social insurance institutions can be characterized by three phenomena, which are again opposed by three corresponding principles of healthcare providers seeking for service maximization:

1. Healthcare politics and financiers promote the subsidiarity principle, that is, the provision of healthcare should take place where relevant services can be provided at their lowest level possible. Hospitals, on the other hand, assume the capacity principle. This means that it should not only be the subsidiary institutions who provide care, but also all those who have the capacity to provide it. Illustrating an example, one could think of university hospitals which provide simple medical care when there is capacity for it, even if this care could be provided just as well in other facilities (as it is the case in Austria).
2. The Federal Government, the *Länder,* and social insurance institutions have an incentive to pursue the appropriateness principle. This means that the range of healthcare services provided to a certain patient is limited by the scale of services which are thought to be appropriate in order to achieve a certain medical outcome. Opposing this, hospitals apply the availability principle in the sense that it is not necessarily the reasonable and moderate range of services which is provided, but the services which are available (Ferguson & Smith, 1997).
3. In hospitals, it is the optimal principle which is applied rather than the minimal principle when it comes to actual service provision. This means that from a certain range of available healthcare services, all those will be chosen by hospital physicians which appear optimal for both the patient and the health services provider. Contrasting this optimal principle is the minimal principle which is endorsed by the Federal Government, the *Länder,* and social insurance institutions. Applying this minimal principle to the same variety of possible services available, only those services should be chosen whereby the desired outcome can just about be achieved with the least effort possible. Putting the optimal principle pursued by hospitals into practice, this may mean that if there is available capacity for an exact diagnostic examination using a computer tomography, it will be chosen instead of a conventional x-ray. Applied in a hospital laboratory context, all manner of analyses will be carried out as far as possible, and not just those deemed necessary for the case in hand.

Similar conflicts can be observed on the cost-level, too (Stepan, 1997): On the one hand, the Federal Government, the *Länder,* and social insurance institutions strive for cost minimization in order to achieve the lowest costs possible for the provision of a particular service. Hospitals, on the other hand, are rather inclined to the principle of cost optimization in a sense that for the maximal range and scope of services which the hospitals seek to provide costs should be optimized.

The principle of structural diversification is then endorsed by health politics and financiers in order to realize the overall objective of cost minimization. Put into practice, this principle requires that service-provision structures have to follow the according cost structures in a treatment chain. Hospitals, however, perceive this issue differently by pursuing the principle of structural monopolization which implicates the organization and management of institutional structures in such a manner that cost advantages are achieved not through diversification, but through the portfolio of services provided within a certain unit. This means that certain departments in hospitals should offer the most extensive care possible, and only within the departments themselves is it decided which unit actually provides which services. The conflicts triggered by the question of the differentiation of healthcare structures can be clearly observed in the current discussion about the spin-off of hospitals' out-patient departments in Austria, where redundant structures are still predominant with the same services provided to out-patients by hospital departments on the one hand and by physicians in private practice on the other (Fiedler, 1998).

Different objectives of hospitals as well as health politics and financiers can be moreover identified on the service-level when analyzing the principle of statics vs. the principle of dynamics. The former principle pursued by the Federal Government, the *Länder,* and social insurance institutions means that there should be as few changes as possible, as a low quota of change is commonly associated with a modest, if any, cost increase. In contrast to this, hospitals are rather inclined to apply the principle of dynamics. Pursuing this approach, healthcare providers attempt to promote and bring in as much innovation into the individual areas of healthcare as possible so that a maximization of services can be achieved through competitive advantages whilst achieving cost optimization at the same time.

Referring back to the original situation, a reciprocity of objectives can be identified between the service-level and cost-level in a way that the optimization of services and optimization of cost as well as the principles of service maximization and cost minimization are thought to behave in a reciprocal manner.

These conflicts of interests between healthcare systems operators and financiers on the one hand and hospitals on the other, and consequently between the different hospitals themselves and at the boundaries to practicing physicians' service portfolios of the private sector too, lead to additional costs as well as other financial burdens. However, it has to be taken into account that along with the expansion of costs over the last few decades, a substantial increase in the amount as well as quality of healthcare services provided has taken place, which may well be regarded as a predominantly positive occurrence (Becker & Beck, 1999).

If one now wants to assess this system of potentially competing objectives in association with a decentralized geographic service area according to the principles of integrated healthcare services provision, three systematic conditions have to be restored in order to resolve this conflict of interests (Staudinger, 2004b):

1. A sufficient convergence between the issues, claims, and objectives of all stakeholders of the healthcare system has to be created paying particular attention to higher priority objectives (Cuadras-Morató, Pinto-Prades, & Abellán-Perpiñán, 2001).
2. An up-to-date range of healthcare services provided has to be guaranteed for the entire population.
3. Healthcare structures which allow for a further sophistication of services have to be established.

The convergence of stakeholders' objectives was, for the most part, able to be achieved in Austria through the implementation of the 1997 structural reform and its accompanying measures for the in-patient sector (Laimböck, 2000). Taking into consideration the divergent objectives which were put forward by various interest groups when devising this reform, it appears to be valuable to take a closer look at the regulatory instruments with which the Federal Government and the *Länder* attempted to bring the objectives of hospitals as well as health system operators and financiers onto a common basis. As shown in Table 2, this attempt on establishing a convergence of objectives through legislation can indeed be described as a stipulated structural compliance from the hospitals towards the objectives of healthcare politics and financiers.

Considering the weighting of services provided and the evaluation of performance-oriented diagnosis-related case groups (PODRG) points it has to be noted, though, that these mechanisms do not necessarily have the desired control effect. Rather, healthcare providers, as seen in Austrian practices so far, still strive for service maximization which in turn leads to imbalances in the system.

Service optimization vs. service maximization can be attained through an obligatory national health plan based either on service provision planning or on the more traditional planning of locations and specialties offered (Hofmarcher, 2006). By the means of promoting the expansion of the extramural sector, it is intended to strengthen the subsidiarity principle. Hospital funding via PODRG points has been introduced in order to transparently record and demonstrate the appropriateness of medical services provided, and the conducted weighting of the services and LDF points is thought to support the implementation of the minimal principle when it comes to the actual service provision (Zweifel, 1997).

The most considerable cut on the cost-level represents the introduction of capped hospital budgets, as hospitals are now actively encouraged to shift their strategic focus from cost optimization to cost minimization. Moreover, the measures taken here encompass the

Table 2. Means of convergence

Federal Government, *Länder*, and Social Insurance Institutions	Hospitals	**Means of Convergence**
service optimization	service maximization	**obligatory hospitals and major equipment plan**
subsidiary principle	capacity principle	**expansion of extramural service provision**
appropriateness principle	availability principle	**PODRG points***
minimal principle	optimal principle through LDF points	**weighting of services provided and PODRG points**
cost minimization	cost optimization	**capping of budgets**
principle of structural diversification	principle of structural monopolization	**revenue-oriented expenditure policy**
principle of statics	principle of dynamics	**additional specific funding of university teaching hospitals**
* PODRG: Performance-orientated diagnosis-related case groups. The number of points assigned to a PODRG determines the PODRG flat rate (Hormarcher & Rack, 2006).		

implementation of revenue-oriented expenditure policy (administered by so-called *Länder*-funds) as well as the introduction of additional controlled financing for the university teaching hospitals in order to curb the system immanent principle of dynamics.

Functionality Requirements of an HIS Caused by Trade-Offs between Stakeholders' Objectives

The political requirements intended to serve as means of convergence in the conflict of interest outlined above (see Table 2) force healthcare providers and hospitals in particular to redefine their own information management, hospital information systems (HIS) and logistics in order to prevent redundancies as far as possible (Kaushal et al., 2005). System adapted behavior does not allow for in-patients remaining too long in hospital due to inadequate process support of in-house information management or a diagnostic laboratory working too slowly in order to merely attain an unambiguous diagnosis.

Consequently, the standardization of medical services and in particular processes has become more significant over the last decade and this in turn has resulted in two further consequences: (1) Whilst information management played a rather insignificant role in Austrian hospitals up to the implementation of the 1997 healthcare reform due to the objective of enhanced transparency and comparability of institutions being of no systematic importance, HIS today play an essential role in the (re-)engineering and management of hospital processes. (2) The integration of extramural facilities represents another important consequence, as strategic planning within hospital management appears to be indispensable in order to achieve continuity and smooth patient pathways within the treatment chain (Staudinger, 2004b).

The primary requirement of an HIS, caused by the consequences of system adapted behavior outlined above, is the capability to serve as a nodal point for different healthcare providers in order to ensure their integration into healthcare networks (Montreuil & Garon, 2005). Here, one has to consider that the different healthcare providers in question have to be integrated along treatment chains as a whole (Kaushal et al., 2005), but may well feature different typologies and profiles, which again plays a vital role when establishing networks and even when just expanding communication structures.

The bases of each HIS are patient and treatment data in context with process management and control, which again have to reflect the different typologies of healthcare providers in more than just one sense:

1. First the question of the validity of the data has to be considered in order to figure out whether the diagnostic findings of one particular healthcare provider in the context of a treatment process will be able to be taken on by the subsequent treatment units without further examination. Criteria of common data security have to be de-

cided upon and implemented in order to prevent time-consuming multiple examinations, which lead to an unnecessary increase in cost. Requirements of plausibility examinations are therefore of particular importance when implementing and operating integrative HIS.

2. The question of the availability of data and data access also needs to be addressed in context with different types of healthcare providers participating in a particular treatment chain. According to the corresponding norms of the Austrian Data Protection Act of 2000, within the context of an integrated chain of treatment only those data sets may be made available to the service-providing physician or health professional which are sufficient to carry out a particular treatment. All other patient data are subject to data protection (Schwamberger, 1999).
3. This fact consequently leads to the next challenge of data management addressing the question of which minimum data sets have to be available to all participating facilities in order to cover both the legal and medical requirements. Simultaneously, it has to be considered that the financiers and political system operators both demand feasible decision transparency within the treatment process also in order to able to verify whether financial and political systems requirements are translated into practice by healthcare providers.

Summing up, this means that within an HIS, a particularly defined and differentiated authorization system has to be established for data access and at the same time a consensus about a minimum data setting encompassing all healthcare providers as well as processes has to be achieved or maintained. Furthermore, additional authorizations for the entire treatment chain have to be realized for the specially developed processes which reflect predefined treatment paths (Haak et al., 2002).

Another vital requirement of an HIS represents the functionality of integrative resource planning and control in a way that medical healthcare provision can be planned throughout the entire treatment chain and that individual services can be incorporated into the total planning irrespective of the actual provider (Bradley et al., 2002). The importance of this capacity is in particular due to the fact that any HIS has to be combinable with the structural planning of geographic service areas as well as with the accounting system demanded by the finance mechanism.

Apart from these institutional requirements, the patient also has to be incorporated into the entire system too, as it is the patient who has to give consent to all services provided throughout the treatment chain and hence is in need of information about the whole devised treatment process. Moreover, the patient taking the role of an independent and responsible partner in the system still has the choice of which healthcare provider he or she charges a particular healthcare service with, irrespective of a predefined treatment chain. If the patient now decides not to stick to the predefined treatment path, data management and HIS then face the challenge of allowing for customized processes to be included (Leonard, 2004).

The basic challenge outlined above, namely the solution of the structural and institutional conflict between different stakeholders, can be addressed by the implementation of integrative HIS, however, to a rather limited extent. On the one hand, medical processes have to be supported and structural requirements have to be implemented as specified above. On the other, it is in the objective of healthcare providers—even if they are part of regional service networks—to define isolated positions and aims and make them the basis of their future operations.

An efficient HIS now shows the aptitude to indirectly mitigate the conflict within the context of the described structural conditions as it substantially contributes to the cost-effectiveness of the whole range of processes and makes a wider database available to stakeholders, which enables quicker decisions and more accurate planning. Moreover, this common database bears the advantage for all system participants of a comparability of different means of healthcare service provision, which in turn allows for a clearer definition of the scope of operations and reforms and therefore also for the increase of one's own efficiency.

FUTURE TRENDS

The different issues, claims, and objectives of healthcare system stakeholders such as patients, healthcare providers, and financiers as well as political decision-makers are likely to prevail in the future and can be expected to still have an impact, even on the level of individual medical decision-making. The current trend of merging healthcare providers into networks on the basis of treatment paths and geographic service areas in the context with a uniform financial system is able to mitigate this problematic of conflict of interests, but not able to ultimately solve it. As far as data management is concerned, one therefore has to take into consideration that different system participants may also have different requirements of an HIS and of integrated data management, and that at the same time, IT-management finds itself right in the middle of this conflict (Staudinger, 2004b).

One may therefore well assume that due to changed structures of healthcare service provision, the requirements on data management will increase in various ways: on the one hand, technical problems such as the ability of different HIS to correspond and the question of data quality and process support have to be addressed. On the other hand, the systemic specifications of data management are also likely to increase, especially when these data form the basis for healthcare system planning or medical controlling. It is here in particular that there is the opportunity for information technology to support the change processes in healthcare institutions and facilities so that individual interests can be suppressed or modified to conform to higher level objectives. This in particular concerns the cost-cutting and service increasing tasks such as knowledge management, quality assurance in the medical sector, the integration of patients into the information system, and the combining of medical healthcare providers with commercial systems as well as in the area of planning and resource management (Hain, 2002; Power, 1999; Smirnov, Pashkin, Chilov, Leveshova, & Krizhanivsky, 2005). In all of these areas, a win-win situation can be brought about through information management which corresponds to the general objectives of all system stakeholders.

CONCLUSION

Healthcare systems seen on an international level are complex structures which are influenced by the differing objectives of system stakeholders. In contrast to pure market economy systems whereby the balance of interests is maintained (in theory) through market mechanisms, healthcare systems define themselves as systems which are planned and controlled from the supply-side even though being ultimately demand-induced. In these systems legislators and financiers seek to gain influence on decision processes, system profiles and system suppliers by the active management of the general regulatory, political and financial framework.

Using the example of Austrian healthcare reforms of the last decade, different operating principles and objectives of healthcare system stakeholders were portrayed in detail. Through the implementation of a performance-orientated financing system as well as through elements of central planning and specific monetary incentives, the Federal Government, the *Länder,* and social insurance institutions attempt to accomplish their objectives of subsidiary healthcare provision, cost orientation, and transparent decision making. On the other hand, healthcare providers and, in particular, hospitals, attempt to enforce their own objectives, which diverge with the above mentioned interests of health politics and financiers. The interest of healthcare providers encompass the provision of a maximal range of services for patients, the retention of a service-induced profile and maximal integration of medical advances in treatment paths whilst incorporating maximum facility independence. Through the mechanisms implemented by the healthcare reforms, healthcare providers nowadays are forced into stronger networking, transparency, and standardization, without having to completely give up their own objectives.

The new mechanisms of healthcare finance as well as planning have then brought new challenges for IT management, particularly in hospitals. A stronger rate of HIS implementation could be observed in first stage and consequently the networking of different healthcare providers became a main challenge for data management. Of particular importance here was the support in the area of medical process standardization as well as the question of communication ability between the facilities. In association with these requirements was the question of data protection and quality assurance of data as well as the definition of a minimum data set.

Only once these requirements have been met in a sustainable manner will an integrative information system be available to the healthcare providers as well as politics and financiers, which will at least partially be able to contribute to the solution of the conflict of interests through the bringing about of win-win situations, particularly in the areas of resource management, cost transparency, and process security.

KEY TERMS

Healthcare Financier: Persons or organizations funding the provision of healthcare services.

Healthcare Network: A (regional) group of healthcare providers offering differentiated ranges of services in a coordinated manner.

Healthcare Provider: Persons or organizations providing health services to third persons and, in particular, patients.

Healthcare System: The system assigned with the preservation of mental and physical health through services offered by physicians and other health professionals.

Medical Treatment Chain: The organized sequence of healthcare services for a certain indication.

Patient Pathway: The sum and sequence of healthcare services offered to a certain patient by various healthcare providers in order to achieve a certain medical outcome.

Stakeholder: A person or organization having a genuine concern or interest in a certain system or entity.

INTRODUCTION

Today, medical infrastructures are subject to organisational change the world over. The reasons for this are manifold. On the one hand, it can be observed through scientific innovation and gaining of knowledge that a more in-depth specialisation is taking place, which means that medical healthcare providers are able to offer in-depth knowledge in narrowing fields. On the other hand, through increased process orientation of treatment pathways for patients, the necessity for superior organisational principles has been established. This effects that organisational cooperation models have to be found, which integrate singular specialised institutions into an organisational whole, which then employ integrative processes, information, and quality requirements.

Such organisational structures can be set up in real structures by the spatial accumulation of scattered service units, so that centralised medical centres establish. Alternatively, organisational and technical integration may substitute the physical integration. The individual medical service units stay dislocated, but appear as a virtual medical centre or as specialised medical networks having a clearly defined profile.

The management of the information technology in a virtual medical service centre is subject to different requirements than the IT-management of a hospital resembling more a closed shop.

Building a virtual centre calls for performance of an open shop principle, because the entire treatment chain cannot be mapped within one single institution, but requires integrated cooperation in order to manage a patient's clinical pathway.

Not only the spatial displacement, but also the unavoidable higher process orientation within a virtual cooperation deserves particular consideration.

Additionally, the information management is challenged by the fact that the provision of relevant information in standardised form is an indispensable element of a virtual centre. In this context, the question about potential structural assembling, and organisational principles and elements of virtual medical service centres has to be answered in order to conclude on the basic requirements of data management and the appropriate solution approaches.

This shall be presented partly using the example of the virtual oncological medical centre in Tyrol.

BACKGROUND

The question about the role of medical informatics in modified organisational structures has been frequently posed in the context of medical service supply (Power, 1999). In particular, an integrative IT-policy has considerably increased in importance through the standardisation of patient pathways, introduction of evidence-based medicine, standards, guidelines, and directives, and therefore, the inevitable necessary cooperation of healthcare providers. Especially in the earlier stages, exemplary models were introduced which were supposed to make the changed requirements more manageable (Ölvingson, Hallberg, Timpka, & Lindqvist, 2002). This, however, does not only affect the cooperation between healthcare providers, but also the technical-based integration of patient data, as well as the extensive bonding of other persons and units involved with the treatment chain. Particularly opened by the evolution of telemedicine, concepts are currently being developed in this area (Bradley, Williams, Brownsell, & Levi, 2002), which integrate technical possibilities such as virtual reality into medical treatment processes (Burdea, 2003).

The first and pivotal approaches of information technology in medical networks primarily concentrate on the field of electronic patient record. Correlating to this, scientifically evaluated projects and models introduced criteria which have to be considered by the IT-management in medical networks (Van den Haak, Mludek, Wolff, Bützlebruck, Oetzel, & Zierhut, 2002). It can therefore be adhered to, that through this structural development of the various sectors of the health system which are geared towards integrated care, medical informatics becomes more complex, too. Increased dialogue structures, principles of the standardisation of terminology, data exchange, and the comparability of data, and the resulting necessary transparency of medical healthcare providers have become subject matters of discussion and research (Coddington, 1997; Francis & Hart, 1998).

Beside the altered basic conditions, it can be observed that the aspired construct of "patient oriented health networks" actually take shape by the affiliation of medical disciplines towards patient oriented service centres, and hence in practice, forces a complex IT-management (Montreuil & Garon, 2005).

Linked to this is not only the question of the requirements and the practical implementation of such systems (Day & Norris, 2006), but also the investigation about barriers and restraints of a successful realisation of new concepts (Cashen, Dykes, & Gerber, 2004). At least the differing intentions and interests of single system partners (e.g., administration) also play an important role (Hassan, 2005), as do the requirements of health politics (Kaushal, Bates, Poon, Ashish, & Blumenthal, 2005). Dealing with the subject of virtual medical centres, science particularly has to focus on standardising the processes in the networks, and also on the quality of data (Hain, 2002; Stoop & Berg, 2003).

IT-BASED VIRTUAL MEDICAL CENTRES AND STRUCTURES

The Model of the Virtual Medical Centre

Based on the newer findings about organisational concepts and structures in medicine, Tyrolean (Austria) health politics initiated a project in 2000, whereby it was attempted to integrate oncological healthcare providers in the province of Tyrol into a virtual network. The network was supposed to be implemented on the basis of uniform medical standards coupled in clearly defined treatment paths. The participation in the virtual medical centre was voluntary, but all participants had to comply with the commonly derived directives. Simultaneously, the basic organisational principles of the virtual oncology centre were developed in order to be able to work out the requirements for the subsystems (e.g., the data management).

The basic principle of the virtual medical centre in Tyrol can be described through structural tripartism into strategical, tactical, and operative level. On a processual level, this principle can be best compared with a cybernetic model, whereby the learning ability of the system is centrally controlled and ensured by the interaction of all system participants.

A medical board is operating on the strategic central level, its main task being that of serving as a steering board for the entire medical centre. Its particular function is to validate directives and processes, as well as to adjust system parameters in the area of quality assurance. Complimentary, those carriers who additionally to medical competency have the key competencies for steering the entire system are part of the board (e.g., clinic management executives).

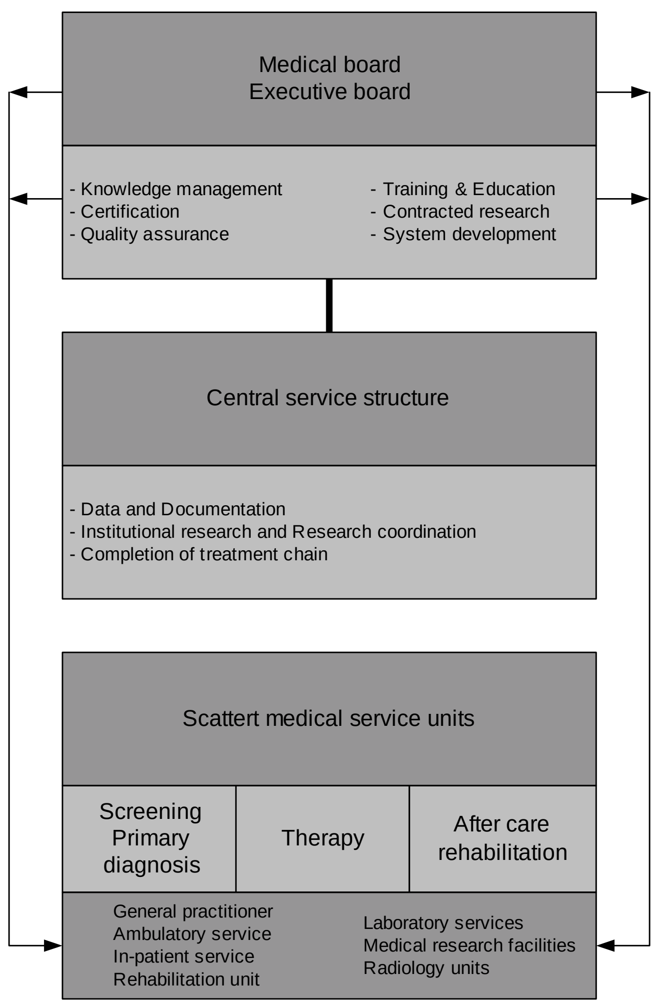
As contract research and pursuit of research projects are related on the board level, an "Open Shop" solution for communication instruments has to be provided (Ohly, 1995). For a consequence, communication and interaction structures have to be connected beyond the virtual medical centre. Pipelines to supraregionally and internationally active healthcare and research centres are provided, as well as structural ties to industrial partners involved with research.

As a tactical element, the central service structure particularly serves data and patient management, and has to include all documentation systems which are of superior importance. Irrespective of this, a regionally spanning consensus still has to be reached about documentation criteria—of patient files for example (Leiner, Gaus & Haux, 1995). This appears feasible if well-described and tested models are employed (Yamasaki & Satomura, 2001). Furthermore, own research projects as well as institutional research is steered and coordinated on the central service level. Treatment structures are only to be maintained up to a certain degree as gaps in the treatment chain within the framework of decentralised efficiency structures have appeared, and cannot be qualitatively and quantitatively closed by decentralised healthcare providers.

The decentralised medical service units concern patient-related healthcare providers who have been certified by the medical board on the basis of the derived standards and quality directives, as well as the resolved treatment chain. The healthcare providers are therefore responsible for screening right through to aftercare in the areas of standard patient medicare and the provision of research related medicare (Ruggiero, Giacomini, Sacile, Sardanelli, Nicolo, & Lombardo, 1995). These decentralised service structures are represented by health facilities or sectors of health facilities according to which fields were certified in the cooperation agreement.

The participation of the healthcare providers as part of a virtual medical centre is on a voluntary basis and is decided by mutual rights and obligations, or rather, by agreed behaviour modalities of the system participants amongst themselves. The area of mutual obligations primarily refers to the willingness to accept and employ standards and directives—which were defined on the part of the board in terms of "good clinical practice" and were subject to international evaluation—as well as the willingness to adapt clinical, therapeutic, and other processes and procedures according to these directives and guidelines (Medical Committee, 1999). This means that certification by the board has to take place when a participant enters the entire system, whereby the objectives of structural networking and system compatibility in particular have to apply, as well as the aspects of training standards and quality assurance. In

Figure 1. Model of a virtual medical competence centre



addition, through certification, it has to be ensured that the processes and procedures, as well as documentation and treatment plans, are adapted to the ongoing and continually changing basic conditions and directives, and therefore correspond to the processual element of medical development. This means that certification cannot be one singular act which is coupled to participant entry into the system. It is rather a periodically reoccurring procedure which evaluates the content and quality of the changed processes.

As the healthcare providers on this operative level face each other in an interactive and quality assured network, material and formal conformity and transparency of processes and service profiles are ensured (Göbel & Pfeiffer, 2001), and patients can be led through the entire treatment process without having to question the structure quality of a single network participant (Schoop & Wastell, 2001). Out of this basis, the mutual rights of the participants are able to be derived. These mutual rights consist in particular of gaining shortest possible and interpreted access to new medical findings. In conjunction with standardised training programmes and a superior information management, this leads to system participants gaining both medical and forensic confidence. Additionally, competencies and functions which have to be purchased from third parties (e.g., laboratory reports) by single system partners may be integrated simply standardised into their own operational structuring respectively into their processes. A major advantage on this level is the possibility to gain an overall (anonymous) data overview, and to have valid and broad data material available in order to put research cooperation or internal research projects onto a basis, and to find the current status of research prepared in its final form (Schnabel, 1996).

Cooperation Directions Within the Network

Not all descriptions of a particular structure or process have the same degree of validity. It is therefore important to make the distinction that the degree of commitment of a directive is clearly higher than the degree of commitment of a guideline which, as the name suggests, should provide guidance in a particular section of the process but with less commitment than is the case with a directive. Both directives and guidelines move within defined medical standards, whereby this term is not without controversy in connection with the history of standards in literature. In particular, newer works point to the problem that within defined standards (e.g., in the branch of clinical pharmacology), industrial interests can be found (Tenery, 2000; Wazana, 2000). This question is of importance, particularly for the medical director, as he is primarily responsible for introducing standards, guidelines, and directives, according to Austrian hospital law (Staudinger & Mair, 2001).

Important for describing a virtual medical centre is the semantic discrepancy of the terms "virtuality" and "centre." These prima-facie of alternative concepts can only then be combined if the centralisation term is not seen in a spatial sense, but rather in its substantial core, and the spatial dimension is reduced to a roughly fenced territory.

This network approach—aggregating decentralized healthcare providers to a nonmaterial entirety on an operational level, where, in a spatial sense, central strategic, and tactical elements are effective—corresponds to the cybernetic model approach, as long as self-learning elements from interactive processes are integrated.

Within such centres, the subsidiary principle applies to the healthcare providers. Simply put, each of the respective healthcare providers, who just is qualitatively and quantitatively in the position to render a particular service, actually renders this service. It can be assumed that an optimal degree of decentralisation can be achieved with a system-immanent service distribution (Sacile, 1995), but rather in context with a qualitative service hierarchy than a structural one.

Structural and Functional Requirements for Data Management

Against the given background, it seems necessary to develop or engage communication tools which ensure process and directive orientation, as well as the interaction ability of healthcare providers in an entire system (Geißler & Rump, 1999). Linking elements of process-orientated resource planning and optimization items of networked structures additionally arises necessary from the fact that self-learning systems with a high degree of networking and interaction are deeply exposed to a considerable pressure, regarding qualitative and quantitative outcome, as well as cost-effectiveness.

Apriori, it can be assumed that data management is carried out on central parameterizable systems. A medical clinical information system (CIS) serves as a basic platform (Steffens, 1995) in which all communication steps necessary for patient care can be carried out. Various types of documents, such as patient-related messages, incoming and outgoing reports for diagnostic results, or other confidential data are transported. An entire hospital information system (HIS) is eked by additional functions which cover all areas not directly consisting of medical documentation, but serve as a basis in all branches of care delivery. Namely order management, patient management, and administration processes serve as examples here (Kaloczy, 2001). A key element of the hospital information system is the compilation of diagnoses and service delivery (usually from standard catalogues such as ICD-9 and ICD-10). As a rule, the catalogues aim at several objectives of patient documentation. Beside the feasibility of diagnoses and medical treatment also, relevant balancing aspects are included (Pernice, Doare, & Rienhoff, 1995).

These IT tools have to be implemented according to a specified profile that is aligned with strategic parameters, in order to be able to ensure the corresponding planning and optimisation basis of the entire system, and subsequently, to prevent undesired maximisation activities of individual system participants.

This integrative point of view of communication technology in health systems, taking virtual medical centres into particular consideration, impedes an over centralisation of data and process management or process and resource planning, rather it advances regional integration and consistent regional structuring of health facilities. Thereby, both individual tracts of the system, as well as the entire system have to remain able to communicate and interact with other regional health structures. This is of particular importance where the patient joins different parallel health systems, as patients might have need for health treatment beside the oncological treatment.

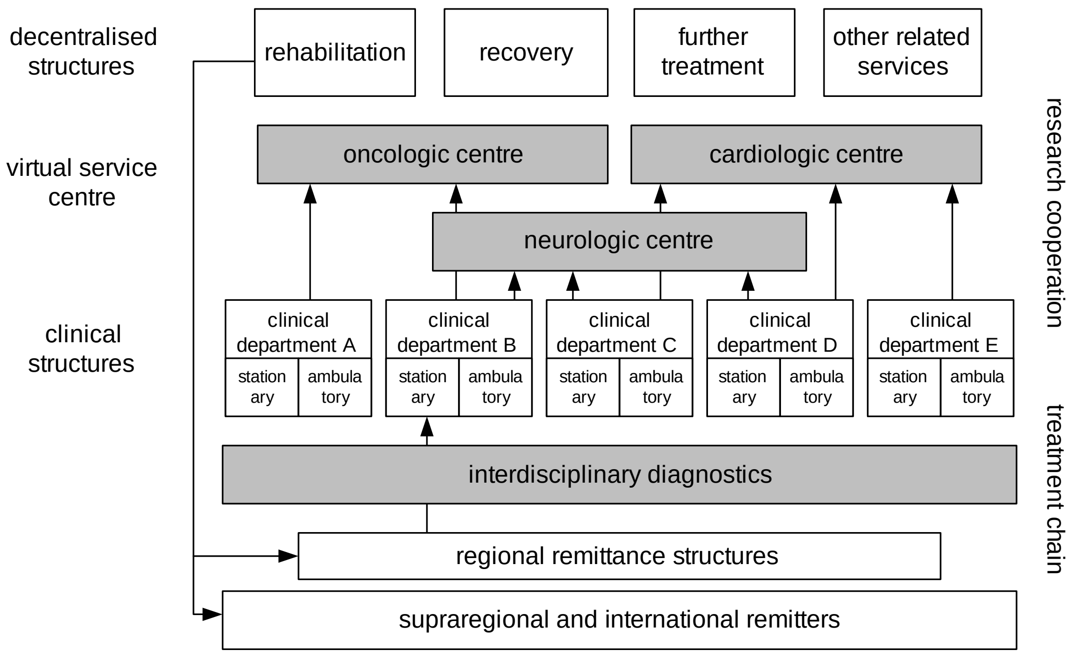
The fact that communication systems in context with virtual medical centres quasi take on the function of a transmitter is also of particular importance. Consequently, standardised communication within the predefined processes shall be able take place at any appearance. A transfer of data and results, as well as planning processes (Bachert & Classen, 1995) from one system participant to another, as well as within the whole system on a dialogue-orientated basis is therefore assured. Data redundancies and subsequent error vulnerability in data structures may be minimised (Gustafson, Hawkins, Boberg, Pingree, Serlin, & Graziano, 2001).

The reorganisation of a clinical information system and regional interaction system is chained with additional considerable cost and workload (Becker & Arenson, 1995), which can only then be justified when it opposites a benefit. This striven benefit in turn has to legitimate that a change in a running and functioning system leads to irritations within the operational structuring. In particular, each facility which shows a partial monopoly in oncological care is especially affected by this paradigm shift. On evaluating the new information system according to strategic objectives, the focus may not only be on technological solution, but rather the superior aim of organisational development which is compatible with strategic bases and development potential (Haux, 1995) must be drawn into account.

The self-conception and right to exist of single medical service structures are defined—along side other important factors—by the catchment area and prominence within the treatment chain. The catchment area neither has fixed size nor is it legally determined—leaving the basic political contract for primary healthcare out of equation. For healthcare providers in association with a virtual oncological medical centre, this means that their external communication structures have to be clearly defined to patients and remitters and have to assume a activity standard which ensures stronger quantitative and qualitative integration into the area of competence. Viewing the inner structure of the communication system operation and communication structures not only have to satisfy the current clinical requirements, but also must contain a cost and service orientated component (Kyriacou, Davatzikos, Zinreich, & Bryan, 2001).

The integration of the remitter (e.g., general practitioner, practicing specialist, primary care centres) into the clinical information system aims at a change from concerned people into partners. The question whether an organization member is part or not of a legal unit is of superior relevance, if integrative structures are set up. Rather the degree of service and information quality, which is achieved by the system change, comes to the foreground and may be an essential competitive advantage beside the clinical performance and efficiency. This assumes however, that the quality of communication and information within the hospitals or between the hospitals and the decentralized healthcare facilities achieves a level that enables to implement patient-orientated operating procedures. Whilst commercial

Figure 2. IT conceptions using Tyrol as an example



systems, particularly in the hospital branch, show a high and extensive functional state of development, medical systems are of a minor evolution standard (Clayton, 2001), particularly in context with the above field of problems.

Before a specification profile for a communication structure can be realised, it is appropriate to analyse and briefly describe the status of the structural development of healthcare regions, whereby it has to be pointed out that these structure conceptions may only be used as an example, as new IT conceptions have to primarily support highest structure flexibility.

The Tyrolean Concept of an Oncological Network

What particularly shall be highlighted with this example, is that both regional and supraregional remittent structures are, as regards function, directly tied into the diagnostic, therapeutic, and subordinated elements. Therefore, the design of the treatment chain forces the initial contact with the patient as a starting point, even if the initial contact occurs during a public screening event.

On the level of interdisciplinary diagnostics, an integrative conception of diagnostic services (called "medical setup") is established on the basis of diagnostic standards (Todd & Stamper, 1994). Particularly through the additional employment of patient and resource planning instruments, as well as optimised time and process management, brings essential quality and cost advantages. All the more as consistent data structures are accessed within the entire system (Mahr, 1995). As the main result, the interdisciplinary diagnostic responds with further treatment and therapy levels (Berner, Webster, Shugerman, Jackson, Algina, & Baker, 1995), and compiles an optimal (primarily for patients but also for institutions) patient scheduling cooperatively with remitters and clinical facilities.

The intensity of employment of the single facility (stationary or ambulatory) within the entire IT-conception, referring planning, communication, and optimizing tools, too, has to represent the targeted importance within the treatment chain respectively within the research chain.

FUTURE TRENDS

On the whole, it is to be assumed that the question of the interaction and integration of different medical healthcare providers will increase in importance within areas of medical care, as well as within expert chains of treatment. As a consequence, the development of process and information standards has to be developed by the individual specialist associations. Thereby, the scope of intervention potential of single healthcare facilities has to be taken into increasing consideration in order not to restrain the efficiency of a medical facility during a certain step of the treatment chain caused by the organisational and technical paradigm change. This involves integrative and highly standardised IT tools which show a high degree of parameterisation. Beside the impact of more transparent treatment chains, cost efficiency and optimized exploitation of existing health structures, the emerging consistent data will enforce research over the entire treatment chain, as this occurs already (e.g., in nursing with the nursing minimum data set). Minimum data sets for other medical and healthcare providing fields will inevitably arise.

Continuing this approach, the question about the interaction and communication ability of different medical networks with each other arises (i.e., the question about the communication of two or more systems on the meta-level, as well as the operational level respective to integrated patient pathways). In this area, the particular challenge of communication ability is fulfilled, which in turn causes increased research activity in connection with the development of internationally useable terminologies and with the definition of superior standards.

Finally, it is to be assumed that development towards medical networks, aligned processes and real, as well as virtual, medical competence centres will continue to strengthen. In this context, the evolution of organizations' profiles will be of considerable importance, as well as the question of information transfer, knowledge transfer, and quality assurance.

CONCLUSION

All operative healthcare providers in the healthcare branch, be it hospitals, therapy or diagnostic centres, general practitioners or rehabilitation facilities, are subject to considerable cost restrictions while medically expanding both qualitatively and quantitatively.

In the last few years, a higher degree of specialisation of these health facilities has been assessed—considering the entire chain of treatment—which has led to considerable problems in interaction between the health institutions.

Against this background, it appears necessary to create regional cooperations for distinct medical topics. Considering the entire regional treatment chain, the defined care mandates, the areas of competency as well as patient data management, the constitution of a data and communication platform between these institutions on one hand, and shaping this platform dialogue and interaction-capable on the other, challenges organization executives.

In addition, it also seems necessary to integrate optimisation tools, guidelines, and standards into defined interactive and comprehensive processes, which enable methodical and action-orientated resource management supervised by quality standards.

We have detected that patient-orientated communications and operating structures are of strategic importance. The principle question about system functionality and effectiveness of the entire organisation and the organisational structures associated with it is at least of equal importance. In practically all major hospitals, structural organisation occurs according to the historical development of medicine. Even at first glance, it can be recognised that this practice lacks an organisational theoretical basis if the criterion of strategic efficiency should apply (Zulehner, 1999). The reason for this lies in the fact that the abstract levels, according to which the hospitals were traditionally structured, are of a different nature, and are not necessarily compatible with each other. On the one hand, this must lead to double and multiple structures, and on the other, to gaps in the clinical portfolio. In this way, the hospitals are conceptually organised according to an institution or group of institutions, range of services, age of the patients, certain illnesses or diseases, methods and forms of therapy, as well as technical criteria. The medical organisational development of the past decades has of course authority, too, gained from the different speeds at which innovation progresses for the individual lines of expertise. There, it is ensured that single medical sectors that are able to be well combined can develop in the same or similar way, and do not have to experience constraints from other sectors. In the middle and long term, these present organisational structure—if it is not supplemented and reworked in essential areas—will noticeably restrict clinical and economical efficiency. Because of this, it is necessary that new organisational and service structures be defined along side current and continually developing clinical structures for the purpose of a virtual structure or virtual medial centre.

This is particularly characterised by combined standardised processes, a continuous chain of treatment, clear terminology, and uniform quality requirements.

KEY TERMS

Directive: Operation and action recommendation with lower commitment than SOPs. Directives describe process paths which should be normally followed during the implementation of the process. Deviations in justified circumstances are allowed.

Effectiveness of Personnel Management: Based on a theoretical maximal quantitative output of an organisation unit in the area of personnel management in connection with costs and efficiency criteria, the effectiveness of personal management is calculated from the difference between the theoretical output and the actual output. It is measured by the different measurement criteria (process quality, data quality, process stability, cost—performance relation, frequency of errors, and so on).

Guideline: Operation and action orientation with lower commitment that directives. Guidelines provide an operation framework in which the process should move. Deviations are not usually sanctioned.

Human Resource Information System (HRIS): Specifically developed software for Human Resource Management (HRM) (e.g., software packets which document, support, and make analysable the digitisable components of HRM). The Human Resource Administration System (HRAS) is an administration-specific subarea of HRIS.

Process Integration: The process integration specifies the degree of the theoretical and actual commitment of processes within structures.

Process Types: Definitions of certain process types. They are distinguishable from another by characteristics in the area of the degree of standardisation and the degree of integration.

Standard Operation Procedures (SOPs): Operation and action instructions. They are there to make sure of the uniform, predictable, and integrated dealing of replaceable process individuals within the framework of working structures.

Virtual Centre: Network of organisational commitments in order to reach cooperation without frontiers between different service units even if they are members of different legal organisations.

IT-Standards and Standardization Approaches in Healthcare

INTRODUCTION

E-health basically comprises health services and information delivered or enhanced through the Internet and related technologies (Eysenbach, 2001). The future healthcare system and its services, enabling e-health, are based on the communication between all information systems of all participants of an integrated treatment. Connecting the elements of each healthcare system (general practitioners, hospitals, health insurance companies, pharmacies, and so on)—even across national boarders—is an important issue for information systems research in healthcare. Current developments, such as upcoming or already-deployed electronic healthcare chip cards (that are to be used across Europe), show the need for Europe-wide standards and norms (Schweiger, Sunyaev, Leimeister, & Krcmar, 2007). In this article, we first outline the advantages of the standards, and then describe their main characteristics. After the introduction of communication standards, we present their comparison with the aim to support the different functions in the healthcare information systems. Subsequently, we describe the documentation standards, and discuss the goals of existing standardization approaches. Implications conclude the article.

BACKGROUND

The advantages of generally accepted standards for the processes in healthcare and the medical market can be summarized as follows (CEN/TC 251 European Standardization of Health Informatics, http://www.centc251.org/; Wirsz, 2000):

- Standards increase competition and reduce costs;
- Standardized products could easily be replaced or updated;
- Standardized products of various suppliers could easily exchange medical information;
- Healthcare institutions are able to iteratively extend their offers/capabilities;
- Standardized products could reduce errors and make healthcare services safer.

Several national and international committees, German as well as European or American (CEN/TC 251 European Standardization of Health Informatics; DIN, http://www.din.de; Integrating the Healthcare Enterprise (IHE), http://www.ihe.net; Integrating the Healthcare Enterprise-Europe (IHE-E), http://www.ihe-eurpoe.org; World Health Organization (WHO), http://www.who.int), have been founded to ensure unified standardization of national and international healthcare systems. Accordingly, there are numerous standardization attempts, which partly correspond to, but also disagree with, each other (Märkle & Lemke, 2002). Two main objectives of these committees can be distinguished: the development of standards for communication, and standards for documentation in healthcare. The former focuses on enabling an efficient and effective combination of medical information systems, in order to enable the exchange of data between different medical information systems (refer to IHE). The latter are supposed to ensure the right interpretation of the content of electronically exchanged information (Haas, 2005).

IT-STANDARDS IN HEALTHCARE

The transmission of data between heterogeneous and isolated medical information systems requires interoperability of systems and data (Hasselbring, 1997). The interoperability on its side is composed of norms, interfaces, and standards—the basis for data exchange and communication between participating applications (refer to World Health Organization (WHO), http://www.who.int). For an overview of common interoperability standards in the healthcare sector, and the graphical classification of its relations, see Figure 1.

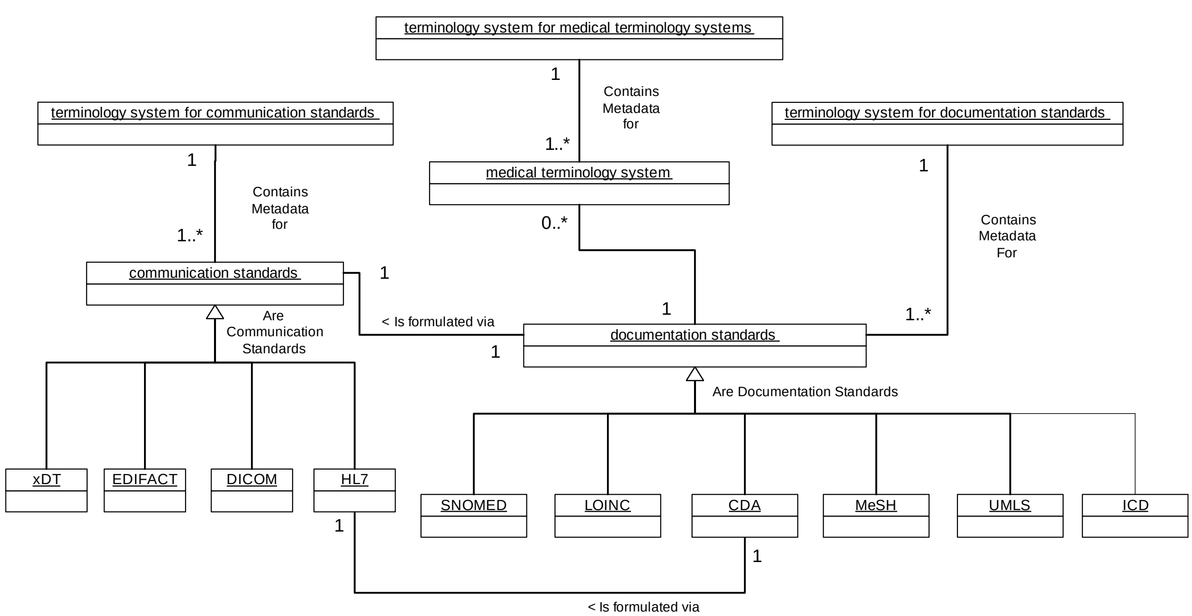
Communication Standards

Communication standards, also called syntactical standards, ensure a correct transmission of medical and administrative data between different information systems. In the clinical area, one can distinguish them worldwide, mainly between the established standards of Health Level 7/Clinical Document Architecture, (HL7/CDA), Digital Imaging and Communications in Medicine (DICOM), and Electronic Data Interchange for Administration, Commerce and Transport (EDIFACT) (Pedersen & Hasselbring, 2004). The reason for their acceptance is mainly the openness of these standards.

Health Level 7 is an international, vendor-independent, and main communication standard in healthcare for the exchange of information between systems and institutions. The Version 2 family of this standard is based on events that trigger the exchange of data. Beginning from Version 3 XML[1], data structure is supported, alleviating the integration of data into information systems, since adequate libraries for XML handling are available. HL7 operates at the application layer of the ISO/OSI reference model (ISO7498-1, International Organization of Standardization (ISO), 2006). The Clinical Document Architecture (Health Level Seven Inc., http://www.hl7.org/) amplifies the HL7-standard with the description of the structure and the contents of clinical documents (e.g., discharge summaries and progress notes), based on an XML-format. HL7/CDA also offers a model for the exchange or the common use of information, and the option to individually re-use this information (Dolin, Alschuler, Boyer, Beebe, Behlen, & Biron, 2006).

Digital Imaging and Communications in Medicine (National Electrical Manufacturers Association (NEMA) , http://medical.nema.org) is an open standard

Figure 1. Medical communication and documentation standards



for the exchange of images in healthcare. Besides the image, it can also contain additional meta-information, such as the patient's name, date of admission, device parameters, or attending physician. The standard lists the data fields (e.g., images, diagnosis, patients, studies, series, and so on), functions of network services, as well as syntax and semantics for the commands and messages. DICOM can store the images with or without loss of information, in accordance to TIFF and JPEG formats, and enables electronic archiving of images in all medical information systems.

Electronic Data Interchange For Administration, Commerce and Transport (EDIFACT, 2006) standardizes the formats for the electronic exchange of administrative data amongst others in healthcare information systems. Orders, calculations, and payment orders in the health service are often based on it. EDIFACT is, unlike the other introduced communication standards, not specifically designed for the healthcare field—it is used globally by business partners of different kinds of business areas to exchange accounting-relevant data.

In the sector of general practitioners in Germany, there are additionally specific standards, so called xDT-standards (KBV, 2006). xDT is a set of several German standards, which are supposed to simplify the communication and the data exchange between healthcare providers (i.e., physician's offices, hospitals, and so on) and health insurance companies. As a result, xDT aims at the reduction of waste of paper by applying information technology using the following data formats:

- **ADT:** AbrechnungsDatenTransfer (invoice data for medical services)
- **AODT:** AmbulantesOperierenDatenTransfer (securing the quality of out-patient surgery)
- **BDT:** BehandlungsDatenTransfer (for the communication between general practitioners)
- **KVDT:** KassenaerztlicheVereinigungDatenTransfer (standard for communication between physician's offices and health insurances)
- **LDT:** LaborDatenTransfer (communication with laboratories)
- **GDT:** GeraeteDatenTransfer (communication with medical devices)
- **ODT:** OnkologischerDatenTransfer (oncological data carrier for the documentation of tumor information)

Even though all of these xDT-standards serve different purposes, they are structured according to the same basic rules and principles.

There are currently efforts to harmonize the introduced communication standards on an XML-basis: HL7/CDA incorporates already the XML-format for structuring clinical documents; additionally, there are also XML-based specifications for the DICOM standard (refer to NEMA), for the xDT-standards (Bundesministerium für Gesundheit und Soziale Sicherung, 2004), and for EDIFACT (EDIFACT, 2006). The advantages of introducing XML-based data structures can be described as follows:

- Automatic processing can be simplified when using established XML programming libraries.
- XML is an open and platform-independent standard.
- XML can be read and understood by users.

The introduced communication standards support different functions in healthcare information systems (Table 1: "x" connotes that the standard supports the function, "-" connotes the opposite case). Such a use of miscellaneous standards in several healthcare service sectors is the most current problem in electronic communication in medicine (Lenz, Beyer, Meiler, Jablonski, & Kuhn, 2005).

Documentation Standards and Standardization Approaches

For the right interpretation of the content of the electronically exchanged messages between different medical information systems, there are terminology and documentation standards, called semantic standards (see also Figure 1). The semantic standards are responsible for the conversion of encoded medical data, in order to, for example, correctly identify the diagnosis. Logical Observation Identifiers Names and Codes (LOINC®, http://www.regenstrief.org/loinc) offers a multidimensional terminology system for clinical laboratories. It allows detailed descriptions of medical circumstances for almost each clinical problem to be solved automatically.

Classifications are medical systems of concepts that are used for medical documentation. In comparison to terminology systems, classifications are less complicated, and thus mostly one-dimensional. "International

Classification of Diseases" (ICD) (DIMDI, http://www.dimdi.de; refer also to WHO) is an example for such a classification of illnesses and related health issues.

Systemized Nomenclature of Medicine (SNOMED, http://www.snomed.org/index.html) is a nomenclature. Nomenclatures are combinations of terms that are based on determined concept orders. SNOMED CT covers the arrangement of a unified terminology for expressions in the medical field, and supports the languages English, German and Spanish.

The thesaurus Medical Subject Headings (MeSH) (United States National Library of Medicine, 2006) is an extension of a nomenclature. MeSH mainly enables indexing international publications—such as journals, articles, and books—for the United States National Library of Medicine (NLM). Enriching a thesaurus with semantic and linguistic information yields a metathesaurus. The "Unified Medical Language System" (UMLS, http://www.nlm.nih.gov/research/umls) is a metathesaurus that tries to integrate all important medical terms in only one term, and to represent all possible term relations accordingly.

Because of the existence of different documentation standards, a lot of incompatibilities occur, such as if different users use different terminology systems for the documentation (McDonald, 1997). The complete interoperability, the consent identification concerning the meaning of the medical data and meaningful

Table 2. Overview of current standardization approaches in healthcare

Standardization approaches in healthcare	Characterisation and Goal	Approach and assignment of internationally accepted standards
Integrating the healthcare enterprise (IHE) (Hornung, Goetz, & Goldschmidt, 2005)	IHE is an international initiative, driven by health-care professionals and industry, to improve the communication of medical information systems and the exchange of data.	IHE's approach for the information integration is based on the propagation and integration/usage of HL7 and DICOM standards. IHE promotes and advances these standards as a suggestion for standardizing bodies.
Professionals and citizens network for integrated care (PICNIC) (Danish Center for Health Telematics, 2003)	PICNIC is a European project of regional healthcare providers in a public-private partnership with industry to develop new healthcare networks, and to defragment the European market for healthcare telematics.	The development is an open source model, an open and interoperable architecture with exchangeable components (aim is an easy and simple integration of external products). All components must be based on established standards, such as HL7/CDA.
Distributed healthcare Environment (DHE, http://www.gesi.it/dhe)	DHE has been created as a part of previous development projects (e.g., HANSA-Project (http://www.ehto.org/ht_projects/initial_project_description/hansa.html) for the integration of clinical information systems) to build a platform to both integrate legacy healthcare systems, and support the development of new ones.	DHE is an open middleware, which is based on the "Healthcare Information System Architecture" (HISE, CEN/TC 251 European Standardization of Health Informatics) (Scherrer & Spahni, 1999). DHE tries to specify generic healthcare services, which are based on predefined database-schemata, and offers them on a common platform (e.g., with HL7-interfaces).
Open electronic health record (The openEHR foundation, http://www.openehr.org)	The openEHR foundation is dedicated to develop an open specification and implementation for the electronic health record (EHR). openEHR advances the experiences of Good Eurpoean Health Record-Projects (Blobel, 2006; GEHR, http://www.chime.ucl.ac.uk/work-areas/ehrs/GEHR/) in England and Australia.	The project works closely with standards (e.g., HL7). However, it does not adopt them verbatim, but tests, implements, and improves their integration and application, while giving feedback to the standardizing bodies.
Standardization of communication between information systems in physician's offices and hospitals using XML (Gerdsen, Müller, Bader, Poljak, Jablonski, & Prokosch, (2005); SCIPHOX, 2006)	SCIPHOX is a German initiative with the aim to define a new common communication standard for ambulant and inpatient healthcare facilities.	The basis for the information exchange is the XML-based HL7/CDA standard. SCIPHOX adapts and improves this global standard for local (German) needs.
www.akteonline.de (Schwarze, Tessmann, Sassenberg, Müller, Prokosch, & Ückert, 2005; Ückert, Görz, Ataian, & Prokosch, 2002)	akteonline.de is German state-funded project to develop a Web-based electronic healthcare record.	akteonline.de developed dynamic Web pages, which can be accessed via Internet, and look similar to physicians and hospital software. The project is based on the common communication standards (DICOM and HL7/CDA).
All introduced initiatives, with the exception of SCIPHOX, defined and developed an "Electronic Healthcare Record" (EHCR) (Tang, Ash, Bates, Overhage, & Sands, 2006)		

cooperation of functions, are the primary ones of the main challenges for the near future of development of healthcare information systems (Frist, 2005). There are many different approaches to standardize the electronic communication and documentation in healthcare to achieve the interoperability. Some of the promising standardization initiatives are summarized in Table 2.

The analysis described in Table 2 shows that the existing standardisation approaches for interoperability in healthcare can be divided in two opposing groups (Märkle & Lemke, 2002). On the one hand, there is basically industry that propagates and adopts proprietary standards like HL7 and DICOM. On the other hand, there are generally university- and state-funded initiatives which use and support open standards as initiated by European Committee of Standardization (CEN/TC 251 European Standardization of Health Informatics). This difference is also based regionally—the former are mainly located in the U.S., whereas the latter initiatives come from Europe. For the future healthcare system, it remains to be aspired that both camps learn from each other and may grow together, and with it, the vision of complete interoperability in the healthcare sector can become true. Nevertheless, they all provided important issues and contributed indispensable knowledge in attaining the present status.

IMPLICATIONS

Standards in healthcare are supposed to enable an efficient and effective communication of distributed and isolated medical information systems. Unfortunately, the current situation is not satisfying in terms of interoperability. Until there is no generally accepted standardization for syntactic as well as semantic standards in the healthcare sector, all advantages of standardized solutions listed in the introduction cannot be exploited (Haux, 2006). To improve health services and reduce costs, the problem of interoperability (standardized software solutions) has to be solved. Such interoperable information systems can influence the quality of healthcare services and the adjunctive costs very positively (Berger & Partner GmbH, 1997; Warda & Noelle, 2002).

The issue of interoperability as major driver for efficiency in healthcare requires efforts as to harmonization of standards, especially on the semantic level. The existing and introduced communication standards are able to deal with and connect different medical information systems. But a great percentage of the potential benefits still remain useless without prior harmonisation of standards on a semantic level. Future efforts from research and practice should focus on this topic.

KEY TERMS

Classification: Given representation of abstract concepts, which are assigned to a set of categories.

Communication (Syntactic) Standards: Communication standards ensure a correct transmission of electronic data between different information systems, in terms of a particular syntactical format.

Documentation (Semantic) Standards: Documentation standards ensure the right interpretation of encoded medical data.

Interoperability: Denotes the ability of different, independent, and heterogeneous information systems to exchange electronic data for their further processing.

Metathesaurus: A thesaurus enriched with additional semantic and linguistic information.

Nomenclature: An accumulation of principles for the consistent naming of objects.

Thesaurus: A given vocabulary with related terms.

ENDNOTE

1 The standard extensible mark-up language XML, as defined by the World Wide Web Consortium (W3C), is used for the creation of machine- and human-readable documents in the shape of a tree structure, and is hereby defining the structure of these files. An actual document requires the definition of several details, particularly the definition of elements of structure and their arrangement within the document tree.
XML is a subset of the Standard Generalized Mark-up Language (SGML). It is also a metalanguage, which is capable of defining numerous amounts of different mark-up languages, which are still closely related in their basic structure. In order to describe the structure of XML documents, a so-called "scheme language" is used. The two most important scheme languages are the Document Type Definition (DTD) and the XML schema.

J

Judging the Value of Mobile Healthcare Solutions for Improving Outpatient Adherence

Mihail Cocosila
McMaster University, Canada

Norm Archer
McMaster University, Canada

Yufei Yuan
McMaster University, Canada

INTRODUCTION

A serious problem in today's health care is the growing incidence of chronic diseases and conditions with dire human and financial consequences. For instance:

- The worldwide burden of chronic conditions will increase from approximately 600,000 *Disability Adjusted Life Years (DALYs),* that is, lost years of healthy life caused by premature death or disability, to over 900,000 *DALYs* worldwide during the period 1990-2030 (WHO, 2003);
- The care of the 90 million Americans with chronic conditions consumes more than $1,000 billion each year, 75% of national medical costs (Chin, 2002); and,
- The high incidence of chronic illnesses is one of the causes for increasing health care costs in Canada, with total health care costs reaching about 10% of the gross domestic product (GDP) (Coambs, 2002).

The implications of chronic diseases and conditions, associated with a growing elderly population that needs more medical attention (Siau, Southard, & Hong, 2002), represent a supplementary challenge for health care systems. These are already facing an increasing divergence between population demands for better care and the resources available to meet these demands (Cowling, Newman, & Leigh, 1999).

Managing some chronic illnesses in outpatient conditions may provide solutions to alleviate some of the pressure on the health care system. Keeping patients out of hospitals while providing them the best treatment conditions possible could be a win-win situation for both people and society. However, there is a serious obstacle to this solution: patient adherence to treatment is no more than 50% on average, with dire human and financial consequences (Dezii, 2000; WHO, 2003).

The problem of low adherence in outpatient conditions on one side and the ubiquity of mobile communications and data services on the other side suggests an innovative idea: improve some forms of outpatient adherence through the use of mobile information technology (IT). This idea springs from the general approaches recommended for improving adherence in relevant medical literature (Haynes, Yao, Degani, Kripalani, Garg, & McDonald, 2005; McDonald, Garg, & Haynes, 2002). Although the philosophy of using the newest technology for promoting wellbeing may seem attractive, various human, technological, and financial issues must be considered first (Cocosila & Archer, 2005b).

On the adoption of mobile technology, an important aspect that has not been addressed adequately in the literature is the business perspective. The objective of this study is to introduce a framework for determining the business case for mobile information technology (IT) solutions that will help to increase outpatient adherence.

BACKGROUND

Chronic diseases and conditions are either infectious (e.g., HIV-AIDS, tuberculosis) or non communicable (e.g., diabetes, hypertension, or asthma). They have several distinct features:

- Duration (permanent or necessitating a long period of care);
- Consequences (caused by nonreversible pathological deterioration and associated with remanent disability); and,
- Treatment (necessitating multidisciplinary management and special conditions and training for patient rehabilitation) (WHO, 2003).

Because of the long-term treatment required, maintaining high adherence becomes a fundamental issue, especially in outpatient conditions where patient contact with health care providers is infrequent. Adherence is a complex phenomenon, still little understood, being simultaneously influenced by several categories of factors (e.g., sociodemographic, economic, medical condition-related, therapy-related, health care team, and system-related, and, above all, patient-related) (WHO, 2003). Since "current methods of improving adherence for chronic health problems are complex, labor-intensive, and not predictably effective" as McDonald et al. (2002, p. 2868) pointed out, a newer approach that uses mobile IT solutions may be justifiable. It must be recognized that the immediate influence of adherence-improving interventions may be small. However, the long-term effects on patients, their social environment, and society in general could mean a significant gain.

Mobility in the context of communication and information "should not be understood simply as a new distribution channel, a mobile Internet, or a substitute for PCs" (Yuan & Zhang, 2003). A mobile IT solution is justified only by the particular *location* of the user, who needs an information or communication service, or by the *utility* or *urgency* of that service (Mennecke & Strader, 2003). All three elements justify the use of mobile solutions to improve outpatient adherence in self-management programs for chronic illnesses. A further important characteristic of any mobile solution is the *identification of a unique person,* as stressed by Junglas and Watson (2003). Thus any communication between a mobile device and health providers would be automatically linked with the mobile device owner's identity.

It is unrealistic to expect mobile solutions to improve adherence automatically. Mobile solutions should aim at facilitating the communication and exchange of data between the patient and the health care provider. Consequently, to maximize the chances of success, any mobile solution aimed at enhancing outpatient adherence should target several adherence factors within the complexity of clinical interventions, where improving the patient-health provider relationship is a key factor. Starting from the recommendations of pertinent medical research (Haynes, McDonald, & Garg, 2002), six possible mobile health care solutions (monitoring of health parameters, reminding about taking a medication or performing a behavioural change, consulting with health providers, receiving support from family and peers, keeping informed, and being educated about the disease and treatment) and their envisioned benefits have been described in previous work (Cocosila & Archer, 2005a). These solutions address adherence factors and extend existing ways of communication and data exchange between outpatients and the health care system (e.g., mail, landline telephone, or the Web), encompassed under the definition of telemedicine (Bashshur, Shannon, & Sapci, 2005).

Existing Applications

Advances in wireless and Internet technology have already made possible the development of new health care services. Two of the most popular are remote monitoring and disease management for patients in homecare. A synthesis of some existing or proposed mobile applications, as mentioned in the literature, is presented in Table 1.

Trials of distance monitoring of blood glucose or blood pressure with the help of a computer showed improved outcomes and efficiency together with more active participation of patients (Balas & Iakovidis, 1999). Extrapolating from the success of preliminary results with the *Telephone-Linked Care* technology, Friedman, Stollerman, Mahoney, and Rozenblyum (1997, p. 424) suggest that "the market demand for technology-based delivery systems used by patients in their homes will be strong." Husemann (2004) sees a future in the emerging field of information-based medicine for solutions like monitoring vital measurements on-the-go or for pill dispensers reminding the patients to take the appropriate medicine.

Electronic monitoring is constantly expanding and innovative devices and applications are becoming increasingly available for a variety of diseases. In particular, analysts foresee wireless medical devices helping chronically ill outpatients with asthma or diabetes (Duan, 2003; Hoise, 1999) and distance monitoring of diabetic patients has already proven to ameliorate the

Table 1. Existing or proposed applications of mobile health care addressing outpatient adherence

Study	Type of intervention	Stage of mobile IT implementation	Disease
Husemann (2004)	Monitoring of vital measurements	Proposed	Not specified
Duan (2003)	Not specified	Proposed	Asthma, diabetes
Hoise (1999)	Not specified	Proposed	Asthma, diabetes
Weingarten et al. (2002)	Monitoring	Not specified	Diabetes
Wexler (2001)	Monitoring health parameters, alerting	Proposed	Diabetes
Dunbar et al. (2003)	Reminding about taking medication and behavioural changes	Implemented	HIV
Conlin (2000)	Patient information and communication with physicians	Implemented	Not specified
Wirelessnewsfactor (2000)	Reminding about taking medication	Implemented	Not specified
Huseman (2004)	Monitoring the taking of medication	Implemented	Not specified
Maglaveras et al. (2002)	Monitoring	Not specified	Not specified
ProWelness (2004)	Monitoring	Implemented	Diabetes
Van Impe (2001)	Monitoring	Implemented	Not specified
Bludau (2003)	Monitoring blood pressure, pulse rate, or temperature in hospitals	Implemented	Not specified
Poropudas (2001)	Monitoring	Not specified	Not specified

clinical outcomes (Weingarten et al., 2002). Wexler (2001) reports on a development by the *IMetrikus Company* that allows diabetics to test their health parameters and upload the results to a Web site. The future could, reportedly, bring a Web-free solution using a direct connection between the glucose monitor and a cell phone, without patient intervention. Furthermore, a health care alert triggering feature could also be incorporated. A study of 25 HIV-positive participants included sending them between three and eight text message reminders per day about taking their medications. Patients reacted positively with resulting behavioural changes. They "expressed high satisfaction with the messaging system and reported that it helped with medication adherence" (Dunbar et al., 2003, p. 11).

Medtronic CareLink™Network has been promoting a remote Web-based monitoring service for patients with implanted cardiac devices. Patients can send timely information to their clinics from regular phones (Medtronic, 2004). *WellMed Inc.* developed a wireless application allowing patient data transmission (e.g., health or insurance information) and communication with health care providers (e.g., physicians) (Conlin, 2000). *SmartMeds.com* and *AT&T Wireless* from the USA. have jointly developed a wireless solution for reminding patients to take prescribed medications and allowing patient feedback about complying with the reminders (Conlin, 2000; Wirelessnewsfactor, 2000). *IBM* researchers pioneered an information technology solution to track vital health signs and send them to remote sites. The device includes a pillbox and a wristwatch-like blood pressure monitor able to communicate via a Bluetooth short-range radio connection to a cell phone. The phone, in turn, sends the data to health care personnel. Only authorized personnel are able to view the patient data. This technology is thought to reduce the number of check-ups, hospitalization periods, and patient health risks (Husemann, 2004).

In recent years, significant work has been underway in Europe on Internet or wireless remote monitoring. Maglaveras et al. (2002) advocate the "necessity for restructuring medical knowledge for education delivery to the patient" and exemplifies this by the novel idea of a contact centre enabled by wireless technology to manage the home care of patients remotely. Patients using *ProWelness,* a Web-based information system for remotely managing several chronic diseases including diabetes, are able to record specific disease management activities daily by fixed phones or cell phones. The philosophy behind the system is the two key elements essential for the success of a chronic disease (e.g., diabetes) management: "careful self-care and good communication with the care team" (ProWellness, 2004). Following the implementation of a 3 year project financed by the *British Engineering and Physical Sciences Research Council*, doctors in the UK were able to monitor remotely the health condition of patients by analyzing medical data gathered by a device communicating through a cell phone (Van Impe, 2001). Bludau (2003) describes a platform for patient home monitoring by hospital physicians. The solution uses Bluetooth-enabled modular sensors and cell phone technology to send data such as blood pressure, pulse rate, and temperature. *Arbonaut*, from Finland, and *Virtual Medical World Solutions*, from the UK, have been developing a platform for real-time remote monitoring. This solution targets patients with a "stable medical condition that allows a near normal life but may suddenly deteriorate and put life at risk" (Poropudas, 2001, p. 1).

MOBILE SOLUTIONS TO IMPROVE OUTPATIENT ADHERENCE: A BUSINESS EVALUATION

A careful evaluation of the business value proposition for mobile applications in the health care sector is necessary in order to assess the risks associated with deployment. Business evaluation is a step-by-step process, as described by Archer (2004) and depicted in Figure 1. In Figure 1, solid arrows represent information and process flows, whereas the dashed arrow represents moderating influences. The business process is described in more detail in the following.

Business Goal or Operational Imperative

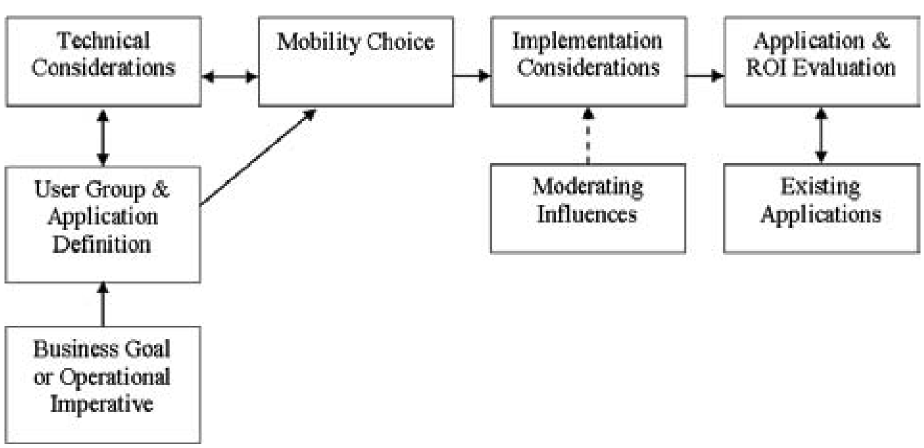
The pillars supporting the option for a mobile health care solution must be emphasized from the very beginning. They should not be a mere justification for the deployment of a particular application or technology. The main reasons for using mobile solutions to improve outpatient adherence should be present for the three most important stakeholders:

- Better quality of care and life for patients (e.g., less medical, personal, and social consequences of their diseases) (WHO, 2003);
- Better use of health providers' professional time and work resources (e.g., less waste for unnecessary diagnostic tests, appointments, and follow-ups) (Weiner, 2004); and,
- Increased savings of human and financial efforts for the health care system and society (e.g., better redistribution of resources to patients needing them most) (Dezii, 2000).

User Group and Application Definition

Mobile solutions addressing nonadherence in outpatient conditions have as users a group of patients with an active lifestyle (i.e., going to work, school, or various locations) treated through long-term care in out-of-hos-

Figure 1. Process framework for mobile solutions to improve outpatient adherence—business case evaluation—adapted from Archer (2004)



pital conditions (i.e., primary and/or home care). The most suitable patients for these types of applications are those suffering from chronic diseases or conditions that require frequent measuring and evaluation of health parameters as well as communication (e.g., seeking advice from the responsible nurse) and data exchange (e.g., sending glucose test results to a monitoring centre for recording and comparison purposes) with health providers.

Technical Considerations

Deploying a new technology application poses several types of technical issues of which the most important are: integration with existing infrastructure, consideration of application and device capabilities, and harmonization with systems already in place (Turisco & Case, 2001). Mobile solutions have in addition several types of technical inhibitors, compared to the wired Internet, due mainly to limitations of the application and mobile device: limited connectivity, low bandwidth, limited input/output capabilities, small memory and low processor capability, and inability to support face-to-face interactive dialogue between patient and provider for observation and examination.

Security and privacy are an additional concern for mobile applications involving patients or patient data. Although there is still a widespread perception that wireless communications are less secure then their wired equivalents, appropriate encryption measures are available and in use for health care information transmission and storage regulated by the Health Insurance Portability and Accountability Act (HIPAA) in the USA and the Personal Information Protection and Electronic Document Act (PIPEDA) in Canada, for instance.

Mobility Choice

An initial question is to ask whether the solution for outpatient adherence should be 100% wireless. Mobility does not automatically imply wireless access. Wireless is only one technology (e.g., cell phones) that enables mobility by the use of specific wide area networks. *Wireless technology is best suited for enabling the required features in most of the previously identified interventions to improve adherence*. Nurturing patient self-confidence and perceived protection, realizing a virtual permanent connection with health providers as well as with social support groups, receiving timely information of interest, alerting the health care system when some indicators exceed the normal limits, and asking for assistance and fast intervention in emergency situations cannot be effective without a wireless connection between the patient and the health care system. However, this linkage must be selective and gradual, based on segmentation and prioritization of patient conditions, so as to not overload the health care system with unnecessary information when patient situations do not require intervention. Thus, "the system would have improved efficiency in managing the patients' uncommon conditions" (Cocosila, Coursaris, & Yuan, 2004).

For other self-management features, it is arguable whether a wireless connection is necessary. With the goal of improving patient quality of care, while offering savings of health care resources, some other features such as constantly monitoring or reminding patients to take the prescribed medication, for adhering to a prescribed diet, or performing self-tests at the required time may be fulfilled by a portable but not wireless application implanted in the patients' mobile devices. Wireless networks and always-on connectivity should only be used for remotely contacting health care personnel in out-of-normal situations, as well as for alerts and emergency functions. For normal situations, the application might only use the built-in capabilities of the mobile device. However, this would prevent real-time access to the health care system, providing information on patient health and medication state, and it would be unable to provide useful provider feedback, which is known to encourage patient adherence. In order to assess the balance between functionality and cost effectiveness, a more complete analysis of business aspects is necessary to find the best compromise for patient care.

Implementation Considerations

Implementing mobile solutions to improve outpatient adherence would have to take into account several issues (Tarasewich, 2003; Venkatesh, Ramesh, & Massey, 2003): system design, device and vendor choice, deployment planning, installation, support and training, prototype and usability testing, and installing of control mechanisms for the deployment stage and for future use. For maximizing the chances for success of adherence improving initiatives, it is advisable to use existing wireless networks but to allow flexibility in the choice of device. Mobile devices should best fit the previously identified groups of user needs. For instance, for active people already using or familiar with cell phones, it would be rational to use this type of common mobile device (with text messaging capabilities) for health care activities since cell phones would also be used frequently by patients for other activities. Regular cell phone use has social importance, since it diminishes the risk of indicating a chronic health problem to colleagues and friends. A cell phone may also increase confidence in using the latest technology and giving better social status. On the other hand, for other people such as the elderly, or for those living mostly in a fixed location, some more specific and easier to use devices could be considered. In addition, for these people the possibility of integration of mobile devices with self-test devices (e.g., blood pressure monitors) for automatically measuring and transmitting data to health care providers would likely be relevant.

Moderating Influences

Moderating influences refer to factors that affect successful implementation and are similar to any application that is new to an organization. Some critical success factors refer to: top management support, a well-planned implementation process, setting up an appropriate mobilization team, a significant degree of e-business implementation, an appropriate organizational culture, choosing the right Value Added Retailer (VAR), establishing communication channels, providing education and training, ensuring comprehensiveness of system functions, and setting up appropriate control mechanisms (Luarn, Lin, & Lo, 2003). In addition to these is the full understanding and matching of user needs. This question is fundamental for health care applications since complex issues such as the social image of mobile application users could have a decisive influence. For instance, using an advanced mobile device and application could improve social image, thus contributing to the acceptance of the application. However, a contrary view is that a mobile application reminding a user to take a certain medication or to perform self-tests may be an embarrassing indication of a chronic illness to colleagues and friends.

Mobile Application and Return on Investment Evaluation

An essential condition prior to evaluation of the Return On Investment (ROI) is that the business goals are properly addressed by the project (Archer, 2004). Financial measures upon which ROI is based include the cost of software, hardware, implementation, ongoing maintenance, and operating costs. Savings include quantifiable (or tangible) and nonquantifiable (or nontangible) elements. Quantifiable elements refer to medical savings, and other (personal and social) savings. Nonquantifiable benefits may be at or above the importance of quantifiable benefits: improving outpatient quality of care and of life (including better integration and social image), prolonging lives, or more professionally rewarding work for health care providers.

Two basic approaches are possible in implementing mobile solutions for outpatient adherence: a *minor change* (that would be an improvement in terms of quality and efficiency of the existing system where the main point of contact for outpatients is represented by homecare nurses), or a *major change* (such as an important advance in existing systems, such as the involvement of physicians in remote consultations). Although improving productivity in health care may translate to reductions in medical staff because of their substitution by technology, this work does not promote such a perspective because it may generate unease among health care workers (Jacobs, 1999). Rather, it endorses the view of Montori, Helgemoe, Guyatt, and Dean (2004) where, even in the most conservative situation when adherence is not improved and there are not savings in health care worker time, mobile solutions for outpatients may help in redistributing health care provider time and work resources more fairly to the patients needing them most. A final step in the evaluation of ROI is to compare the mobile solution with the existing process and its associated business model so as to make sure that radical change in the existing system is better than incremental change. "Technology will not solve an existing business process problem, and implementing mobile solutions should not be just a costly excuse to implement new technology" (Archer, 2004, p. 180).

FUTURE TRENDS

Previous research addressed the issue of possible human, technical, and financial issues *as well as opportunities and barriers for the possible deployment of* mobile information technology addressing outpatient adherence only at a general level (Cocosila & Archer, 2005b). Future research should look at specific chronic diseases and conditions with high medical, personal, and social impact (e.g., diabetes, asthma, hypertension, congestive heart failure). Quantifiable and nonquantifiable effects of such interventions should be considered when comparing the effects of newer technology with the existing level of care through business lenses.

CONCLUSION

The low level of adherence, especially of chronically ill people in outpatient conditions, is an increasing concern for society because of its consequences for all stakeholders. Novel mobile health care solutions embedded in clinical initiatives may contribute to addressing some of these adherence problems. However, the success of deploying such solutions is a totally new area that must be approached cautiously with a carefully designed, step-by-step, process. This article has raised some questions and offered some suggestions and a step-by-step process framework for developing mobile solutions in health care. Our view is that the real benefit of mobile health care solutions will be realized only when technology and process are built around a logical framework that exploits the particular features of mobile communications and data services.

KEY TERMS

Cost/Benefit Analysis of Health Care Services: The cost of providing/receiving health care services vs. the value of the services, from multiple perspectives.

Disability Adjusted Life Years: Lost years of healthy life caused by premature death or disability.

Mobile Health Care: Using mobile telecommunication technology and portable devices to provide health care services.

Outpatient Conditions: Patients cared for in out-of-hospital conditions (i.e., primary care and home care).

Patient Adherence: A patient's willingness and practice of following medical treatment and advice.

Patient Self-Management: The responsibility and practice of patients managing their own medical care, with the support of advice and education by medical practitioners.

User Adoption: The acceptance and use of a system based on usefulness, ease of use, or other factors.

Managing Operating Room Cost in Cardiac Surgery with Three Process Interventions

INTRODUCTION

Health care providers in both public and private sectors are facing increasing pressure to improve their cost efficiency and productivity. The increasing cost of new technological solutions has enforced the application of operations management techniques developed for industrial and service processes. Meyer's (2004) review of existing research shows that, on average, operating rooms (ORs) operate only at 68% capacity. Using OR time efficiently is especially challenging when long operations are scheduled to fixed OR block time. This situation is typical in open heart surgeries where a high variability in the length of required OR time combined with four and a half hour average OR time duration makes scheduling two operations during a normal eight-hour workday difficult.

The objective of this chapter is to analyze the effect that three process interventions have on the OR cost in ORs performing open heart surgeries. The investigated process interventions are four days OR week (4D), the better accuracy of operating room time forecast (F), and doing anesthesia induction outside the OR (I). These interventions emerged from practical organization context.

This chapter is organized as follows. First we provide a review of the existing literature on measures of OR utilization and the investigated three interventions. Based on existing literature, we construct a simulation model to test the interventions' effects on OR utilization. Conclusions of results are presented, and practical implications and new contributions to existing theory of OR management are discussed.

BACKGROUND

Operating room efficiency is typically defined as raw utilization, which means a percentage of time that patients are in the operating room during resource hours (Donham, Mazzei & Jones, 1996). This definition for OR efficiency, however, does not take into account the cost of overused time, which emerges when operations are stretched. Thus, a more valid measure for OR efficiency is a weighted sum of underused and overused OR time (Dexter, 2003). Estimates for relative cost of overused to underused OR time varies in literature from 1.75 (Dexter, Traub & Macario, 2003) to 4 (Dexter, Yue & Dow, 2006). Besides this relative cost, the total OR cost depends on substitutive tasks for underused OR time. Therefore, when evaluating the effect of various process improvements to OR cost, results have to be calculated with case-specific, relative cost for operating time, underused time, and overused time. In the next section, we consider the estimated interventions from existing literature's point of view.

4 Days OR Week (4D)

Especially in long operations, the lengthening of the OR shift has been mentioned as a relevant method to improve OR utilization. In open heart surgeries, the hypothetical advance will be achieved by reallocating the working hours of Friday to the other four working days. Nearly 10 hours OR block time improves the possibility to schedule two operations per day. Despite statistical advances to lengthen the OR block, it has been shown that moving to a four-day week might lead to an increase in sick leaves (Dzoljic et al., 2003). In this case, it was assumed, however, that allocating resources for four 10-hour OR sessions per week is more effective than continuing with 8-hour blocks in open heart surgeries.

The Better Accuracy of Operating Room Time Forecast (F)

An accurate modeling of time distribution as well as an estimation of operating room times has been recognized as an important factor in effective OR planning and scheduling systems (May, Strum & Vargas, 2000; Spangler, Strum, Vargas & May, 2004). The more accurately the required OR time for planned operation can be estimated, the more exactly can the OR resource hours be scheduled while still avoiding overtime. Many researches show that forecasting a required OR time for planned operation is difficult (Macario & Dexter, 1999), but the best estimates can be derived from historical surgeon and surgery type-specific durations (Strum, Sampson, May & Vargas, 2000). Determination of individualized operating room times associated with definition of a daily limit in scheduled OR resource hours resulted in reduction of time overruns and delays before surgery (Broka, Jamart & Louagie, 2003). In open heart surgeries, a hypothetical advance of better OR time forecasting was to get more OR sessions with two operations being performed.

Doing Anesthesia Induction Outside the OR (I)

By moving the anesthesia induction outside the OR and doing it simultaneously with a previous operation, an additional operation can be scheduled for fixed OR block time (Friedman, Sokal, Chang & Berger, 2006). The effect of doing anesthesia induction in parallel with a previous case is best when it makes it possible to increase the amount of performed operations from one to two per day. This is a recurring situation in open heart surgeries. On the other hand, parallel processing requires more nursing staff per OR, and that has to be taken account when assessing a total effect of the intervention (Torkki, Alho, Peltokorpi, Torkki & Kallio, 2006).

RESEARCH QUESTIONS AND METHODOLOGY

The research questions of this chapter are:

1. What is the effect of a four-day OR week, the better accuracy of operating room time forecast, and doing anesthesia induction outside the OR, as well as their combinations, on OR cost per patient?
2. How does the relative cost for operating time, slack time, and overtime impact the effects of the interventions?

The effects of three process interventions and their combinations are tested with a discrete-event simulation model on the open heart surgery patient process. Discrete-event simulation enables the evaluation of alternative productivity improvement proposals while maintaining the dynamic nature of the open heart patient queue. The simulation model was constructed based on Kuopio University Hospital (KUH) open heart surgery process.

CASE UNIVERSITY HOSPITAL

Kuopio University Hospital (KUH) has the special responsibility of treating severe illnesses that call for special expertise and technology in the Hospital District of Northern Savo, Finland. The average yearly number of open heart surgeries is about 1,000. One of the focus areas in KUH is to increase productivity in the operation theater, which was identified as one of the resources that limited the throughput of open heart surgeries. KUH offers coronary bypass surgeries for external hospital districts, and it is losing patients to its competitors. Thus, improving productivity of coronary bypass surgeries would directly increase hospital turnover and profitability.

The input data for developing both the operation time forecasting model and the simulation model was the actual data of all the 2,603 open heart surgeries performed at KUH hospital during the years 2001–2003.

Open Heart Operation Time Model

The average operating theater time usage for open heart surgery is more than four hours, with the actual operation taking 3:21 hours (Table 1). In the simulation model, the OR time is randomly assigned from the historical patient data. A more accurate forecast for needed OR time can be determined based on operation, patient, and surgeon variables (Lehtonen, Kujala, Kouri & Hippaläinen, 2006).

Simulation Model for Evaluation of Production Improvement Proposals

A discrete event simulation model was created to capture the most important elements of the operation theater scheduling system in the case organization (Figure 1).

The emergency patient weekly arrivals are modeled by a Poisson (7,15) distribution. Each of these arrivals is randomly assigned to a weekday. When the assigned weekday is reached, the arriving emergency patient is placed in either an operating room or an emergency patient queue. The OR time as well as OR time forecast are assigned by randomly selecting from the historical emergency patient data. Ten operating rooms per week are reserved for the emergency patients, leaving on average 2.85 rooms per week for elective patients. The emergency surgery overcapacity is supplemented by a specific buffer (fillbuffer), which models the possibility of calling patients from the elective queue at short notice. For each emergency operation, the buffer is checked for the possibility of a second operation during the day. The sum of forecasted operating room times must be less than the length of a workday and of the planned slack. The buffer is filled weekly from the elective queue.

Elective patient arrivals are modeled so they fill the elective queue up to the maximum queue limit. It is assumed that the available demand of operations is larger than operating capacity. Operating time, OR time forecast, and priority are randomized through selecting from historical patient data. There are three priority classes. Priority controls the time a patient may wait in the queue; when the maximum queuing time is reached, the patient is then moved to the front of the queue. Operation planning is done each week for the two operating rooms according to patient priority. For each scheduled patient, a check is preformed to see whether there is another patient in the elective queue whose surgery also can be preformed that day. The OR time that is forecast for the second operation must be less than a day's work in length with the planned slack. If there is no such candidate, only one surgery is scheduled.

To calculate the average cost of surgery for various scenarios, we need to define the relative cost for overtime, slack time, and operating time. Operating time and slack time equals regular hours. Slack time cost depends on how flexibly an organization can reallocate its resources to tasks other than operating during the slack time, such as administration, consultation, or research. The overtime represents the additional cost for overtime work. The following weights for hourly OR time costs were used in the simulation (see Table 2).

The average cost of operation was measured based on the following formula:

$$Cost\_weighted\_OR\_time\_(hr/patient) = \frac{w \times Operating\_time + s \times Slack\_time + o \times Overtime}{Number\_of\_operations}$$

By multiplying the cost weighted OR time by cost of OR hour for the team, we get the average cost per patient (Box 1).

Table 1. The average operating room time usage for open heart surgery (n=2603)

Stage	Start	Room ready	Anaesthesia start	Operation	Anaesthesia end	End	Total
Duration h:mm	0:01	0:24	0:27	3:21	0:16	0:00	4:31

1	1	5
1	0.5	2
1	0.5	3
1	0.5	5

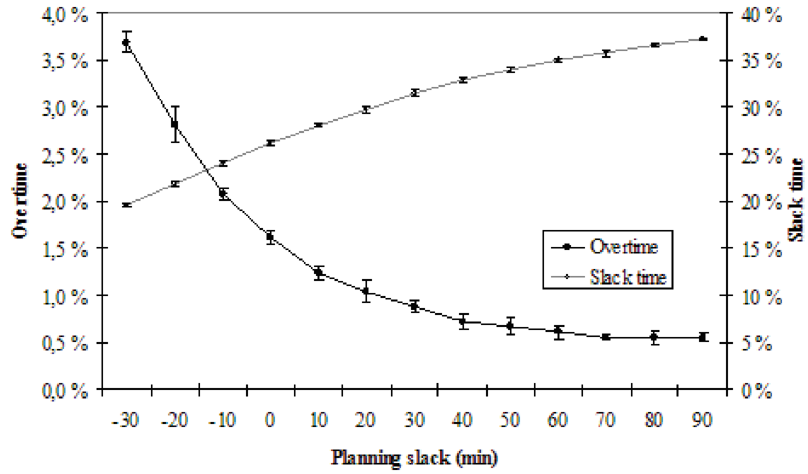
Experimental Variables and Design

The experimental variables included in the simulation experiments were forecast accuracy, induction, and four-day week. The following contains an explanation of how these variables were operationalized in the simulation model experiments:

- **A four-day week (4D):** A change where one of the two elective patient operating rooms is having for a four-day-week instead of a five-day-week, as not everyone is willing to have a four-day week.
- **Forecast accuracy of the OR time (F):** A low value (0) is the forecast based on linear regression, while a high value (1) is a hypothetical improved forecast. The improved forecast is obtained by 0.75 * linear regression forecast + 0.25 * true value.
- **The induction of anesthesia is done outside the operating room in order to reduce other than operation time between two consecutive operations (I):** The reduction achieved by induction when scheduling two operations is around 30 minutes per patient.

The planning slack is the time margin applied between a sum of forecasted OR times and workday length when making a decision of accepting a second opera-

Figure 2. Overtime and slack time with different planning slacks in percentage of cost of regular hours in the "base case" (4D=0, F=0 and I=0), and with slack time penalty s=0.5 and overtime penalty o=5



tion for the day. The effects of the three experimental variables are evaluated over planning slack range from –30 minutes to 90 minutes at 10-minute intervals.

In the simulation experiments, a warm-up period of 100 days was used. Each individual result is based on a three-year run (1,095 days) with 10 replications, without including the warm-up period.

Simulation Results

The chart in Figure 2 shows the overtime and slack time variables in percent of cost of regular hours in the base case (4D=0, F=0 and I=0). The overtime increases at increasing speed as the planned slack is reduced, while the slack time does not decrease as fast as the overtime increases. Also, one can see that there is much more slack time than there is overtime throughout the range of planning slack, which demonstrates the problematic length of open heart surgery in comparison to average working day length.

As the planning slack is decreased, more operations can be performed. This is shown in Figure 2 indirectly, as the slack time decreases and overtime increases as planning slack is reduced.

Table 3 shows for each of the three factors the decrease in costs per patient across all scenarios, each evaluated at the planning slack value that produced optimum results; that is, the average difference between

Table 3. The effect of implementing each of the three interventions in all scenarios at optimum planning slack values. The effect is shown in decreased cost weighted hour per patient and decreased OR cost per patient (calculated with OR time per hour cost for the team = 259 €).

Relative cost		Factor decrease in cost weighted OR time (hr/patient)			Factor decrease in €/patient		
Slack time	Overtime	4-day	Forecast	Induction	4-day	Forecast	Induction
1	2	0.022	0.047	0.407	5.6 €	12.1 €	105 €
	3	0.020	0.068	0.408	5.3 €	17.5 €	106 €
	5	0.027	0.112	0.431	6.9 €	29.0 €	112 €
0.5	2	0.012	0.037	0.327	3.2 €	9.6 €	84.6 €
	3	0.016	0.057	0.330	4.2 €	14.8 €	85.5 €
	5	0.031	0.099	0.325	7.9 €	25.7 €	84.0 €

a factor's highest and lowest values over all the other factor values. The planning slack resulting to optimum value varied between -30 min and 10 min. High overtime valuation, low slack-time valuation, and presence of induction all increased the planning slack value that resulted to optimum.

Factor decrease in euros are calculated by multiplying the cost weighted OR time by 259 €, which is based on OR team staffing (3 doctors and 3.5 nurses) and hourly cost in Finnish wage level (Statistics Finland, 2006, The Finnish Medical Association, 2006). One can see that at the overall level, when using optimal planning slack in scheduling, the most effective intervention is induction. The forecast accuracy has a smaller overall effect but is strongly dependent on weight that is used for overtime work. The four-day week has the smallest impact and appears to be influenced by overtime penalty when s = 0.5 but not that much when s = 1. However, one must remember that the 4D affects only one of the four operating rooms, while forecasting accuracy and induction affect all four. Even in that one room that it affects, is effect clearly smaller than that of induction and, depending on relative costs, smaller or bigger than that of forecasting accuracy?

DISCUSSION

The cost effect of various process improvement interventions depends on relative cost of normal working time, slack time, and overtime. An organization with flexible working hours and an ability to allocate resources to other productive activities for both scheduled and unscheduled slack time is most cost-efficient for performing surgeries whose length is difficult to forecast in advance.

Although performing induction outside the OR seems to be the most efficient intervention in this research, it has to be taken into account that induction typically requires additional personnel (Torkki, Alho, Peltokorpi, Torkki & Kallio, 2006). The actual need for additional personnel, however, depends on type of surgeries and how induction is organized. For example, is it possible for an anesthesiologist to perform anesthesia induction parallel with a previous operation, and are additional nurses required for induction outside the OR?

Compared to existing literature (Friedman et al., 2006; Torkki et al., 2006), this chapter strengthens the argument that performing induction outside the OR is very beneficial when it is possible to add operations to the end of the day. Practically, implementing induction outside the OR requires space and equipment investments.

A four-day week has been mentioned earlier as unwelcome for OR personnel (Dzoljic et al., 2003), and this research also indicates that it does not lead to significant improvements in cost-efficien**cy**. Based on this case, an implementation of a four-day week will need strong management with trade unions.

Based on the literature, improving OR time forecast accuracy is hard work (Macario & Dexter, 1999). This chapter shows that minor improvement in forecasting does not mean remarkable savings in OR cost per patient. Implementing a better forecasting system will require a specific project, and its results are still unpredictable.

FUTURE TRENDS

Recent studies highlight the role of process management methods in operating units. Flexible process and space solutions (Friedman et al., 2006), effective scheduling (Spangler et al., 2004) and personnel incentives are also becoming general in cardiac surgery units. Due to the complexity and multidimensionality of an operating unit, simulation and other computer-based tools will increasingly be utilized when evaluating organizational and process changes.

CONCLUSION

This chapter shows that using anesthesia induction outside the OR improves cost-efficiency. A four-day OR week and better forecasting accuracy have both a positive but relatively smaller impact on OR cost per patient. Forecast accuracy becomes more crucial when the penalty for overtime increases. The benefit of implementing a four-day week and induction are not as much depending on weights for overtime. Based on results, it also can be seen that the effect of all three interventions is more limited if an organization can reallocate its resources to other tasks during the slack time.

For health care managers, this study implicates that the optimal case-specific planning slack times for scheduling can be determined based on discrete event simulation model and by doing anesthesia induction outside the OR in order to reduce OR cost per patient.

In this chapter, a simulation model was used for scheduling patients for operations. The scheduling algorithm as such was not a subject of study (Dexter, Macario & Rodney, 1999). The main benefit of using simulation was its flexibility; that is, the relative ease of developing a descriptive model and the ability of experimenting with it. Simulation can be used in operative scheduling (Lehtonen, Ruohola, Appelqvist & Mattila, 2003), and the simulation model of this article can conceivably also be implemented for OR scheduling, although not without modifications and linking it to existing information systems.

KEY TERMS

Anesthesia Induction: Time when the anesthesiologist begins the administration of agents intended to provide the level of anesthesia required for the scheduled procedure.

Discrete Event Simulation: A simulation model where significant changes occur at discrete time instances.

Operating Time: Time patient is in the operating room during regular hours.

Overtime: Time that patient is in the operating room after regular hours.

Planning Slack Time: Minimum time that has to be left nonscheduled at the end of regular hours.

Slack Time: Time operating room is empty at the end of regular hours.

Managing Paramedic Knowledge for Treatment of Acute Myocardial Infarction

INTRODUCTION

There are about 280,000 acute myocardial infarctions (AMI) each year in the United Kingdom (British Heart Foundation (BHF), 2004). Up to half of these events will prove to be fatal, many within the first few hours following symptom onset as a result of disturbances of cardiac rhythm. For those patients who survive the initial period of vulnerability, subsequent mortality and the risk of disabling chronic heart failure can be markedly reduced by prompt restoration of blood flow through the affected coronary artery.

This can be achieved in patients sustaining a STEMI by mechanical means (percutaneous coronary intervention) or pharmacologically by thrombolytic ("clot buster") therapy (Antman et al., 2004) or where initial thrombolytic treatment fails—"rescue" intervention. Mortality benefit from thrombolysis is time dependent; for patients presenting with STEMI in the first 2 to 3 hours from onset, each minute's delay equates to 11 days loss of life expectancy (Department of Health (DoH), 2003).

BACKGROUND

In England, publication of the National Service Framework (NSF) for coronary heart disease (CHD) has resulted in dramatic improvements in the timeliness of thrombolytic treatment (DoH, 2000), with half of eligible STEMI patients starting treatment within the NSF standard of 60 minutes from the call for help (Birkhead et al., 2004) compared to one in 10 in the years preceding the NSF (Quinn, Allan, Birkhead, Griffiths, Gyde & Murray, 2003). These improvements are largely a result of improved hospital processes (Birkhead et al., 2004), but further increasing the proportion of patients treated within the NSF "call to needle time" is reliant on thrombolysis commencing prior to hospitalization (Quinn et al., 2003), administered mainly by ambulance paramedics.

Significant government investment in emergency ambulance services in England has facilitated universal availability of 12 lead electrocardiograph (ECG) equipment, programs to enhance training of paramedics in assessment of patients with suspected STEMI for thrombolysis eligibility (and other aspects of cardiac care), and procurement of the appropriate thrombolytic drugs.

The United Kingdom provides a mainly paramedic-led ambulance service in contrast to several other countries where some ambulances are manned by physicians or intensive-care trained nurses (Bouten, Simoons, Hartman, Van Miltenburg, Van der Does & Pool, 1992; Leizorovicz et al., 1997). This has led to concern in some quarters about the feasibility and safety of nonphysicians administering thrombolysis in the ambulance setting.

Recent UK studies, however, have confirmed that paramedics can accurately identify patients with suspected AMI requiring specialist coronary care (Quinn, Allan, Thompson, Pawelec & Boyle, 1999) and, in particular, patients presenting with ST segment elevation (the cornerstone of decision-making in this context) on the ECG (Whitbread et al., 2002) and eligibility for thrombolysis (Pitt, 2002; Keeling et al., 2003). Moreover, a recent international clinical trial has demonstrated that the efficacy and safety of prehospital thrombolysis was independent of physician presence (Welsh et al., 2005). Around 4,000 patients in England have received "paramedic thrombolysis" since 2003.

Nevertheless, the government's own Review of Early Thrombolysis (DoH, 2003) has acknowledged concerns about paramedics' retention of knowledge and skill in relation to thrombolytic treatment; in particular, in relation to the low exposure to this aspect of emergency care in low-density populations in rural areas. The review acknowledges the need for research to address the question of a "volume-outcome" relationship between paramedics' exposure to the procedure and patient safety.

LEARNING, SKILL, AND KNOWLEDGE RETENTION

It is appropriate to make a distinction between learning (a change in behavior as a result of experience) (Haskell, 2001) and skill retention (persistence of skill proficiency after a period of no practice) (Cree & Macauley, 2003).

Although there is a paucity of research specific to the areas of learning and skill retention around paramedics and thrombolytic treatment, the literature on other aspects of paramedic practice may be relevant. For example, paramedics' skill acquisition, retention, and decay have been assessed in relation to tracheal intubation (Barnes, 2001), neonatal resuscitation (Skidmore & Urquhart, 2001), and laryngeal mask intubation (Coles, Elding & Mercer, 2001). Studies of skill decay in the delivery of cardiopulmonary resuscitation demonstrate poor skill and knowledge retention with a return to pretraining levels within six months (Roach & Medina, 1994). Issues of motivation, competence, confidence, and assessment come in to play (Chamberlain & Hazinski, 2003).

COMPETENCE

While these are essentially psychomotor skills, the safe administration of thrombolytic treatment requires paramedics to demonstrate a range of competencies (Quinn, Butters & Todd, 2002) involving patient assessment, ECG interpretation, identification of contraindications to treatment (the latter largely aimed at reducing risk of intracranial and other haemorrhagic complications), weight estimation (Hall et al., 2004), and explaining the risks and benefits of treatment to patients.

The presence of a so-called rural paramedic paradox has been suggested in which patients living further away from hospitals tend to be in low-density, rural populations where an individual paramedic's exposure to severe emergencies (e.g., STEMI) may be low, but the distance and time to reach a hospital may mean that the need for highly skilled paramedic intervention is highest (Rowley, 2001). Whether this results in poorer patient care is unknown.

A volume outcome relationship for STEMI patients has been reported in relationship to physician exposure to the condition (Tu, Austin & Chan, 2001). However, with an estimated 700,000 emergency attendances with chest pain to hospitals in England and Wales per annum (Goodacre et al., 2005), it is likely that paramedics will be performing many more assessments and ECG recordings than they will be administering thrombolysis to or referring for primary intervention; therefore, the key assessment skills will be subject to frequent exposure.

KNOWLEDGE MANAGEMENT

A number of studies have put forth the notion of incorporating KM in health care as a way out of the imminent information explosion crisis (Koretz & Lee, 1998; Wyatt, 2001). The average physician spends as much as a quarter of his or her professional activities managing information and has to learn an estimated 2 million clinical specifics (Wyatt, 2000), a burden compounded by the doubling of biomedical literature every two decades. The burden on other health professionals, including paramedics, has not been reported. Paramedics, as registered health professionals, also are required to maintain their knowledge base, although currently didactic clinical guidelines are prepared and distributed nationally. As with other generalist health professionals, paramedics' scope of practice (and thus, underpinning knowledge) is potentially enormous.

"Knowledge is the enemy of disease" (Brice & Gray, 2003) and serves ultimately to protect the patient from harm. Data from NHS information sources (Brice & Gray, 2003) indicate the scale of the problem of serious failures in health care. From these sources, we learn that annually:

- 400 people die or are seriously injured in adverse events involving medical devices.
- Nearly 10,000 people are reported to have experienced serious adverse reactions to drugs.
- Around 1,150 people who have been in recent contact with mental health services commit suicide.
- Nearly 28,000 written complaints are made about aspects of clinical treatment in hospitals.
- The NHS pays out around £400 million a year for settlement of clinical negligence claims, and has a potential liability of around £2.4 billion for existing and expected claims.
- Hospital acquired infections, around 15% of which may be avoidable, are estimated to cost the NHS nearly £1 billion.

As skills and knowledge exist in both individuals and organizations, the essence of knowledge management is how best to identify and capture knowledge and experience in order to disseminate it further throughout the organization. There have been several attempts to bring various forms of clinical information to the clinician at the point of care. They include:

- Developing computer applications that stand alone, although they are often network accessible and are available to the clinician upon his or her request.
- Incorporating the clinical knowledge directly into clinical information systems used by clinicians while giving care (once there, the computer-based system can automatically prompt the clinician or the clinician can request help).
- Requesting help from an outside source (Sittig, 2005).

FUTURE TRENDS

While many of these approaches relate to physicians in primary and secondary care settings, the use of computerized decision aides in emergency cardiac care has been reported (Grisjeels et al., 1996; Lamfers et al., 2004); although these are not widely used in the ambulance service in England, the development of the National Programme for Information Technology across the National Health Service (NHS) raises new opportunities (Humber, 2004), including wider utilization of on-board computers on emergency ambulances (Bastow, 2003).

Paramedics often are required to make rapid life or death decisions that can have far-reaching consequences for patients. As previously stated, these decisions include such competencies as patient assessment, ECG interpretation, identification of contraindications to treatment, weight estimation, and explaining the risks and benefits of treatment to patients. Therefore, paramedics need to embrace appropriately designed, tested, and reliable tools and techniques of knowledge management to facilitate rapid and safe processing of pertinent knowledge.

IT-based clinical knowledge is managed by way of such tools as medical decision support systems, which themselves are a product of clinical practice guidelines issued by various government and medical associations. Clinical practice guidelines are effectively rule-based knowledge that guides the decision makers in a medical setting (Field & Lohr, 1992). These guidelines have been developed over the years to reduce the variations among medical practices with a common goal to provide cost-effective and high-quality health care services.

This has to be balanced against the reality of the contemporary environment and associated employee performance and safe practice within this rapidly changing practice environment. There is an acknowledged gap between the importance of assessing what employees can do and not what they know. Del Bueno, Weeks, and Brown-Stewart (1987) report a study carried out among test takers who have difficulty performing a procedure or recognizing warning signs in a patient experiencing difficulty. The use of criterion-based performance measures determines practice competencies in employees as well as identifies where need exists to correct skill or knowledge deficiencies.

TOWARD A CARDIAC CARE KNOWLEDGE MANAGEMENT SYSTEM (KMS) FOR PARAMEDICS

Knowledge Management Systems (KMS) consist of appropriate information technologies (IT), policies, processes, and procedures to manage the creation, storing, sharing, and reuse of knowledge. In this context, knowledge is any information that is relevant and actionable and is based on a person's experience (Davenport, De Long & Beers, 1998). For paramedics, an accessible cardiac care KMS would assist in the reduction of health care costs, which are growing at an unsustainable rate (up 20% since 2001) and placing a major burden on the economy (Warner, 2004). KMSs have the potential to reduce medical errors, which cause an estimated 1 million injuries and 98,000 deaths each year (Davenport & Glaser, 2002; Warner, 2004).

For the creation of a viable cardiac care KMS, further work is required to assist health care organizations in carrying out activities better, faster, and cheaper (Dwivedi, Bali, James, Naguib & Johnson, 2002). Such research work would include (a) analyzing and forming a suitable KM strategy for the paramedic function; (b) adopting best practice from established KM strategies and implementations (from the nonclinical environments); and (c) capturing and integrating paramedic perspectives on clinical knowledge which few previous studies have managed effectively.

CONCLUSION

In a publicly funded health system driven by accountability, defining competence has been described as one of the most challenging and essential components in the accountability paradigm (Redman, Lenburg & Hinton Walker, 1999). With more and more medical interventions such as thrombolysis being delegated to nonphysicians (and in this case, particularly paramedics), there is a need for improved understanding of how knowledge is managed and how best to optimize effective clinical decision-making.

KEY TERMS

Emergency Cardiac Care: Includes resuscitation from cardiac arrest and care of patients with suspected heart attack (acute myocardial infarction) and its complications.

Knowledge Management: The collection, organization, analysis, and sharing of information held by workers and groups within an organization.

Myocardial Infarction: Another term for a heart attack; occurs when a blood vessel (an artery) to the heart is blocked.

Paramedic: Registered health care professional who provides emergency and urgent care and treatment to patients who are either acutely ill or injured; paramedics usually work outside the hospital environment and are able to perform a variety of advanced skills, administer a range of drugs, and carry out certain surgical techniques.

Thrombolysis: Use of drugs to break down a blood clot that is obstructing a blood vessel (usually an artery).

Mapping Information of Operating Theatre Waiting List Process

Gerhardine Foo
University of Southern Queensland, Australia

Latif Al-Hakim
University of Southern Queensland, Australia

INTRODUCTION

An operating theatre waiting list (OTWL) is a list that patients are enrolled in once they opt to pursue an elective procedure, assuming they cannot get this procedure performed immediately (Chua, 2005). Operating Theatre Waiting Lists are of great concern in society nowadays because of their societal and political priority, their link to the quality of individual patients' lives, relation to the economic management of operating theatres and management of patient flow through the hospital, and distribution of scarce medical resources (Al-Hakim & Fitzgerald, 2003; Foote, North & Houston, 2004; NSW Health, 2002). They are used by politicians as measures of success or otherwise measures of government action on the health services.

It is generally accepted that waiting lists are unacceptably long and create a number of problems (Foote et al., 2004). Long waiting times are a problem for patients, not only because of uncertainty but also because the state of the patient may deteriorate if he or she is not treated early enough (Council of Europe, 2005). Nothing is more important to patients than the length of time they have to wait for treatments. The impact of fast, effective treatment, diagnosis and treatment on a patient's health and well-being is incalculable (Scottish Executive, 2001). Disruptions and delay affect the quality of patient care and may cause stress, anxiety, and discomfort for patients as well as cause costs to escalate as sessions overrun and much more (Buchanan & Wilson, 1996). Also, if a patient does not arrive in the operating theatre on time, the surgeon may be left idle or left to perform routine duties, which is expensive for the hospital and frustrating for the staff (Buchanan, 1998). There also have been reports about the depressing effects on patients of cancelling surgeries and on the high level of emotional involvement before surgeries. Late cancellation of scheduled operations is also a major cause of inefficient use of operating-room time and a waste of resources; it is potentially stressful and costly to patients in terms of working days lost and disruption to daily life as well (Schofield et al., 2005).

Sometimes waiting lists are so long that patients have to be turned away. In September 2005, it was found that more than 30 patients were turned away daily from the Royal Brisbane and Women's Hospital (Sommerfeld, 2005). Long waiting lists also have been found to distort the clinical judgement of doctors, thereby causing suffering for some of the most seriously ill patients. It has been found that half of the consultants in England admitted deferring surgery in high priority cases to treat less urgent patients because of the pressure to cut waiting lists in those areas (Carvel, 2001). The consultants who admitted to treating patients in the wrong order said that this had a negative impact on the patients' conditions.

OTWL Activities

OTWL comprises a large number of activities that can be grouped into five main categories:

1. **Pre-admission.** This includes activities related to the referral from the GP or specialist and the deciding of the level of categorization that the patient is given as well as the booking of appointment.
2. **Peri-operative.** This includes the activities of patient booking, operating scheduling, and patient preparation. It consists of:
    - Expanding the scope of peri-operative care to include all activities from the hospital receiving the recommendation for admission form to discharge from either the day-only or recovery unit

- An expanded scope of responsibility—bundling activities with responsibility delegated to an individual to enable new processes to occur
- A collocation of related activities—booking and scheduling with the pre-admission clinic, day-only and day-of-surgery unit located adjacent to the operating theatres

3. **Intra-operative.** Involves managing operating theatre resources and procedures directly associated with the surgery to ensure safe and effective patient outcomes.
4. **Bed management.** Concerned with making different types of beds available to patients. Relevant admission and discharge policies are required to manage bed availability on an hour-to-hour, day-to-day basis. Examples identified include elective day surgery admissions and patients cared for in the ambulatory unit following surgery.
5. **Discharge planning.** Encompasses activities aimed at the smooth transition of the patient from hospital to their home or place of residence.
6. **The information flow.** Involves the exchange and use of data to manage surgical services and operating theatres. These include:
   - Surgeon/specialty session allocation, including changes due to individual surgeon's availability throughout the year
   - Surgeon and hospital waiting list data
   - Seasonal/population demands
   - Patient data and clinical information
   - Operating theatre booking and scheduling, including resources, equipment, and prostheses
   - Patient bookings, including appointment dates and times for the pre-admission clinic, and admission dates and times for day-only and day-of-surgery admissions
   - Real time activity data to manage elective and nonelective/emergency cases
   - Availability of acute beds, including intensive care unit and high dependency unit beds and the number of patients being discharged
   - Hospital and operating theatre utilization and outcome data; for example, pre-admission clinic attendance rates, day-only and day-of-surgery rates, and cancellation rates

Potential Causes of the Problem

There is often a lack of consistency between planned theatre session lists and the manner in which these actually run. Theatre staff and users frequently fail to keep to regular session start and finish times; thus, late starts and overruns of sessions are commonplace. This is because once the list has been drawn up, it is still vulnerable to multiple alterations and modifications (Audit Commission, 2002; 2003; Buchanan & Wilson, 1996; Healthcare Commission, 2005; McAleer, Turner, Lismore & Naqvi, 1995; Schofield et al., 2005). Following is a list of the main causes of the problem of long OTWL:

- Accommodating emergency cases that are given priority
- No separate emergency theatre session, leading to interruptions in routine lists
- Over-ambitious, poor list planning
- Unanticipated variation in the patient's condition, only known during the surgery
- Unpredictability of procedure's length of time
- Unanticipated variations in the time of patient's stay in the recovery ward
- Cancellation of operations on the day of intended surgery
- Preoperation tests are not done properly or completed on time
- Unavailability of beds in recovery wards
- No agreed start and finish times for theatre sessions
- Lack of commitment by theatre staff and users to ensure they arrive on time
- Delays due to external factors such as patients, equipment, and supplies not being delivered to the theatre on time
- Patients delaying surgery due to personal reasons (e.g., fear)
- Unavailability of resources, such as specialists, porters, surgical equipment, and so forth

Sometimes a poorly maintained information system also contributes to the problem of the waiting list. Generally, decisions about theatre lists are entered in multiple patient records by a number of staff and officers who do not always communicate their independent actions. This is not helped by the fact that there is difficulty arranging meetings with all the specialists, who are very busy people with overcrowded schedules (McAleer et al., 1995). The reasons and causes identified previously are not exhaustive. They only serve to indicate the complexity of the problem and the importance of developing an effective methodology for mapping information flow of the OTWL process.

Traditional process mapping methodologies cannot recognize the various activities' elements other than their inputs and outputs. Accordingly, these methodologies lack the ability to determine the interdependencies among all elements of process activities and, accordingly, cannot be used to map information flow among all these elements or interdependencies. Failure to map information flow comprehensively may affect the successful implementation of BPR.

The objective of this chapter is to develop a theoretical framework for mapping information between various activities' elements of the OTWL process that provides a valid platform for evaluating various OTWL scenarios to enable the most applicable design to be selected. It is hoped that with a better design to coordinate the activities of the OTWL process, the quality of health care will improve. This research is part of a larger project for redesigning the operating theatre process (Project No. 1000819), which is supported by the Faculty of Business at the University of Southern Queensland. The project is initiated by the second author and comprises two research students: a Master's Degree researcher and an Honour Degree researcher (the first author).

SOLUTION APPROACHES

Researchers have used various ways to attempt to solve the problem of long OTWL; namely, by using various kinds of techniques to identify the problems. Operations research, in particular, has been popular. Operations research is concerned with the conduct and coordination of activities within complex systems, using tools such as mathematical modeling, queuing theory, and simulation to study the consequences of alternative courses of actions and to optimise performances of the system (Buhaug, 2002). The aim of operations research is to provide numerical answers to problems and insights into the nature of the problem as well, thereby helping hospital staff and managers to ask the right questions, make sense of the answers, and look in the right direction for solutions. Some of the operations research approaches are discussed here.

McAleer, et al. (1995) used Visual Interactive Simulation (VIS) for the simulation of a hospital's theatre suite. The study was undertaken to identify delays and restrictions in the system (due to resources imbalance) by using a VIS model to explore the relationship among various throughput levels and resource allocations. However, the aim is to only optimise the use of resources, and they did not take into account the interdependencies of the activities.

The simulation software program Witness was used by Ivaldi, Elena, and Testi (2003) to develop a discrete-event simulation model of a surgical department. Ramirez-Valdevia and Crowe (1997) attempted to use a methodology called Simulation Service Quality System (SSQS) to improve operating performance measures in light of a patient's preferences. Patients' expectations are used to set performance standards, and then a model of such is simulated using the discrete-event simulation package SIMAN.

Most of the research work analyzing waiting lists in Spain has been based on queuing theory. Gonzalez-Busto and Garcia (1999) attempted a systems dynamic approach to solve the waiting list problem in Spanish hospitals. Their research involves building a simulation model in order to improve the understanding of how waiting lists behave over time and to analyze the long-term effectiveness of the policies commonly used when managing them. This simulation model includes the policies currently in practice (subcontracting activities to public and privately owned hospitals, the so-called special programs, waiting list updating or revision) and some new proposals (capacity investment decision and staggering of vacation periods).

Attempts to build Priority Queuing Models to reduce waiting times in emergency care (Johnson, Jones & Siddharthan, 1996) have been attempted as well. Their claim as the solution to the problem is to force nonemergency users to realize the social costs of their actions and to impose additional waiting times.

Foote, North and Houston (2004) report findings of case studies of problematic ultrasound waiting lists and provide some insight into the understanding of hospital waiting lists. They highlighted that waiting lists are better conceptualized as a set of interacting issues instead of viewing them as a rational queue, and that technical solutions would not be sufficient to address the problem.

Barlow (2002) tried to find a critical factor affecting the waiting list by measuring the gap between the expectations and perceptions of the OTWL services of the patient. He concluded that the actual time of delay is not of significant importance; rather, it is the difference between the customer perceptions and expectation that create the level of satisfaction.

Methods such as scheduling have been used but have proved to be too simplistic and insufficient in addressing the complexity of the OTWL process. This can be seen in the NSW Health Operating Theatre Management Project conducted by KPMG consultants (NSW Health, 2002). Despite the huge financial investment in the project, the end result was a simple scheduling and identification of the major activities. There was insufficient description of specific details; for instance, the transfer of a referral letter from a doctor.

Buchanan and Wilson (1996) tried to use Business Process Re-engineering to redesign the surgical patient trail from referral to a specialist by a general practitioner through admission, treatment, and discharge. Motives for doing so include cost reduction, improvements in theatre's capacity utilization, improvements in staff morale, and quality of patient care.

The use of the fuzzy logics approach to scheduling to support decision-making about queues in operating theatre suites has been used (Al-Hakim, 2006; Al-Hakim & Fitzgerald 2003). It is a very deterministic approach in the sense that it gives a yes or no answer instead of more or less.

OTWL PROCESS MAPPING AND INFORMATION MAPPING

A process cuts across the functional boundaries of an organization and is the means by which an organization achieves its stated objectives (Bal, 1998). Process complexity is often difficult to visualize. To adequately address the issues, there is a need to map the OTWL process. Process mapping is a technique used to detail business process activities by focusing on the important elements that influence those activities (Soliman, 1998); it consists of constructing a model that shows the relationships among the activities, people, data, and objects involved in the production of a specified output (Biazzo, 2002). Process mapping is used to re-engineer or improve a system and encourages a process orientation and overview (Buchanan, 1998); its models can offer useful and relatively inexpensive descriptions that can help toward improving and redesigning business processes (Biazzo, 2002). With staff participation, it broadens cross-functional awareness and understanding; potentially fosters mutual respect for different contributions to the patient trail; and can deepen appreciation of the extent to which problems are shared, which activities may be unnecessarily duplicated, and how problems can be unwittingly passed on from one stage on the trail to another (Buchanan, 1998).

To successfully map a process, we need to go beyond the detailing of each activity in the process. There is a need to understand the interdependencies among various elements of the process as well as the flow of information. In other words, there is a need to adequately map OTWL process (Al-Hakim, 2006). To do so, the first step is to comprehend what constitutes an activity—the elements of an activity.

Generally, OTWL comprises two main aspects: technical and social. Therefore, sociotechnical theory is applicable here in addressing these issues (Fernandez, Jacobs, Kauffman & Keating, 2001). The previous studies of OTWL mainly examined the technical aspects of the process with a few mentioning but not taking into account social factors, or vice versa.

Most of the typical process mapping efforts such as flowcharts and Gantt charts show only how the input and output of activities are linked. The direct consequence of conceptualizing processes as flowcharts is an implicit assumption that the problem of process innovation can be faced using the hard engineering approach of systems engineering and systems analysis that are both based on a systematic rational search for the best means/system of tackling problems and objectives, which are assumed to be clearly and objectively defined as technical specifications (Biazzo, 1998). They do not take into account other elements of the activities such as resources and rules. They also did not fit with the sociotechnical concept of systems but mainly examined the technical aspects of the process with a few mentioning but not taking into account social factors, or vice versa. Table 1 provides a summary of some of the reviewed literature.

Gap in Literature

After reviewing the literature, it became apparent that despite many attempts to map the processes of the OTWL, few took the requirements of the sociotechnical system theory into consideration. This includes

Table 1. Summary of some of the reviewed literature

Author	Title	Aim	Findings
Al-Hakim, 2006	Web-based hospital information system for managing operating theatre waiting list	To present a Web-based system for managing OTWL; there is the use of fuzzy logics	It is essential to map the process in order to identify the interdependencies between the process's elements.
McAleer et al., 1995	Simulation of a hospital's theatre suite	This study was undertaken to identify delays and restrictions in the system by using the VIS model to explore the relationship among various throughput levels and resource allocations.	There is no simple answer to the original problem of increasing throughput.
Buchanan & Wilson, 1996	Re-engineering operating theatres: the perspective assessed	Process re-engineering of the hospital work system based on analysis of the activity chain across the organization	Re-engineering perspective does not deliver clear solutions but provides a platform for further investigation.
Buchanan, 1998	Representing process: the contribution of a re-engineering frame	BPR to address the problems of scheduling patients to their OT and surgical teams to avoid both delays and overruns to the schedule.	BPR has many critics and weaknesses, but it can assist in being a tool to shape the definition of organization problems.
Foote et al., 2004	Toward a systematic understanding of a hospital waiting list	To find out why increased funding to clear waiting lists proves ineffective	Due to the social construction of the waiting list problem, translating research findings is unlikely to be straightforward.
NSW Health, 2002	Operating theatre management project	Define a set of appropriate performance indicators to flag variations in management and practice of operating theatres and to identify characteristics of operating theatre management that maximize effective theatre utilization	A conceptual framework of operating theatre management has been done.
Audit Commission, 2003	Operating theatres: a bulletin for healthy bodies	Explores common problems of operating theatres	There is an impetus for change, and good quality information is essential; an awareness of what is possible will help improve the situation.
Fulscher & Powell, 1999	Anatomy of a process mapping workshop	To share their experience in using IDEF0 in the workshop setting of redesigning the core auto insurance business	IDEF0 helped to focus the work of the group.
Biazzo, 2002	Approaches to business process: analysis	Highlights and compares alternative techniques and approaches of business process analysis	Process mapping plays an important role in helping to understand the structural dimensions of workflows. One of the reasons business process change is not successful lies in the fact that process designs pay insufficient attention to the social context of work.

the mechanism and control elements of the activities and the interdependencies as well as information flow between them. Thus, this is the gap in the literature that this research is attempting to fill. This chapter raises the following question: How can the flow of information and the interdependencies between the elements of the activities of the OTWL process be identified and mapped for the purpose of process re-engineering?

THEORETICAL FRAMEWORK

There are two ways to improve OTWL process: (1) through incremental changes, and (2) through breakthroughs (Evans & Lindsay, 2005). Incremental changes are small and improvements gradual in specific sections in OTWL. Breakthroughs are large or rapid improvements. Breakthroughs require redesigning the OTWL process; this is a reference to business process re-engineering (BPR) (Al-Mashari & Zairi, 1999). So far, most of the studies deal with the gradual change and improvement to the system (Audit Commission, 2002; Lismore, McAleer & Naqvi, 1995; NSW Health, 2002). There are limitations in the studies that deal with the re-engineering of emergency and OTWL process (Levary, 1997). This research looks to frameworks leading to re-engineering the OTWL process. The required initial step is to develop a framework that allows practicians to successfully implement the BPR.

As part of a sociotechnical system, each activity of the OTWL process has elements other then input and output. These additional elements are the resources that include information necessary to perform the activities and the rules that govern the activity's implementation. Therefore, the OTWL process is made up of complex sets of elements that are interdependent with each other. Mapping an OTWL process by breaking down the process into activities and tracing the input-output relationships of the activities is an essential step to improve the process, but it is not sufficient. An input-output relationship is only one type of interdependency between two types of elements. An activity within a sociotechnical system comprises elements other than input and output, and accordingly, there are interdependencies other than input-output relationships. An effective process mapping that allows us to improve or re-engineer the process also necessitates effective information mapping. This requires the following:

- Identifying the elements of each activity
- Determining the interdependencies among the elements of various activities

By determining the interferences, the information flow between the interdependent elements can be mapped. Coordination theory (Crowston, 1997; Lewis & Talalayevsky, 2004) offers a framework for understanding and managing the interdependencies. This research also finds that a structured process mapping technique referred to as IDEF0 (Fulsher & Powell, 1999; NIST, 1993) can be used effectively to identify elements of OTWL activities as well as the interdependencies among them. The identification of interdependencies among the elements of activities of the OTWL process allows us to coordinate the elements of the interdependencies and redesign the whole OTWL process.

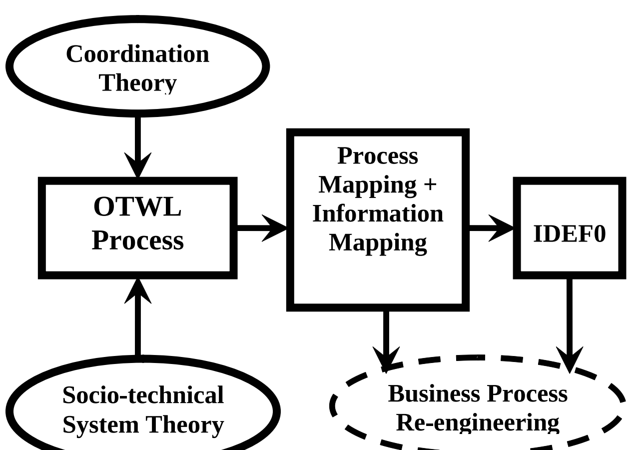
Figure 1 illustrates the developed theoretical framework. Following are brief descriptions of BPR and the related theories: sociotechnical systems theory and coordination theory.

Business Process Re-Engineering (BPR)

Business process re-engineering can be defined as the fundamental rethinking and radical redesign of business processes in order to achieve dramatic improvements in critical, contemporary measures of performance such as cost, quality, service, and speed (Al-Mashari & Zairi, 1999; Horna, 1995). The term "business process redesign" was first coined during a research program that started in 1984 at MIT (Biazzo, 2002).

In hospitals, it has been noted that during their stay, patients normally will come into contact with a range

Figure 1. Proposed theoretical framework



of professional staff in the hospital, each with their own management structures and hierarchies. This can result in a fragmented approach to care delivery, which fails to put the patient at the center of the process, thus disempowering the patient and providing less than effective care delivery (Buchanan & Wilson, 1996). Process re-engineering brings a holistic perspective to the hospital work system based on the analysis of relevant activities across the hospital, ignoring the functional boundaries and adopting a fresh start or a "blank-sheet" approach to process redesign. The cross-functional analysis of workflows in an organization and the novel ways of representing activity chains visually can be used to legitimatise and trigger a creative dialogue concerning ways to redesign work processes (Buchanan, 1998).

BPR is being considered for OTWL process problem because despite extensive studies being made in this area to understand the OTWL process, none of them has managed to adequately solve the problem. Only a process-based radical design of a sociotechnical system like the OTWL process is likely to succeed in improving the situation.

Sociotechnical Systems Theory

Sociotechnical Systems (STS) theory is a systems-based approach for process analysis and redesign (Fernandez et al., 2001). The term "sociotechnical" refers to the essential interdependence between the technical and the social systems. It was first coined in the 1960s by researchers in the Tavistock Institute of Human Relations, growing out of consulting work carried out while working on technical changes in coal mining, which was based on conceptual models from psychoanalysis (The Bayswater Institute, 2004; Sorensen, 1985). A systems-based approach provides a holistic consideration of the "problem system." This includes the social and technical elements, their formal and informal relationships, emergent patterns, and the unique context of the problem (Keating, Kauffman & Dryer, 2001).

Loughman, Fleck, and Snipes (2000) gathered the following insights that are pertinent to systems analysis from studying people in sociotechnical systems:

- People do not always use rational methods to make decisions; political methods can be as pervasive, if not more so.
- They view their world metaphorically and symbolically as well as literally.
- They will not always do what they are told to do.
- They can be very creative in sabotaging structures and processes they fear or dislike.
- The formal organization exhibited in the organizational chart inadequately describes how organization members actually conduct their business.

Therefore, it can be said that the internal system of any organization type consists of two distinct subsystems: the technical subsystem and the social subsystem, which relate, interdepend, and interact among themselves in a mutually inclusive fashion (Angelis & Antivachis, 1999).

The process mapping of the OTWL system should show the relationships among the activities, people, data, and objects (patients) involved in the production of a specified output. However, as already mentioned, the previous process mapping studies mainly examined the technical aspects of the situation with a few mentioning but not taking into account social factors. Under the social aspect of the OTWL process, the more important issues that are highlighted as found upon doing an analysis of the case studies are the following:

- **The behavior of the object (patient) is not predictable, and it varies.** This has been found from the case study with a hospital. For example, a patient's cancellation of surgery at the last minute is very common, resulting in much waste of resources and the need to reschedule the patient, thus causing further delay.
- **Surgeon effectiveness variability.** It is hard to measure how effective surgeons perform each and every surgery, because every surgeon differs in terms of skills and expertise. Effectiveness is using a skill in a way that raises the probability of success. Effectiveness here could be measured in terms of success.
- **Variability of the degree of success of the operation.** The success of the operation is hard to determine before the operation because of reasons such as variations in a patient's condition, which cannot be fully assessed until a surgical procedure is underway.
- **Variability of surgical time.** The resultant unpredictability of surgical time renders difficult any attempt at precision scheduling of theatre lists.

Therefore, it can be said that OTWL consists of not just the technical aspect but also the social aspects, and the STS theory is used to address this issue.

Coordination Theory

Coordination theory provides part of the theoretical background to this research. Its intent is to analyze organizations in a way that facilitates redesign (Crowston, 1997). Coordination theory offers a framework for understanding and characterizing various types of dependencies and identifies the processes that can be used to manage these dependencies (Lewis & Talalayevsky, 2004). The aim of this theory, therefore, is to define the interdependencies of the processes and attempt to improve performance. Coordination problems arise from dependencies that constrain the performance of the tasks (Crowston, 1997). Given this perspective, alternative processes would be identified for performing a desired task.

In this research, the OTWL management process can be described as a kind of producer/consumer relationship that occurs when the output of one step in the process sequence is the input to the next. Producer/consumer relationships can lead to the following kinds of dependencies (Malone & Crowston, 1994):

- **Prerequisite constraints.** A producer activity and a consumer activity are dependent because the producer activity must be completed before the consumer activity can begin. This is similar to the Coordination Theory idea of a sequential interdependency.
- **Transfer:** When one activity produces something that is used by another activity, the thing produced must be transferred from the producer activity to the consumer activity. The transfer, be it physical or just communication of information, is a coordination activity. This can be defined as a reciprocal interdependency under the Coordination Theory.

Table 2. A typology of dependencies and associated coordination mechanisms (Crowston, 1997)

Interdependence	Coordination Activity
Task-task	
Tasks share common output	
Same characteristics	- look for duplicate tasks - merge tasks or pick one to do
Overlapping	negotiate a mutually agreeable result
Conflicting	pick one task to do
Tasks share common input (shared resource)	
Shareable resource	no conflict
Reusable resource	- notice conflict - schedule use of the resource
Nonreusable resource	pick one task to do
Output of one task is input of other (prerequisite)	
Same characteristics	- order tasks - ensure usability of output - manage transfer or resources
Conflicting	- reorder tasks to avoid conflict - add another task to repair conflict
Task-resource	
Resource required by task	- identify necessary resources - identify available resources - choose a particular set of resources - assign the resources
Resource-resource	
One resource depends on another	- identify the dependency - manage the dependency

The OTWL management process comprises all the interdependencies mentioned so far, including the pooled, sequential (prerequisite constraint), reciprocal (transfer), and task/subtask dependencies.

Dependencies can be between tasks, between tasks and the resources they need, or between the resources used (Crowston & Kammerer, 1998). Table 2 shows examples of generic coordination activities in relation to the type of interdependencies. The classification is based on tasks and resources. Table 2 implies the importance of identifying the interdependencies in order to determine the information flow within and among these interdependencies.

USING IDEF0 TO BUILD PROCESS/INFORMATION MAPPING

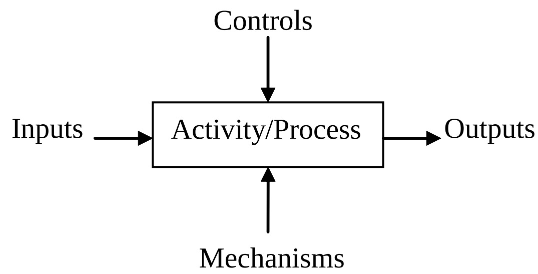
IDEF0 is one part of a comprehensive process definition and computer systems implementation methodology that was originally developed for the United States Air Force (Fulsher & Powell, 1999). It is widely used in process mapping and is, in fact, the official standard of the U.S. government for this purpose (Bal, 1998). It is a modeling technique based on combined graphics and text that are presented in an organized and systematic way to gain understanding, support analysis, and provide logic for potential changes. It is a highly structured and disciplined framework within which logical and consistent process maps can be drawn to any desired level of detail (NIST, 1993). Figure 2 shows generically how IDEF0 is used to depict activities and their associated elements: inputs, outputs, controls, and mechanisms.

In IDEF0, the components of the IDEF0 syntax are boxes and arrows, rules and diagrams. The boxes represent functions, also known as activities or processes. Arrows represent data or objects related to the activity.

The Elements of an Activity

The result of applying IDEF0 is a model that consists of diagrams, text, and glossary, all cross-referenced to each other. The box and arrow meanings are used to relate several subfunctions on a diagram comprising a more general function. Inputs are data or objects that are consumed or transformed by an activity; they are represented by arrows entering the left side of the box.

Figure 2. IDEF0 elements



Outputs are data or objects that are the direct results of an activity; they are shown as arrows leaving the right side of the box. In this research, the OTWL processes are described as a set of linked activities, each with inputs and outputs. External or internal factors control each activity. Controls are data or objects that specify conditions that must exist for an activity to produce correct outputs and is represented by arrows entering the top of the box. It can also be said that the controls of an activity refer to the actions, policies, or regulations that direct the activity. Each activity requires one or more mechanisms and/or resources. They support the successful completion of an activity but are not changed in any way by it. Mechanisms are represented in the graphical diagram by arrows connected to the bottom side of the box. It is assumed that each activity may have several inputs and outputs, and may be embraced by a number of controls and may require several mechanisms (Al-Hakim, 2006; Fulscher & Powell, 1999; NIST, 1993). IDEF0 allow the user to "tell the story" of what is happening in the system (Liyanage & Perera, 2001).

Creating Process Maps with IDEF0

IDEF0 is chosen over competing methods because it uses a hierarchical top-down approach and focuses the discussion on the conceptual basis for a process rather than on the detailed sequence of specific microlevel activities required to deliver the end result (Fulscher & Powell, 1999); therefore, it suits the multicriteria objective of the operation theatre waiting list management process. The hierarchical series of diagrams gradually display increasing levels of detail describing functions and their interfaces within the context of a system. There are three types of diagrams: graphic, text, and glossary. The graphics diagrams define functions and functional relationships via box and arrow syntax and semantics as seen in Figure 3. The figure also shows that the primary hierarchical relationship is between a parent box and the child diagram that details it.

A box in an IDEF0 model represents the boundaries drawn around some activity. Looking inside the parent box leads to the discovery of the breakdown of the activity into smaller activities as seen in the child diagram, which together comprises the box at the higher level. This is useful for hiding unnecessary complexity from view until a more in-depth understanding is required by looking inside the box at its decomposition (Mayer, Painter, & deWitte, 1992).

IDEF0 has been most commonly used in the visualization of manufacturing systems (Bal, 1998). There have been a few attempts to use it in the hospital context (Chick, Sanchez, Ferrin & Morrice, 2003) but not in the area of the surgical waiting lists.

Decomposition is generally necessary for any improvement or intervention as only a thorough decomposition allows for a pervasive recomposition like the re-engineering of the OTWL process (Van Der Zwaan & De Vries, 2000). IDEF0 allows such decomposition of a system's activities to take place. Also, the interactions among activities are not only in the form of inputs and outputs, but in many cases the output of an activity may control another activity or may form a feedback that requires the reworking of a prior activity. As seen in Figure 4, the output of Function A forms input into both Function B and C, while the output of Function B controls Function C, while at the same time the output of Function C controls Function B (NIST, 1993). This is a constructive example of information mapping in which information resulted from an activity (Activity C) can control another one (Activity B). Figure 4 shows that information control activity A is also control Activity B.

Identifying Interdependencies with the IDEF0 A/C Matrix

Once the processes are mapped in IDEF0, the software also produces an Activity/Concept (A/C) matrix that effectively identifies the interdependencies among the inputs, control, outputs, and mechanisms, both within

Figure 3. Example of hierarchical top-down model (NIST, 1993)

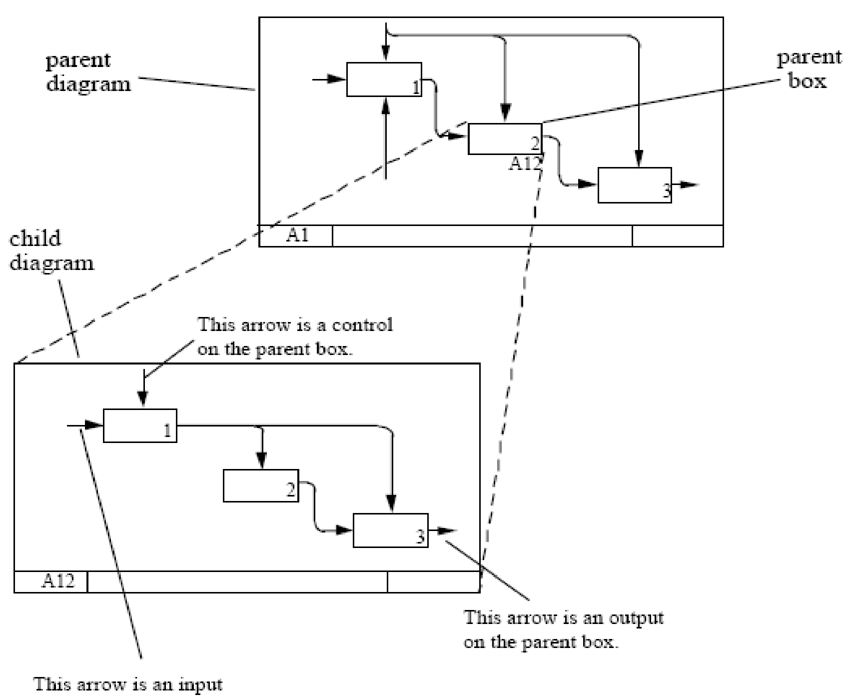


Figure 4. Interdependencies between activities (NIST, 1993)

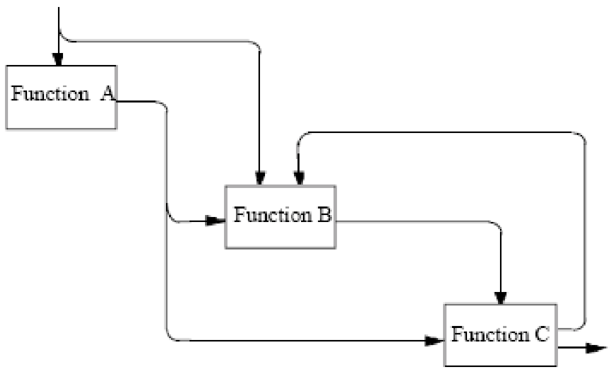


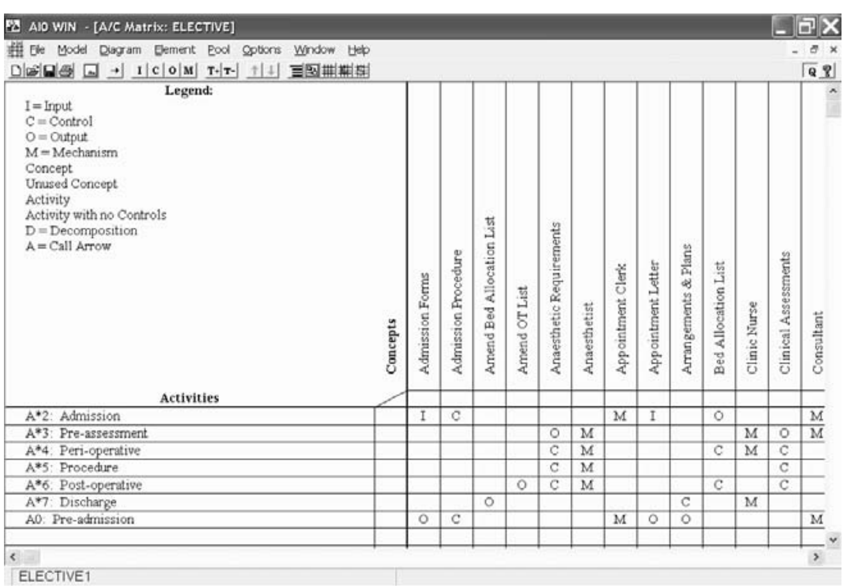
and between the activities (see Figure 5 for an example A/C matrix). This matrix shows the relationships among the activities' elements in terms of input (I), output (O), control (C), and mechanism (M). These relationships form the other facet of information mapping between these elements.

Classifying Interdependencies from IDEF0 Process Maps

Al-Hakim (2006) identified the following six basic forms of interdependencies among the elements of activities or tasks represented in an IDEF0 process map. Each numbered dependency type corresponds to the same number as seen in the diagram in Figure 6.

1. **Input/input dependency.** The same input is required for multiple activities. This can be seen in how the arrow representing the use of the input branches out into two arrows into the activities A1 and A1 respectively. They use the same input and thus it can be said that there is an input/input interdependency between them.
2. **Output/input dependency.** The output from one activity acts as input to another activity and can be seen in how the arrow representing the output of A2 becomes an input for activity A4.
3. **Output/control dependency.** The output from one activity acts as a control for another activity. In Figure 6, the output of activity A1 forms a control for A4; thus, there is output/control interdependency between activity A1 and activity A4.
4. **Input/control dependency.** The input for one activity acts as a control for another activity. This can be seen in how an input for activity A1 is a control for activity A5 as well, and so there is input/control dependency between these two activities.
5. **Control/control dependency.** The same control applies to multiple activities as seen in how both activities A4 and A5 are under the same con-

Figure 5. Activity/concept matrix



Activities / Concepts	Admission Forms	Admission Procedure	Amend Bed Allocation List	Amend OT List	Anaesthetic Requirements	Anaesthetist	Appointment Clerk	Appointment Letter	Arrangements & Plans	Bed Allocation List	Clinic Nurse	Clinical Assessments	Consultant
A*2: Admission	I	C					M	I		O			M
A*3: Pre-assessment					O	M					M	O	M
A*4: Peri-operative					C	M				C	M	C	
A*5: Procedure					C	M						C	
A*6: Post-operative				O	C	M				C		C

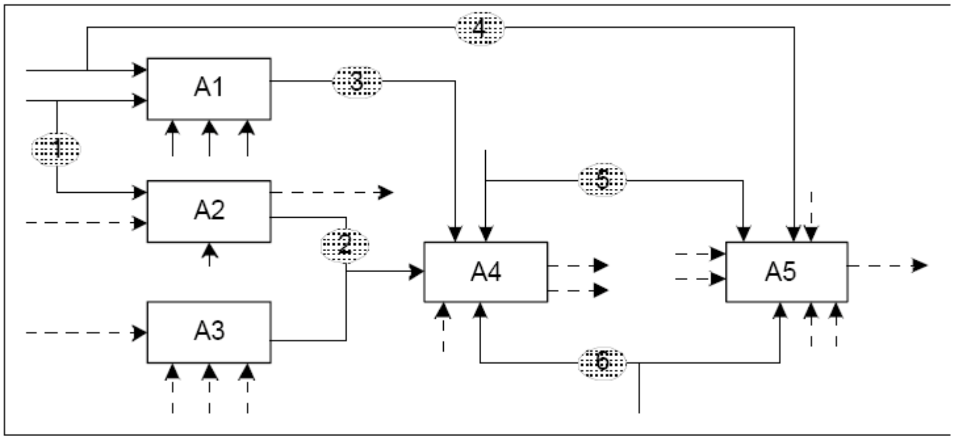
A0: Pre-admission	O	C					M	O	O				M

Figure 6. Six forms of interdependencies representing the flow of information mapping (Al-Hakim, 2006)



trol.

6. **Resource/resource dependency.** The same resource is used by multiple activities. Activities A4 and A5 both utilize the same resources, as seen in the following figure, and so they have a resource/resource dependency.

The mentioned forms of interdependencies in this section are those that can be identified from the result of IDEF0 mapping.

CLASSIFICATION OF INTERDEPENDENCIES

A comparison of the interdependencies identified by Crowston (1998) in Table 2 and by Al-Hakim (2006) in Figure 6 reveals that while the two lists overlap to some degree, there are also differences in both content and the use of terms. For the purpose of classifying interdependency types, the two lists are compared and contrasted, with a summary presented in Table 3.

All six of Al-Hakim's (2006) interdependency types are classified from the activity/task viewpoint, and therefore, all six are task-task interdependencies. Also, Crowston's (1998) typology of interdependencies does not include the influence of controls at all, nor does Crowston differentiate between inputs (data or objects consumed or transformed by the activity) and resources (mechanisms or objects that support the completion of the activity but that are not consumed by the activity). The resource-resource interdependency identified by Crowston is different in context and meaning to the resource-resource interdependency identified by Al-Hakim. Crowston uses the term resource-resource dependency to refer to the situation when one resource is dependent on another resource within the same activity. While this situation may occur within the OTWL process, the A/C matrix does not include any way of showing this type of dependency at all. The best the matrix can do is to show the task-resource dependencies; that is, identify all resources needed for the same task. Al-Hakim uses the term resource-resource dependency to mean that at least two or more tasks are dependent on the same resource (see number 6 in Figure 6), and this meaning will be adopted in this research.

Thus, there are two major groups of interdependencies: (1) dependencies among activities; and (2) dependencies within an activity. Table 3 summarizes the interdependency types identified by both Crowston (1997) and Al-Hakim (2006). Table 3 also illustrates that all but one of the interdependency types can be located using the IDEF0 A/C matrix by either reading down a column, or reading across a row.

For example, Figure 3.6 shows output/control dependencies in the Clinical Assessments column, the Anaesthetic Requirements column, and the Bed Allocation List column. A task-resource interdependency occurs in the pre-assessment activity (A3) with the anaesthetists, clinical nurses, and consultants all being required resources for this activity to function. A resource-resource dependency occurs with the anaesthetist being required for four activities: pre-assessment, peri-operative, procedure, and post-operative.

Table 3. Comparison of Crowston's and Al-Hakim's type of interdependencies

	Task–Task (interdependency *among* tasks)	**Crowston (1997)**	**Al-Hakim (2006)**	**A/C Matrix Location**
1		Tasks share common output	-	Column
2		Output of one task is input of other	Output/Input (or vice versa) dependency	Column
3		Tasks share common input	Input/Input dependency	Column
4		Tasks share common input	Resource/Resource dependency	Column
5		-	Output/Control dependency	Column
6		-	Input/Control dependency	Column
7		-	Control/control dependency	Column
8	***Task–Resource*** (interdependency *within* a task)	Resource required by task	-	Row
9	***Resource–Resource*** (interdependency *within* a task)	One resource depends on another	-	Not represented in A/C matrix

Limitation of IDEF0

Mapping with IDEF0 comprises some limitations. IDEF0 does not include representation of time. Also, the logical flow of the elements and activities is not really meant to depict the sequence of events exactly. The hierarchical decomposition of activities means that we can only analyze each level and section on its own; the software does not allow cross-section/-level analysis in itself.

CONCLUSION

The OTWL process is a very complex and dynamic process within the hospital, which itself is a complex sociotechnical system. Problems related to growing operating theatre waiting lists are getting worse, and there are many reasons behind this. Despite much research and many attempts to solve the problem using flowcharts and other forms of process mapping, no previous study has taken the requirements of the sociotechnical system theory into consideration by including the resource/mechanism and control elements of the activities and by identifying the interdependencies that exist among all four input, control, mechanism, and output elements of the OTWL process. Identifying the interdependencies provides a picture of information flow within and among the elements of the activities. Using IDEF0, and with the concept of BPR and coordination theory as well, this research tries to address this problem.

The theoretical framework of this research is deemed appropriate for the topics of mapping the sociotechnical system of the OTWL process because of the following issues (Foo & Al-Hakim, 2006):

1. It takes into account the social and technical aspects of a process
2. It identifies and maps the four elements (input, output, resource, control),
3. As well as the interdependencies of the activities/elements and the flow of information between the elements

4. It is easy to identify the flow of information and interdependencies from the graphic description of the systems in IDEF0
5. There is also the allowance for an activity to form a feedback that requires the reworking of a prior activity
6. The coordination theory allows us to see if the elements are linked effectively, giving us the opportunity to change the relationship of the elements and to create new interdependencies; thus, the process can be redesigned.

As a result, this theoretical framework is useful for redesigning a process. Therefore, the research question—How can the flow of information and the interdependencies among the elements of the activities of the OTWL process be identified and mapped for the purpose of process reengineering?—has been effectively addressed.

INTRODUCTION

Flexible endoscopy is used to inspect and treat disorders of the gastrointestinal (GI) tract without the need for creating an artificial opening on the patient's body (Phee, Ng, Chen, Seow, & Davies, 1997). The endoscope is introduced via the mouth or anus into the upper or lower GI tracts respectively. A miniature camera at the distal end captures images of the GI wall that help the clinician in diagnosis of the GI diseases. Simple surgical procedures (like polypectomy and biopsy) can be performed by introducing a flexible tool via a working channel to reach the site of interest at the distal end. The types of procedures that can be performed in this manner are limited by the lack of maneuverability of the tool. More technically demanding surgical procedures like hemostasis for arterial bleeding, suturing to mend a perforation, and fundoplication for gastrooesophageal reflux cannot be effectively achieved with flexible endoscopy. These procedures are often presently being performed under opened or laparoscopic surgeries.

With the invention of medical robots like the Da Vinci (Intuitive Surgical Incorporation) surgical systems, clinicians are now able to maneuver surgical tools accurately and easily within the human body (Carrozza, Dario, & Phee, 2003). Operating from a master console, the clinician is able to control the movements of laparoscopic surgical tools real time. These tools (also known as the slaves) are designed with sufficient degrees of freedom to move according to the natural hand and wrist motion allowing the clinician to perform intricate procedures with minimal technical difficulties.

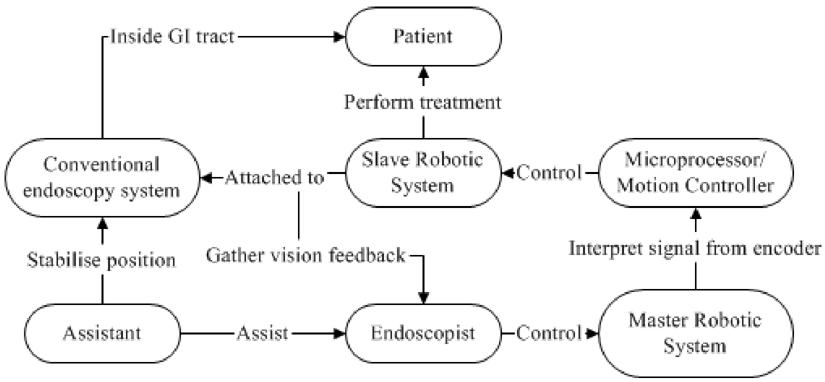
Thus far, master-slave surgical robotic systems like Zeus and Da Vinci are either completely rigid or do not have a significant length of flexible body (Low & Phee, 2004). The slave manipulators enter the human body by means of incisions on the body. In this article, we propose a robotic system with flexible slave manipulators that could be attached directly to flexible endoscopes. Similar to a conventional flexible endoscopic procedure (e.g., gastroscopy), the "robotic endoscope" bundle could negotiate the curves and bends in the GI to reach the desired position within the gut. This system empowers the surgeons to perform more difficult surgeries that are otherwise impossible with the conventional endoscopic tool.

OVERALL ROBOTIC SYSTEM

Figure 1 shows the proposed system layout whereby the endoscopist work on the master console while gathering visual feedback from the endoscope. A

M

Figure 1. Proposed system layout for the overall robotic system



computer console will interpret the readings from the master console that will in turn give instruction to the slave robotic system to perform the treatment to the patient. This system allows complicated treatment to be performed with the added benefit of easy and intuitive control for the endoscopist.

THE SLAVE MANIPULATOR

The 3D model of the intended slave manipulator can be seen in Figure 2. In order for the surgeon to perform the necessary dexterous actions, the slave manipulators should possess a high number of Degrees of Freedom (DOF). The emphasis of the project is to make the slave manipulator to be as intuitive to control as possible. As such, the DOF and joints of the slave manipulator are modeled after a simplified human arm as shown in Figure 3. Altogether there are five DOF for positioning of the slave and an extra DOF for manipulating the end effector and the axis or rotation. Two slave manipulators are used instead of one since it can perform actions such as pulling and cutting of polyps or suturing bleeding sites. Furthermore two slave manipulators are more intuitive to use since they resemble the two human arms.

In order for the slave manipulator to be able to go through human GI tract, the slave manipulator has to be small yet flexible. Due to this unique requirement, tendon-sheath actuation is used. The prime movers are located outside the human body and it transmits power to the mechanism by pulling and releasing tendons in a sheath accordingly.

Figure 2. 3D model of slave manipulators attached with the endoscope

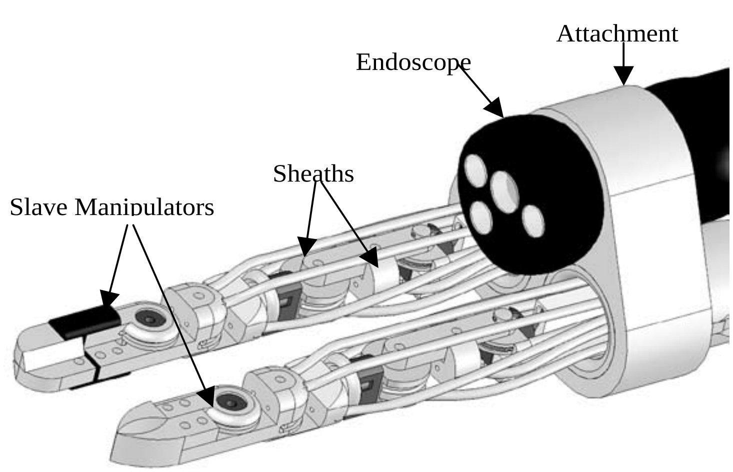


Figure 3. The DOFs for one arm of the slave manipulator together with its simplified joint diagram

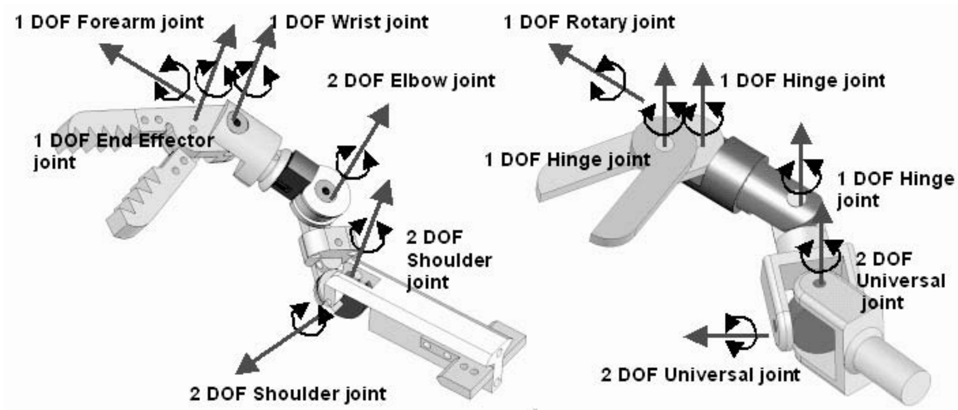

The design of the mechanism is such that the two antagonistic tendons that control each DOF motion are independently actuated by one direct current (DC) motor. In addition, the rotational displacement of each joint is directly proportional to the linear displacements of the tendon. These characteristics allow the serial slave manipulator to be controlled more easily. With the help of the software, the manipulator will not face singularity conditions in the prescribed range of motion for the manipulators.

Different types of end effectors have been designed to perform different types of actions during surgery. One of the tools includes electrodes that can perform monopolar cauterizing. The picture of the current developed prototype can be seen in Figure 4. Take note that the attachment that held the endoscope and manipulators is not fixed to the current prototype yet.

To pass the endoscope and slave system to the desired site of the GI tract, an overtube can be used. Currently the size of the whole slave manipulator is approximately 25mm in diameter. Future developments will be on the miniaturizing of the slave manipulator till it is comfortable to be used on human beings.

THE MASTER CONTROLLER SYSTEM

The ergonomic master device is built as a 6 DOF structure to control the 6 DOF slave mechanism. As the slave manipulators resemble the human arms, the anthropomorphic data of the surgeon's arm is used as the control parameters in order to give the surgeon better perception in performing the joint-to-joint control of the slave.

The schematic of the master controller is shown in Figure 4. Two cable-actuated position sensors are used to measure the two contributing rotations of the shoulder joint that cause the up-down and in-out movement of the upper arm. Two optical rotary encoders are used to measure the flexion and supination-pronation movement of the elbow joint. Another similar encoder is used for flexion-hyperextension movement of the wrist, and the finger grip comes with an encoder inside the holder.

A virtual plane is formed using the reference of the shoulder joint with the two position sensors. The sensor locations can be modified to meet the required workspace that lies on one side of the plane. For the full range of upper arm movement, an additional sensor will be needed. As the comfortable workspace for

Figure 4. Figure of the current slave prototype for the robotic system

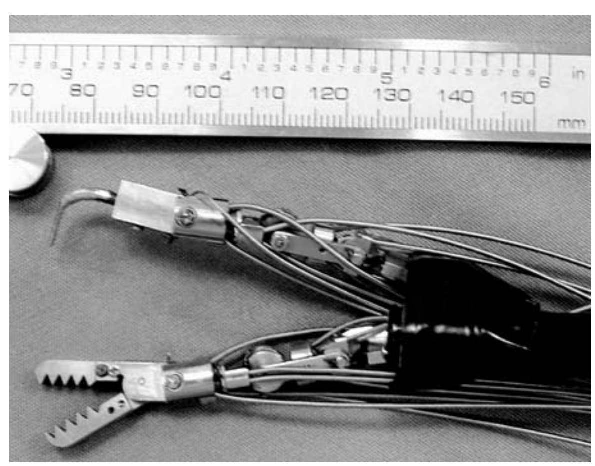

Figure 5. The whole schematic of the master setup (a) frame with two cable sensors for each arm (b) left arm with sensors attached

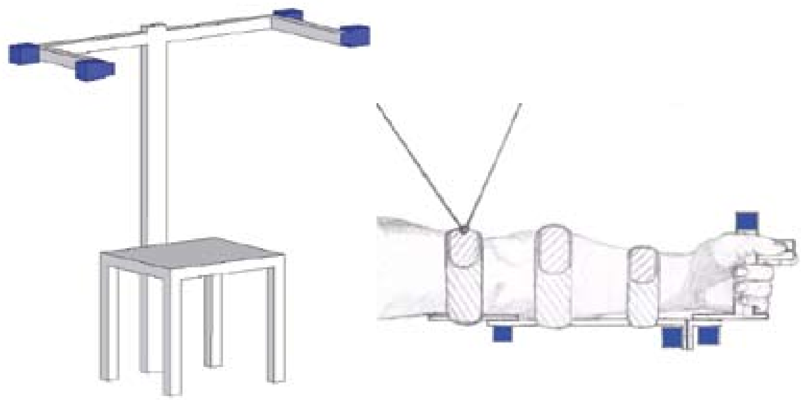


the surgeon's upper arm lies in a quarter of a spherical space, two position sensors are sufficient to get the anthropomorphic data of one arm in that range.

The position sensors are located in such a way that the cables do not impose any disturbance on the surgeon's vision and movement. Furthermore the tensions of the cables facilitate the surgeon as a counterweight from his own arm moments, reducing the fatigue.

Assuming the shoulder joint to be a ball and socket type, the point of cable-attached upper arm is determined by three spheres formed by upper arm length and two cable lengths. In Figure 6, L_1 and L_2 are the two cable lengths and L_3 is the upper arm length.

In $X_0Y_0Z_0$ coordinate system,

$$\left({}^0P_x - {}^0P_{1x}\right)^2 + \left({}^0P_y - {}^0P_{1y}\right)^2 + \left({}^0P_z\right)^2 = L_1^2 \qquad (1)$$

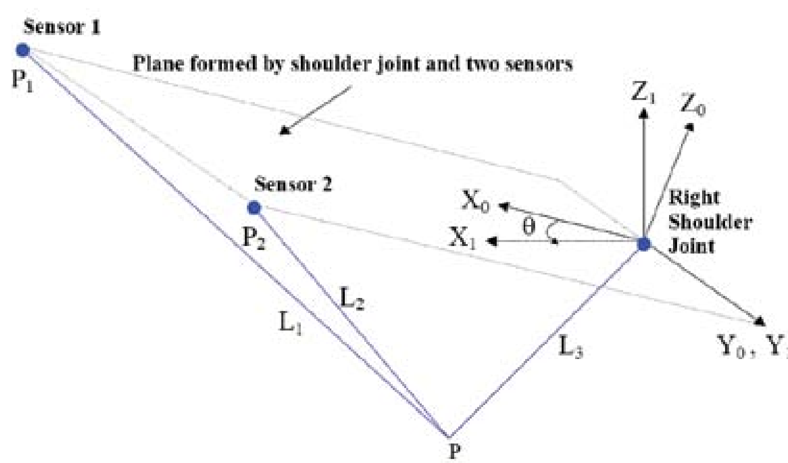
$$\left({}^0P_x - {}^0P_{2x}\right)^2 + \left({}^0P_y - {}^0P_{2y}\right)^2 + \left({}^0P_z\right)^2 = L_2^2 \qquad (2)$$

$$\left({}^0P_x\right)^2 + \left({}^0P_y\right)^2 + \left({}^0P_z\right)^2 = L_3^2 \qquad (3)$$

The point ${}^0P(x,y,z)$ below the plane can be solved from above equations and it can be transformed into $X_1Y_1Z_1$ by rotation matrix about Y-axis.

$$\begin{Bmatrix} {}^1P_x \\ {}^1P_y \\ {}^1P_z \end{Bmatrix} = \begin{bmatrix} \cos\theta & 0 & \sin\theta \\ 0 & 1 & 0 \\ -\sin\theta & 0 & \cos\theta \end{bmatrix} \begin{Bmatrix} {}^0P_x \\ {}^0P_y \\ {}^0P_z \end{Bmatrix} \qquad (4)$$

Figure 6. The location of cable-attached upper arm in two coordinate systems



[1]P(x,y,z) can be used to calculate the shoulder joint up-down and in-out angles.

The mobility range of the master is constrained only at the upper arm by the virtual plane formed by the shoulder joint and two cable sensors. The other joints accommodate the full range of motion of the surgeon.

SOFTWARE CONTROL

A dedicated computer software is programmed to control and interface the slave and master robotic system. First it takes in real time readings from each encoder of the master device to determine the motion generated by the user. This data is processed and appropriate signals are sent out to actuate the respective motors to bring about the required movements of the slave. The system framework adopts a two-layer architecture. The bottom layer is the hardware control module that uses low-level drivers for hardware control. The top layer modules are the kernel algorithms, which perform the signal processing to compensate for backlash and noise disturbances.

PRELIMINARY EXPERIMENTS

In vitro experiments with the master-slave system have been conducted in carrying out some tasks. By handling the master device, the surgeons are able to control the slave manipulators to perform tasks such as pick and place as well as grab and cut a soft object. In the future, animal trials will be conducted to verify its functionality. During experimentation, it was found that the mechanism is capable of producing at least 1.0N for each DOF.

DISCUSSION

One of the biggest problems in the tendon-sheath driving robot system control is the nonlinear characteristic due to the friction between the tendon and sheath (Kaneko, Paetsch, & Tolle, 1992, pp. 96)

As a result, delays and movement hysteresis are noticeable and can be seen in the following relationship:

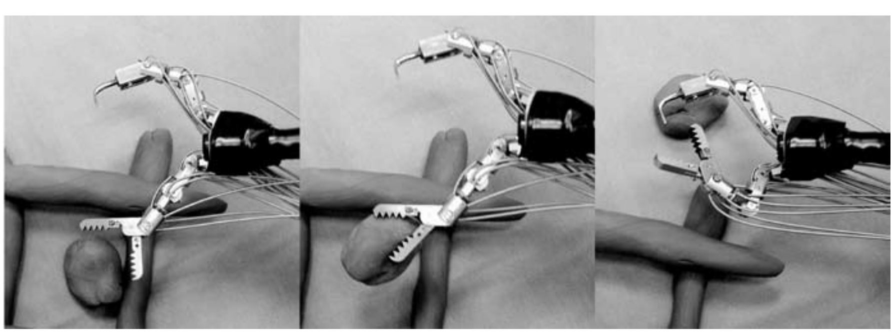
$$\delta(L) = \frac{T_0 L}{EA} \frac{\exp(\lambda) - \lambda - 1}{\lambda} \quad (5)$$

Where T_0 is tendon-pretension, L is the length of the tendon-sheath, E is Young's modulus, A is the cross section area of tendon, λ is a nondimensional parameter and indicates the total friction force acting on the tendon under unit tendon-tension. We can regard $\delta(L)$ as a kind of backlash for the tendon-sheath driving system. For any tendon-sheath driving system, L, E, and A can be considered as constant. λ can also be considered as a constant if the curve of the tendon-sheath does not vary much. From (5), the backlash length is only a function of the cable tension T_0. To improve the performance of the system, a pretension device is introduced so that the tendon is always in tension. The modified mechanism from (Hirose & Chu, 1999) can also minimize the problem of wire elongation after repeated use.

The pretension is set in such a way that the tension change during robot movement is trivial compare to the pretension, so that backlash length $\delta(L)$ can be considered as a constant.

To further reduce the movement delay of the slave, the software will record the movement of each slave joint and whenever a direction change is detected, additional actuator displacement is used to compensate

Figure 7. Using the robot to perform pick and place tasks



M

for the backlash. Experiments have been designed and performed to obtain the appropriate backlash compensation displacement for each joint. Using this method, the delay of the slave can be reduced by up to 0.5 second. The system can be improved in the future with the modeling of the system as well as making use of force sensors on the slave robot.

FUTURE TRENDS

To minimize the size of the slave manipulator while maintaining a high force, it is necessary to study and improve on the current tendon sheath system. This is because it has been found that the bulk of the force is lost as friction between the long and flexible tendon and sheath.

Another important aspect that needs to be implemented is haptics. To achieve haptics, there must be knowledge of the force experienced by the slave manipulator. However fixing sensors on the small slave manipulator is a difficult task and there are currently studies made to obtain the information of the force experienced by the slave manipulator.

CONCLUSION

A master slave robotic system that can enhance gastrointestinal endoscopic procedure has been designed and built. The developed slave robotic system consists of a long and flexible body that allows it to follow the endoscope through the human natural orifice. This characteristic has the potential to allow treatment such as suturing to be performed on the patient without the need of any incision. A user was able to apply the master-slave system to perform tasks such as grabbing and cutting as well as pick and place. Future animal trials are planned using the developed system.

Medical Privacy and the National Health Information Network Initiative

Edward J. Szewczak
Canisius College, USA

INTRODUCTION

Traditionally, medical data were typically collected and stored as records in physicians' offices and hospitals. Often the data were recorded manually and retrieved manually. Today collection and retrieval of medical data are increasingly done using information technology (IT). The introduction of IT, especially e-technologies, has changed the handling of medical data in ways that are both promising for improving health care as well as threatening to the individual patient's medical privacy.

This chapter will examine medical privacy and the National Health Information Network (Kaushal et al., 2005) initiative. Other technologies such as radio frequency identification device (RFID), voice over IP (VOIP), and telemedicine, while relevant to the topic of medical privacy and IT, are tangential to the more central issues of electronic health records, medical databases, and the development of a national health information network. Although the focus will be on medical privacy in the United States, it is evident that people in other countries are also concerned about their medical privacy. Singaporeans, especially Malays, worry that their medical histories may result in racial discrimination. In the area of medical research, the Chinese and Indians want their medical information confined only to the area of study that was originally agreed to and not disseminated widely (Tan, 2006).

THE MEDICAL RECORD

Patient data form the *medical record* and its contents (www.eff.org/Privacy/Medical/1993_ota_medical_privacy.report).

Medical records may contain patient data such as name, address, age, next of kin, names of parents, date and place of birth, marital status, religion, history of military service, Social Security number, name of insurer, complaints and diagnoses, medical history, family history, previous and current treatments, an inventory of the condition of each body system, medications taken now and in the past, use of alcohol and tobacco, diagnostic tests administered, findings, reactions, and incidents. Records may also contain subjective information based on impressions and assessments by health care workers such as mental ability and psychological stability and status. In addition to data about the patient's current condition, the medical record may also contain the results of genetic research and testing that enable predictions of future medical conditions and the prospects of developing specific medical problems.

Traditionally, the creation and maintenance of medical records were done manually by health professionals, mostly as an aid to memory. But IT is changing this practice. Notes handwritten by doctors and nurses are being put into electronic form in the name of faster, more extensive access to needed information. Healtheon and other health care companies are competing to get doctors to write prescriptions over the Internet and to persuade people to place their personal health records on the Internet (Consumer Reports, 2000). Companies have made software available that an individual can use to create an Internet-based personal health record that can be used to organize family medical histories, including medical conditions, medications, and allergies. These personal records may be transmitted to health professionals over a computer network (Rubenstein, 2005).

Medical records are available online to medical practitioners for the purposes of decision-making and improving health care. They are also available to other users and institutions in nontreatment contexts. Medical records are used to conduct federal government-mandated medical community audits of physician competency and performance. They are also used by insurance companies in the assessment of an applicant's eligibility for health and life insurance and in claims processing to detect medical fraud. Medical information is also used by private employers, educational institutions, credit investigators, and law enforcement agencies for a variety of nonmedical reasons.

THE IMPORTANCE OF MEDICAL PRIVACY

Cate (1997) identified a number of conceptions of what constitutes privacy from the literature. Privacy has been viewed as an expression of one's personality or personhood, focusing on the right of the individual to define his or her essence as a human being; as autonomy—the moral freedom of the individual to engage in his or her own thoughts, actions, and decisions; as citizens' abilities to regulate information about themselves and thus control their relationships with other human beings; and as secrecy, anonymity, and solitude.

In the area of medical information, the definition of *privacy*—"the claim of individuals, groups, or institutions to determine for themselves when, how, and to what extent information about them is communicated to others" (Westin, 1967, p. 7)—is consistent with the confidential relationship between doctor and patient. Confidentiality refers to how data collected for approved purposes will be maintained and used by the individual, group, or institution that collected it, what further uses will be made of them, and when individuals will be required to consent to such uses. Privacy may be construed as a balance struck by society between an individual's right to keep information confidential and the societal benefit derived from sharing the information and how the balance is codified into legislation, giving individuals the means to control personal information (Office of Technology Assessment, 1993).

Various public opinion polls conducted since 1993 have uncovered a basic concern people have about the privacy of their medical records and how these records may be used (www.epic.org/privacy/medical/polls.html). Among the major concerns of those polled are the following:

- Personal health insurance information might be used by employers to limit job opportunities.
- Sensitive health information might leak because of weak data security.
- Protecting the confidentiality of medical records is absolutely essential or very important in health care reform.
- Existing federal health privacy rules protecting patient information may be reduced in the name of efficiency.
- The trend of the health care system to keep medical records electronically raises threats to their privacy.
- Medical records are more secure on paper than in electronic form.
- Medical and government researchers should not be allowed to study an individual's genetic information unless they first obtain his or her consent.
- Government agencies, insurance companies, and researchers are allowed to see medical records without the patient's permission.
- The federal government is requiring everyone to be assigned a medical identification number, similar to a Social Security number, to create a national medical database.
- Insurance companies are getting more information from patients' doctors than is needed.
- Medical information from a computerized national health information system will be used for many nonhealth purposes.
- It is important that individuals have the legal right to obtain a copy of their own medical record.

Federal and state governments have attempted to deal with these issues in ways that satisfy the needs of various stakeholders, such as doctors, dentists, chiropractors, insurance companies, researchers, law enforcement, and data processing firms, as well as individuals. The result has been various legislative measures that provide legal compromise for the stakeholders.

MEDICAL PRIVACY LEGISLATION

It should be noted that the Bill of Rights does not address privacy issues at all. However, in *Griswold v. Connecticut* (381 U.S. 479 (1965)), the Supreme Court found sources for a right to privacy in the First, Third, Fourth, Fifth, and Ninth Amendments to the Constitution of the United States in the form of "zones" or "penumbras" of privacy (www.eff.org/Privacy/Medical/1993_ota_medical_privacy.report). A major modern discussion of an information privacy right is *Whalen v. Roe* (429 U.S. 589 (1977)), wherein the Supreme Court accepted that a right of privacy includes a generalized "right to be let alone," which includes "the individual interest in avoiding disclosure of personal matters." The court noted that it was "not unaware of the threat to privacy implicit in the accumulation of vast amounts of personal information in computerized data banks or other massive government files." However, the court has not expanded on this idea in any significant way (National Research Council, 1977).

The first comprehensive set of federal regulations of health information is provided by the Health Insurance Portability and Accountability Act (HIPAA) of 1996. HIPAA provides for two rules related directly to medical privacy: the Privacy Rule (45 *Code of Federal Regulations* 164.500–164.534) and the Security Rule (45 *Code of Federal Regulations* 164.103–164.318) (www.archives.gov/federal-register/index.html).

The HIPAA Privacy Rule

The HIPAA Privacy Rule provides the federal floor of privacy of protected health information (PHI) in the United States. It only applies to medical records maintained by covered entities (i.e., health care providers, health plans, and health care clearinghouses/data processing firms) in any form (electronic or nonelectronic, including oral). It allows more stringent state laws to continue in force. An individual has a number of rights under the Privacy Rule, including the following (adapted and expanded from www.epic.org/privacy/medical):

- To access, inspect, and copy PHI held by hospitals, clinics, health plans, and other covered entities with some exceptions.
- To request amendments to PHI held by covered entities.
- To request an accounting of disclosures that have been made without authorization to anyone other than the individual for purposes other than treatment, payment, and health care operations (i.e., medical practice evaluations for accreditation).
- To receive a Notice of Privacy Practices from doctors, hospitals, health plans, and others in the health care system.
- To request restrictions on uses and disclosures of PHI.
- To complain about privacy practices to a covered entity and to the Secretary of Health and Human Services.

Although many health care practitioners have been concerned with the privacy and confidentiality of patient information as a matter of course, HIPAA ensures that standards are being applied equally (Deshmukh & Croasdell, 2005). The Privacy Rule includes civil and criminal penalties for violations of an individual's privacy. Criminal penalties can approach $250,000 and/or 10 years imprisonment if the offense is committed with intent to sell, transfer, or use PHI for commercial or personal gain, or for malicious harm.

It should be noted that the HIPAA Privacy Rule does not prohibit the disclosure of PHI when such disclosure is required or permitted by other federal law. For example, the Gramm-Leach-Bliley Act does not prohibit the sharing of information among affiliated companies (such as banks and brokerages, which are *not* covered entities). So an individual's credit card account transactions may include data about where an individual goes for health care, and this data may be shared among affiliated companies and is not protected by HIPAA. The HIPAA Privacy Rule also explicitly includes a number of exceptions to the rules for use and disclosure. In fact, there are a number of uses and disclosures of information for which an authorization or opportunity to agree or object is *not* required (for example, for judicial and administrative proceedings, and for law enforcement purposes), including the use of PHI for marketing purposes (which, according to the Department of Health and Human Services, may be too difficult to distinguish from treatment purposes) (www.privacyrights.org/fs/fs8a-hipaa.htm).

Because HIPAA does not prohibit the sharing of PHI among various covered entities or their business associates, PHI could be used in ways other than for treatment or billing. An individual could be charged higher loan rates because of some piece of data in his or her medical record, and it would be impossible to prove the data were shared, because there is no required disclosure audit. Also, data networks may be Internet-based and global in reach. Individual health records may be transmitted overseas and handled by subcontractors in ways the individual is completely unaware. Another security challenge is the data breach. A hacker or even a trusted employee can steal data from a computer system and offer them for sale to interested parties (*Consumer Reports*, 2006).

Arguing that under HIPAA anyone can disclose, use, sharem and sell PHI without the individual's knowledge or consent, Senator Patrick Leahy proposed the Medical Information Privacy and Security Act in 1999, which provides for the following patient's rights (www.leahy.senate.gov/press/199903/990310a.html):

- To inspect, copy, and supplement your own medical record.
- To a clear explanation of who can see your health information and why before it is disclosed.
- To limit disclosure of your health information only to those directly involved with your health care.
- To have privacy protections for your medical records as strong as your video rental records by requiring law enforcement agents to first obtain a warrant before access to your health files.
- To ask your state officials for even stronger medical privacy protections.

The HIPAA Security Rule

The HIPAA Security Rule provides security standards and implementation specifications for three kinds of safeguards (administrative, physical, and technical) to protect PHI in *electronic* form. It also divides the implementation specifications into required and addressable (i.e., not required but recommended). Covered entities have a certain amount of flexibility in implementing addressable specifications. In deciding which security measures to adopt, the covered entity must consider its own size, complexity and capabilities, technical infrastructure, hardware and software security capabilities, the costs of security measures, and the probability and criticality of potential risks to electronic PHI. For example, covered entities may choose to adopt encryption as a technical safeguard for the transmission security standard. But since encryption is given as an addressable implementation specification, it is not required by HIPAA but simply recommended. In addition, while encryption and other technologies may keep patient data private and secure, it is what people who have access to the decrypted data do with it that is important to the issue of medical privacy (Patton, 2005).

HIPAA is not specific as to the exact technology that should be used to implement transmission security, since technology changes and progresses in ways that are difficult to predict. Current implementation of transmission security will most likely involve the use of firewalls, user authentication, encryption/decryption, antivirus/malware software, and anonymizers (Cheng & Hung, 2006; Fung & Paynter, 2006; Janczewski, 2000). These implementation choices will be replaced as newer, more effective technologies become available.

NATIONAL HEALTH INFORMATION NETWORK

The federal government is promoting a national system of electronic health records (EHRs) and the building of a National Health Information Network (NHIN), which will connect EHRs to health care providers, insurers, pharmacies, laboratories, and claims processors (Kaushal et al., 2005). HIPAA makes explicit mention of Electronic Data Interchange (EDI). However, implementation of EDI by covered entities has resulted in many proprietary EDI formats, resulting in a lack of common industrywide standards. This lack of uniformity is viewed as a major obstacle to realizing potential efficiency and savings (45 *Code of Federal Regulations*, Part 162). Since EDI has been replaced by the use of TCP/IP in Internet-based networks, it is likely that any future NHIN will use TCP/IP as its fundamental protocol, perhaps together with legacy systems for a time (www.amia.org/pubs/symposia/D005234.pdf ; Cheng & Hung, 2006; Deshmukh & Croasdell, 2005).

One proposal for NHIH implementation is to mimic the Santa Barbara County Data Exchange (SBCDE) on a national level. The SBCDE is a peer-to-peer network in which medical files are exchanged directly among users. A central host provides security and linking functions but does not store data. Suppliers of data must integrate data from a number of sources (e.g., pharmacies, laboratories, physicians) (Kaushal et al., 2005).

Another approach to developing an NHIN is the Veterans Administration's Veterans Health Information System and Technology Architecture (VistA), which was introduced in 1996 and is based on the client-server architecture. The VA plans to develop Health*e*Vet-VistA, which will allow veterans to access their medical records online (www.va.gov/vista_monograph/docs/vista_monograph2005_06.pdf). *Consumer Reports* (2006, p. 40) relates how the system currently works:

Two physicians at the Veterans Affairs Medical Center in Washington, D.C., showed us how a patient's computerized record gives them access to layers of information, including notes from office visits, hospital admissions and discharge notes, special patient problems, allergies, diagnostic test results, and a list of the patient's medications.

Alerts signal the doctor if the patient is due for a test or procedure. With a click, test results fill the screen. … A doctor at any of the VA's 1,300 care-center locations across the nation can pull up a patient's file and add information to it if a veteran is treated at that facility.

MEDICAL DATABASES

The role of medical databases in an NHIN is extremely important. However a database is implemented, the EHRs comprising it will be accessed by many interested parties over the NHIN. There is a number of benefits as well as disadvantages of medical databases (www.lbl.gov/Education/ELSI/privacy-main.html). Among the benefits are the following:

- A patient's medical information would be immediately available to an attending doctor, including life-saving information.
- Researchers would be able to track certain diseases as well as patients' responses to certain drugs.
- Medical databases would allow for better organization and more legibility of medical files.
- EHRs may be more secure than paper records since security systems can monitor medical databases.

Among the disadvantages of medical databases are the following:

- Employers may access medical information about their employees, which they might use to deny employment or job advancement.
- Insurers may use medical information to deny insurance to people they consider to be high risk.
- Digitizing medical records will allow many more people legitimate access to medical records, with the increased possibility that the information may be misused by one or more of them.

One of the largest central databases of EHRs is the Medical Information Bureau (MIB). It is shared by insurance companies to obtain information about life insurance and individual health insurance policy applicants. If the applicant reports a condition that the insurer considers significant, or if the results of a required examination, blood test, or urine test raise questions for the insurer, the insurer will report that information to the MIB. MIB EHRs consist of codes indicating a particular condition or lifestyle (such as the individual smokes cigarettes). As such, MIB does not include the totality of an individual's medical record (www.privacyrights.org/fs/fs8a-hipaa.htm).

The Children's Hospital of Philadelphia (CHOP) is collecting DNA profiles on as many as 100,000 child patients in order to develop an anonymous database that researchers can use to study children's genetic profiles. Research results may reveal which genes underlie problems affecting children, such as diabetes, obesity, asthma, and cancer. This research could lead to the development of diagnostic tests and drugs. By linking genetic information to EHRs, CHOP may obtain research funds and patents and forge partnerships with drug companies (Regalado, 2006).

Various federal, state, and local governments maintain databases of personal (including medical) information. As *Consumer Reports* (2000, p. 23) notes:

The federal government maintains electronic files of hundreds of millions of Medicare claims. And every state aggregates medical data on its inhabitants, including registries of births, deaths, immunizations, and communicable diseases. But most states go much further. Thirty-seven mandate collection of electronic records of every hospital discharge. Thirty-nine maintain registries of every newly diagnosed case of cancer. Most of these databases are available to any member of the public [emphasis added] who asks for them and can operate the database software required to read and manipulate them.

A computer privacy researcher at Carnegie Mellon University was able to retrieve the health records of the governor of Massachusetts from an "anonymous" database of state employee health insurance claims by knowing his birth date and ZIP code. The researcher demonstrated that she could do the same for 69% of the 54,805 registered voters on the Cambridge, Massachusetts, voting list (*Consumer Reports*, 2000).

Although many of these government database records are stripped of information that could be used to identify individuals (e.g., Social Security numbers), it is still possible to link the records to private sector medical records using standard codes for diagnoses and procedures employed by the United States health care system. The codes are usually included on insurance claims and hospital discharge records. In addition, a patient's anonymity may be compromised by the fact that personally identifiable health information is needed for a variety of research purposes (e.g., to check for duplicate records or redundant cases and for longitudinal studies) (www.epic.org/privacy/medical/GAO-medical-privacy-399.pdf).

Electronically available public records (e.g., court records) are also a source of an individual's medical information (Ogles, 2004). An individual's medical record may be entered into court documents (i.e., if an individual sues over payment claims), which are available online. Public records also have a connection to junk mail, since counties have sold information from public records to commercial companies that then repackage it and resell it to other companies and individuals (Leach, 2004). Junk mail in itself may not be overly troublesome to an individual. But what these companies and individuals may do with public record information in addition to creating and sending junk mail is cause for some concern.

Much personal health information that is available to the public is volunteered by individuals themselves by responding to 800 numbers, coupon offers, rebate offers, and Web site registration. The information is included in commercial databases like Behavior-Bank sponsored by Experian, one of the world's largest direct-mail database companies. This information is sold to clients interested in categories of health problems, such as bladder control or high cholesterol. Drug companies are also interested in the commercial databases (*Consumer Reports*, 2000). This interest will be heightened as hospitals link up electronically with doctors' offices' medication records (Landro, 2006). Data mining is often the rationale for wanting access to this information (Krzysztof & Moore, 2002; Prather, Lobach, Goodwin, Hales, Hage & Hammond, 1997). (For an account of the benefits of data mining to consumers, see Cook & Cook, 2004).

FUTURE TRENDS

The future of medical information will involve the use of an NHIN in increasingly sophisticated ways. However, the greatest obstacle to the success of NHIN implementation appears to be the medical profession itself (Patton, 2005). Many physicians have small practices with few extra resources or connections to large medical institutions. These physicians have little financial incentive to acquire expensive IT needed to link up with an NHIN. Nor do physicians want to have to pay to share medical information. Finally, many physicians do not have the time to log on to a computer to retrieve medical information. It seems that a physician champion of IT (perhaps the U.S. Surgeon General) will be needed in order to convince fellow physicians of the worth of an NHIN.

Patients will also have a say in how their medical information will be shared by the various HIPAA-covered entities. As the ultimate consumers of medical services, how patients view the information sharing practices of doctors, nurses, administrators, claims processors, and registration clerks in various hospitals and offices will impact how a NHIN is valued and used.

CONCLUSION

The implementation of am NHIN is technologically feasible and offers great promise for lowering medical costs, improving medical decision-making, and providing better quality medical care. How the users of the NHIN safeguard the medical privacy of patients will ultimately determine the success of the NHIH initiative. In particular, physicians must be convinced of the worth of the information sharing that the NHIH will make possible and feel confident that doctor-patient confidentiality will not be jeopardized. Patients must be convinced that their medical privacy will be assured and not sacrificed to commercial interests.

INTRODUCTION

Twenty years ago, researchers identified the difficulties physicians have answering the clinical questions that arise during medical care (Covell, Uman & Manning, 1985). Fifteen years ago, the "evidence-based medicine" movement arose (Cohen, 2001) and exhorted clinicians to use computers to look up the answers to questions as they arise during clinical care.

Fortuitously for the proponents of evidence-based medicine, the Internet matured in the 1990s (Hersh 1996 #3370), epitomized by the launching of PubMed by Al Gore in June 1997. PubMed, developed by the National Institutes of Health, provided the first free access to millions of biomedical research articles at MEDLINE.

Unfortunately, the Internet has not fulfilled its potential to assist physicians in answering clinical questions. A recent study found that physicians obtain answers to only 40% of questions that arise during patient care (Ely, Osheroff, Chambliss, Ebell & Rosenbaum, 2004); this rate is not much different than the rate of 30% reported 20 years ago (Covell et al., 1985).

BACKGROUND

This chapter focuses on information retrieval of general medical information by health care professionals. We will review research on information retrieval and medical publishing in order to describe the idealized medical search engine for health care professionals. This chapter does not address retrieval of patient-specific information, which is done by electronic medical records. This chapter does not address retrieval of general medical information by patients, although the principles are similar.

Performance parameters of the idealized medical search engine: We propose that the idealized medical search engine should provide scientifically valid and actionable answers to 95% of questions received. In addition, the total time to use the search engine, including query formation, searching, and interpretation of results, should be less than two minutes. An ideal search engine should search and include search results from all relevant sources.

The first parameter, scientifically valid answers, comes from research showing that knowledge resources vary in the validity of their content. Antman, Lau, Kupelnick, Mosteller, and Chalmers' (1992) seminal study using cumulative meta-analysis to retrospectively summarize changing medical evidence over multiple years showed that expert opinion as reflected in review articles and textbook chapters either may conflict with evidence or may delay 15 years in incorporating new evidence. Fortunately, new online hypertexts, such as UpToDate, PIER, Clinical Evidence, and others, implement systematic editorial processes such as peer review of chapters, extensive attribution of evidence with footnoting, regular and frequent updates, systematic literature surveillance or searches, grading of source evidence, and other techniques that presumably increase the validity of the content of hypertexts. We label these online resources systematic hypertexts and propose that they replace textbooks as a principle information resource.

The importance of succinct, actionable answers is demonstrated in surveys that ask physicians desirable traits of an information resource (Ely et al., 2004) and in studies of uptake of content by physicians and medical students (Beck & Bergman, 1986; Grol, Dalhuijsen, Thomas, Veld, Rutten & Mokkink, 1998). Many of the systematic hypertexts listed previously use bulleted lists and succinct recommendations rather than the traditional prose structure of printed textbooks. This attention to usability adds further justification for these hypertexts to be a principle information resource.

The importance of providing fast answers is noted in studies of the barriers to the pursuit of evidence (Dee & Blazek, 1993; Ely et al., 2002). In a study that directly observed physician behavior, an average of two minutes was spent to answer each question (Ely et al., 1999). Although our parameter of two minutes may seem stringent, Sackett and Straus (1998) found that even two minutes was a barrier to using resources. Unfortunately, breaking the two-minute barrier will require medical publishers to write more succinct and usable content. One of the most commonly used current knowledge resources, UpToDate, may require 15 minutes to read and interpret (Lucas et al., 2004). The medical outpatient visit is packed with information management and competing demands that may reduce quality of care (Redelmeier, Tan & Booth, 1998) or even prevent care (Yarnall, Pollak, Ostbye, Krause & Michener, 2003). Therefore, physicians must find answers quickly.

The need for an information resource to answer a high proportion of questions is found in studies that show belief that an answer that exists to a question is a strong determinant of whether a physician will pursue an answer (Ely et al., 2004). We arbitrarily designate 95% as the proportion of questions that should be answered by a knowledge resource in order to encourage physicians to continue using the resource.

THE IDEALIZED MEDICAL SEARCH ENGINE

Features of the Idealized Medical Search Engine Needed to Achieve Satisfactory Performance

To achieve 95% success within two minutes, we propose that the idealized medical search engine should have the following features. First, the search engine should search multiple information resources. Second, the main targets of the search engine should be high quality systematic hypertexts. Third, MEDLINE should be among the other targets of the search engine in order to answer. Fourth, the search form should be easy to use and accept natural language or Boolean results. Fifth, query expansion should use a broad thesaurus such as the Unified Medical Language System (UMLS). Sixth, links to the documents retrieved must be carefully fused into a single page of information. The order of the fused results is based on three dimensions: publication date, publication type (primary vs. secondary vs. tertiary), and publication quality.

The search engine should access multiple information resources in order to achieve completeness of search space. Studies have shown that no single information resource can answer more than 80% of questions (Alper, Stevermer, White & Ewigman, 2001; Fenton & Badgett, 2005; Lucas et al., 2004). This search engine should be a federated search that simultaneously queries multiple resources and then returns the results to the user in a single Web page. This is in contrast to the more common structure of an Internet portal that gives the user access to multiple resources, but the user must manually search the resources in sequence. We discuss next the details on how the search results should be displayed after fusing and sorting.

The principle targets of the search engine should be high quality tertiary publications. Others have noted the need to search tertiary publications first (Haynes, 2001). Research has shown that physicians can query textbooks faster than MEDLINE (Chambliss & Conley, 1996). The quicker use of textbooks is due to the more organized representation of medial knowledge in tertiary publications in contrast to the fragmented nature of the millions of citations on MEDLINE. As already noted, the ideal tertiary publications to be targets of a search are systematic hypertexts. Systematic hypertexts strive to improve validity of content by using processes such as peer review (Goodman, Berlin, Fletcher, & Fletcher, 1994), attribution (Kunst, Groot, Latthe, Latthe & Khan, 2002), frequent updating, stating the search date of the current version (Kunst et al., 2002), objective grading of underlying evidence, and structured literature searches. In addition, systematic hypertexts strive to improve usability by use of actionable and prescriptive recommendations (Ely, Osheroff, Chambliss, Ebell & Rosenbaum, 2005; Grol et al., 1998), succinct and bulleted summaries (Beck & Bergman, 1986; Ely et al., 2005), and layered content in which summary recommendations precede detailed explanations.

MEDLINE should be among the other targets of the search engine. Lucas, et al. (2004) found that UpToDate, one of the most commonly used systematic hypertexts, was helpful in only 71% of patients. A separate study found that UpToDate covered 80% of clinical questions (Fenton & Badgett, 2005). As MEDLINE is the most comprehensive repository of biomedical knowledge, it can provide relevant information for uncommon topics not covered in the derived literature. Google may provide this role as well (Greenwald, 2005) but has not been formally compared to MEDLINE. Unfortunately, MEDLINE is very difficult to search due to its size (15 million articles), difficult linguistics, and unstable nature. Although it is clear that the common method of searching MEDLINE—manually formulating a Boolean search and manually revising the strategy when too few or too many results are retrieved—consumes too much physician time, the best way to search MEDLINE is not clear. Two options are Boolean searching with automated revision of searches that retrieve excessive or too few results (used by SUMSearch) vs. relevancy searching with weighting of results utilizing PageRank (used by Google). There are theoretical reasons why SUMSearch's method might be better. Medical research findings are unstable; a third of high impact trials are subsequently refuted or attenuated (Ioannidis, 2005). Unfortunately, the initial findings may be reported in a high impact journal, whereas the subsequent refuting study may be in a lower impact journal (Ioannidis, 2005). Boolean queries allow results sorted by publication date, which might reduce the chance of a physician overlooking the second publication in a journal that has a lower PageRank; however, this has not been tested. In addition, as Google relies on links to documents to become aware of new documents, Google may not be as good at finding newly published research. These problems could become worse as the Internet ages and the need increases to recognize the dimension of time in the display of search results. Currently, the Internet is young compared to the age of MEDLINE.

The search form should be easy to use and accept natural language or Boolean results. Some physicians have difficulty with logical operators (Kingsland, Harbourt, Syed & Schuyler, 1993; Walker, McKibbon, Haynes & Ramsden, 1991). Automated query expansion, using a broad thesaurus such as the Unified Medical Language System (UMLS), serves two purposes. First, when searchers must manually browse a thesaurus, underutilization of canonical terms occurs when synonymous medical words exist (Kingsland et al., 1993). Second, use of a thesaurus also allows the search engine to vary the targets of the search based on the location of the search term in the thesaurus' tree structure. For example, if a search term is from the infectious disease branch of the thesaurus, a search of the CDC Web site can be included. If the search contains a drug name, searches of a drug resource and the FDA are included.

Links to the documents retrieved on the Web page returned to the physician must be carefully fused and sorted. When reviewing search results, clinicians have trouble screening out needless hits (Williamson, German, Weiss, Skinner & Bowes, 1989) and not recognizing incomplete searches (Walker et al., 1991).The order of the fused results are based on two dimensions: publication type (primary vs. secondary vs. tertiary) and publication date.

We proposed the following display order. Please note that this schema is theorized but has not been empirically studied. The principal resource, a systematic hypertext, is displayed first whenever it has content that matches all search terms. Next, the search engine would emphasize the display of other resources when their results are published more recently than the last update of the systematic hypertext, or when their results better match the search terms.

The procedure indicated in Table 1 creates the display order. For each search submitted to the proposed search engine, the results found from all resources are summarized in a temporary data array that is sorted according to the rules shown in Table 1.

Three scenarios to demonstrate sorting described in Table 1.

In the first scenario, the systematic hypertext has the most recent content and also matches all search terms. The search engine displays the results from the systematic hypertext first; then the engine provides the remaining links in a section titled "For more detailed information."

The second scenario is the same, except there is a randomized controlled trial that is very recently published and not covered by any of the derived literature (tertiary or secondary publications). The search engine displays the recent research first in a section labeled emerging research, then displays the systematic hypertext, and finally displays the other links in a section titled "For more detailed information."

Table 1. Dynamically determining the display order of search results

Publication Type	Example of This Publication Type	Notes	Primary Sort Order*	Secondary Sort Order
Tertiary publication	Systematic hypertext such as UpToDate or PIER		1	
Secondary publication	Practice guideline such as found at the National Guidelines Clear-inghouse	Among secondary publications, these are listed first because they usually have a broader scope and less frag-mentation than systematic reviews.	2	1
	Systematic review such as produced by the Cochrane col-laboration		2	2
	Narrative review articles	Among secondary publications, these have the least editorial quality but are very important for rapid summaries of emerging topics or for summariz-ing topics with sparse evidence.	2	3
Primary publications	Articles		3	

In the third scenario, original research is found that contains all of the user's search terms, whereas the resources in the derived literature only partially match the search terms. In this scenario, the search engine displays the original research, first in a section titled "Best matches for your search," following by the systematic hypertext and then the remaining links.

Barriers to the Implementation of the Idealized Medical Search Engine

Significant barriers hinder the development of the idealized search engine. These barriers are lack of evidence that providing rapid access to extrasomatic general medical knowledge improves patient outcomes, lack of evidence that a search engine can generate revenue for its owners, and lack of standards for B2B communications between medical publishers and search engines.

The impact of facilitating information retrieval on the quality of medical care is difficult to establish. In a cleverly designed before-and-after-study, Lucas found that 14% of medical in-patients had improved treatment plans as judged by blinded reviewers after attending physicians were provided with literature searches (Lucas et al., 2004). However, in regard to physicians doing their own searches, there is no randomized controlled trial that shows physicians with rapid access to medical knowledge provide better care than physicians without access. We acknowledge extensive literature documenting the failure to change physician behavior through education. Interventions, such as continuing medical education (CME) and practice guidelines, in which educators actively push knowledge to recipients, show physicians do not change their medical practice without intensive multifactoral interventions (Thomson O'Brien, Freemantle, Oxman, Wolf, Davis & Herrin, 2001). However, there is strong theoretical support for making knowledge accessible to physicians. Surveys show that when clinicians choose to actively pull medical knowledge to themselves by either conducting their own searches for information (Blackman, Cifu & Levinson, 2002; Brassey, Elwyn, Price & Kinnersley, 2001; Del Mar et al., 2001) or asking others to search on their behalf (Lindberg, Siegel, Rapp, Wallingford & Wilson, 1993), clinicians are very willing to let the information that they find influence their clinical care. The difference in the effectiveness of knowledge that is pulled by the clinician rather than being pushed to the clinician is consistent with theories of changing adult behavior, including that of physicians (Stross, 1999). When clinicians pull information, they have recognized a gap in their knowledge and are predisposed to changing their decision-making.

Another barrier is the lack of a business case to support a search engine. Studies of the electronic medical records (EMRs) to retrieve patient-specific medical information, which have been more thoroughly studied than retrieval of general medical knowledge, show cost savings from components of the EMR (Kaushal et al., 2005). However, the complete EMR is not financially viable, and hence, the government is considering incentives. The benefit of retrieval of general medical knowledge is not studied. There is a perception that hospitals are reluctant to invest in resources such as librarians and knowledge support (Wolf, Chastain-Warheit, Easterby-Gannett, Chayes & Long, 2002; Doyle, 2003).

The last barrier is the lack of connectivity and interoperability to support search engines to perform live searches of medical resources. Currently, very few resources offer search results in XML format. Standards such as OpenSearch (http://opensearch.a9.com/) are needed. In addition, no medical Web sites provide metadata that adequately describe the currency of the page. While Web pages display the date of the last editorial update, more important is the date of the literature search for the evidence that underlies the page's content. The Dublin Core standard (http://dublincore.org) allows for rich metadata, but the Dublin Core standard needs expanding, as the date of a Web page's literature search is not an element.

PubMed, GOOGLE, SUMsearch, AND Medscape: SEARCH ENGINES WITH CONTRASTING METHODS

We contrast four very different search engines. Each engine has many purposes aside from point-of-care retrieval of general medical information, so our comments should not be taken as summative criticisms of each engine. All four engines share the features of free access to search results and broad scope of content. Unfortunately, they also share lack of a systematic hypertext as their central target. In addition, none has adequate representation of knowledge in the display of search results. More specifically, none can vary the sorting of results by interacting the currency and publication type of the citations retrieved. The search engines are summarized in Table 2.

We now detail SUMSearch, which was created in 1998 to provide some of the features of the idealized medical search engine. In 1998, Badgett launched SUMSearch (http://SUMSearch.UTHCSA.edu), a search engine that automates a federated search for evidence from Medline and selected other resources (Booth & O'Rourke, 2000; Badgett, Paukert & Levy, 2001a). SUMSearch is unique because it (1) searches

Table 2. Comparison of selected search engines as a point-of-care tool

Search Engine	Strengths	Weaknesses
PubMed	1. Free access 2. Most comprehensive repository of world's biomedical knowledge	1. Does not have a systematic hypertext as its central target 2. Since principle clinical target of PubMed is MEDLINE, results are fragmented
SUMSearch	1. Free access 2. Live federated searching with large biomedical search space 3. Results are sorted by publication type with a secondary sort of publication date	1. Does not have a systematic hypertext as its central target 2. Results are fragmented 3. Although results are sorted on two dimensions, there is no interaction between the dimensions in order to vary the sort of publication types based on the currency of the documents retrieved
Google	1. Free access 2. Recently introduced organizing results by publication type 3. Fast	1. Does not have a systematic hypertext as its central target 2. Results are fragmented 3. Uncertain ability to search MEDLINE
Medscape	1. Free access 2. Access to full text of selected journals.	1. No identifiable primary resource in spite of Medscape's ownership of eMedicine, which has characteristics of a systematic hypertext 2. No access to important journals such as *New England Journal of Medicine* even though the Medline XML is free to Medscape 3. No logical sort and display; initial links are sponsored; other links are a fragmented collection of journal articles

multiple remote resources in real time, (2) detects when a search returns too few or too many (Blair, 1980) results and automatically revises and executes a new strategy, and (3) provides tailored suggestions to users when contingency searches cannot provide an optimal number of articles. SUMSearch has been recognized internationally (Alton & Eliasson, 2000; Anagnostelis, 2002; Booth & O'Rourke, 2000; Dearness & Tomlin, 2001; Glanville, Wilson & Richardson, 2003). Although originally developed for point-of-care searches, unexpectedly it has been used for formal literature searches for published meta-analyses. It is queried 300 to 500 times a day.

In spite of the positive published reviews already noted, positive feedback in the medical student course in which SUMSearch is used and positive e-mailed comments from the international community in a controlled trial showed that use of SUMSearch did not increase medical students' self-reports of frequency of searching (Badgett, Paukert & Levy, 2001b). We hypothesize that even when a search engine successfully delivers the relevant studies, the clinician still faces the task of synthesizing an answer by reading and integrating multiple articles during patient care. The difficulty in assimilating multiple pieces of fragmented information has been noted before (Ely et al., 2002). This hypothesis supports the need to incorporate a systematic hypertext within the metasearch and is consistent with the 4S strategy proposed by Haynes (2001).

In summary, none of the search engines adequately meet the need of the busy physician. Google and SUMSearch have the largest search space and put the most effort into how results are displayed and sorted, but both are hindered by not having a systematic hypertext as the central target of the search.

FUTURE TRENDS

Hopefully, the near future will see resolution of the barriers—financing and standards of interoperability—to the creation of a search engine. In addition, more research is needed on the best manner of searching MEDLINE.

Unresolved issues in medical publishing will have a great impact on information retrieval. It is presently unclear whether the national push for open access to medical publications will influence medical information retrieval by health care professionals during clinical care. So far, the push has been for open access to federally sponsored research. This means a large portion of original research reports (primary publications), a small proportion of federally funded meta-analyses (secondary publications), and no tertiary publications. Because the tertiary publications followed by secondary publications will be the most viewed results provided by the search engine, we doubt that the current movement toward open access to federally sponsored research will impact information retrieval. The exception is if Wikipedia's medical content matures and Wikipedia becomes an important provider of medical information.

Another issue in medical publishing is improving the readability of medical writing. As previously noted, 15 minutes may be needed to read and interpret UpToDate when answering a clinical question (Lucas et al., 2004). This time is too long. Medical writing that is for the busy physician must abandon long blocks of prose in favor of more succinct forms of text (Ely et al., 2005).

It is unclear what the NIH's role will be in providing point-of-care medical information. It has had rudimentary efforts in this area (http://gateway.nlm.nih.gov/). However, because the NLM is focused on access to content rather than creating original content, the NIH will not have a major role with its current policy. In addition, the NLM focuses more on reports of research than the hypertexts that are needed by physicians. The NLM does host books at their Bookshelf, but these are books whose authors and publishers have agreed to give open access to a copy of the book. Since high-quality tertiary publications are expensive to produce, the NIH will not have a significant role unless either Wikipedia emerges as a strong medical resource or the NLM allows publishers to retain a subscription-based business model with the NLM providing users with content.

Regarding PubMed's role as a point-of-care tool, PubMed does offer clinical queries. But as PubMed uses Boolean searching but does not automate revisions of searches that retrieve excessive results, PubMed will have a limited role in information retrieval for physicians. Research has shown how infrequently PubMed is used in this role (Ely et al., 1999).

CONCLUSION

In spite of the arrival of the Internet, retrieval of general medical information has significant problems, and 20% of office visits to primary care physicians contain questions posed by the physician that are not answered. The Internet provides the technology to create a high performance medical search engine; however, we must solve several barriers. These barriers include the justification and financing of information retrieval, improved interoperability among medical Web sites, and improvements in medical publishing that facilitate quick comprehension of medical writing.

ACKNOWLEDGMENT

Drs. Badgett and Pugh's research is supported in part by the VERDICT Research Enhancement Award Program, South Texas Veterans Health Care System Department of Medicine, and the University of Texas Health Sciences Center. The views expressed in this chapter are those of the authors and do not necessarily represent the views of the Department of Veterans Affairs. Dr. Boppana's research has been supported by National Science Foundation (NSF) grants EIA-0117255 and ANI-0228927 and the San Antonio Life Sciences Institute grant 10001642. This research is also sponsored in part by a summer research grant to Suresh Chalasani from the University of Wisconsin system.

KEY TERMS

MEDLINE: The database of citations and links to much of the world's biomedical research. MEDLINE is maintained by the National Library of Medicine of the National Institutes of Health. More information is available at http://www.nlm.nih.gov/databases/databases_medline.html.

MeSH Terms: MeSH stands for Medical Subject Headings (MeSH®). It is a set of keywords and vocabulary produced by the National Library of Medicine and used for indexing, cataloging, and searching for biomedical and health-related information and documents. More information is available at http://www.nlm.nih.gov/mesh/.

Primary, Secondary, and Tertiary Publications: Primacy publications are source documents such as journal articles and press releases. Secondary publications are summaries and syntheses of primary publications. Examples of secondary publications include practice guidelines, review articles, and meta-analyses. Tertiary publications are printed textbooks and online hypertexts.

PubMed: The public search engine for MEDLINE that is maintained by the National Center for Biotechnology Information. PubMed is available at http://pubmed.gov.

SUMSearch: SUMSearch is a federated medical search engine that in response to a query from a user performs live searches of remote Internet sites and automates revising of searches that retrieve excessive or too few documents. SUMSearch is available at http://sumsearch.uthscsa.edu.

Systematic Hypertexts: We introduce this term to distinguish online hypertexts that have a systematic method to their creation and maintenance. These methods have either been shown in studies or requested by physicians in surveys to improve the validity or usability of medical information. Examples of methods to increase validity include systematic editorial processes such as use of peer review of chapters, extensive attribution of evidence with footnoting, regular and frequent updates, systematic literature surveillance or searches, and objective grading of source evidence. Examples of techniques to improve usability include succinct, actionable answers and a standardized structure for each chapter. We propose that systematic hypertexts replace textbooks as a principle information resource.

The Unified Medical Language System (UMLS®): Metathesaurus is a vocabulary that links together multiple medical vocabularies. More information is available at http://www.nlm.nih.gov/pubs/factsheets/umls.html.

Minimal Invasive Surgery and Therapy (MIS and MIT) in Hirschsprung's Patients

INTRODUCTION

The generally accepted treatment for Hirschsprung's disease is through surgical intervention. Currently, the recognized techniques include the Swenson technique, which is less frequently used as the operation is delicate and can give rise to complications; the Duhamel technique, which is arguably the simplest approach and consistently provides good results; and the Soave technique, which also provides good results but is often more complex than the Duhamel approach. However, surgical and diagnostic procedures of the future will evolve from embracing current technologies that enable minimally invasive approaches to extremely targeted, localized, and high-precision endoluminal techniques. This requires entirely new types of surgical tools capable of entering the human body through natural orifices (by insertion, ingestion, or inhalation), very small incisions (injections), or even through skin absorption and maybe configuring themselves in complex kinetic structures at the specific site of intervention. Moreover, such approaches necessitate modification of classic surgical techniques. While the advantages of minimally invasive surgery and minimally invasive therapy (MIS and MIT) are widely acknowledged, this chapter serves to highlight the advantages of such procedures in pediatric medicine, both at the diagnostic and intervention levels and the consequent implications to classic surgical techniques. The particular focus of the chapter pertains to the specific advantages the following techniques can bring into pediatric diagnostic and surgical techniques in the case of Hirschsprung's disease: (1) endoluminal miniaturized tools for gastrointestinal endoscopy, (2) gastrointestinal capsules for digestion (e.g., M2A capsule), and (3) laparoscopic tools for surgery. Both technological and economic perspectives are discussed.

BACKGROUND

Hirschsprung's disease (also known as congenital megacolon or congenital intestinal aganglionosis) occurs when some of the nerve cells that are normally present in the intestine do not form properly while a baby is developing during pregnancy. In children with Hirschsprung's disease, a lack of nerve cells in part of the intestine interrupts the signal from the brain and prevents peristalsis in that segment of the intestine. Because stool cannot move forward normally, the intestine can become partially or completely obstructed (blocked) and begins to expand to a larger than normal size. Today it is agreed that Hirschsprung's disease can only be cured through surgery (Rehbein, Morger, Kundert & Meher-Ruge, 1966; Soper & Figueroa, 1971; San Luis, Nemoto & Beardmore, 1968; Soaue, 1964)). The goals of the surgical treatment are to establish regular and spontaneous bowl function and maintain complete continence.

The three recognized surgical techniques include (1) the Swenson technique, developed by Swenson in 1947 but today is less frequently used, as the operation is delicate and can give rise to complications; (2) the Duhamel technique, which is arguably the simplest approach and consistently provides good results; and (3) the Soave technique, which also provides good results but is often more complex than the Duhamel approach.

With the advent of technologies, minimally invasive surgery (MIS) is becoming more and more prevalent in various areas of surgery. Essentially, MIS is done through small incisions using specialized techniques, including miniature cameras with microscopes, tiny fiber-optic flashlights, and high-definition monitors, so that surgeons in many specialties can perform surgery through an incision that requires only a stitch or two to close. For patients, MIS has several benefits since it can minimize pain, speed up recovery, and eliminate potential complications. For health care delivery, MIS represents an avenue to offer high-quality health care delivery and yet minimize costs associated with longer hospital stays and recovery. The area of pediatric surgery has only just begun to investigate the possibilities of incorporating MIS techniques. We discuss the role of MIS and MIT in the context of Hirschsprung's disease.

MIS/MIT TECHNIQUES AND TOOLS

MIS and MIT are growing and evolving areas that use many tools and techniques. Depending on the specific treatment domain (e.g., spine surgery vs. gastrointestinal surgery) naturally different tools and techniques are more suitable. Three MIS/MIT techniques that are particularly suitable in the context of pediatric gastrointestinal treatment include:

1. Endoluminal miniaturized tools for gastrointestinal endoscopy
2. Gastrointestinal capsules for digestion
3. Laparoscopic tools for surgery

We briefly discuss each in turn.

ENDOLUMINAL MINIATURIZED TOOLS FOR GASTROINTESTINAL ENDOSCOPY

Pediatric gastroenterology, which was born in the early 1970s, is nowadays increasingly related to the application of gastrointestinal endoscopy for the diagnosis and treatment of digestive diseases in children (Gilger, 2001; Olives et al., 2004).

Today, gastrointestinal endoscopy plays an important role in the diagnosis of manifold pathologies, including Hirschsprung's disease (HD), which may be detected by three tests: contrast enema X-rays, manometry, and biopsy (North American Society for Pediatric Gastroenterology Hepatology, and Nutrition). In particular, rectal suction has recently demonstrated to be the most accurate test for diagnosing HD (De Lorijn et al., 2005). This procedure enables preoperative hystochemistry on mucosal-submucosal specimens for proper enteric nervous system (ENS) evaluation (Martucciello et al., 2005). It is traditionally performed using the biopsy tool conceived by Noblett (Campbell & Noblett, 1969; Noblett, 1969) in the late 1960s. By using this instrument, a physician can create suction within the lumen and then use a cutter for mucosa sampling. Although such a system is atraumatic and easy to use, it requires two operators, while the size of the specimen and the depth of sampling are inconstant. In order to overcome all these limitations, Prato, Martucciello, and Jasonni (2001) have devised the "Solo-RBT." More recently, Bio-Optica has developed a kit for enzymatic-histochemistry.

Although barium enema is not essential to confirm the diagnosis of HD in many cases, it is useful in evaluating the level of aganglionosis and aids in the decision regarding the surgical approach (i.e., transanal, transabdominal laparoscopic, or open). Manometry, although not necessary, is generally exploited with rectal biopsy and barium (Martucciello et al., 2005).

It is assumed that the development of biopsy instrumentation could benefit by both the advancements in microfabrication technologies and the employment of new and biocompatible materials. For example, by exploiting Wired Electrical Discharge Machining (WEDM) and Nitinol, miniaturized biopsy tools for a gentle approach to the GI tract are feasible (Menciassi, Moglia, Gorini, Pernorio, Stefanini & Dario (2005). Biopsy could be eventually customized for usage in pediatrics, where minimization of intrusion is critical due to the narrow spaces. Nonetheless, biopsy can be somewhat painful for patients, since it requires the removal of samples of tissue. In order to preserve the tissue, there is a growing interest to find new and less traumatic modalities to perform biopsy. In this sense, a promising technique is optical biopsy, given that the optical properties of a biological tissue depend on its biochemical composition and its cellular and subcellular structure. Therefore, optical measurements have a strong potential for the development of noninvasive *in vivo* medical diagnostic tools. Such techniques should significantly improve the efficiency of biopsies or help in determining pathologies margins in a surgical field. Several types of optical properties can be measured, such as fluorescence, Raman scattering, and absorption and scattering, each of them giving complementary information on the tissue. As an example, past studies have proved that the absorption and scattering of tumor tissues differ from their surrounding normal tissue (Bevilacqua, Piguet, Marquet, Gross, Tromberg & Depeursinge, 1999). At the Ecole Polytechnique Fédérale de Lausanne (EPFL) in Switzerland, a research group reported *in vivo* clinical measurements performed endoscopically on a human GI tract (Charvet et al., 2002; Charvet et al., 2004).

GASTROINTESTINAL CAPSULES FOR DIGESTION

The Wireless Capsule Endoscopy (WCE) indicates a swallowable and disposable vitamin-size pill able to acquire images from inside the gastrointestinal (GI) tract. This device offered for the first time a noninvasive way to enter the small intestine, which has always been known as a "black box" because of the intrinsic difficulties to enter it from either the mouth or the anus. The feasibility of WCE has been certainly possible thanks to the advancements in several technologies, including Complementary Metal Oxide Semiconductor (CMOS), Application Specific Integrated Circuit (ASIC) transmitter, and synchronous switching of Light Emitting Diode (LED).

Although interest in WCE emerged in the past few years, actually its roots date back to the middle of the 20th century when Jacobsen et al (Nebeker, 2002) developed the first device for wireless monitoring systems: endoradiosondes, also called radio-pills, for medical and biological studies. Later, Nagumo et al (1962) conceived a passive echo capsule for temperature and pH monitoring.

Today, the most famous WCE is the PillCam™ SB, announced in 2000 and currently marketed by Given Imaging, an Israeli company (Given Imaging; Moglia, Menciassi, Schurr & Dario, 2006). The PillCam™ SB Capsule Endoscope is carried through the GI tract by peristalsis and, as its name implies, works inside the small bowel. It is 26mm in length and 11mm in diameter; it is battery powered and possesses a CMOS camera able to acquire two images per second. Once captured, pictures are transmitted via an array of sensors secured to the abdomen, to the DataRecorder™ affixed to a belt worn around the patient's waist. The examination lasts eight hours and can be carried out while a patient continues normal daily activities. Later, the patient returns the DataRecorder™ for processing on the RAPID® workstation. The RAPID® application enables the physician to view and analyze the Patient Rapid Report (PRR).

Since its adoption in clinical studies, WCE has been exploited in the diagnosis of a larger and larger number of pathologies. First applications have concerned obscure gastrointestinal bleeding (OGIB) and Crohn's disease (CD), while currently WCE is emerging for celiac disease diagnosis.

In October 2003, Given Imaging got clearance to market capsule endoscopy for use in pediatric patients ages 10 to 18. The company offers a Pediatric Accessory Kit for children and small stature patients, consisting of the Pediatric Recorder Belt and the Pediatric Sensor Array. Aabakken, Scholz, Ostensen, Emblem, and Jermstad (2003) proved the feasibility of WCE in children, while Guilhon de Araujo Sant'Anna, Dubois, Miron, and Seidman (2005) performed the first clinical study. In a clinical trial, PillCam™ SB detected linear and aphthous ulcers of the jejunum or ileum not recognized by other imaging techniques (Seidman, Sant'Anna & Dirks, 2004). Additionally, WCE detected the presence of OGIB in a 2.5-year-old patient, so far the youngest one who has received WCE treatment (Kavin, Berman, Martin, Feldman & Forsey-Koukol, 2006). Moreover, WCE was evaluated in the graft vs. host disease in young patients (Silbermintz, Sahdev, Moy, Vlachos, Lipton & Levine, 2006).

The higher diagnostic yield of WCE over conventional procedures and its high degree of tolerance have suggested to expand the application of WCE to the surveillance of oesophageal disorders such as gastroesophageal reflux disease. In 2004, PillCam™ ESO was launched by Given Imaging. This pill has the same dimensions of PillCam™ SB. However, it comes with two cameras, at the front and back end of its body.

A dedicated WCE for colon, named PillCam™ COLON, was unveiled at the United European Gastroenterology Week (UEGW) 2006, Berlin, Germany. This two-camera pill is a bit larger than those for small bowel and oesophagus; in fact, it is 32mm in length and 11mm in diameter. At present, the device is undergoing first clinical tests.

LAPAROSCOPIC TOOLS FOR SURGERY

The term minimally invasive surgery (MIS) was introduced by John Wickam to describe the emerging therapeutic approach designed to minimize the traumatic insult to the patient by surgical procedures.

The evolution of MIS techniques for adults has been among the most important surgical developments of the last century. In fact, by reducing the size of the incision, the postoperative pain should be limited (Zitsman, 2003; Georgeson, 2003).

However, the adoption of MIS techniques in young patients has been a slower process than in adults for several reasons. First, surgical instruments developed for adults are cumbersome and unsafe when used in infants and children. Additionally, no single procedure propelled the evolution of MIS in neonates like laparoscopic cholecystectomy in adults. Then, the absolute length of an incision in a neonate is short and thought to be less traumatic. Yet from a relative perspective, these incisions are at least as long as the incisions for similar surgical procedures in adults.

During the past 15 years, laparoscopic surgery has been a major driving force for the technological advances that can be grouped into three categories: facilitative, enabling, and additive. *Facilitative technologies* improve the efficiency of performance of the procedure and reduce the level of difficulty of its execution, although not necessarily its safety. Examples of facilitative technologies include the newer high-power ultrasonic dissection systems (Ultracision and Autosonix), hand-assist devices, and the cutting impedance-controlled bipolar coagulation (LigaSure). *Enabling technologies* make possible certain surgical procedures that would be impossible or very difficult without them. Enabling technologies are, of course, relative to specific interventions. Examples include radio frequency (RF) thermal and other physical tissue ablators used for laparoscopic in situ ablation of hepatic tumors, inflatable bands for obesity surgery, and linear cutting endostaplers for colorectal and upper GI surgery. *Additive technologies* bring sophistication to surgical manipulations but are not considered essential, although they may, as the technology advances, replace existing systems, but this seems unlikely in the near future. Additive technologies are usually expensive and, hence, limited to only a few centers. The best example is provided by the DaVinci system (Cuschieri, 2005).

The management of HD disease has been radically changed by endoscopic surgery. In particular, the laparoscopic-assisted transanal endorectal pull-through allows early biopsies to determine the extent of aganglionic and dysfunctional bowel (Georgeson & Robertson, 2004). Mazzotti and Langer (2001) reported the first study on laparoscopic surgery to obtain full-thickness intestinal biopsies in children. They especially pointed out that laparoscopic full-thickness intestinal biopsy is safe and effective for a variety of gastrointestinal disorders in children such as HD. Ruckauer and von Dobschuetz (2005) proved the effectiveness of laparoscopically assisted colorectal resection in HD. Moreover, by using laparoscopy prior to the transanal endorectal dissection, the transition zone can be gauged precisely (Georgeson & Robertson, 2004). A new and effective technique named laparoscopic cecostomy button placement for the treatment of CD was documented by Yagmurlu, Harmon, and Georgeson (2006).

In the future, robotic capsules integrating imaging system, instruments, and suture modules could be employed in pediatrics to help physicians manage disorders that may occur in the GI tract of young patients. According to this scenario, the surgeon will be able to guide the robot into the exact positions where lesions may be present, by means of a dedicated computerized console. In particular, robotics will bring several advantages to pediatrics surgery. First and foremost, the associated *tremors* to the surgeon's hands during their movement, crucial when working in narrow spaces, could be countered by the computer interface of the robot. Moreover, with *motion scaling*, the computer will be able to scale down a movement of several centimeters of the surgeon's hand into a small fraction. The scale factor may be varied and be independent from translations and rotations of the tiny surgical instrumentation. Another benefit of robotics is *indexing*, the ability to continue moving a tool continuously in any direction beyond the limits of the surgeon's arm (Hanly & Talamini, 2004; Kant, Klein & Langenburg, 2004; Woo, Le, Krummel & Albanese, 2004).

SOME ECONOMIC CONSIDERATIONS

Even if innovation in pediatrics, more than in other medical and surgical fields, is often driven by ethical considerations rather than by its economic implications (Goodman, 2004), some economic notes about the diffusion and cost-effectiveness of the herein proposed technologies could be usefully introduced in order to contribute to the debate—still controversial in literature—of technological innovations as the culprit of increasing costs in health care.

The diffusion of new technology in pediatric practices is now quite broad. A study carried out in 1998 by of the University of Arkansas School for Medical Sciences and Arkansas Children's Hospital resulted in 82% of the surveyed pediatric surgeons (all the members of the American Pediatric Surgical Association were surveyed) performing MIS. Laparoscopic cholecystectomy was the procedure more frequently reported (Christensen, Anthony & Roth, 2004). The results of this study suggest that the diffusion of new technology in pediatric surgery could follow the same pathway as for adult general surgery.

It is worth remarking that the benefits of MIS in children could appear (and so it was at the beginning of its application in pediatrics) less evident than in adult surgery: as children's bodies are smaller than adult bodies, surgical incisions are naturally smaller; children naturally recover in shorter time than adults; and anesthetic and analgesic doses are naturally less than for adults (Cataliotti, 2003). Even costs of minimally invasive pediatrics procedures could appear higher than for conventional surgical treatments: MIS procedures could take more time, which would entail increasing costs of medical and nursing staff and higher costs for using the operating rooms; furthermore, disposable equipments have to be used (Cataliotti. 2003). Nevertheless, regarding Hirschsprung's disease, laparoscopically assisted primary endorectal pull-through is now considered the standard treatment (Firilas, Jackson & Smith, 1998).

While approaching new technology in pediatrics from a Health Technology Assessment (HTA) perspective and focusing first on the potential cost-effectiveness of MIS compared with conventional treatments, the following elements should be considered:

- Patient outcomes
- Operative times
- Anesthetic requirements
- In-patient hospital days
- Complications
- Length of follow-up
- Pain
- Cosmetic results
- Psychological impact

Evidences already exist supporting the cost-effectiveness of new, minimally invasive treatments for Hirschsprung's disease.

To give an example, the study carried out at the Section of Pediatric Surgery of University of Tennessee during the period of February 1993 and March 1996 could be mentioned (Zitsman, 2003). Data were collected on 33 children suffering from Hirschsprung's disease; 18 of them were treated through the traditional (open) two-stage Duhamel procedure, while on 15 of them, the single-stage laparoscopic pull-through was performed.

The operative times were not considerably different for the two procedures, while the number of in-patient hospital days was significantly shorter for patients treated through laparoscopic rather than open procedure ($2{,}5 \pm 3{,}5$ vs. $5{,}3 \pm 1{,}9$ days). Complications were more frequent in the group treated with open technique that often required further interventions. The length of follow-up was longer in the open group ($12{,}2 \pm 14{,}4$ months vs. $6{,}7 \pm 3{,}2$ months). The total cost of managing Hirschsprung's disease through minimally invasive procedure was $19,088 ± 13,075, while for the open intervention, the total cost was $ 34,102 ± 19,443.

If approaching Hirschsprung's disease from a cost of illness perspective, intangible costs (and intangible cost savings) should also be considered. So less pain, better cosmetic results, and consequent less negative psychological impact would increase the advantages of minimally invasive treatment for Hirschsprung's.

The debate about cost-benefits/effectiveness of new technology in pediatrics is still very open, but as for health care technology in general, we would stress two points that we consider very critical while assessing innovative technologies:

1. The "global approach": to take into consideration and evaluate all aspects and implications of new technology, such as:
   - Technical properties
   - Safety
   - Efficacy and/or effectiveness
   - Economic impact
   - Social, legal, ethical, and/or political impacts
2. The "early assessment": new health technologies need to be carefully assessed from the first phases of their development process, even if no scientific evidence is still available. Currently, HTA methods are only applied at the end of the biomedical products development process, usually at the commercialization phase, with the aim to support the decision makers in their decision concerning the introduction of new health technologies.

   We believe that each stage of the health technology development process, from concept to final outcome, should be followed by HTA analyses carried out through models, simulations, and evaluation protocols in order to provide information about potential costs, benefits, effects, and impacts to technologists, producers, and users. This could also help researchers, developers, and producers adjust the technology development trajectory toward more effective, safe, and/or economic standards.

DISCUSSION AND CONCLUSION

The primary purpose of this chapter is to highlight the possibility for incorporating MIS/MIT tools and techniques into pediatric surgery. We did this by first discussing the instance of Hirschsprung's disease, a problem experienced by children who today are treated through complex surgical techniques that may have unpleasant side-effects due to the nature of the surgery that takes time for the patient to recover fully. We have suggested that a combination of three MIS/MIT tools and techniques should be considered in this surgical procedure. In doing so, we believe that it is indeed possible to address the orthogonal goals within health care delivery of cost-effective quality delivery of care. While we have no empirical data at this point to substantiate our claims based on other areas where MIS/MIT tools and techniques have enabled superior results, we are confident that the incorporation of these techniques into the surgical treatment of Hirschsprung's disease will also enjoy similar success.

In closing, we note that the implications of this chapter are somewhat deeper and more generalizable. As globally health care delivery struggles to satisfy the orthogonal goals of cost-effective and quality health care delivery, we can see that in surgery (as well as other treatment/clinical initiatives) and administratively, the incorporation of technology is critical. It becomes imperative on researchers and health care professionals then to continuously look for ways to incorporate technology so that superior health care delivery can ensue.

KEY TERMS

Endoluminal Capsule Monitoring: A noninvasive medical diagnostic procedure that uses a miniaturized wireless radio transmitter embedded into an ingestible water-tight capsule to monitor the gastrointestinal system.

Endoscopy: Looking inside the human body for medical reasons.

Hirschsprung's Disease: Also known as congenital megacolon, occurs when some of the nerve cells in the intestines do not form properly.

Minimally Invasive Surgery (MIS): Surgery performed by entering the body through a small orifice.

Minimally Invasive Techniques (MIT): Techniques required to ensure that MIS can occur.

A Mobile Computing Framework for Passive RFID Detection System in Health Care

Masoud Mohammadian
University of Canberra, Australia

Ric Jentzsch
Compucat Research Pty Limited, Australia

INTRODUCTION

The cost of health care continues to be a world wide issue. Research continues into ways and how the utilization of evolving technologies can be applied to reduce costs and improve patient care, while maintaining patient's lives. To achieve these needs requires accurate, near real time data acquisition and analysis. At the same time there exists a need to acquire a profile on a patient and update that profile as fast and as possible. All types of confidentiality need to be addressed no matter which technology and application is used. One possible way to achieve this is to use a passive detection system that employs wireless radio frequency identification (RFID) technology. This detection system can integrate wireless networks for fast data acquisition and transmission, while maintaining the privacy issue. Once this data is obtained, then up to date profiling can be integrated into the patient care system. This article discussed the use and need for a passive RFID system for patient data acquisition in health care facilities such as a hospital. The development of profile data is assisted by a profiling intelligent software agent that is responsible for processing the raw data obtained through RFID and database and invoking the creation and update of the patient profile.

BACKGROUND

Health is on everyone's agenda whether they are old or young. Millions of hours of lost time is recorded each week by employers' whose staff are in need of health care. It is and has been known that more research into applications and innovative architectures is needed. To this end the use of Radio Frequency Identification (RFID), a relatively new technology and is showing itself to be a viable and promising technology as an aid to health care (Finkenzeller, 1999; Glover & Bhatt, 2006; Hedgepeth, 2007; Lahiri, 2005; Schuster, Allen, & Brock, 2007; Shepard, 2005). This technology has the capability to penetrate and add value to nearly every area of health care. It can be used to lower the cost of some services as well as improving service to individuals and the health care provider. Although many organizations are developing and testing the possible use of RFIDs, the real value of RFID is achieved in conjunction with the use of intelligent software agents. Thus the issue becomes the integration of these two great technologies for the benefit of assisting health care services.

To begin with, let us look at data collection. In health care, we can collect data on the patients, doctors, nurses, institution itself, drugs and prescriptions, diagnosis, and many other areas. It would not be feasible to do all of these nor would all of these be able to effectively use RFID. Thus for our perspective we will concentrate on a subset with the understanding that all areas could, directly or indirectly, benefit from the use of RFID and intelligent software agents in a health care and hospital environment.

In this research, we begin to look at the architecture of integrating intelligent software agents technology with RFID technology, in particular in managing patients' health care data in a hospital environment.

An intelligent software agent can continuously profile a patient based on their medical history, current illness, and on going diagnostics. The RFID provides the passive vehicle to obtain the data via its monitoring capabilities. The intelligent software agent provides the active vehicle in the interpretation profiling of the data and reporting capacity. There are certain data that is stored about each patient in a hospital. The investigation of this data provides an analysis that describes the patient's condition, is able to monitor their status, and cross reflect on why the patient was admitted to the hospital. Using this information an evolving profile of each patient can be constructed and analysed.

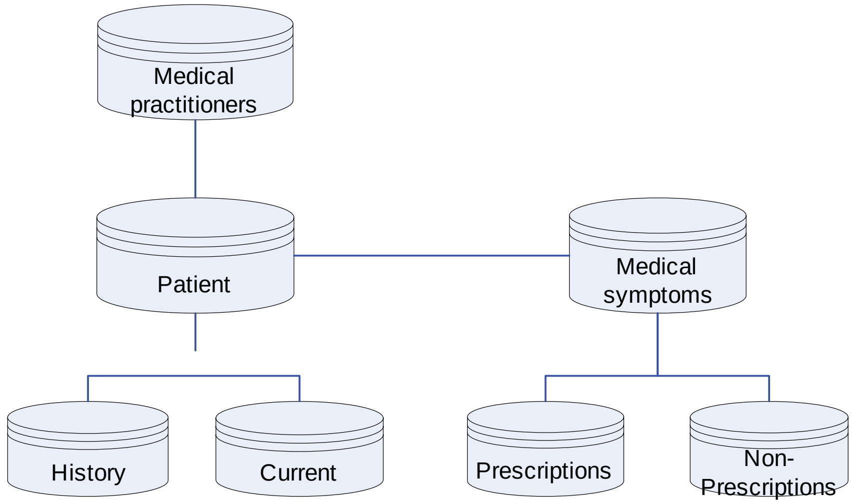
Using the data and analysis this will allow us to assist in deciding what kind of care he/she requires, the effects of ongoing care, and how to best care for this patient using available resources (doctors, nurses, beds, etc.) for the patient. The software agent is used to build a profile of each patient as they are admitted to the health care institution. Although not shown in the illustration, an additional profile for each doctor can be developed that practices in the hospital can be developed. If this is done, then the patient and doctor profile can be correlated to obtained the availability of the best doctor to suit the patient. However, this will require an additional data repository, as shown in Figure 1.

The patient profiling is useful in a variety of situations:

- The profile provides a personalized service based on the patient and not on symptoms or illness. to a particular patient. For example, by identifying the services that the patient requires this will allow us to target that which will be directed to speeding up their recovery progress;
- A good profile will assist the medical facilities in trying to prevent the need for the patient to return to the hospital any sooner than necessary;
- Disambiguating patient's diagnostic based on patient profile may help in assisting in matching a doctor's specialization to the right patient;
- When a patient needs to re-enter a hospital, a past profile can make it easier to match the patient's needs to a relevant available doctor;
- Presenting information about the patient on an on-going, continuous basis for the doctors means that current up to date information is available rather than information that needs to be searched for and compiled before it is useful; and
- Providing tailored and appropriate care to reduce health care costs.

Profiling is being done in many business operations today. Often profiling is combined with personalization, and user modeling for many e-commerce applications such as those by IBM, ATG Dynamo,

Figure 1. Data repositories for patient and doctors



BroadVision, Amazon, and Garden (18). However, there is very little in the way of the use of such systems in hospital and very little in health care in this perspective has been reported. It must be remember that there are different definitions of personalization, user modeling, and profiling. In e-commerce the practice of tracking information about consumers' interests by monitoring their movements online is considered profiling or user modeling. This can be done without using any personal information, but simply by analyzing the content, URL's, and other information about a user's browsing path/click-stream. Many user models try to predict the user's preference in a narrow and specific domain. This works well as long as that domain remains relatively static and, as such, the results of such work may be limited.

In this research, profiling is a technique whereby a set of characteristics of a particular class of person, patient, is inferred from their past and data-holdings are then searched for individuals with a close fit to symptom characteristics. One of the main aims of profiling and user modeling is to provide information recipients with correct and timely response for their needs. This entails an evolving profile to ensure that as the dynamics of that which is being monitored change, the profile and model reflects these updates as appropriate.

There are several ways in which a patient's visit to a hospital can be recorded. A patient's visit may simply be classified as a regular visit. This may be for a check up, for tests, or at the request of a doctor. A patient might be at the hospital because of an emergency or an ad hoc appointment due to lack of other facilities being available. Of course there are a whole set of patients that visit the hospital for reasons that are less well defined. In each situation, the needs of the patients are different.

The patient's profile can assist the attending doctor in being aware of the particular patient's situation. This provides the attending doctor with information that is needed without waiting for the patient's regular doctor. The regular doctor may be unavailable and therefore the profile of the patient can be matched with the available doctor suitable to the needs of the patient. The patient to doctor assignment is a type of scheduling issue and is not going to be discussed in this article.

However, in an emergency visit, there is no assigned doctor for such a patient. The doctor in emergency section of the hospital will provide information about a patient after examination and a patient profile then can be created. In this case, the intelligent agent can assist the patient by matching the profile of the patient with the doctors suitable to the needs of the patient. Also the doctors can be contacted in a speedier manner as they are identified and their availability is known.

An appointment visit is very similar to a regular visit but it may happen only once and therefore the advantages mentioned for regular patients applies here.

We will endeavor to describe several of these, but will expand on one particular potential use of RFIDs in managing patient health data. First let us provide some background on RFIDs and present some definitions. We will discuss the environment that RFIDs operate in and their relationship to other available wireless technologies such as the IEEE 802.11b, IEEE 802.11g, IEEE 802.11n, and so forth, in order to fulfill their requirements effectively and efficiently.

This research is divided into four main sections. Section two is based on the patient to doctor profiling and intelligent software agents. The third section is a RFID background; this will provide a good description of RFIDs and their components. This section discusses several practical cases of RFID technology in and around hospitals. It will also list three possible applicable cases assisting in managing patients' medical data. The final section discusses the important issue of maintaining patients' data security and integrity and relates that to RFIDs.

PATIENT TO DOCTOR PROFILING

A profile represents the extent to which something exhibits various characteristics. These characteristics are used to develop a linear model based on the consensus of multiple sets of data, generally over some period of time. A patient or doctor profile is a collection of information about a person based on the characteristics of that person. This information can be used in a decision analyze situation between the doctor, domain environment, and patient. The model can be used to provide meaningful information for useful and strategic actions. The profile can be static or dynamic. The static profile is kept in prefixed data fields where the period between data field updates is long such as months or years. The dynamic profile is constantly updated as per evaluation of the situation. The updates may be performed manually or automated. The automated user profile building is especially important in real time decision-making systems. Real time systems are dynamic. These systems often contain data that is critical to the user's decision making process. Manually updated profiles are at the need and discretion of the relevant decision maker.

The profiling of patient doctor model is base on the patient/doctor information. These are:

- The categories and subcategories of doctor specialization and categorization. These categories will assist in information processing and patient/doctor matching.
- Part of the patients profile based on symptoms (past history problems, dietary restrictions, etc.) can assist in prediction of the patient's needs specifically.
- The patients profile can be matched with the available doctor profiles to provide doctors with information about the arrival of patients as well as presentation of the patients profile to a suitable, available doctor.

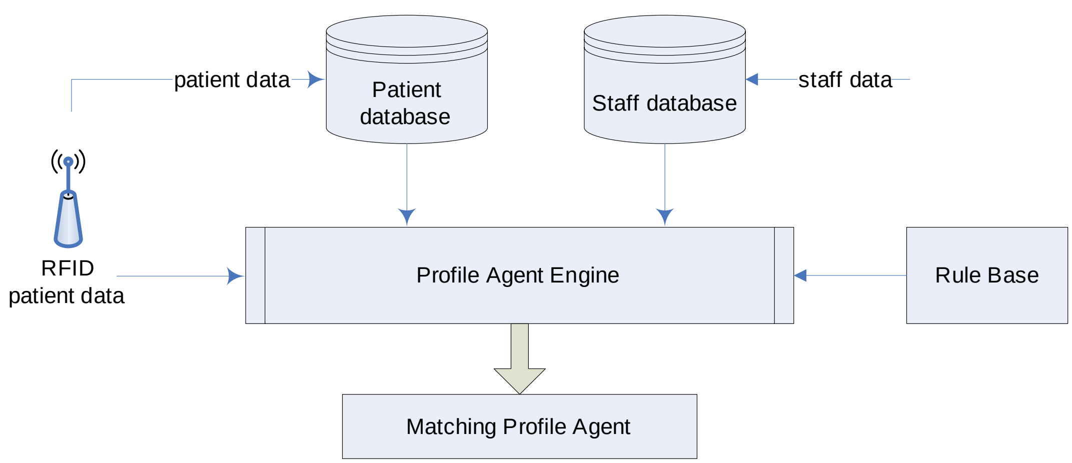
A value denoting the degree of association can be created form the above evaluation of the doctor to patient's profile. The intelligent agent based on the denoting degrees and appropriate, available doctors can be identified and allocated to the patient.

In the patient/doctor profiling, the agent will make distinctions in attribute values of the profiles and match the profiles with highest value. It should be noted that the agent creates the patient and doctor profiles based on data obtained from the doctors and patient namely:

- Explicit profiling occurs based on the data entered by hospital staff about a patient.
- Implicit profiling can fill that gap for the missing data by acquiring knowledge about the patient from its past visit or other relevant databases if any and then combining all these data to fill the missing data. Using legacy data for complementing and updating the user profile seems to be a better choice than implicit profiling. This approach capitalizes on user's personal history (previous data from previous visit to doctor or hospital).

The proposed agent architecture allows user profiling and matching in such a time intensive important application. The architecture of the agent profiling systems using RFID is given in Figure 2.

Figure 2. Agent profiling model using RFID



PROFILE MATCHING

Profile matching done is based on a vector of weighted attributes. To get this vector, a rule based systems can be used to match the patient's attributes (stored in patient's profile) against doctor's attributes (stored in doctor's profile). If there is a partial or full match between them, then the doctor will be informed (based on their availability from the hospital doctor database).

INTEGRATION OF INTELLIGENT SOFTWARE AGENTS AND RFID TECHNOLOGIES

Intelligent software agent technology has been used in order to provide the needed transformation of RIFD passive data collection into an active organizational knowledge assistant (Finkenzeller, 1999; Glover & Bhatt, 2006; Hedgepeth, 2007; Lahiri, 2005; Schuster et al., 2007; Shepard, 2005). Intelligent agent should be able to act on new data and already stored profile/knowledge and thereafter to examine its current actions based on certain assumptions, and inferentially plans its activities. Furthermore, intelligent software agents must be able to *interact* with other agents using symbolic language (Bigus & Bigus, 1998; Wooldridge & Jennings, 1995) and able to substitute for a range of human activities in a situated context. (In our case the activities are medical/patient assignment and the context is a hospital environment)

Context driven Intelligent software agents' activities are also dynamic and under continuous development in an historical time related environment (Bigus & Bigus, 1998; Wooldridge & Jennings, 1995).

Medical and hospital patient applied ontology's describing the applied domain are necessary for the semantic communication and data understanding between RFID inputs and knowledge bases inference engines so that profiling of both patients and doctors can be achieved (Gruber, 1993; Guarino, Carrara, & Giaretta, 1994).

The integration of RFID capabilities and intelligent agent techniques provides promising development in the areas of performance improvements in RFID data collection, inference, knowledge acquisition, and profiling operations.

By using mediated activity theories, an RIFD agent architecture could be modeled according to the following characteristics:

- The ability to use patient/doctor profile in natural language, ACL, or symbolic form as communicative tools mediating agents cooperative activities.
- The ability to use subjective and objective properties required by intelligent software agents to perform bidirectional multiple communication activities.
- The ability to internalize representations of medical/patient profile patterns from agents or humans.
- The ability to externalize internally stored representations of medical assignment patterns to other agents or humans.

The Agent Language Mediated Activity Model (ALMA) agent architecture currently under research is based on the mediated activity framework described and is able to provide RFID with the necessary framework to profile a range of internal and external medical/patient profiling communication activities performed by wireless multi-agents.

RFID DESCRIPTION

RFID or Radio Frequency Identification is a progressive technology that has been said to be easy to use and well suited for collaboration with intelligent software agents. Basically an RFID can:

- Be read-only;
- Volatile read/write; or
- Write once/read many times
- RFID are:
  - Noncontact and
  - Non line-of-sight operations.

Being noncontact and non line-of-sight will make RFIDs able to function under a variety of environmental conditions and while still providing a high level of data integrity (Finkenzeller, 1999; Glover & Bhatt, 2006; Hedgepeth, 2007; Lahiri, 2005; Schuster et al., 2007; Shepard, 2005).

MAIN COMPONENTS

A basic RFID system consists of four components:

1. The RFID tag (sometimes referred to as the transponder);
2. A coiled antenna;
3. A radio frequency transceiver; and
4. Some type of reader for the data collection.

Basically there are three components as often components are combined such as the transponder or transceiver or the antenna.

Transponders

The reader emits radio waves in ranges of anywhere from 2.54 centimeters to 33 meters. Depending upon the reader's power output and the radio frequency used and if a booster is added that distance can be somewhat increased. When RFID tags (transponders) pass through a specifically created electromagnetic zone, they detect the reader's activation signal. Transponders can be online or off-line and electronically programmed with unique information for a specific application or purpose. A reader decodes the data encoded on the tag's integrated circuit and passes the data to a server for data storage or further processing.

Coiled Antenna

The coiled antenna is used to emit radio signals to activate the tag and read or write data to it. Antennas are the conduits between the tag and the transceiver that controls the system's data acquisition and communication. RFID antennas are available in many shapes and sizes. They can be built into a doorframe, book binding, DVD case, mounted on a tollbooth, embedded into a manufactured item such as a shaver or software case (just about anything) so that the receiver tags the data from things passing through its zone (Finkenzeller, 1999; Glover & Bhatt, 2006; Hedgepeth, 2007; Lahiri, 2005; Schuster et al., 2007; Shepard, 2005).

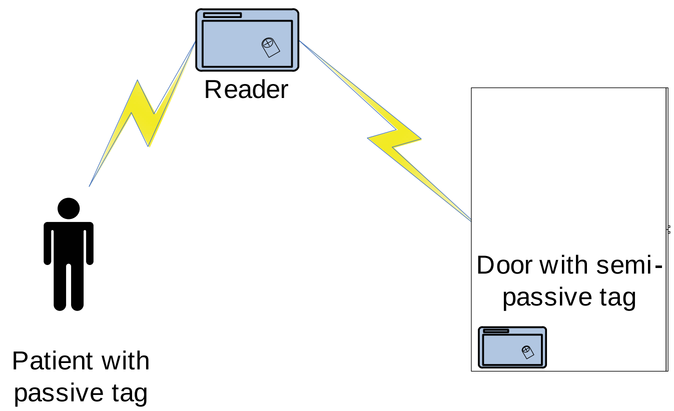
Transceiver

Often the antenna is packaged with the transceiver and decoder to become a reader. The decoder device can be configured either as a handheld or a fixed-mounted device. In large complex, often chaotic environments, portable or handheld transceivers would prove valuable.

TYPES OF RFID TRANSPONDERS

RFID tags can be categorized as active, semi-active, or passive. Each has and is being used in a variety of inventory management and data collection applications today. The condition of the application, place and use determines the required tag type.

Figure 3. Semi-passive tag



Active Tags

Active RFID tags are powered by an internal battery and are typically read / write. Tag data can be rewritten and/or modified as the need dictates. An active tag's memory size varies according to manufacturing specifications and application requirements; some tags operate with up to 5 megabyte of memory. For a typical read/write RFID work-in-process system, a tag might give a machine a set of instructions, and the machine would then report its performance to the tag. This encoded data would then become part of the tagged part's history. The battery-supplied power of an active tag generally gives it a longer read range. The trade off is greater size, greater cost, and a limited operational life that has been estimated to be a maximum of 10 years, depending upon operating temperatures and battery type (Finkenzeller, 1999; Glover & Bhatt, 2006).

Semi-Active Tags

The semi-active tag comes with a battery. The battery is used to power the tags circuitry and not to communicate with the reader. This makes the semi-active tag more independent than the passive tag, and it can operate in more adverse conditions. The semi-active tag also has a longer range and more capabilities than a passive tag (Shepard, 2005). Linear barcodes that reference a database to get product specifications and pricing are also data devices that act is a very similar way. Semi-passive tags are preprogrammed, but can allow for slight modifications of their instructions via the reader/interrogator. However, it is bigger, weighs more, and is more complete than a passive tag. A reader is still needed for data collection.

Passive Tags

Passive RFID tags operate without a separate external power source and obtain operating power generated from the reader. Passive tags, since they have no power source embedded, are consequently much lighter than active tags, less expensive, and offer a virtually unlimited operational lifetime. However, the trade off is that they have shorter read ranges, than active tags, and require a higher-powered reader.

Read-only tags are typically passive and are programmed with a unique set of data (usually 32 to 128 bits) that cannot be modified. Read-only tags most often operate as a data device that utilizes a database for all data storage (Finkenzeller, 1999; Shepard, 2005).

Range

RFID systems can be distinguished by their deployment and frequency range. RFID tags generally operate in two different types of frequencies that make them adaptable for nearly any application. These frequency ranges are:

Low Frequency Range (Short Range)

Low-frequency (30 KHz to 500 KHz) systems have short reading ranges and lower system costs. They are most commonly used in security access, asset tracking, and animal identification applications (Glover & Bhatt, 2006; Hedgepeth, 2007; Lahiri, 2005).

High Frequency Range (Long Range)

High-frequency (850 MHz to 950 MHz and Industry, Science and Medical - 2.4 GHz to 2.5 GHz) systems, offer longer reading ranges (greater than 33 meters) and high reading speeds. These systems are generally used for such applications as railroad car tracking, container dock and transport management, and automated toll collection. However, the higher performance of high-frequency RFID systems incurs higher system operating costs (Glover & Bhatt, 2006; Schuster et al., 2007).

Hospital Environment

In hospitals, systems need to use rules and domain knowledge that is appropriate to the situation. One of the more promising capabilities of intelligent software agents is their ability to coordinate information between the various resources.

In a hospital environment, in order to manage patient medical data we need both types; fixed and handheld transceivers. Also, transceivers can be assembled in ceilings, walls, or doorframes to collect and disseminate data. Hospitals have become large complex environments.

In a hospital, nurses and physicians can retrieve the patient's medical data stored in transponders (RFID tags) before they stand beside a patient's bed or as they are entering a ward.

Given the descriptions of the two types and their potential use in hospital patient data management we suggest that:

- It would be most useful to embed a passive RFID transponder into a patient's hospital wrist band;
- It would be most useful to embed a passive RFID transponder into a patient's medical file (there are several versions and perspectives that we can take no this).

Doctors should have PDAs equipped with RFID or some type of personal area network device. Either would enable them to retrieve some patient's information whenever they are near the patient, instead of waiting until the medical data is pushed to them through the hospital server (there are several versions and perspectives that we can take no this):

- *Active RFID tags* are more appropriate for the continuous collection of the patient's medical data. Since the patient's medical data needs to be continuously recorded to an active RFID tag and an associated reader needs to be employed. Using an active RFID means that the tag will be a bit bulky because of the needed battery for the write process and there is a concern with radio frequency admissions. Thus, it is felt that an active tag would not be a good candidate for the patient wrist band. However, if the patient's condition is to be continuously monitored, the collection of the data at the source is essential. The inclusion of the tag in the wrist band is the only way to recorder the medical data on a real-time base using the RFID technology. As more organizations get into the business of manufacturing RFIDs and the life and size of batteries decrease, the tag size will decrease and this may be a real possible use.
- *Passive RFID tags* can be also used as well. These passive tags can be embedded in the doctors PDA, which is needed for determining their locations whenever the medical staff requires them. Also, passive tags can be used in patients' wrist bands for storage of limited amount of data- on off-line bases, for example, date of hospital admission, medical record number, and so forth.

After examining both ranges, we can suggest the following:

- *Low frequency range tags* are suitable for the patients' band wrist RFID tags. Since we expect that the patients' bed will not be too far from a RFID reader. The reader might be fixed over the patient's bed, in the bed itself, or over the door-frame. The doctor using his/her PDA would be aiming to read the patient's data directly and within a relatively short distance.
- *High frequency range tags* are suitable for the physician's tag implanted in their PDAs. As physicians use to move from one location to another in the hospital, data on their patients could be continuously being updated.

One final point in regards to the range of RFIDs: until 2002, the permissible radio frequency range was not regulated, that is, it still operated in some low frequency ranges (30- 500 KHz) and in the free 2.45 GHz ISM band of frequency. The IEEE's 802.11b and IEEE's 802.11g (WiFi) wireless networks also operate in the same range (actually there are many other wireless application that operate in that range). This band of frequency is crowded. Where equipment in a hospital is often in the ISM band of frequency, there may be some speed of transmission degradation. The IEEE 802.11n builds upon previous 802.11 standards by adding MIMO (multiple-input multiple-output). MIMO uses multiple transmitter and receiver antennas to allow for increased data throughput via spatial multiplexing and increased range by exploiting the spatial diversity. Note that 802.11n draft 2.0 has been released but the certification of products is still in progress. What this means is that even though 802.11n has greater benefits then previous standards, it is still a draft. The full version is not expected until 2008; thus; products may take several years to be compliant and incorporate that into RFIDs (Hedgepeth, 2007).

Shapes of RFID Tags

RFID tags come in a wide variety of shapes and sizes. Animal tracking tags that are inserted beneath the animal's skin can be as small as a pencil lead in diameter and about one centimeter in length. Tags can be screw-shaped to identify trees or wooden items, or credit card shaped for use in access applications. The antitheft hard plastic tags attached to merchandise in stores are RFID tags (Glover & Bhatt, 2006). Manufacturers can create the shape that is best for the application, including flexible shaped tags that act like and resemble human skin. RFID tags can be flexible and do not have to be rigid.

Transceivers

The transceivers/interrogators can differ quite considerably in complexity, depending upon the type of tags being supported and the application. T\he overall function of the application is to provide the means of communicating with the tags and facilitating data transfer. Functions performed by the reader may include quite sophisticated signal conditioning, parity error checking, and correction. Once the signal from a transponder has been correctly received and decoded, algorithms may be applied to decide whether the signal is a repeat transmission, and may then instruct the transponder to cease transmitting or temporarily cease asking for data from the transponder. This is known as the "Command Response Protocol" and is used to circumvent the problem of reading multiple tags over a short time frame. Using interrogators in this way is sometimes referred to as "Hands Down Polling." An alternative, more secure, but slower tag polling technique is called "Hands Up Polling." This involves the transceiver looking for tags with specific identities, and interrogating them in turn. A further approach may use multiple transceivers, multiplexed into one interrogator, but with attendant increases in costs (Glover & Bhatt, 2006; Hedgepeth, 2007; Lahiri, 2005; Schuster et al., 2007).

Hospital patient data management deals with sensitive and critical information (patient's medical data). *Hands Down polling* techniques in conjunction with multiple transceivers that are multiplexed with each other, form a wireless network. The reason behind this choice is that, we need high speed for transferring medical data from medical equipment to or from the RFID wrist band tag to the nearest RFID reader, and then through a wireless network or a network of RFID transceivers or LANs to the hospital server. From there it is a short distance to be transmitted to the doctor's PDA, a laptop, or desktop through a WLAN IEEE 802.11b, 802.11g, or 802.11n, or wired LAN which operates at the 5.2 GHz band with a maximum data transfer rate exceeding 104 Mbps.

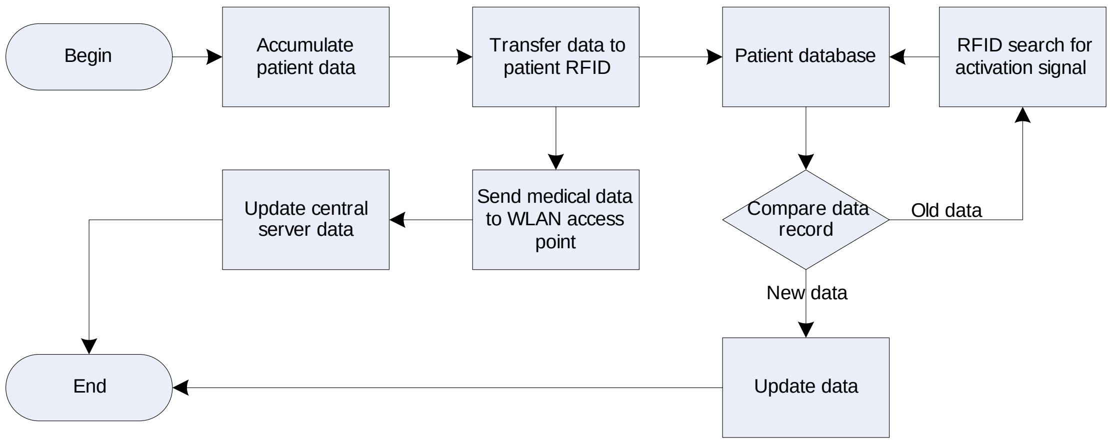
The "Hand Down Polling" techniques, as previously described, provides the ability to detect all detectable RFID tags at once (i.e., in parallel). Preventing any unwanted delay in transmitting medical data corresponding to each RF tagged patient.

RFID TRANSPONDER PROGRAMMERS

Transponder programmers are the means, by which data is delivered to write once, read many (WORM) and read/write tags. Programming can be carried out off-line or online. For some systems re-programming may be carried out online, particularly if it is being used as an interactive portable data file within a production environment, for example. Data may need to be recorded during each process. Removing the transponder at the end of each process to read the previous process data, and to program the new data, would naturally increase process time and would detract substantially from the intended flexibility of the application. By combining the functions of a transceiver and a programmer, data may be appended or altered in the transponder as required, without compromising the production line.

We conclude from this section that RFID systems differ in type, shape, and range; depending on the type of application, the RFID components shall be chosen. Low frequency range tags are suitable for the patients' band wrist RFID tags. Since we expect that a patients' bed is not too far from the RFID reader, which might be fixed on the room ceiling or door-frame. High frequency range tags are suitable for the physician's PDA tag. As physicians use to move from on location to another in the hospital, long read ranges are required. On the other hand, transceivers which deal with sensitive and critical information (patient's medical data) need the Hands Down polling techniques.

Figure 4. Acquisition of patient data



These multiple transceivers should be multiplexed with each other forming a wireless network.

PRACTICAL CASES USING RFID TECHNOLOGY

This section explains in details three possible applications of the RFID technology in three applicable cases. Each case is discussed step-by-step then represented by a flowchart. Those cases cover issues as acquisition of Patient's Medical Data, locating the nearest available doctor to the patients location, and how doctors stimulate the patient's active RFID tag using their PDAs in order to acquire the medical data stored in it.

Case I: Acquisition of Patient's Medical Data

Case one will represent the method of acquisition and transmission of medical data. This process can be described in the following points as follows:

1. A biomedical device equipped with an embedded RFID transceiver and programmer will detect and measure the biological state of a patient. This medical data can be an ECG, EEG, BP, sugar level, temperature or any other biomedical reading.

   After the acquisition of the required medical data, the biomedical device will write-burn this data to the RFID transceiver's EEPROM using the built in RFID programmer. Then the RFID transceiver with its antenna will be used to transmit the stored medical data in the EEPROM to the EEPROM in the patient's transponder (tag) which is around his/her wrist. The data received will be updated periodically once new fresh readings are available by the biomedical device. Hence, the newly sent data by the RFID transceiver will be accumulated to the old data in the tag. The purpose of the data stored in the patient's tag is to make it easy for the doctor to obtain medical information regarding the patient directly via the doctor's PDA, tablet PC, or laptop.
2. Similarly, the biomedical device will also transfer the measured medical data wirelessly to the nearest WLAN access point. Since high data rate transfer rate is crucial in transferring medical data, IEEE 802.11b or g is recommended for the transmission purpose.
3. The wirelessly sent data will be routed to the hospitals main server; to be then sent (pushed) to:
   i. Other doctors available throughout the hospital so they can be notified of any newly received medical data.
   ii. To an online patient monitoring unit or a nurse's workstation within the hospital.

iii. Or the acquired patients' medical data can be fed into an expert (intelligent) software system running on the hospital server. To be then compared with other previously stored abnormal patterns of medical data, and to raise an alarm if any abnormality is discovered.

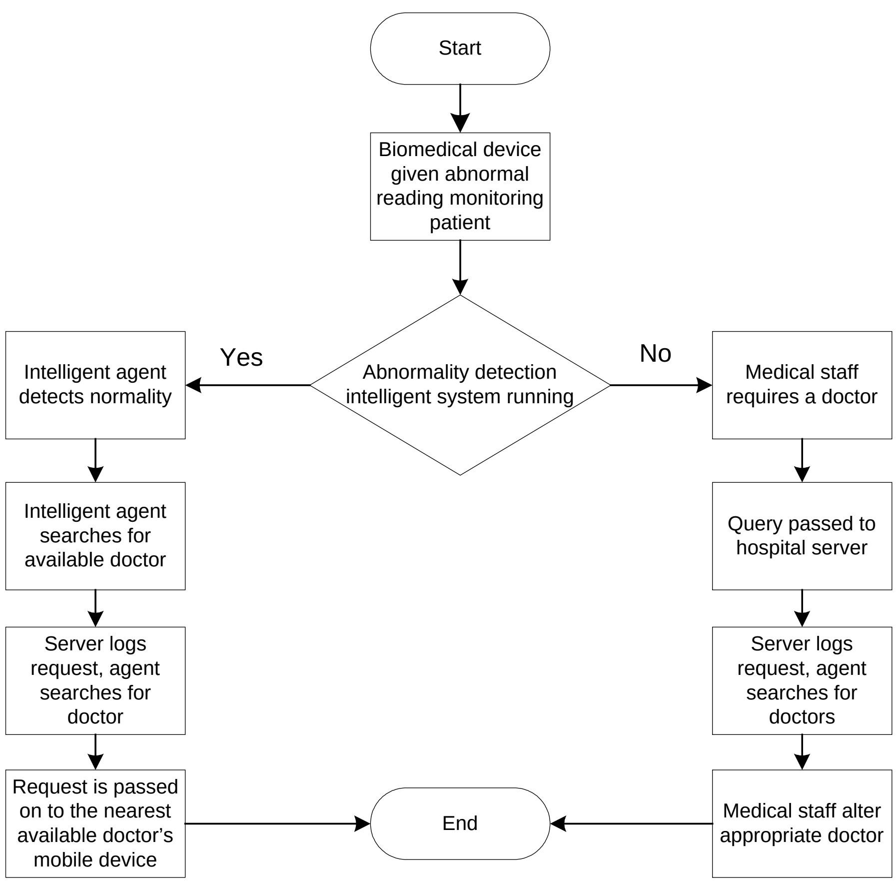
4. Another option could be using the in-built-embedded RFID transceiver in the biomedical device to send the acquired medical data wirelessly to the nearest RFID transceiver in the room. Then the data will travel simultaneously in a network of RFID transceivers until reaching the hospital server.

Case II: Locating the Nearest Available Doctor to the Patients Location

This case will explain how to locate the nearest doctor who is needed urgently to attend an emergency medical situation. This case can be explained as follows:

1. If a specific surgeon or physician is needed in a specific hospital department, the medical staff in the monitoring unit (e.g., nurses) can query the hospital server for the nearest available doctor to the patient's location. In our framework an intelligent agent can perform this task.
2. The hospital server traces all doctors' locations in the hospital through detecting the presences of their wireless mobile device; for example, PDA, tablet PC, or laptop in the WLAN range.
3. Another method that the hospital's server can use to locate the physicians is making use of the

Figure 5. Locating nearest doctor



RFID transceivers built-in the doctor's wireless mobile device. Similarly to the access points used in WLAN, RFID transceivers can assist in serving a similar role of locating doctor's location. This can be described in three steps, which are:

i. The fixed RFID transceivers throughout the hospital will send a stimulation signal to detect other free RFID transceivers—which are in the doctors PDAs, tablets , r laptops, and so forth.
ii. All free RFID transceivers will receive the stimulation signal and reply back with an acknowledgement signal to the nearest fixed RFID transceiver.
iii. Finally, each free RFID transceiver cell position would be determined by locating to which fixed RFID transceiver range it belongs to or currently operating in.

4. After the hospital server located positions of all available doctors, it determines the nearest requested physician (pediatrics, neurologist, and so forth) to the patient's location.
5. Once the required physician is located, an alert message will be sent to his\her PDA, tablet PC or laptop indicating the location to be reached immediately. This alert message could show:
   i. The building, floor, and room of the patient (e.g., 3C109).
   ii. Patient's case (e.g., heart stroke, arrhythmia, etc.)
   iii. A brief description of the patient's case.
6. If the hospital is running an intelligent agent as described in the proposed framework on its server, the process of locating and sending an alert message can be automated. This is done through comparing the collected medical data with previously stored abnormal patterns of medical data, then sending an automated message describing the situation. This system could be used instead of the staff in the patient monitoring unit or the nurse's workstation where nurses observe and then send an alert message manually.

Case III: Doctors Stimulate the Patient's Active RFID Tag Using their PDAs in Order to Acquire the Medical Data Stored in it

This method can be used in order to get rid of medical files and records placed in front of the patient's bed. Additionally, it could help in preventing medical errors- reading the wrong file for the wrong patient and could be considered as an important step towards a paperless hospital.

This case can be described in the following steps:

1. The doctor enters into the patient's room or ward. The doctor wants to check the medical status of a certain patient. So instead of picking up the "hard" paper medical file, the doctor interrogates the patient's RFID wrist tag with his RFID transceiver equipped in his\her PDA, tablet PC, or laptop, and so forth.
2. The patient's RFID wrist tag detects the signal of the doctor's RFID transceiver coming from his\her wireless mobile device and replies back with the patient's information and medical data.
3. If there was more than one patient in the ward possessing RFID wrist tags, all tags can respond in parallel using Hands Down polling techniques back to the doctor's wireless mobile device.
4. Another option could be that the doctor retrieving only the patient's number from the *passive* RFID wrist tag. Then through the WLAN the doctor could access the patient's medical record from the hospital's main server.

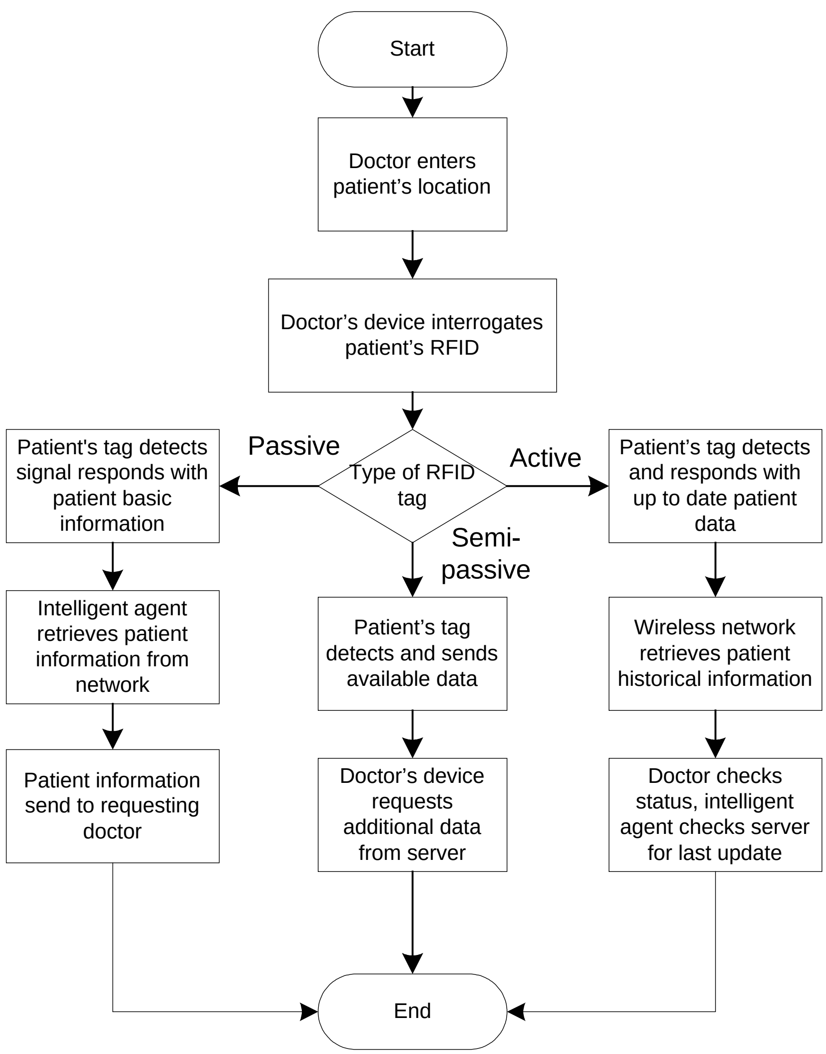
RFID technology has many potential important applications in hospitals, and the discussed three cases are a real practical example. Two important issues can be concluded from this section: WLAN is preferred for data transfer; given that IEEE's wireless networks have much faster speed and coverage area as compared to RFID transceivers\transponders technology. Yet, RFID technology is the best for data storage and locating positions of medical staff and patients as well.

The other point is that we need a RFID transceiver & programmer embedded in a biomedical device for data acquisition and dissemination, and only a RFID transceiver embedded in the doctor's wireless mobile device for obtaining the medical data. With the progress the RFID technology is currently gaining, it could become a standard as other wireless technologies (Bluetooth, for example), and eventually manufacturers building them in electronic devices; biomedical devices for our case.

MAINTAINING PATIENTS' DATA SECURITY AND INTEGRITY

Once data is transmitted wirelessly, security becomes a crucial issue. Unlike wired transmission, wirelessly transmitted data can be easily sniffed out leaving the transmitted data vulnerable to many types of attacks. For example, wireless data could be easily eavesdropped on using any mobile device equipped with a wireless card. In worst cases wirelessly transmitted data could be intercepted and then possibly tampered with, or in best cases, the patient's security and privacy would be compromised. Hence emerges the need for data to be initially encrypted from the source.

Figure 6. Functional flow



In this section, a discussion on how to apply encryption for the designed wireless framework for hospital is considered. Suggesting exactly where data needs to be encrypted and\or decrypted depending on the case that is being examined does this.

First a definition of the type of encryption that would be used in the design of the security (encryption\decryption) framework is discussed, followed by a flowchart demonstrating the framework in a step-by-step process.

Layers of Encryption

Two main layers of encryption are recommended. They are:

Physical (Hardware) Layer Encryption

This means encrypting all collected medical data at the source or hardware level before transmitting it. Thus, we insure that the patient's medical data would not be compromised once exposed to the outer world on its way to its destination. So even if a person with a malicious intent and also possessing a wireless mobile device steps into the coverage range of the hospitals' WLAN, this intruder will gain actually nothing since all medical data is encrypted, making all intercepted data worthless.

Application (Software) Layer Encryption

This means encrypting all collected medical data at the destination or application level once receiving it. Application level encryption runs on the doctor's wireless mobile device (e.g., PDA, tablet PC, or laptop) and on the hospital server. Once the medical data is received, it will be protected by a secret pass-phrase (encryption\decryption key) created by the doctor who possesses this device. This type of encryption would prevent any person from accessing patient's medical data if the doctor's wireless mobile device gets lost, or even if a hacker hacks into the hospital server via the Internet, intranet or some other mean.

Framework of Encrypting Patient's Medical Data

The previous section (Practical Cases using RFID Technology) focused on how to design a wireless framework to reflect how patients' medical data can be managed efficiently and effectively leading to the elimination of errors, delays, and even paperwork. Similarly, this section will focus on the previously discussed framework from a security perspective, attempting to increase security and data integrity.

i. Acquisition of Patients' Medical Data
ii. Doctors stimulating the patient's active RFID tag using their wireless mobile devices in order to acquire the medical data stored in it.

While the third case which was about locating the nearest available doctor to the patients location, is more concerned about locating doctors than transferring patient's data, so it is not discussed here.

The lower part of Figure 6 represents the physical (hardware) encryption layer. This part is divided into two sides. The left side demonstrates the case of a doctor acquiring patient's medical data via a passive RFID tag located in a band around the patient's wrist. The passive RFID tag contains only a very limited amount of information such as the patients name, date of admission to the hospital and above all his/her medical record number (MRN), which will grant access to the medical record containing the acquired medical data and other information regarding the patient's medical condition. This process is implemented in six steps, and involves two pairs of encryption and decryption. The first encryption occurs after the doctor stimulates the RFID passive tag to acquire the patient's MRN, so the tag will encrypt and reply back the MRN to the doctors PDA for example. Then the doctor will decrypt the MRN and use it to access the patient's medical record from the hospital's server. Finally the hospital server will encrypt and reply back the medical record, which will be decrypted once received by the doctors' PDA.

The right side of Figure 6 represents a similar case but this time using an active RF tag. This process involves only one encryption and decryption. The encryption happens after the doctor stimulates the active RFID tag using his PDA which has an in-equipped RFID transceiver, so the tag replies with the medical data encrypted. Then the received data is decrypted through the doctors' PDA.

The upper part of Figure 6 represents the application encryption layer, requiring the doctor to enter a pass-phrase to decrypt and then access the stored medical data. Whenever the doctor wants to access patient's medical data, the doctor simply enters a certain pass-phrase to grant access to either wireless mobile device or a hospital server depend where the medical data actually resides.

CHOOSING LEVEL OF SECURITY FOR THE WIRELESSLY-TRANSMITTED MEDICAL DATA

Securing medial data seems to be uncomplicated, yet the main danger of compromising such data comes from the people managing it, for example, doctors, nurses, and other medical staff. For that, we have seen that even though the transmitted medical data is initially encrypted from the source, doctors have to run application level encryption on their wireless mobile devices in order to protect this important data if the devices gets lost, left behind, robbed, and so forth. Nevertheless, there is a compromise. Increasing security through using multiple layers, and increasing length of encryption keys decreases the encryption\decryption speed and causes unwanted time delays, whether we were using application or hardware level of encryption. As a result, this could delay medical data sent to doctors or online monitoring units.

Figure 6 represents the case of high and low level of security in a flowchart applied to the previously discussed two cases in the last report.

At the end of this section, we conclude that there are two possible levels of encryption, software level (application layer) or hardware level (physical layer), depending on the level of security required. Both physical (hardware) layer and application layer encryption are needed in maintaining collected medical data on hospital servers and doctors wireless mobile devices.

Encrypting medical data makes the process of data transmission slower while sending data unencrypted is faster. We have to have a compromise between speed and security. For our case, medical data has to be sent as fast as possible to medical staff, yet the security issue has the priority.

CONCLUSION

Managing patients' data wirelessly (paperless) can prevent errors, enforce standards, make staff more efficient, simplify record keeping, and improve patient care. In this research report, both passive and active RFID tags were used in acquiring and storage of medical data, and then linked to the hospitals' server via a wireless network Moreover, three practical applicable RFID cases discussed how the RFID technology can be put in use in hospitals, while at the same time maintaining the acquired patients' data security and integrity.

This research in the wireless medical environment introduces some new ideas in conjunction to what is already available in RFID technology and wireless networks. Linking both technologies to achieve the research main goal, delivering patients medical data as fast and secure as possible, to pave the way for future paperless hospitals.

Finally, as reported by Frost and Sullivan, the high cost of radio frequency identification (RFID) technology is a deterrent for health care providers, though RFID has great benefits to hospitals in tracking patients, monitoring patients, assisting in health care administration, and reducing medical costs. With the reduction in cost of radio frequency identification (RFID) technology, increased use of RFID technology in health care in monitoring patients and assisting in health care administration is expected.

A Model for the Discussion of Medical Tourism

Mary Ann Keogh Hoss
Eastern Washington University, USA

Harm-Jan Steenhuis
Eastern Washington University, USA

INTRODUCTION

In recent years, the phenomenon of medical tourism has attracted increased media attention. Similar to manufacturing outsourcing where activities (and jobs) leave the United States, for example, because they can be conducted cheaper elsewhere, medical tourism deals with medical activities that can be conducted cheaper elsewhere. The phenomenon of medical tourism is relatively new, and scientific studies on this topic are rare. The objective in this chapter is to explore the issue of medical tourism. This chapter takes the viewpoint of the United States: What are the potential consequences of medical tourism for the United States?

BACKGROUND

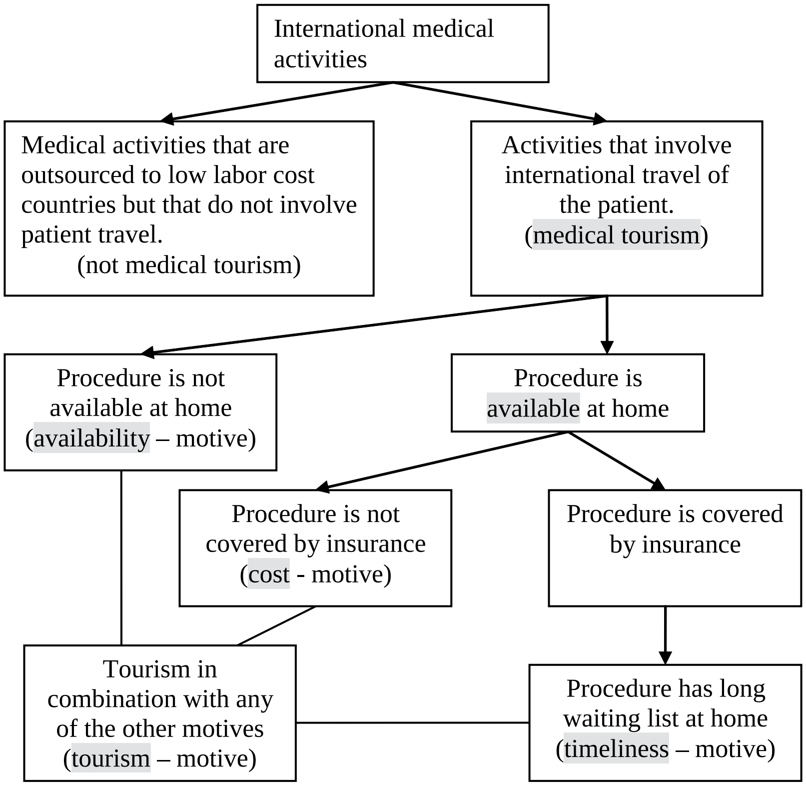
There are different types of medical tourism. In the past, medical tourism may have occurred primarily due to the lack of treatment or procedures at home; for instance, as a consequence of laws. Other types of motivation have occurred. One of these is the cost involved in the procedure. CBC News reported that many medical tourists from the United States are seeking treatment at a quarter or sometimes even a tenth of the cost at home (CBC News Online, 2004). Another motivation is waiting lines for treatments. For yet others, medical tourism may provide a chance to combine a tropical vacation with elective or plastic surgery. Figure 1 provides a theoretical framework for this analysis.

As Figure 1 illustrates, medical tourism is considered in *those situations where individuals travel abroad for medical treatment or procedures*. These individuals (the patients) may have several types of motives for traveling abroad. The direction for travel may depend on the motive. Offshore diagnostics is not included in the definition of medical tourism. Instances where medical analyses are outsourced to India because of lower costs but without the actual travel of the patients is not included as medical tourism. These instances may affect the U.S. health care industry. When medical tourists travel from the United States to a developing country like India, this doesn't mean that the care in India is of a lower quality. Doheny (2006) illustrates that if one chooses wisely, the care will be as good or even better than it is in the United States. Some overseas hospitals are accredited by the U.S.-based Joint Commission International (JCI), which is affiliated with the Joint Commission on Accreditation of Health care Organizations, which accredits U.S. hospitals (Doheny, 2006). Some countries such as Brazil, Cuba, Costa Rica, Hungary, India, Israel, Jordan, Lithuania, Malaysia, and Thailand are actively promoting medical tourism and are turning to this type of new industry in an attempt to generate hard currency (Bradley & Kim, 1994; Xinhua News Agency, 2005).

Availability Motive

The issue of availability has occurred with regard to abortions or artificial insemination (English, Mussell, Sheather & Sommerville, 2005). These topics were

Figure 1. Motives for medical tourism



related to the laws in specific countries that would not allow certain procedures to take place. Individuals could opt to go to other countries with different laws that would allow them to undergo a specific procedure. The travel may be primarily from less developed areas with either fewer treatments or procedures available due to lacking technology and/or local laws. It is unlikely at this time that this motive plays a major role for U.S. residents since most medical procedures are available in the United States.

Cost Motive

Another motive for medical tourism is the cost of the procedure or treatment. For example, some medical treatments may be cheaper in low labor cost countries. Doheny (2006) states that a U.S. surgeon's fee for a full face-lift averaged $4,822 in 2004. In the United States, this type of treatment does not include a hospital stay, and therefore, there are no hospital costs involved. At Bumrungrad Hospital in Bangkok, the surgeon's fee for a full face-lift is about $1,200, and this includes a neck lift and upper and lower eyelid lifts. With hospital and other fees, the total bill is about $4,000. This motive is also affected by what is covered by insurance or not (Landers, 2005; Moser, 2005). Since this customer motive will likely play a role for U.S. residents, it is discussed in a later section.

Timeliness Motive

A third motive is timeliness. The distinction between this motive and the availability motive is that the procedures are available in the home country, but there are long waiting lists. For example, MacIntosh (2004) mentions that across Canada, thousands are on waiting lists for surgeries that can last a year. This type of motive is likely to be found for residents of countries such as Canada, the United Kingdom, or Germany, but less likely to be found for U.S. residents since waiting lines are typically not that long in the United States (Hutchinson, 2005). The flow of these medical tourists is from countries with universal health care systems. The universal health care systems may cover much of the procedures but simultaneously create more demand for certain procedures or treatments that cause waiting lists. A country like the United States may become the destination for these tourists. In other instances, countries such as India may become the destination if the procedure can be provided there in a more timely manner (Gentleman, 2005).

Tourism Motive

The tourism motive combines any of the earlier motives with traveling to some exotic location for a vacation. For example, Rajagopal (2006) states that many of the tourists to Ayurveda in India combine their visit with a health care package. Most of these tourists end up in five-star spas and massage parlors, although there are also a few tourists who seek genuine treatment. Landers (2005) makes a similar observation when he states that for India, recovering patients often have time and money left for a visit to the Taj Mahal or another of India's sights. For this motive, there is also likely to be a move from a country such as the United States or Western European countries to other more exotic locations such as Costa Rica, India, or Thailand.

MEDICAL TOURISM AND THE UNITED STATES

Several motives for patients have been mentioned already. Why Americans may become medical tourists and the impact of this tourism on the U.S. health care system is reviewed.

Motives of Americans to Become a Medical Tourist

Americans may become medical tourists for different reasons. Availability of treatment, the cost of treatment, and timeliness of treatment are cited most often by patients (Hutchinson, 2005).

Availability. If treatment is not available in the United States, then alternative sites can be found easily with current availability of information such as the Internet. A variety of businesses in the travel and tourism industry have made it easy for a U.S. patient to shop and compare locations and prices.

Cost. For treatments that are available in the United States, some may be covered by insurance and some may not. With estimates of 43 million uninsured in the

Table 1. International cost comparisons in U.S.$. Based on (a) Nundy (2005), (b) Balaba (2005), (c) Firefly Medical Corporation, (d) Hutchinson (2005), (e) Reader's Digest (2006)

Procedure	India	Singapore	Thailand	United States
Coronary Angiogram	N.A.	2450 (e)	2886 (b)	25,6000 (e)
Coronary Bypass	10,000 (a)	N.A.	N.A.	86,000 (e)
Knee Replacement	16500 (c)	6207 (b)	7500 (b)	36300 (e)
Hip Replacement	16500 (c)	7200 (e)	N.A.	40800 (e)
LASIK Eye Surgery	730 (d)	730 (d)	750 (e)	4000 (e)

United States, coverage and insurance have no meaning for this group (Hutchinson, 2005). This means that cost becomes a major concern. Even for those who have insurance, the burden of coverage is shifting from the employer to the employee with higher deductibles and co-payments. As more plans become selective in what will be covered to keep premium prices down, even having insurance may cause a patient to look outside the United States because of cost.

In an interview with MedRetreat, currently the only U.S.-based business medical tourism company, MedRetreat indicated that the highest demand area for U.S. medical tourists is cosmetic/plastic surgery. Next is the demand for dental surgery, followed by orthopedic procedures. Cosmetic and dental procedures may not typically be covered by health insurance. MedRetreat has been in business for three years and has hospital partners in Argentina, Brazil, Costa Rica, India, Malaysia, South Africa, Thailand, and Turkey. All hospital partners are accredited through Joint Commission International or are in the process of accreditation. Hospitals are state of the art, and some are test sites for the newest technology being developed by companies such as General Electric, Philips, and Siemens.

MedRetreat stated that generally for most procedures, India will be the least expensive, and that in general the surgery procedures are 50% to 80% less expensive in their partner hospitals than in the United States.

Cost comparisons for types of medical procedures are provided in Table 1.

Timeliness. For many Americans, living with pain related to ambulation and mobility drives them to look for alternatives to free them from pain. Orthopedic surgeries most often are covered by insurance, but the criteria one has to meet before authorization is provided for this surgery can severely limit someone's life style. Also, medications used to alleviate pain can have long-term undesirable side-effects.

Tourism. Add to any of the aforementioned motives the opportunity for a luxury vacation paradise for recuperation with personal attendant care and the motivation to become a medical tourist increases. For example, a knee or hip replacement with a vacation thrown in has appeal because of the location and personal care provided during the time in the country. U.S. consumers are concerned about the typically short hospital stays that follow these surgeries and the type and place of follow-up care. A luxury setting (sometimes five-star facilities) with personal care, and a longer in-hospital recovery period at a reasonable price is much more appealing. Furthermore, even though the patient receiving the treatment may not feel up to a sightseeing vacation, those that are accompanying the patient may take advantage of it. For those patients who are ambulatory, a new country and location are incentives to exercise and see the sights, possibly speeding up the recovery process.

Destinations

The leaders in the medical tourism industry are Thailand, Singapore, India, and Costa Rica. Argentina, Brazil, Cuba, Jamaica, South Africa, Turkey, Jordan, Malaysia, Israel, Hungary, Latvia, and Estonia are all trying to break into the market (Hutchinson, 2005). The four leaders—Thailand, Singapore, India, and Costa Rica—are discussed.

Thailand. In a year-end briefing on this coming year's bright economic spots, Oliver (2005) states that 16 hospitals in Thailand are recommended for international patients. Bumrungrad Hospital in Bangkok stands out with accreditation by JCI. In 2004, more than 1 million medical tourists with 80% using private hospitals received medical care ranging from dental work to heart bypass surgery (Oliver, 2005). Oliver (2005) states, "At Bangkok's Bumrungrad Hospital, a standard cardiac surgical procedure costs on average US $7500, but it would cost $60,000 in a US hospital. Another benefit is that waiting lists are non-existent and patients enjoy luxury similar to a five-star hotel and personal care that would easily add thousands in a US situation. At US$ 110 million, the Bumrungrad ranks as one of the most technically advanced private hospitals in Asia. It is part of the Global Care Solutions network, a Luxembourg- registered company" (p.2). The hospital reported a 24% increase in patient volume in 2004 and is expecting a 15% increase in 2005 (Gentleman, 2005). Laohachewin (2005), the executive director of the Thai Trade Centre, states that the number of international patients has grown 200% in the last few years. A National Public Radio interview (Block, 2005) describes the hospital as a 17-story $100 million facility with a Starbuck's, McDonald's, and a sushi restaurant with 350,000 non-Thai patients. The hospital boasts of having more than 200 U.S. board-certified physicians. In 2005, Bumrungrad treated nearly 58,000 U.S. patients (Doheny, 2006).

Singapore. Singapore entered the medical tourism industry about a decade ago with the government banking on its clinical image as a key selling point in attracting 1 million patients by 2012 according to Oliver (2005). Singapore has a Johns Hopkins branch at the Singapore International Medical Centre. Singapore has nine Joint Commission International accredited hospitals. The Singapore Tourism Board has identified medical tourism as a high priority. Competition is strong for Singapore with Thailand and Malaysia. Singapore has generally higher costs than neighboring countries (Yong, 2004). In order to be competitive, Singapore has slashed fees by 20% to 30% in some areas (Brennan & Benzie, 2004). Loo Choon Yong, M.D., executive chairman of the Raffles Medical Group, states that Raffles Hospital, one of Singapore's top health care providers, was offering "prices that are competitive and comparable to the Thai hospitals" (Yong, 2004, p.889). To be competitive, the hospital was discounting 10 standard operations. According to Hutchinson (2005), more than 250,000 patients per year visit Singapore.

India. India is viewed as a relative newcomer in the industry (Hutchinson, 2005). With strong government backing, India hopes to be the destination point for medical tourism. The Ministry of Tourism is working on a campaign to be launched oversees (Chowdhury, 2005). Additionally, the government has set up several expert committees to deal with medical insurance and human resource development. Currently, India has two hospitals that are Joint Commission International accredited. Medical tourism is "forecast to become a $2.3 billion business for India by 2012, and some analysts predict that it will be the next major driver of the Indian economy after information technology" (Gentleman, 2005, p. 1). Already, about 150,000 visitors seek treatment every year, and the figure is rising at 15% annually (Gentleman, 2005). By marketing India as a global medical tourism destination, the Indian government hopes to capitalize on the low-cost, high-quality medical care available in the country (Businessline, 2005).

India has some clear advantages over other countries. Their educational system is producing many medical professionals, and some hospitals already have international reputations. It has kept up with technological advances, and price is a major selling point. Some of their hospitals use telemedicine to communicate with locations internationally, and teleconferencing enables them to follow up with their patients around the world. "Unlike many of its competitors, India also has the technological sophistication and infrastructure to maintain its market niche. Also, Indian pharmaceuticals meet the stringent requirements of the U.S. Food and Drug administration. Additionally, India's quality of care is up to American standards, and some Indian medical centers even provide services that are uncommon elsewhere" (Hutchinson, 2005, p. 4).

Costa Rica. For the North American patient, the Asian destinations are considered very far away because of the flight distance. Costa Rica provides a South American location that is known for its inexpensive, high-quality medical care. This country is noted for its commitment to sanitation and high-quality medical care for its citizens, which makes it a great location for Westerners. Costa Rica has no JCI-accredited hospitals. A 1991 survey conducted by the University of Costa Rica found that 14.25% of all visitors to Costa Rica come to receive some sort of medical care (Underwood, 1996). Costa Rica is renowned for its plastic surgery services. While this country has a reputation for plastic surgery, it should be noted that a full range of medical procedures is available, including transplants. Physicians are mostly educated in Costa Rica and then branch out around the globe to enhance their education, with many speaking multiple languages (Underwood, 1996).

Two well-known private hospitals, Clinica Biblica and Clinica Catolica, offer first-class, ultra-modern services, lower than U.S. costs, and affiliations with U.S. hospitals (Underwood, 1996).

Selection of a Destination

In the previous sections, the emphasis has been on the availability and/or costs. When medical tourists choose an international location for their medial treatment, they should also be concerned with the quality of the treatment. Aside from personal care and a luxurious room, how do these foreign locations rate? Essentially, patient safety is the number-one concern. Factors that are related to patient safety are the education and credentials of the staff, starting with the physician. Another factor is accreditation. If a hospital has the hospital JCI accreditation, then it assures that the hospital meets the standards that most U.S. hospitals meet.

Another important issue relevant for the U.S. health care system is the amount of time for recovery for the procedure. What is, for example, the follow-up and by whom? This includes the type of professional, but also whether, for example, the follow-up has to be conducted in the United States since this may place an unfair burden on the U.S. hospital system.

Yet another issue is whether the overseas hospital has electronic copies of the patient files. From a patient safety and continuity of care perspective, electronic medical records provide a means of communication from other countries to the United States. Medications, follow up care, and communication from the primary physician to the specialist in another country can occur.

FUTURE TRENDS: IMPACT ON THE U.S. HEALTH CARE INDUSTRY

Loss of income. The international lure for less expensive procedures is driving cash customers for health care out of the United States for both uncovered as well as (partly) covered services. For example, the Bumrungrad Hospital states that it served 58,000 Americans in Thailand in 2005 (Doheny, 2006). Consequently, the income generated from these U.S. patients is lost for the U.S. hospitals and the U.S. economy. The cumulative amount of money spent by U.S. medical tourists elsewhere may be a significant loss for the U.S. economy. Currently, most of the U.S. medical tourists pay for the medical treatments themselves, because it is either not covered by their insurance or only partly covered, which still makes it cheaper to go overseas. One can only speculate what would happen if U.S. health insurance companies realize the cost savings they can achieve by sending insured patients to cheaper overseas hospitals.

Cost to U.S. hospitals. Why are the costs in U.S. hospitals so high? As a parallel, in manufacturing situations, low labor-cost countries are also often thought of as attractive, but although the labor cost may be low (in cost per hour), the total cost of manufacturing goods in other countries may turn out to be much higher than in the United States (Markides & Berg, 1988). This is the case because the productivity of labor is often lower, and more importantly, labor is usually only a small percentage of the total cost (on average 15%). Other costs involved include costs related to quality, materials, machinery, and so forth, which are often higher in low labor-cost countries. For hospitals, this is not the case (i.e., labor costs are the major costs for a hospital (Finkler, 2005). Therefore, the low labor-cost countries have a major advantage that is not likely to disappear in the near future.

U.S. hospitals are at best in a fragile state (American Hospital Association, 2005). Continued vacancies for nurses, pharmacists, and imaging and lab technicians are affecting patient access to services. Work force shortages are projected to get worse, not better. Rising costs of pharmaceuticals and other medical supplies put a further strain on hospital budgets. Payment shortfalls and the growing number of uninsured are pressuring the current hospital systems. The costs of the U.S. health care system are high. The trend of U.S. medical tourists may make it worse. If fewer patients are served, then the fixed costs of U.S. hospitals have to be spread among fewer patients, which increases the cost for those patients. This in turn makes medical tourism become even more attractive. Such a cycle could spiral out of control with the result that only emergency treatments or procedures, or treatments that have to take place locally will remain in the United States.

Competition. U.S. hospitals may now face international competition. This is essentially an alien concept for hospitals that traditionally have a geographically determined patient base. Now this situation is changing, which impacts the income generated in U.S. hospitals. To make matters worse, U.S. hospitals may not only be competing with international health care systems. Many of the nations' governments mentioned earlier have targeted medical tourists explicitly. For example, a company like MedRetreat is clear about pointing out that over the last 10 years, global advances have been made in countries that desire to build their economy. Health care has provided a means for these countries to look at attracting the relatively wealthy U.S. patient. The ease of access to information on the Internet has helped to inform the U.S. consumer. Responses for organizations like MedRetreat are immediate and very customer friendly. Aside from this government support, these countries also are explicitly targeting tourists. Their tourist offices are involved in attracting medical patients. This is a completely new way of competing. More research needs to be completed regarding U.S. insurance and self-insured businesses' view of medical tourism.

CONCLUSION

This chapter has explored the issue of medical tourism from a U.S. perspective. The motives for patients to become medical tourists and the potential destinations for these patients have been described. The consequences for the U.S. health care system have been examined. At the moment, it seems that the U.S. health care system is extremely uncompetitive and unprepared to deal with this new international challenge.

KEY TERMS

Asian Health Care: Those health care organizations and systems that provide health services in Asia and the Pacific Rim.

Health Care Competition: Rivalry between health care organizations and health care systems for patients.

Health Care Insurance: The contractual relationship that exists to provide health care services between the insurer and the insured.

Hospitals: Institutions providing medical or surgical care and treatment for the sick and injured.

Medical Tourism: A need for a medical procedure or treatment in combination with a motive of availability, timeliness, or cost with the desire to travel to another country where the individual chooses another country for care.

Medical Tourism Companies: Companies assisting patients to have a medical procedure or treatment in another country.

U.S. Health Care Industry: The U.S. health care system is comprised of for profit, not for profit, and governmental health care organizations and systems.

A Model to Evaluate the Flow of an Emergency Department

M.C.J. Schnellen
University of Twente, The Netherlands

INTRODUCTION

Little is published about generic models that describe the physic and information process of an emergency department. This chapter expounds the development of a general model that describes the current physic and information processes of an emergency department; it is based on observations of emergency departments in The Netherlands and the United States. This model can be of great value for the management of an emergency department, since it is useful to first analyze a current situation before improving organizational processes (Daft, 2000).

The main purpose of this chapter is formulated as "the creation of a model that can evaluate the physic and information flow of an emergency department by using literature and emergency department observations." This research investigates if it is possible to develop this kind of model, and if this is possible, then how this model can be used to compare the physic and information flows for different emergency departments.

This research is defined inside one of the projects of the department Organizations, Operations and Human resources of the University of Twente. This is a four-year project involving the emergency department of a large hospital in The Netherlands, led by ir. R. J. Rosmulder and guided by prof. dr. ir. J.J. Krabbendam. The project includes the improvement of organizational processes at this emergency department by using business theories in order to develop new ways of controlling the organizational processes of the emergency department.

BACKGROUND

In order to develop the model, observations were made in the emergency departments of larger hospitals in The Netherlands and the United States. The United States was chosen because many differences were expected between the Dutch and American emergency departments due to the more denationalized health care, the managed care, and the differences in medical education in the United States.

The foundation of the developed model is based on Miller and Rice (1967) who developed a theory of one generic framework where organization, human activities, and tasks are conciliated. Based on the findings of Miller and Rice (1967), the developed model encloses tasks, human activities, and organizational aspects. In addition, the operations model of Slack, et al. (1998) is used. Here, Slack, et al. (1998) describe the division in design of the process, planning, and control of the process and improvement of the process. Since only the current process of an emergency department is involved in the model, it demarcated the model boundaries. In addition, to gain knowledge about the input, throughput, and output of the process, and especially about the input and output of patients, the model of Asplin (2003) is used. To use a framework in this research, the theory mentioned in Processen in Organisaties is used, written by dr. ir. H. Boer and prof. dr. ir. J.J. Krabbendam (1996). They expose a step-by-step plan to analyze the different characteristics of a process inside an organization. To analyze the two observed emergency departments, their division is used.

DEVELOPING THE MODEL

Simplification of the Model

Similar to manufacturing organizations as referred to in Slack (1998), in an emergency department there is the input, throughput, and output. The input contents patients who enter the emergency department. These patients can be seriously ill or just need some care on that specific moment. Examples of different inputs are given by Asplin (2003).

The throughput is divided into triage, making a diagnosis, treatment inside the emergency department, and a referral to a place outside the emergency department. As heard from authorities and seen in hospitals and emergency department environments, this is an accepted approach of medical personnel to diagnose and treat patients. In this figure, it is assumed that every patient that arrives at the emergency department will successively pass through all these steps except triage. As mentioned in Ceglowski, Chirilov, and Wassertheil (2005), the emergency process is hard to describe, for example, because one nurse serves many patients. In this model, the patient is the central part; it is not mentioned what percentage of the nurse's time is spent on that particular patient. The patient flows through the process.

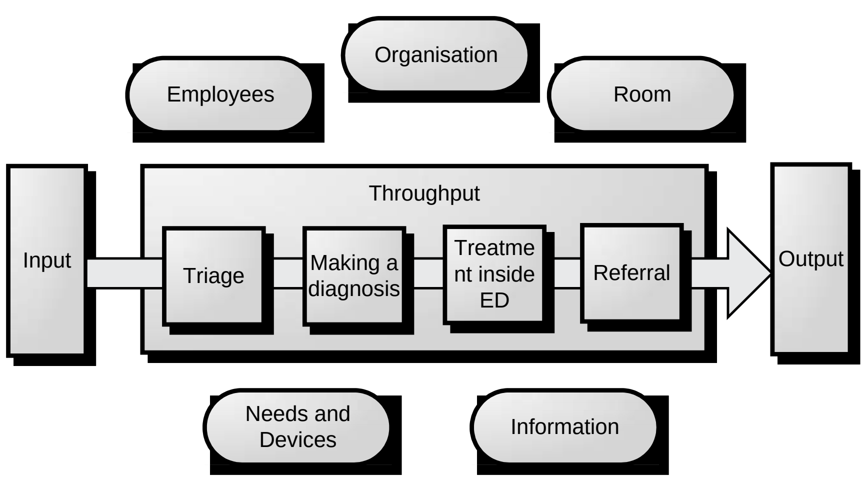
During the throughput process, the organizational arrangements like structure, culture, and procedures are of great influence (dr. ir. H. Boer and prof. dr. ir. J.J. Krabbendam, 1996). In addition, the amount and kind of employees, rooms, needs, devices, and information change. In the triage step of the throughput, for example, there is most of the time one nurse needed, a triage room or waiting area, some simple medical instruments, and information like the patient's medical history. For every step (triage, making a diagnosis, treatment inside the emergency department, and the referral) a combination of employees, rooms, needs, devices, and information is used during that part of the process. By describing every step, at the end the patient flow, its needs are described. In Figure 1, the simplification of the model is presented.

In order to present a simplified model, very specific flows could not be shown here. The output of this process could be cured patients, but far more is possible. Patients can be sent to their homes, admitted to the hospital for either surgery or nurse ward, or referred to another care institute. Asplin (2003) mentioned some in his model, and after experiences in emergency departments, there are some more mentioned in the next model.

The Extended Model

This model has the same basis as the simplification presented previously, but in a more extensive framework and, therefore, more complete. The

Figure 1. The simplification of the model



model is, as mentioned, a framework for the primary physic and information flow process. According to de Vries, Bertrand, and Vissers (1999), to analyze this process, the input must be divided into groups. The division for the input of patients is made by fast-track patients, urgent care patients, and trauma patients. Fast-track patients are patients who don't need urgent care and don't need devices like monitors in their treatment room. Examples of these patients are patients with a simple broken wrist or who need to be sutured for a small wound. Urgent patients in this rapport are defined by patients who need monitoring and specialized care, which will be determined by triage. Trauma patients in this rapport are patients who need immediate care, monitoring, and multiple specialists. This group doesn't see the triage at all, but goes directly to the step where the specialist begins making a diagnosis. The arrows of the first two inputs are already pointing at the second step of the primary process. Take, for example, the step Treatment inside the emergency department. A patient needs an emergency department doctor, a specialist, or a nurse, depending on the group into which the patient is divided. In addition, for this patient, an emergency department treatment room or sometimes the special plaster room can be used. Needs and devices in this step can be medicines or plaster casts or suturing needs. Information needed in this step is, for example, the diagnosis information from the previous step throughput, which is marked in pink. The organization influences the process of the patient through his or her structure and culture. The visualization of this model is displayed in Appendix 1.

FUTURE TRENDS

This model is an example of using management techniques in health care. Management techniques are already applied in health care, but many more applications are possible. The implementation of technologies widely used in other businesses, like operation models or product tracking systems, can be very useful in healthcare as well. Research in healthcare management will grow and become more important. Like other industries, in health care there is a large amount of money presented. Consequently, cost savings due to implementation of management techniques will become more attractive.

An important note is the need to change these business models to applicable models for healthcare, since health care is not comparable with other industries. Management techniques designed for business industries should be adjusted to the characteristics and needs of healthcare; otherwise, there will be a large risk of failure with implementation of these techniques.

CONCLUSION

The model is applied in two emergency departments and proved to be successful. It can be used as guidance for evaluating the physic and information flow in a structural way. The model turned out to provide the user with a lot of useful information about the organization of an emergency department. Using this model for a comparison between emergency departments is more difficult, since the patients flow in detail differ too much, and consequently, different data are gained for every emergency department. In addition, a comprehensive model is complete enough to use for this purpose. But unfortunately, the author did not succeed in developing a proper and complete simplification of this model. Although it would be easy to use a simplification of the model, the level of this simplification is too high to use, since some important steps cannot be visualized.

Hence, this model is a proper tool to evaluate the current physic and information flow of one emergency department, but it did not prove itself as a good way to compare emergency departments, especially due to the totally different ways of working, different inputs of patients, and different environments.

KEY TERMS

Emergency Department: A department within a hospital where immediate urgent care is delivered to patients needing noncritical, urgent, and trauma care.

Emergency Room: The space within an emergency room where immediate urgent care is delivered to patients needing urgent and trauma care.

Fast-Track Patients: Are patients who don't need urgent care and don't need devices like monitors in their treatment rooms.

Healthcare: The service that treats and promotes the well-being of a human being. It contains, but is not limited to, prevention, diagnostics, treatment, and therapeutic and palliative care.

Information Flow: The flow of the information needed during the input-throughput-output process.

Physic Flow: The flow of the patient and the employees, devices, and rooms needed during the input-throughput-output process.

Process Model: A well-known term in process engineering. It is a model that shows the process that can help, but is not limited to evaluating or (re-)designing a process.

Trauma Patients: Patients who need immediate care, monitoring, and multiple specialists. This group doesn't see the triage at all.

Urgent Patients: Patients who need monitoring and specialized care, which will be determined by triage.

INTRODUCTION

Description of the Wolff-Parkinson-White Syndrome

The Wolff-Parkinson-White (WPW) syndrome is characterized by an accessory pathway (by-pass tract) between the atria and ventricles that conducts parallel with the atrioventricular (AV) node-His bundle, but faster (Wolff, Parkinson, & White, 1930; Yee, Klein, & Guiraudon, 1995). An accessory AV connection can conduct in both directions. The presence of these by-pass tracts may predispose to atria-ventricular reentrant tachycardia. Moreover, in the setting of atrial fibrillation, the WPW syndrome may cause a catastrophically rapid ventricular response with degeneration to ventricular fibrillation (VF).

Electrocardiographically, the WPW syndrome can be characterized by a specific sinus rhythm pattern. Its other specific features are paroxysms of re-entry tachycardia (the incidence in the young adult population is about 10% and growing up with age to 30%), more rarely paroxysm of atrial fibrillation (20-30% of patients with the syndrome), or atrial flutter (Guize, Soria, Chaouat et al., 1985; Wellens, Fare, & Bar, 1987).

In the case of WPW syndrome, the electrocardiogram (ECG) tracing is a mixture of the electrical activities caused by the accessory AV connection and normal AV conduction system. The fast impulse conduction produces an initial deflection in the QRS complex (delta wave).

The length of this delta wave is determined by the difference between the accessory AV connection and normal AV conduction times. The modified ventricular activation may cause secondary abnormalities in the ventricular repolarization such as: ST segment displacement (elevation or depression), T wave shape distortion, and abnormal U wave appearance. The conduction capacity variances (changes may occur hour by hour or day by day) of the accessory AV connection may result in alternating WPW pattern (complete, partial, or missing pre-excitation, concertina effect).

An adequate analysis of this phenomenon is important, since 1-2‰ of the population suffer from WPW syndrome (Wellens, Brugada, Penn et al., 1990). When the refractory period of the accessory connection becomes too short, the patient's life is endangered by a possible VF. Unfortunately, the exact risk for developing VF during high ventricular rates is unknown.

WPW Syndrome Analysis

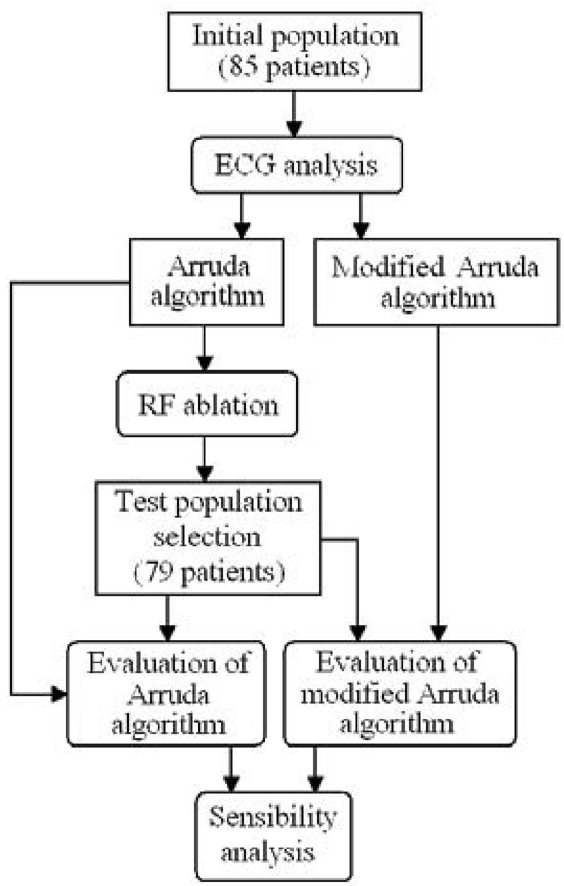
Usually the WPW analysis is focused to develop and validate an accessory pathway (AcP) localization method (Rosenbaum, Hecht, Wilson, & Johnston, 1945). A number of investigations have correlated ECG patterns and processing algorithms for detecting the place of the AcP (Arruda, McClelland, Wang, Beckman et al., 1998; Fitzpatrick, Gonzales, Lesh et al., 1994; Reddy & Schamroth, 1987), while other studies have been focused on the localization, realized through three-dimensional (3D)-heart reconstruction by the inverse solution of the ECG (Huiskamp & Greensite, 1997).

Unfortunately, the inverse problem, in contrast to the forward approximation methods, does not possess a mathematically unique solution. Another not easily by-passable difficulty is rooted in its ill-posed nature, whereby the obtained inverse solution could be unstable and may oscillate widely with the slightest perturbation.

Several approaches have been explored to handle the problem of multiple solutions by using equivalent cardiac generators, such as equivalent dipole (De Guise et al., 1985) and multipole, heart surface isochrones (Huiskamp & Greensite, 1997), or epicardial potential (Guanglin & Bin, 2001; Shahidi, Savard, & Nadeau, 1994). The high sensitivity of solutions to the different disturbances forced the investigators to explore various regularization techniques (Shahidi et al., 1994).

These methods allow a significant progress, but the diverse uncertainty elements of the processing limit

Figure 1. Flow sheet of the research



the potentially beneficial ECG inverse solutions from becoming a routine clinical tool at present.

The Arruda method differs from prior algorithms in its combined use of the resting ECG, utilization of only five ECG leads (I, II, III, V1, aVF), and by prospective validation of the algorithm.

In this article, we present a sensibility analysis of the Arruda's stepwise method (Arruda et al., 1998), and a decomposition algorithm to improve the performance of AcP localization. Our main purpose is to detect more accurately the location of the ventricular insertion.

MATERIALS AND METHODS

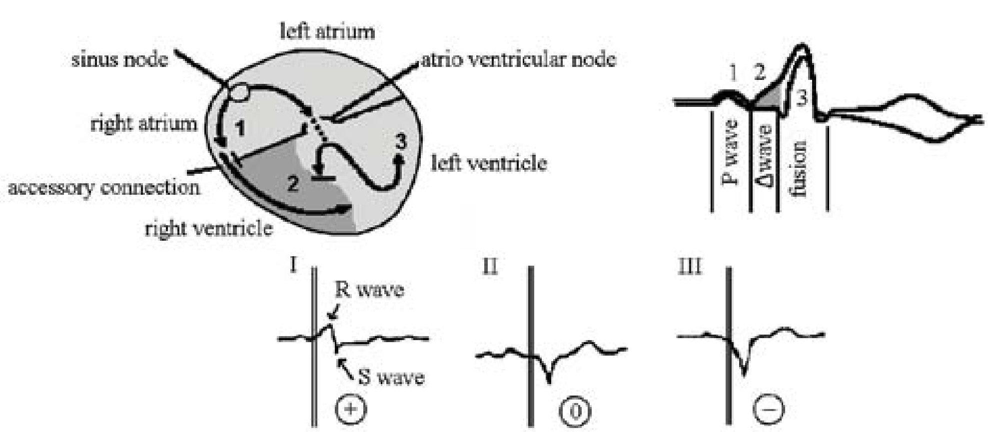
Base Studies

This research starts from the results and considerations published in S. M. Szilágyi's "Sensibility Analysis of the Arruda Localization Method" article (Szilágyi, Benyó, & Frigy, 2004). It has been concluded that the efficiency of the localization method—described in Arruda's "Development and Validation of an ECG Algorithm for Identifying Accessory Pathway Ablation Site in Wolff-Parkinson-White Syndrome" work (Arruda et al., 1998)—depends significantly on the location of the AcP.

According to the above-mentioned studies, we developed a modified Arruda localization method, which was tested and evaluated through our measurements. The schematic representation of the research process can be seen on Figure 1.

The *initial population* (1) of the research consisted of *85 patients* having at least one AcP (delta wave was detected in the preliminary phase of the study). For each patient a 5-10 minutes long 12-lead *ECG* recording was registered. The so obtained data were then preprocessed and *analyzed* (2) in order to provide input for stages 3-4. Thereafter, we separately predicted the AcP locations by means of the *Arruda* (3) and *modified Arruda* (4) *algorithms*. After *radio-frequency (RF) catheter ablation* (5), 6 patients were excluded,due to multiple AcP's, while the remaining *79* were selected as *test population* (6) for further study phases. In the course of *evaluation of Arruda* (7) *and modified Arruda* (8) *algorithms*, the estimated positions of both localization methods (3-4) were evaluated one by one and validated with the outcome of *RF ablation* (5). Finally, within the frame of the *sensibility analysis* (9), the results of stages 7-8 were statistically compared, followed by a vector-space dissection with regard to the spatial location of the ECG leads used by each algorithm.

Figure 2. The emergence of WPW syndrome; the delta wave polarity



Initial Arrangements

In the preliminary phase of the study, we performed a 12-lead ECG measurement for patients manifesting cardiac symptoms that served as a basis to select the subjects suffering from WPW syndrome (initial population—85 persons). The ECG recordings were sampled at 500 Hz frequency with 12-bit resolution.

Our ECG signal processing concerned only accurate detection of the QRS complexes and delta (Δ) waves presented in Figure 2, constituting input parameters for the Arruda and modified Arruda algorithms.

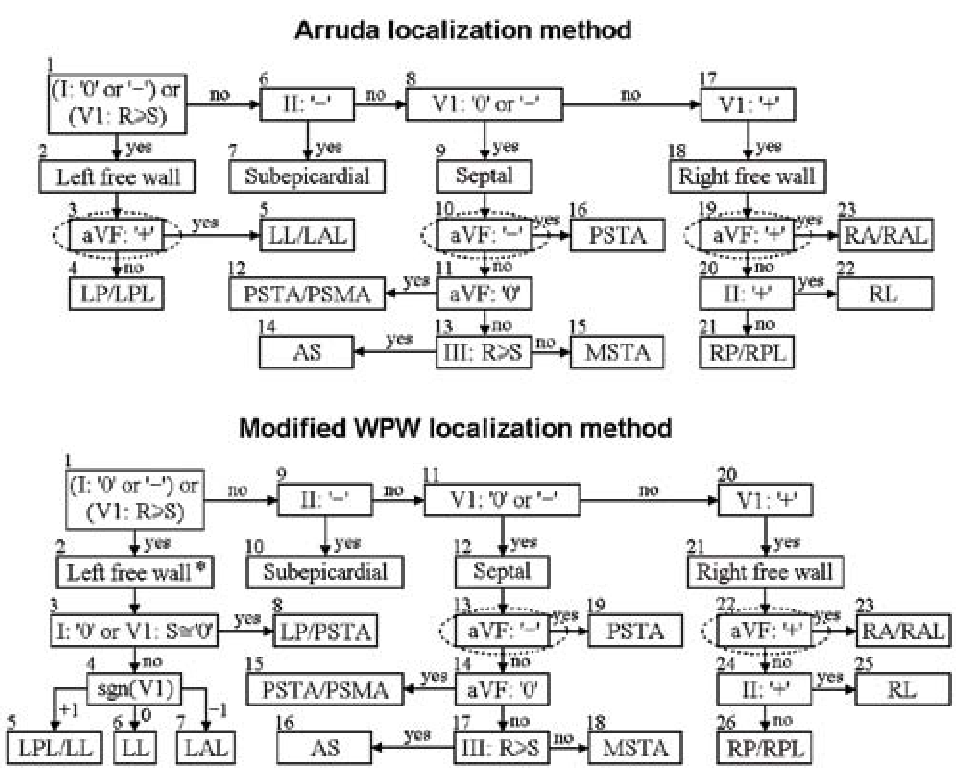
As Figure 2 presents, one cause for a wide QRS-complex that exceeds 0.12 seconds may be the Wolff-Parkinson-White syndrome (WPW syndrome). In this case the QRS-complex initially exhibits an early upstroke called *delta wave*. The two presented ECG signals differ significantly in shape. In both cases the interval from the P-wave to the R spike is normal, but the early ventricular excitation forming the delta wave shortens the PQ-time.

The cause of the WPW syndrome is the transfer of activation from the atrium (region 1 in Figure 2) directly to the ventricular muscle via an abnormal route, called AcP, which bypasses the AV junctions. This partially activates the ventricular muscle (region 2 in Figure 2) before normal activation (region 3 in Figure 2) reaches it via the normal conduction system (after a delay in the AV junction). This process is called pre-excitation, and the resulting ECG depends on the specific location of the accessory pathway (see right side of Figure 2). With the help of localization methods the place of AcP can be determined.

The Arruda Algorithm

The Arruda algorithm is a well known, clinically tested localization method, developed in order to identify the place of a singular accessory connection, reaching up to 90% recognition rate. It uses only five leads (I, II, III, aVF, V1) from the 12-lead ECG recordings.

Figure 3. Presentation of the Arruda and modified Arruda localization method; the left bottom side shows the modified left ventricular branch of the modified algorithm



The first step of the algorithm is to analyze the amplitude relations of the R, S, and delta (Δ) waves in order to determine the AcP location (see Figure 2). The onset of the delta wave in each lead is measured from the onset of the earliest delta wave in any of the 12 leads. After 20 ms the displacement of the delta wave in each lead is classified as positive (+), negative (–) or isoelectric (0) (see Figure 2).

The Arruda algorithm specifies a heart-region as the location of the AcP. According to Arruda, the possible AcP places have been divided into three major regions, which are further divided thereafter, as follows:

- Septal accessory pathways: anteroseptal tricuspid annulus and right anterior paraseptal (AS/RAPS), mid-septal tricuspid annulus (MSTA), posteroseptal tricuspid annulus (PSTA), posteroseptal mitral annulus (PSMA), subepicardial posteroseptal (SEC);
- Right free-wall accessory pathways: right anterior (RA), right anterolateral (RAL), right lateral (RL), right posterolateral (RPL), right posterior (RP);
- Left free-wall accessory pathways: left anterolateral (LAL), left lateral (LL), left posterolateral (LPL), left posterior (LP).

The proper Arruda algorithm might be interpreted as a decision tree consisting of simple two-way (YES/NO) ramifications, so called decision points (see Figure 3). It has five leads (I, II, III, aVF, V1), R and S waves, respectively the displacement of the delta wave in each lead (+, -, 0) as input, while the above mentioned heart-regions (locations) as output.

The Modified Arruda Algorithm

Although it has been statistically concluded that the performance of the Arruda algorithm is about 90%, some modifications in this localization method could be beneficial.

In Szilágyi et al. (2004), we pointed out that in most of the cases the estimation errors of the Arruda algorithm are correlated with aVF sign test. In the same place, we suggested modifying the lead aVF where it is possible.

The modified Arruda algorithm (see Figure 3) developed in order to identify the place of a singular accessory connection uses the same leads, same heart regions for localization of the AcP and same displacement of the delta wave in each lead (+, -, 0) as Arruda. The algorithm might be interpreted as a decision tree consisting of simple two-way (yes/no) ramifications with one exception at place 4 (see Figure 3). Although Szilágyi et al. (2004) revealed that the most sensible aVF sign tests at locations 3, 10, and 19, in Figure 3 we modified only the first one at left free wall (see Figure 3). The other two sensible places are marked as places 13 and 22 in Figure 3. The left free wall region is completely altered for better performance but all other tests are the same as in Arruda's work.

Radio-Frequency Catheter Ablation

RF catheter ablation of cardiac tissue is highly effective in the invasive treatment of WPW syndrome (Cao et al., 2000). During RF cardiac ablation, a catheter is introduced into a heart chamber via percutaneous peripheral venous or arterial conduits and placed in contact with the target ablation region (such as an AcP) at the endocardial surface. A high frequency current is applied between the catheter electrode and a dispersive electrode attached to the patient's skin. The myocardium is heated by Joule heat and heat conduction inside the myocardium. A temperature of 50 C° or higher causes irreversible loss of cellular excitability of tissue and forms a lesion.

In the course of RF ablation, a priori knowledge about the target ablation site(s) could be beneficial due to shorter intervention time and therefore lower risk. The Arruda (as well as the modified Arruda) algorithm predicts the location of a singular AcP, serving as a starting point to the surgeon. However, the exact number and place of the AcPs will be determined only during the surgical operation. Therefore, RF ablation plays a validation role for both localization methods. By means of RF ablation, we excluded from the research 6 patients with multiple AcPs, thus obtaining a test population consisting of 79 subjects.

RESULTS

To evaluate the performance of a localization method, we had to analyze the relationship between the predicted location (based upon the ECG algorithm) and the real location (based upon ablation site) of the AcP.

Table 1 present this relation for both algorithms, indicating the sensitivity and specificity for all AcP locations. Ablation sites are represented in vertical and the predicted locations in horizontal direction.

All AcP location predictions were analyzed in order to determine the strong and weak decision points of both localization methods. The result of this analysis is deductible from Table 1. During performance determination the contribution of each decision point was taken into consideration in when it was possible. In some cases a failed decision made all further evaluation meaningless. Such cases are indicated having no result. The last column shows the decision performance for all possible algorithmic branches. Table 2 represents the global accuracy of each decision point.

DISCUSSION

A penetrative study of the localization method demands much more than a simple evaluation of its overall performance, which proves to depend mostly on the least efficient decision points.

A deeper investigation of Table 2 reflects that applying Arruda localization method the estimation errors often (about 80% of the cases) appear due to wrong decision at places 3, 10, and 19 (see Figure 3). All of these decision points contain an aVF sign test. Furthermore, it is observable that in the diagram none of the aVF sign tests perform reliably.

The main goal of the modified localization method was to eliminate the most sensible decision points and thus to increase the overall performance. Unfortunately, this elimination proves to be easy only theoretically, due to the followings:

The depolarization wave's sphere-symmetric propagation is highly deformed by the fact that the right ventricle wall (4-5 mm) is much thinner than the left (10-12 mm) or the septal (7-8 mm) one. Taking into consideration the fact that the depolarization wave propagates at 300-800 mm/sec, and the sign of the delta wave is investigated over 20-millisecond intervals, it is obvious that vectorial calculations cannot accurately describe the behavior of the right ventricle.

The three leads used by Arruda, namely I, V1, and aVF, are almost orthogonal. Although V2 should perform better than V1, no significant difference proved achievable. Unfortunately, we have to admit that despite Arruda's decision points 10 and 19, which detect the septal and right regions, are sensible, they cannot be wisely replaced within the scope of the 12 lead ECG. This is illustrated also in Figure 3, where the aVF tests are encircled to indicate the necessity of further development.

The thicker wall of the left ventricle allows us to apply vectorial analysis; therefore, in this region significant improvements are possible.

Arruda's leads I and aVF (decision points 1 and 3) do not assure visibility in the direction of x axis. The modified method (decision points 1, 3, and 4) uses the z direction instead, which according to Table 2 at least partially improves the performance. Decision point 6 needs further refinement, because its 95% accuracy is relatively low.

These considerations were tested on our database, and must be used with care, due to the followings:

- Our database was too small to guarantee a solid statistical confirmation;
- The selected patients were not 100% representative (due to the small number);
- We used only few recordings from one patient, so the WPW syndrome could manifest in other way (it could change its behavior hourly).

CONCLUSION

Finally, we can conclude the followings:

- Arruda's leads used for the detection of septal and right regions seem to give optimal solution in the scope of 12-lead ECG.
- Significant improvements are achieved in the left ventricle.
- A more accurate analysis requires further studies and a significantly larger database.

The about 95% recognition rate we considered quite good, but a straightforward comparison with other localization methods (Boersma, Moran, Mont, & Brugada, 2002) performed on the same database would be beneficial in order to create a better noninvasive localization method .

A high localization performance of noninvasive methods is relevant because they can enlighten the necessary invasive interventions and also reduce the discomfort caused to the patient.

KEY TERMS

Accessory Pathway: An abnormal electric conduction route that connects the atria with the ventricles.

Atria: The chambers of the heart that collect the venous blood.

Electrocardiogram (ECG): A graphic produced by an electrocardiograph, which records the electrical activity of the heart over time.

QRS Complex: A structure on the ECG signal that corresponds to the depolarization of the ventricles.

Ventricles: The pumping chambers of the heart.

Wolff-Parkinson-White (WPW) Syndrome: A syndrome of pre-excitation of the ventricles of the heart due to an accessory pathway that causes an abnormal electrical communication from the atria to the ventricles.

INTRODUCTION

Magnetoencephalography (MEG) and electroencephalography (EEG) are noninvasive measurement tools that provide high temporal resolution on the units of milliseconds to investigate neuronal activity in the brain. MEG and EEG measure the magnetic fields and the scalp electrical potentials produced by the current sources, respectively. MEG systems utilize gradiometer and/or magnetometer connected to superconducting quantum interference devices (SQUIDs) as sensors, while EEG systems are metal electrodes connected to differential amplifiers. It is well-known that the main advantage of MEG over EEG is its invulnerability to the distortions caused by various layers of cerebrum such as skull, scalp, muscle, and cerebrospinal fluid (Baillet, Mosher, & Leahy, 2001; Hamalainen, Hari, Ilomoniemi, Knuutila, & Lounasmaa, 1993). Estimating the neuronal source parameters mainly as source locations and magnitudes has been a great interest of researchers, with the aim of imaging the brain with a fine temporal resolution. The techniques for the extraction of these parameters are known as inverse methods. Various inverse methods, such as least-square estimation (Baillet et al., 2001), vector beamformers (Sekihara, Nagarajan, Poeppel, Marantz, & Miyashita, 2001), Multiple Signal Classification (MUSIC) (Mosher, Lewis, & Leahy, 1992), minimum norm solutions (Hauk, 2004), maximum likelihood-based solutions have been proposed in literature. Even in a noiseless environment, there is not a unique solution for the source parameters, which makes the problem ill-posed. Hence, all inverse methods depend on some assumptions about the sources, and when these assumptions are not appropriate in the unknown sources, satisfactory results may not be obtained.

Most information contained in MEG measurements reflects signals originated from the cortex because of the relatively short distances between the cortex and the magnetometers/gradiometers in the MEG system. Nevertheless, there have been some attempts to detect the sources arising from deep areas of the brain, such as brainstem (Parkkonen & Mäkelä, 2002), thalamus (Tesche, 1998), hippocampus (Tesche & Karhu, 2000), and cerebellum (Tesche & Karhu, 1997). However, the success of these attempts was limited.

Before using any inverse method, preprocessing of data may dramatically increase the overall performance in terms of both accuracy and computational efficiency. Preprocessing methods are realized for different goals, including artifact removal, dimension reduction, and noise removal. Among these methods signal space projection (SSP) (Tesche, Uusitalo, Ilmoniemi, Huotilainen, Kajola, & Salonen, 1995; Uusitalo & Ilmoniemi, 1997) relies on removing contributions from undesired sources by exploiting their spatial structures. Because of the assumed orthogonality of source and artifact spaces, the interesting part is also mostly modified while suppressing the undesired part. Popular and efficient signal processing methods such as independent component analysis (James & Gibson, 2003; Vigario, Sarela, Jousmaki, Hamalainen, & Oja, 2000) and adaptive filtering (Ahmar & Simon, 2005; Constantin, Richard, Lengelle, & Soufflet, 2005) have also been employed to cope with similar problems. These techniques mostly suffer from assumptions of strong uncorrelatedness or independency. Gross and Ioannides (1999) defined, evaluated and compared various linear transformation techniques, including the beamspace approach. The beamspace method relies on projecting data by maximizing the power with an orthogonal transformation matrix that spans the space of the leadfield obtained by forward modeling computations. This preprocessing technique has recently been shown to increase the performance of main source localization algorithms (Rodriguez, Baryshnikov, Van Veen, & Wakai, 2006). Signal space separation (SSS), provided first by Taulu and Kajola (2005), is also a novel technique designed principally for removing interferences from MEG measurements. Since there is no charge on the sensor array volume, Laplace's equation becomes satisfied for magnetic scalar potential. Utilizing this fundamental law of physics, the SSS method decomposes the recorded magnetic field into two parts using vector spherical harmonic basis functions: one for the signals coming from the inside the sensor array volume, and the other coming from the outside it. The method can effectively remove the external interferences without imposing unrealistic assumptions by estimating the coefficients in the least-linear square sense.

In this article, we propose a novel preprocessing method in the spherical harmonics domain to decompose the MEG signal into specific parts, whose sources arise from user-prescribed concentric spherical regions. A particular case of this approach is presented to separate the data into parts corresponding to deep and superficial regions of the brain, without using inverse solutions. Throughout this article, plain italics denote scalars, lower case boldface symbols denote vectors, uppercase boldface symbols denote matrices, superscripts T and H stand for transpose and Hermitian transpose, and $\|.\|$, $tr(.)$, * indicate Euclidean norm, and trace and complex conjugate operations, respectively.

BACKGROUND

Our algorithm to decompose the signal into deep and superficial regions is highly dependent on the SSS and beamspace methods, which were briefly introduced in the previous section. In this section, we supply the necessary definitions to support the algorithm development.

The mapping from current sources to the magnetic fields in a noiseless environment can be described as:

$$b_k(t) = \int_{\Omega} \mathbf{h}_k(\mathbf{r}') \cdot \mathbf{j}(\mathbf{r}')\, d\Omega \qquad (1)$$

where Ω is the whole source space, $\mathbf{r}'$ stands for the source locations, and $\mathbf{h}_k$ is the leadfield mapping of the current sources $\mathbf{j}$ to the magnetic field measurements at the k^{th} sensor, denoted as $b_k(t)$. The SSS method decomposes an M channel MEG signal:

$$\mathbf{b} = [b_1(t), b_2(t), ..., b_M(t)]^T =$$

$$\sum_{l=0}^{\infty}\sum_{m=-l}^{l} \alpha_{lm}\mathbf{x_{lm}} + \sum_{l=0}^{\infty}\sum_{m=-l}^{l} \beta_{lm}\mathbf{y_{lm}} = \mathbf{b}_{in} + \mathbf{b}_{out} \qquad (2)$$

into two components, where inner component $\mathbf{b}_{in}$ corresponds to source locations $\|\mathbf{r}'\| < R$, and the outer component $\mathbf{b}_{out}$ corresponds to $\|\mathbf{r}'\| > R$, and R is the radius of the sensor array. Based on the quasistatic approximation of Maxwell's equations, this separation is achieved using two different sums of vector spherical harmonic functions $\mathbf{x}_{\mathrm{lm}}$ and $\mathbf{y}_{\mathrm{lm}}$ (Taulu & Kajola, 2005). Spherical harmonic functions are orthonormal eigenfunctions of the Laplacian operator on the spherical surface, which makes them naturally useful tools for MEG signal processing, and hence has been suggested in literature for different purposes. For instance, Popov (2002) proposed a continuation of MEG data around the surface of the sensor array using a spherical harmonics expansion. They were also commonly utilized for the computation and approximation of the MEG forward problem (Jerbi, Mosher, Baillet, & Leahy, 2002; Nolte, Fieseler, & Curio, 2001; Nolte, 2003).

Equation 2 may be rewritten in an algebraic form as:

$$\mathbf{b} = \mathbf{S}\omega \qquad (3)$$

where the $(M \times p)$ dimensional basis functions matrix $\mathbf{S} = [\mathbf{S}_{in}\ \ \mathbf{S}_{out}]$ comprises inner and outer basis functions:

$$\mathbf{S}_{in} = [\mathbf{x}_{1,-1}, \mathbf{x}_{1,1}, \mathbf{x}_{2,-2}, ..., \mathbf{x}_{L_{in},L_{in}}] \qquad (4)$$

$$\mathbf{S}_{out} = [\mathbf{y}_{1,-1}, \mathbf{y}_{1,1}, \mathbf{y}_{2,-2}, ..., \mathbf{y}_{L_{out},L_{out}}]$$

and the $(p \times 1)$ coefficient vector $\boldsymbol{\omega} = [\boldsymbol{\alpha}\ \boldsymbol{\beta}]^T$ contains the SSS coefficients for inner and outer parts:

$$\boldsymbol{\alpha} = [\alpha_{1,-1}, \alpha_{1,1}, \alpha_{2,-2}, ..., \alpha_{L_{in}, L_{in}}]$$

$$\boldsymbol{\beta} = [\beta_{1,-1}, \beta_{1,1}, \beta_{2,-2}, ..., \beta_{L_{out}, L_{out}}], \tag{5}$$

and if the total number of coefficients is denoted by $p = p_{in} + p_{out}$, then the number of inner coefficients is $p_{in} = L_{in}^2 + 2L_{in}$, and the number of outer coefficients is $p_{out} = L_{out}^2 + 2L_{out}$. It should be noted that the coefficients with $l=0$ and $m=0$ are dismissed in the expansion, since they represent the magnetic monopoles. Then, the SSS coefficients α for the inner part, and β for the outer part, may be estimated using a pseudo-inverse operation as $\hat{\boldsymbol{\omega}} = \mathbf{S}^{+}\mathbf{b}$. Then, the reconstruction of the signal that corresponds to inner sources is obtained easily by $\hat{\mathbf{b}}_{in} = \mathbf{S}_{in}\hat{\boldsymbol{\alpha}}$.

Beamspace method has typically been used for dimension reduction and noise elimination of MEG data (Rodriguez et al., 2006), before it is being processed to extract the source magnitudes and locations by an inverse method. It looks for a linear transformation matrix **T** that maximizes the power in a region of interest, and is obtained by a criterion:

$$\max_{\mathbf{T}} \ tr(\mathbf{T}^T\mathbf{G}\mathbf{T}) \ \text{subject to} \ \mathbf{T}^T\mathbf{T} = \mathbf{I} \tag{6}$$

where **G** is the so-called Gram matrix (Gross & Ioannides, 1999), having the second-order relation between the leadfields:

$$\mathbf{G} = \int_{\Omega} \mathbf{H}(\mathbf{r}')\mathbf{H}(\mathbf{r}')^T \, d\Omega \tag{7}$$

where $\mathbf{H}(\mathbf{r}') = [\mathbf{h}_1(\mathbf{r}'), \mathbf{h}_2(\mathbf{r}'), \ldots, \mathbf{h}_M(\mathbf{r}')]^T$ is the ($M \times 3$) leadfield matrix for all M sensors. Solution of Equation 6 produces a **T** that is obtained as a ($N \times M$) dimensional matrix, whose columns are the eigenvectors of the Gram matrix **G**, those corresponding to the greatest N eigenvalues ($N \leq M$). Hence, the transformed and dimension reduced signal $\tilde{\mathbf{b}}$ is obtained as $\tilde{\mathbf{b}} = \mathbf{T}^{\mathbf{T}}\mathbf{b}$. Rodriguez et al. (2006) provide the details of this criterion that allows for an optimal linear transformation of the magnetic field data in mean-square sense.

MODIFIED BEAMSPACE IN THE SSS DOMAIN

This section presents the development of our algorithm to constrain the MEG signal into parts corresponding to deep and superficial current sources. The schematic representation given in Figure 1 summarizes the main steps of our algorithm.

After the inner SSS coefficients are estimated from the MEG signal, our goal is to optimally manipulate them, such that the reconstruction of the manipulated coefficients will give rise to two components: deep component $\mathbf{b}_{\text{deep}}$, where the electrical current sources come from the spherical region $\|\mathbf{r}'\| < \hat{r}$, and a superficial component $\mathbf{b}_{\text{sup}}$, where the sources arise from the remaining region of the head as $\|\mathbf{r}'\| > \hat{r}$. Here, $\hat{r}$ denotes the separating radius, and is determined by the user such that $0 < \hat{r} < R$. The geometry of this separation is exhibited in Figure 2. This task cannot be achieved only by the SSS algorithm itself, since the condition of the SSS algorithm is a boundary that does not contain current sources like the sensor array volume. However, this is not the case for a region inside the head, since it will always contain neural sources.

In the spherical harmonics domain, the leadfield-like relation between the SSS coefficients α_{lm} and the inner current sources $\mathbf{j}_{in}(\mathbf{r}')$ is formulated (Taulu & Kajola, 2005) as:

$$\alpha_{lm} = \int_{\Omega_{in}} \boldsymbol{\lambda}_{lm}(\mathbf{r}') \cdot \mathbf{j}_{in}(\mathbf{r}') \, d\Omega_{in} \tag{8}$$

Here, λ_{lm}s are leadfield-like vectors directly related to the vector spherical harmonic function $\mathbf{x}_{lm}(\theta,\varphi)$ defined as (Taulu & Kajola, 2005):

$$\boldsymbol{\lambda}_{\mathbf{lm}}(\mathbf{r}') = \frac{i}{2l+1}\sqrt{\frac{l}{l+1}}\, r^l \mathbf{x}_{\mathbf{lm}}^*(\theta,\varphi)$$

$$\mathbf{x}_{\mathbf{lm}}(\theta,\varphi) = \frac{-1}{\sqrt{l(l+1)}}\left[\frac{mY_{lm}(\theta,\varphi)}{\sin\theta}\mathbf{e}_\theta + i\frac{\partial Y_{lm}(\theta,\varphi)}{\partial\theta}\mathbf{e}_\varphi\right] \tag{9}$$

$Y_{lm}(\theta,\varphi)$ is known to be the normalized scalar spherical harmonic function (Arfken, 1985). Since MEG is sensible only to the tangential components of the sources, $\mathbf{x}_{lm}(\theta,\varphi)$ does not have a radial component. Hence, the dimensionality is naturally reduced from three to two. Additionally, the vector spherical harmonics yield an orthogonal representation unlike the nonorthogonal representation by leadfield vectors of forward modeling.

Figure 1.

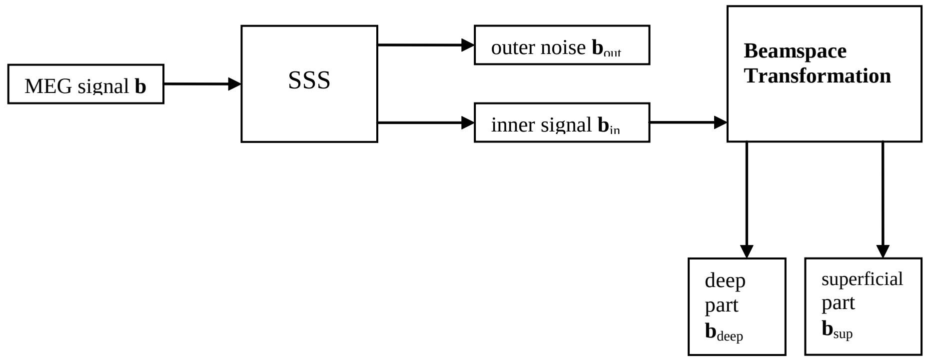

Figure 2.

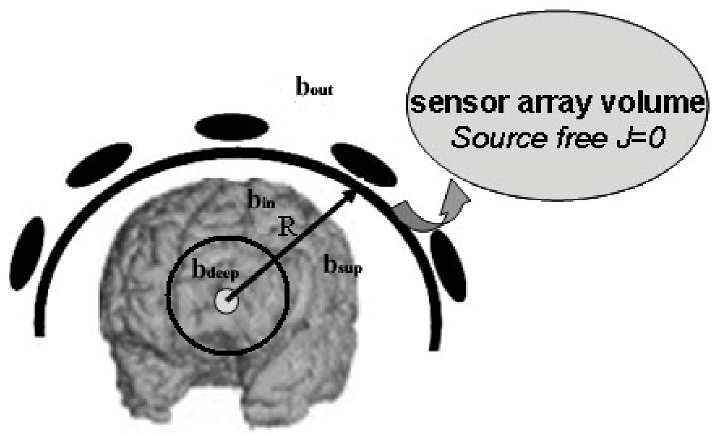

If we assign the (l,m) indexed SSS coefficient as $a=1,\ldots,p$, and the (L,M) indexed SSS coefficient as $b=1,\ldots,p$ for simplicity, then the Gram matrix for the spherical harmonics domain can be defined as:

$$\left(\mathbf{G}\right)_{ab}^{\;S} = \int_{\Omega} \boldsymbol{\lambda}_{lm}(\mathbf{r'}) \cdot \boldsymbol{\lambda}_{LM}(\mathbf{r'})\, d\Omega = \int_{\Omega} \boldsymbol{\lambda}_{a}(\mathbf{r'}) \cdot \boldsymbol{\lambda}_{b}(\mathbf{r'})\, d\Omega$$

$$\mathbf{G}^{S} = \int_{\Omega} \boldsymbol{\Lambda}(\mathbf{r'})\boldsymbol{\Lambda}(\mathbf{r'})^{H}\, d\Omega \tag{10}$$

where $\boldsymbol{\Lambda}(\mathbf{r'}) = [\boldsymbol{\lambda}_{\mathbf{1\text{-}1}}(\mathbf{r'}), \boldsymbol{\lambda}_{\mathbf{11}}(\mathbf{r'}), \boldsymbol{\lambda}_{\mathbf{2\text{-}2}}(\mathbf{r'})\ldots, \boldsymbol{\lambda}_{\mathbf{LL}}(\mathbf{r'})]^{T}$ has dimension $(p_{in} \times 2)$. In practice, p_{in} is chosen to be less than M to estimate the SSS coefficients properly (i.e., after the signal is filtered by SSS, its dimension is already reduced from M to p_{in}).

We apply a beamspace criterion to transform the inner coefficients α, so that the power for the deep component is maximized, and for the superficial component, it is minimized:

$$\max_{\mathbf{T}} \frac{tr(\mathbf{T}^{T}\mathbf{G}_{d}\mathbf{T})/v_{d}}{tr(\mathbf{T}^{T}\mathbf{G}_{s}\mathbf{T})/v_{s}} \quad \text{with the constraint } \mathbf{T}^{T}\mathbf{T} = \mathbf{I} \tag{11}$$

Here, $\mathbf{G}_{d}$ and $\mathbf{G}_{s}$ are Gram matrices, and v_{d} and v_{s} are volumes for deep and superficial components, respectively. Because of the orthonormality property of the vector spherical harmonics (Arfken, 1985), the Gram matrices are diagonal. Then, the a^{th} rows and b^{th} columns of them are computed as follows:

$$(\mathbf{G}_d)_{ab} = \iint_{\varphi\,\theta} \int_{r=0}^{\hat{r}} \left(\frac{i}{2l+1}\sqrt{\frac{l}{l+1}} r^l \mathbf{x}_{lm} * (\theta,\varphi) \right) \bullet \left(\frac{-i}{2L+1}\sqrt{\frac{L}{L+1}} r^L \mathbf{x}_{LM} (\theta,\varphi) \right) r^2 \sin\,\theta dr d\theta d\varphi \qquad (12)$$

$$(\mathbf{G}_s)_{ab} = \iint_{\varphi\,\theta} \int_{r=\hat{r}}^{R} \left(\frac{i}{2l+1}\sqrt{\frac{l}{l+1}} r^l \mathbf{x}_{lm} * (\theta,\varphi) \right) \bullet \left(\frac{-i}{2L+1}\sqrt{\frac{L}{L+1}} r^L \mathbf{x}_{LM} (\theta,\varphi) \right) r^2 \sin\,\theta dr d\theta d\varphi \qquad (13)$$

Equation 12 reduces to the matrix form (Ozkurt, Sun, & Sclabassi, 2006).

$$(\mathbf{G}_d)_{ab} = \delta_{lL}\delta_{mM} \frac{1}{(2l+1)^2}\frac{l}{l+1} \iint_{\varphi\,\theta} |\mathbf{x}_{lm}(\theta,\varphi)|^2 \sin\,\theta dr d\theta d\varphi \int_{r=0}^{\hat{r}} r^{2l+2} dr = \delta_{lL}\delta_{mM} \frac{1}{(2l+1)^2}\frac{l}{l+1}\frac{\hat{r}^{2l+3}}{2l+3} = \delta_{ab}\, y(l) \qquad (14)$$

where $y(l) = \frac{1}{(2l+1)^2}\frac{l}{l+1}\frac{\hat{r}^{2l+3}}{2l+3}$.

Similarly, Equation 13 shrinks to:

$$(\mathbf{G}_s)_{ab} = \frac{1}{(2l+1)^2}\frac{l}{l+1}\frac{R^{2l+3}-\hat{r}^{2l+3}}{2l+3}\delta_{ab} \qquad (15)$$

The solution of Equation 11 leads to a matrix **T** whose columns are eigenvectors of:

$$\mathbf{G}_f = \frac{v_s}{v_d}\mathbf{G}_s^{-1/2}\mathbf{G}_d(\mathbf{G}_s^{-1/2})^T \qquad (16)$$

corresponding to the largest eigenvalues (Gross & Ioannides, 1999). Hence, combining Equations 14, 15, and 16, we obtain the final diagonal Gram matrix:

$$(\mathbf{G}_f)_{ab} = \frac{v_s}{v_d}G_s^{-1/2}G_d(G_s^{-1/2})^T\delta_{ab} = \frac{v_s}{v_d}\frac{\hat{r}^{2l+3}}{R^{2l+3}-\hat{r}^{2l+3}}\delta_{ab} \qquad (17)$$

Then all eigenvectors of $\mathbf{G}_f$ will constitute an identity matrix. Accordingly, Equation 17 suggests a transformation that selects the first inner SSS coefficient $\boldsymbol{\alpha}_{deep} = [\alpha_{1,-1}, \alpha_{1,1}..., \alpha_{s,s}]$ where

$$\frac{v_s}{v_d}\frac{\hat{r}^{2l+3}}{R^{2l+3}-\hat{r}^{2l+3}}$$

is sufficiently large. All the remaining coefficients are eliminated. The reconstruction of α_{deep} will yield an estimate of a component $\hat{\mathbf{b}}_{deep}$ that corresponds to deep components. Similarly, the estimation of superficial sources is achieved by minimizing the reciprocal of the first term in Equation 11, and accordingly, beamspace transformation selects the last inner SSS coefficients where $\boldsymbol{\alpha}_{\sup} = [\alpha_{L_{in}-s+1,-(L_{in}-s+1)},..., \alpha_{L_{in},L_{in}}]$ for the reconstruction of the superficial component of the magnetic signal $\hat{\mathbf{b}}_{sup}$. When l is considered as spatial frequency, the beamspace result can be interpreted as "sharp" low-spatial frequency filtering for the deep part, and high spatial frequency filtering for the superficial part (see Figure 3a). This result agrees with Equation 9, since it shows that the greater the l values of the SSS coefficients are, the greater the contribution from the superficial sources. Although sharp spatial filtering results from the optimality in mean-square sense, weighting coefficients uniformly may not be so reliable, since Equation 9 clearly indicates that the contributions from the sources are rather exponential. To overcome this problem, we suggest an eigenvalue-weighted filtering of the selected SSS coefficients. Hence, the beamspace transformation matrix **T** is modified as **T'=TD,** where **D** denotes the diagonal matrix whose diagonal elements are the selected largest eigenvalues of $\mathbf{G}_f$. This modification leads to a simple manipulation of the SSS coefficients for deep sources as:

$$(\tilde{\alpha}_{lm})_{deep} = \alpha_{lm}\frac{v_s}{v_d}\frac{\hat{r}^{2l+3}}{R^{2l+3}-\hat{r}^{2l+3}} \qquad (18)$$

and reconstructing the signal of interest with the obtained modified coefficients for the deep part:

$$\hat{\mathbf{b}}_{deep} = \mathbf{S}_{in}\left(\tilde{\boldsymbol{\alpha}}_{deep}\right)^T \qquad (19)$$

Estimation of the superficial part is similarly realized by the modification given below:

$$(\tilde{\alpha}_{lm})_{sup} = \alpha_{lm} \frac{v_d}{v_s} \frac{R^{2l+3} - \hat{r}^{2l+3}}{\hat{r}^{2l+3}}$$
$$\hat{\mathbf{b}}_{sup} = \mathbf{S}_{in} \left(\tilde{\boldsymbol{\alpha}}_{sup}\right)^T . \qquad (20)$$

This transformation corresponds to a rather smoother spatial filtering as depicted in Figure 3b.

Some MEG data was simulated in order to verify the accuracy and the performance of the proposed algorithm. Its sensor characteristic was chosen to be compatible with the Elekta Neuromag® 306 channel system, which measures the magnetic signal using 204 planar gradiometers and 102 magnetometers at a sampling frequency of 1 KHz. A spherical head model of radius $R=9$ cm was utilized in the simulations. Two sources dipole were created at coordinates (3,1,2) cm for the deep source, and (6,5,4) cm for the superficial source. Duration of the field data was 600 ms, which corresponds to a data length of 600 samples. The waveforms are sinusoids with frequencies 2 Hz for the deep source, and 10 Hz for the superficial source (Figure 4a). Since there are no external interferences for the synthesized data, we determined $L_{out}=0$, and choosing $L_{in}=10$ was enough to represent the input signal with the SSS coefficients. Therefore, the dimension of the 306 channel magnetic measurement is reduced to $p_{in}=120$. Note that in this simulation, the energies of deep sources and superficial sources contributing to total data were same.

We applied our algorithm to the simulated data with the properties described above for a separating radius $\hat{r}$ =3.6 cm, which specifies a spherical boundary between the deep source ($r_d \approx 3.32$cm), and for the superficial source ($r_s \approx 8.77$cm) of the head model (Figure 4 b). Figure 5 provides overlapping plots of all channels for the simulated data (a), estimated deep part (b), and superficial part (c) with the modified inner SSS coefficients as described in Equations 19 and 20 using the proposed eigenvalue weighted beamspace approach. It can be observed that the algorithm extracted deep and superficial sources reasonably well, although there is still a noticeable superficial leakage in the estimated deep component. In Figure 6, we provide two channels for a better visual comparison. In Figure 6a, it is observed that our algorithm achieves the extraction of the superficial contribution from a channel that is close to deep sources. In Figure 6b, we exhibit how the algorithm resolves the deep component from a channel that has a strong superficial source contribution.

FUTURE TRENDS

Deeper sources, such as the ones arising from the basal ganglia, are related to information processing and storage within the brain, and hence possess the potential importance to be investigated. However, they were not studied thoroughly by MEG community because

Figure 3.

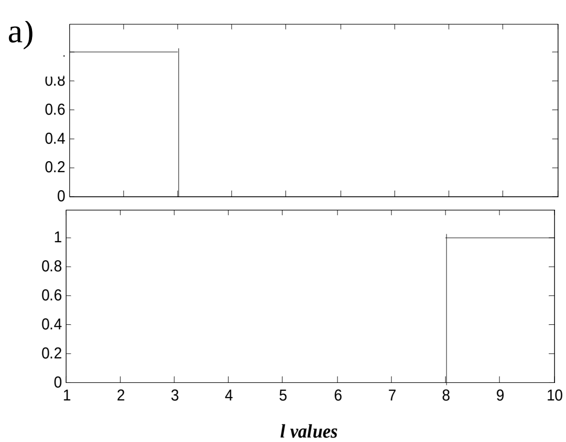
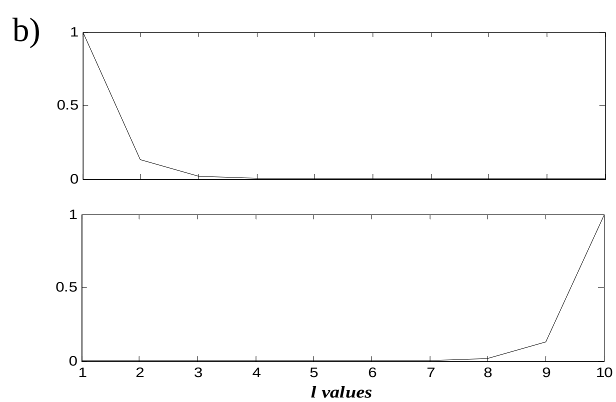
Spatial filtering of the coefficients according to the **modified** beamspace criterion for deep (top panel) and superficial (bottom panel) sources.





of their weakness and longer distance to head, when compared with the cortex. Our study enables the raw MEG data to be decomposed, corresponding to sources within different radial concentric layers. This will help to reduce the masking effect of the strong cortical signals on much weaker signals arising from the deeper regions, and provide a better resolution for the region of interest. Various well-known inverse methods afterwards can be applied to decomposed data to localize the neural activities according to the user's interest. There have been other suggestions, such as in Kim, Kobayashi, and Uchikawa (2003) to constrain the MEG data sources to regions of interest with taking account of the spectral information of the sources. However, our algorithm exploits only the spatial properties, and does not need to assume or impose any prior information about the source waveforms.

CONCLUSION

Decomposing the MEG data to specific locations of the brain without using inverse solutions may provide invaluable insights about the properties of the data. The SSS algorithm is an attempt to realize it by obtaining coefficients for interesting sources inside the sensor array, and the external noise outside it. We propose to extend this algorithm to constrain the data to some desired locations inside the brain. This study showed that with a simple manipulation of the inner SSS coefficients, the signal can be separated into parts that correspond to deep and superficial sources. This simplicity of the derived formulation comes from the natural appropriateness to spherical domain and orthogonality properties of the SSS basis functions that are directly related to the vector spherical harmonics. Beamspace method is used to obtain the optimality in mean-square sense for the modification of the SSS coefficients. It should be noted that it would not be easy to do these computations with classical lead field functions (i.e., since they are not orthogonal, one would have to first determine necessary coordinates by dividing the deep (or superficial) source volume into grids and compute the Gram matrix discretely, unlike the proposed method). Moreover, with our approach, while the beamspace transformation matrix is being obtained, one does not have to deal with the sensor configurations and dimension reduction (i.e., choosing the eigenvectors of the Gram matrix that correspond to the largest eigenvalues). All these procedures are already handled by the SSS method.

This algorithm may also be developed to decompose the signal into different regions of interest, such as left and right hemispheres, and bottom and top parts of the head. In this case, the vector harmonic basis will no longer be orthogonal when integrated across these source regions, which could make it much more difficult to obtain the Gram matrix. We are currently investigating efficient and optimal solutions using spherical harmonics to constrain the data into arbitrarily determined locations. Additionally, parameters such as the separating radius and different energy ratios of deep and superficial parts will affect the performance of the algorithm. We will report the results of these considerations in the near future.

KEY TERMS

Beamspace: It is a preprocessing method to reduce the dimension of the MEG signal by using a linear transformation matrix that is obtained using leadfields.

Forward Problem: It corresponds to calculating the magnetic field outside the head from a given primary source distribution within the brain.

Gram Matrix: It describes the deterministic second order relations among leadfields for different source locations.

Inverse Methods: These methods are utilized to estimate the source locations and strengths from EEG / MEG signals.

Leadfield: It denotes a vector mapping from a unit current source to magnetic measurement on a sensor located in a particular position.

Magnetoencephalography (MEG): It measures extracranial magnetic fields induced by electrical currents in the brain, noninvasively. The very weak magnetic fields of the brain are sensed by superconducting quantum interference devices (SQUIDs).

Signal Space Separation (SSS): A preprocessing method that decomposes the MEG signal into inner source signal and outer noise by using spherical harmonic basis functions.

Spherical Harmonics: They are orthonormal eigenfunctions of the Laplacian operator on the spherical surface, and useful tools to represent EEG/MEG signals on the head for different cases.

Monitoring and Controlling of Healthcare Information Systems (HIS)

Stefan M. Graeber
Saarland University, Germany

Ansgar Kutscha
Diakonie Hospital Schwaebisch Hall gGmbH, Germany

BACKGROUND

Information management (IM) at a health care institution encompasses the management of information, the management of application systems, and the management of information and communication technology whether computer supported or not, that is, IM provides function, performance, and quality of HIS. Management means, as well, the responsible persons and organizational units as the tasks of planning, directing, and monitoring HIS. IM has to be done systematically to enable an orderly processing of information coherent with the goals of the health care institution.

While planning and directing are supported comprehensively by basic methods of strategic planning and project management (Brigl, Ammenwerth, Dujat et al., 2005; Haux, Winter, Ammenwerth, & Brigl, 2004; Winter, Ammenwerth, Bott et al., 2001), the monitoring is neglected sometimes and thus insufficiently supported (Ammenwerth, Ehlers, Hirsch, & Gratl, 2007). As nevertheless a continuous and careful monitoring is a very important task in interaction with all other management tasks, we will define the relevant terms and describe the most significant concepts and methods.

Monitoring

Generally, *monitoring* of HIS means the continuous observation of whether the directives and objectives defined in the strategic information management plan will be reached, and whether the HIS is able to fulfill the required tasks. Therefore, the IM must be able at any time to assess the state of the HIS using quality criteria which can be derived from the objectives. Its results affect directing and planning again by feedback mechanisms.

The tasks of monitoring may be linked to the strategic level (auditing HIS quality as defined by means of strategic information management plan's directives and goals as well as quality of the strategic management process itself), the tactical level (check whether the initiated projects are running as planned and whether they will produce the expected results), and the operational level (verifying the proper working and effectiveness of all HIS components) (Haux et al., 2004, p. 182-184).

Nowadays the management tasks providing an excellent service for all users of HIS are embraced by the term *IT service management* (ITSM). There are several frameworks describing an architecture for installing and maintaining ITSM. The most known framework is the *IT infrastructure library* (ITIL) (www.itil.org). It is a set of best practices enabling organizations to deliver their services more efficiently and thus at last to reach for a maximum of customer (patient) satisfaction. ITIL may be regarded as a guideline for monitoring of HIS.

IT Controlling

Management decisions require information or data. In this context, the part of IM delivering information needed as basis for management decisions is called *IT controlling*. For this purpose, IT controlling applies different approaches and methods, for example, the continuous measuring and interpretation of indicators and characteristic values explaining the current state of HIS, or the realization of evaluation studies. Thus, among other IT controlling, comprises following tasks (the terms reference model, indicator, and evaluation project are outlined below):

- Defining and operationalizing objectives (in cooperation with partners of IM)

- Defining models, selection and application of reference models
- Defining indicators and appropriate values
- Planning, initiating, and continuous measurement of indicators
- Planning and performance of evaluation projects
- Reporting results
- Analyzing results (which may influence all preceding steps by feedback-mechanism) (in cooperation with partners of IM)
- Preparing decisions (in cooperation with partners of IM)

Depending on tasks and questions, different methods of information acquisition are applied. Sometimes one performs ad-hoc-studies (field studies) to find hypotheses, to get some insight in the features of performance measuring, or to detect problems and deficiencies (screening). An example of screening is a survey performed to discover the problems with a new nursing documentation system two weeks after installation. More important are the continuous data collection via indicators and occasional deeper investigations (evaluation).

Indicators and Characteristic Values

Indicators are variables whose values (characteristics values) represent an aspect of HIS. To discern good and bad quality of information processing and to assess the achievement of goals, one has to compare the current value of indicator with one or more predefined reference values. With standardized indicators comparisons between different HIS become possible. Relevant aspects may be all components of HIS, for example, strategy, projects, quality, processes, functionality, or parts of IT infrastructure. The indicators can be qualitative (e.g., user satisfaction), quantitative non-monetary (e.g., failure time), or quantitative monetary (e.g., cost). They should be specified as follows:

- Comprehensive description, including its purpose and correlation with the objectives
- Data source, measurement procedure, and algorithms (when indicators are derived from others)
- Characteristic values and reference values (limits), for example, corresponding to quality goals
- Time interval for measurement (e.g., daily, weekly)
- Time of availability
- Responsible organizational unit and person(s)
- Procedure to check adequateness, completeness, and correctness of results afterwards (evaluation of indicators)

To describe complex aspects of HIS, several indicators have to be considered. The combination of logically associated indicators is called an *indicator system*. The Balanced Scorecard (see next paragraph) is an example for an indicator system.

Balanced Scorecard

A suitable tool for management and controlling is the *Balanced Scorecard* (BSC) (Kaplan & Norton, 1992, 2000). At first developed for strategic management of an organization, the BSC can be applied for purposes of monitoring too. It provides feedback around both the internal business processes and external outcomes in order to continuously improve strategic performance and results. When fully deployed, the balanced scorecard transforms strategic planning into the "nerve center" of an enterprise. Using BSC the manager may establish a "balanced" situation between the traditional financial measures and other success factors of an organization. The BSC combines the continuous measurement of performance with a reviewing and refinement strategy as well an ongoing evaluation process.

The basic terms are so-called *perspectives*, for example, potentials (learning and growth), internal processes, customers, and financial perspective. Depending on the view, the term customer can vary: customers from the view of health care organization are mostly patients, customers from the view of IM are users of IT applications. For each perspective, strategic objectives, indicators, and measures to achieve these objectives must be defined.

Models and Reference Models

A *model* is a simplified representation of a section of the real world (subject area). Models are developed for understanding, analysis, or improvement of subject area. Depending on purposes of modeling the relevant aspects of subject area are selected and built in only. Models become an important tool for the IM, because they help overwhelm the complexity of HIS.

A metamodel can be considered as a toolbox for building models. With general metamodels like ARIS (www.ids-scheer.com/international/english/products/53961), one can describe processes independent of the business field. The three-layer graph-based metamodel (3LGM²) is a specialized tool for static HIS modeling. The domain layer consists of functions and entity types. The logical tool layer focuses on application components, and the physical tool layer describes physical data processing components. Additionally several inter-layer-relationships are defined (Winter, Brigl, & Wendt, 2003). The 3LGM² allows building of models of HIS presenting their current state with adequate levels of granularity. So one can find out, for example, which functions are supported by which application systems, or the kind and scope of communication processes between different applications. In this manner, deficiencies may be detected, too, for example, gaps in information transfer. Additionally the 3LGM² allows to integrate indicator systems and to compute indicators along the relations between the model objects (Kutscha, Brigl, & Winter, 2006).

A *reference model* is a template for a well-defined class of models, that is, from a reference model concrete models are derived by modification, restraints, or additions (Haux et al., 2004, p. 73). Furthermore one can check by comparison, whether concrete models have the same features as the reference model, for example, completeness of functions. Therefore the use of a reference model can deliver relevant indicators. Depending on subject area, there are reference models for organizations, information systems, software, or procedures.

Reference models support the quality assessment better than models. They function like standards, that is, if the quality of reference model is proved, the quality of a concrete model may be made evident by comparison using quality indicators. The reference model itself should be evaluated also to provide that the model is a sufficient map of reality.

For the monitoring of HIS, one needs reference models for information systems to find out whether the business processes are supported by efficient tools, or the necessary information flows are established (Winter et al., 1999). But also reference models for procedures are useful (see examples provided).

Evaluation

Evaluation is the act of measuring or exploring properties of a health care information system (in planning, development, implementation, or operation), the result of which informs a decision to be made concerning that system in a specific context (Ammenwerth, Brender, Nykanen, Prokosch, Rigby, & Talmon, 2004). With the information acquired by evaluation, one can learn something, answer relevant questions, or make decisions. In this manner the screening mentioned above can be regarded as a "simple" evaluation. Evaluation of health care systems is a main topic of research in medical informatics (Brender, 2006; Friedman & Wyatt, 1997). Therefore, here some methodical principles are outlined only.

There is a wide spectrum of evaluation methods. It reaches from simple surveys to exactly planned longitudinal investigations. Some studies are performed like clinical trials. It means that one should try to apply principles of Good Clinical Practice (http://www.ich.org/LOB/media/MEDIA482.pdf). But often some techniques are not applicable (e.g., randomizing or blinding). Nevertheless reliable studies can be performed, if some recommendations are taken into account (Ammenwerth, Graeber, Herrmann, Buerkle, & Koenig, 2003). All decisions and steps should be documented in a detailed study protocol. An adequate study design and appropriate methods to answer the study questions have to be selected. The combination of quantitative and qualitative methods may be helpful. Wherever possible, validated evaluation instruments should be used. Often a multi-methodic and/or multidisciplinary approach is necessary (Ammenwerth et al., 2003).

Evaluation studies can be formative or summative. Formative evaluation strives to improve the HIS component under evaluation by providing the developers (and implementers) with feedback. Summative evaluation tries to demonstrate the outcome of a "mature" HIS component in routine (Friedman & Wyatt, 1997, p. 304).

Organization of IM

Organizational structures for IM differ considerably among health care institutions. In general, each institution should have an adequate organization for strategic, tactical, and operational IM, depending on its size, internal structure, and needs. Reference models for the organization of IM in hospitals are given in Haux et al. (2004, p. 187ff).

The relation between IM and IT controlling may be formed very differently. Between the two "poles" (IT controlling totally embedded without own directives vs. IT controlling as specific organizational unit beside IM) several structures are possible.

Next to organization the performance of IM plays an important role. For example, the performance level of IM can be assessed by the Capability Maturity Model (www.sei.cmu.edu/cmmi/). The IM should have a high maturity level, that is, it should function as *business enabler* for the hospital.

EXAMPLES

Table 1 shows perspectives (without financial perspective) and corresponding objectives from a BSC established at a German university hospital. The main perspectives of BSC were modified slightly. A part of the indicator tree for the subperspective *information management* and the appropriate objective *efficient support of processes by IT* is presented in Table 2. The indicator tree defines the indicators and their dependencies, which have to be measured for a perspective. Overall this BSC contains 11 composite performance indicators reflecting particular strategic objectives. These measures are expressed in terms of actual performance as percentage of expected performance. For further examples of BSC application, see Kaplan and Norton (2000).

Ammenwerth et al. (2007) developed a so-called HIS-monitor to describe the strengths and weaknesses of information processing at hospitals. This monitor is a matrix whose rows represent several quality indicators while the columns define the necessary processes and subprocesses of patient care. The matrix is filled out during standardized interviews with hospital staff. Thus, one can reveal the processes that are not sufficiently supported by IT.

ITIL is an example for a reference model for procedures. It defines the necessary management tasks at tactical level (service delivery, Figure 1) and operational level (service support, Figure 2). The advantage of ITIL for the alignment of IT with business objectives is reported (Kashanchi & Toland, 2006).

An example of a reference model for a hospital information system is the requirements index for information processing in hospitals (Ammenwerth, Buchauer, & Haux, 2002). German experts established the index in a consensus-based, top-down, and cyclic manner. Each functional requirement was derived from information processing functions and subfunctions of a hospital. It contains 233 functional requirements and 102 function-independent requirements. The functional requirements are structured according to the primary

Only three examples of evaluation studies are mentioned here, two of those were conducted and published by the first author. A method for the selection of software for a subsystem of HIS is described in Graeber (2001). An investigation of user satisfaction with clinical workstations was published in Graeber (1997). Machan, Ammenwerth, and Schabetsberger (2006) published the rather comprehensive and understandable description of an evaluation project to assess the electronic transmission of medical findings. Evaluation projects of the last 20 years can be found in the Web-based inventory of evaluation studies in medical informatics (evaldb.umit.at). The database can be searched with keywords. Many entries may be used as patterns for successful evaluation studies in fields of HIS.

Problems and Challenges

Often an insufficient organization of IM is the main obstacle for an effective HIS monitoring. This problem includes the lack of highly qualified staff for ambitious management tasks. Sometimes the objectives of IM are not adequate defined or they are not consequently derived from the enterprise goals (Brigl et al., 2005). Also a general deficiency of awareness of the importance of monitoring and controlling as well as insufficient consideration of the needs of customers and users can inhibit the establishment of an IM resp. ITSM structure at health care institutions.

A further problem is the development from *hospital* information system to *health care* information system. A modern HIS encompasses many different health care organizations and institutions with different IT infrastructures. This complexity makes a comprehensive and effective IM very difficult.

Although the successful use of BSC in health care sector is described (Stewart & Bestor, 2000; Protti, 2002), its application for HIS monitoring yields some new aspects. Especially the following success factors have to be considered:

- The method must be strongly supported by the enterprise management.
- The application of BSC requires a lean management. Otherwise a schism may occur between the management and the need to get detailed understanding of work processes and motivation from staff (Brender, 2006, p. 86).
- An early and continuous communication with employees about the purpose and results of BSC is needed.
- All involved people must have an open mind for definition of perspectives, objectives, indicators, and measures as well for the interpretation of results.
- One should prefer less but significant indicators.
- IT-support of BSC is not compulsory, but helpful. One should strive for the integration of BSC in a data warehouse system.
- The BSC has to be evaluated periodically.

Although the effort for the development of BSC can be considerable, its use for monitoring is very functional. It helps to translate the vision of a health care institution and to gain consensus, to communicate the objectives, to link goals with strategy, to allocate resources, and to provide feedback and ensure learning. It is an efficient way to link day-to-day operating activities to the strategic objectives.

A suitable model of HIS is an important prerequisite for an efficient IM. With the 3LGM² not only technical and semantic aspects but also computer-based and paper-based information processing are integrated in the model. Deficiencies in the current state of HIS can be detected and hence the quality of information processing can be assessed. Such a model can be the basis of the strategic information management plan (Brigl et al., 2005) as well as of economic analyzes (Kutscha et al., 2006). A disadvantage of 3LGM² is the static view. For modeling of dynamic aspects a business process metamodel (e.g., ARIS at www.ids-scheer.com/international/english/products/53961) has to be used.

Contrarily to other branches, reference models for the information management in health care are seldom. A cause may be that most models are too specific and not suited as reference. These restrictions concern the BSC too. Therefore the development of valid reference models for HIS is a major challenge.

Rapid changes in technology (e.g., telehealth) and increasing complexity of HIS cause also new conditions for evaluation projects, for example.

- Studies must be carried out in different types and size sites, with different HIS components and different groups of users.
- People, organizational, social, and ethical issues must be taken into account.
- Evaluation aspects must be incorporated into all phases of a project.
- Importance and effect of formative evaluations are increasing.

Problems and challenges of evaluation projects in medical informatics are discussed detailed in Kaplan and Shaw (2004).

KEY TERMS

Balanced Scorecard: The balanced scorecard (BSC) is a *management* tool that enables organizations to clarify their vision and strategy and translate them into action. Using BSC, the manager may establish a "balanced" situation between the traditional financial measures and other success factors of an organization. The BSC combines the continuous measurement of performance with a reviewing and refinement strategy as well an ongoing evaluation process. The basic terms are so-called perspectives, for example, potentials (learning and growth), internal processes, customers, and financial perspective. For each perspective, strategic objectives, indicators, and measures to achieve these objectives must be defined.

Evaluation: Evaluation is the act of measuring or exploring properties of HIS (in planning, development, implementation, or operation), the result of which informs a decision to be made concerning that system in a specific context. Contrarily to continuous data collection, evaluation studies are carried out to answer special questions, usually in form of a project with a clear time limit. When possible, for such studies the same criteria and methods as for clinical trials should be applied.

Indicators and Characteristic Values: Indicators are variables whose values (characteristics values) represent an aspect of HIS. To discern good and bad quality of information processing and to assess the achievement of goals, one has to compare the current value of indicator with one or more predefined reference values.

IT Controlling: In this context, the term controlling (or more precisely IT controlling) is restricted to the tasks of information acquisition and data collection as basis for decisions of IM. For this purpose IT controlling applies different approaches and methods, for example, the continuous measuring and interpretation of indicators and characteristic values explaining the current state of HIS, or the realization of evaluation studies.

IT Service Management: Beside the internal business processes, the focus of monitoring should be the external outcome, as well. To provide an excellent service for all users of HIS and at last to reach a maximum of customer (patient) satisfaction, nowadays the appropriate management tasks are embraced by the term IT service management (ITSM). There are several frameworks describing an architecture for installing and maintaining ITSM. The most known framework is the IT infrastructure library (ITIL), which defines the necessary management processes at tactical level (service delivery) and operational level (service support).

Monitoring: Monitoring of HIS means the observation as to whether the directives and objectives defined in the strategic information management plan will be achieved, and whether the HIS is able to fulfill the required tasks. Therefore the IM must be able at any time to assess the state of the HIS using quality criteria which can be derived from the objectives. The tasks of monitoring may be linked to strategic level (monitoring of the achievement of strategic information management plan), tactical level (monitoring of projects), and operational level (operational monitoring, that is, verifying proper working and effectiveness of all HIS components).

Reference Model: A reference model presents a kind of model patterns for a certain class of aspects. It can be used to derive a specific model or for purpose of comparison. Comparing a specific model of HIS (or subsystem) with a reference model congruencies and differences may be stated and used for planning and direction of HIS.

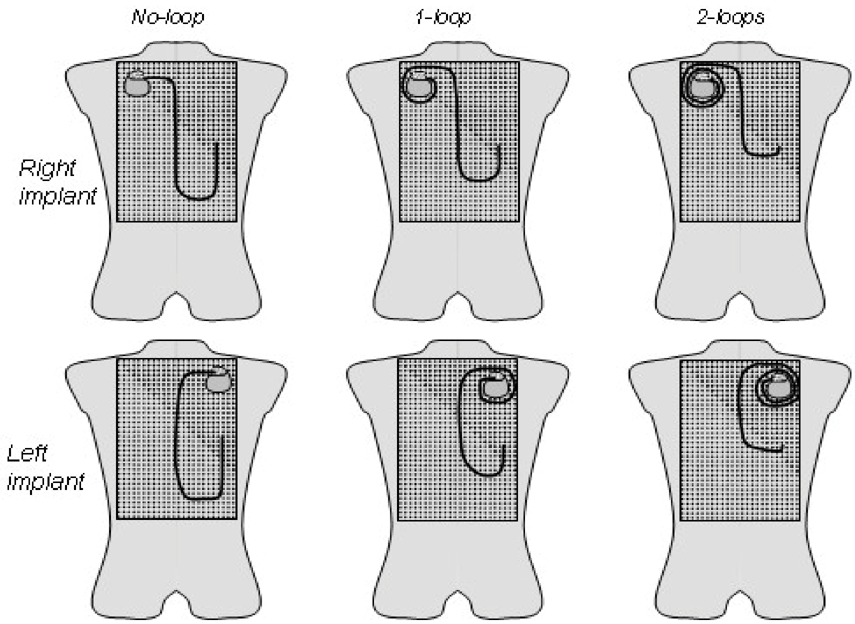
INTRODUCTION

Magnetic resonance imaging (MRI) is a widely accepted tool for the diagnosis of a variety of disease states. The presence of a metallic implant, such as a cardiac pacemaker (PM), or the use of conductive structures in interventional therapy, such as guide wires or catheters, are currently considered a strong contraindication to MRI (Kanal, Borgstede, Barkovich, Bell, Bradley, Etheridge, Felmlee, Froelich, Hayden, Kaminski, Lester, Scoumis, Zaremba, & Zinninger, 2002; Niehaus & Tebbenjohanns, 2001; Shellock & Crues, 2002). Potential effects of MRI on PMs' implantable cardioverter defibrillator (ICDs) include: force and torque effects on the PM (Luechinger, Duru, Scheidegger, Boesiger, & Candinas, 2001; Shellock, Tkach, Ruggieri, & Masaryk, 2003); undefined reed-switch state within the static magnetic field (Luechinger, Duru, Zeijlemaker, Scheidegger, Boesiger, & Candinas, 2002); potential risk of heart stimulation and inappropriate pacing (Erlebacher, Cahill, Pannizzo, & Knowles, 1986; Hayes, Holmes, & Gray, 1987); and heating effects at the lead tip (Achenbach, Moshage, Diem, Bieberle, Schibgilla, & Bachmann, 1997; Luechinger, Zeijlemaker, Pedersen, Mortensen, Falk, Duru, Candinas, & Boesiger, 2005; Sommer, Vahlhaus, Lauck, von Smekal, Reinke, Hofer, Block, Traber, Schneider, Gieseke, Jung, & Schild, 2000). In particular, most of the publications dealing with novel MRI techniques on patients with implanted linear conductive structures (Atalar, Kraitchman, Carkhuff, Lesho, Ocali, Solaiyappan, Guttman, & Charles, 1998; Baker, Tkach, Nyenhuis, Phillips, Shellock, Gonzalez-Martinez, & Rezai, 2004; Nitz, Oppelt, Renz, Manke, Lenhart, & Link, 2001) point out that the presence of these structures may produce an increase in power deposition around the wire or the catheter. Unfortunately, this increased local specific absorption rate (SAR) is potentially harmful to the patient, due to an excessive temperature increase which can bring living tissues to necrosis. The most direct way to get a measure of the SAR deposition along the wire is by using a temperature probe: the use of fluoroptic® thermometry to measure temperature has become "state-of-the-art," and is the industry standard in this field (Shellock, 1992; Wickersheim et al., 1987). When the investigation involves small objects and large spatial temperature gradients, the measurement of the temperature increase and of the local SAR may become inaccurate, unless several precautions are taken. It seems obvious to: (1) evaluate the error associated with temperature increase and SAR measurements; (2) define a standard protocol for probe positioning, which minimizes the error associated with temperature measurement.

Figure 1. Sketches of the six implant configurations tested in a commercial MRI using the human-shaped phantom; no-loop, one-loop, and two-loop for both right and left pectoral implants



BACKGROUND

In most publications dealing with heating of conductive structures during MRI, the reported temperature increase is significantly different, even in cases where the experimental set-up is apparently similar. For example, Achenbach et al. (1997) reported a temperature increase of 63.1°C for a PM lead; Rezai, Finelli, Nyenhuis, Hrdlicka, Tkach, Sharan, Rugieri, Stypulkowski, and Shellock (2002) observed 25.3°C at the end of a deep brain stimulation electrode; Roguin, Zviman, Meininger, Rodrigues, Dickfeld, Bluemke, Lardo, Berger, Calkins, and Halperin (2004) reported a maximum increase of 5.7°C at 3.54 W/Kg whole body specific absorption rate (WB-SAR). Sommer et al. (2000), with a WB-SAR of 1.3 W/Kg, obtained temperature increases ranging from 0.1 to 23.5°C, depending on the electrode type. Several factors influence the degree of heating: (1) the WB-SAR has been shown to correlate to the temperature increase; (2) the cooling effect of the blood around the leads is generally not quantified; (3) the length and the geometric structure of the lead; and (4) the implant location.

In addition, since thin linear structures such as PM leads may generate temperature gradients which cannot be neglected, with respect to the physical dimension of temperature probes, also the relative positioning of the temperature probe to the lead tip significantly affects the measurement, and partially explains the inconsistency of the results in literature.

The aim of this article is first to identify the optimal positioning of fluoroptic® probes to measure the maximum heating of the tip of a PM lead. Then, we use these results to perform measurements in a real MRI system, in order to investigate the effect of the placement of the PM, and of the lead geometry.

MEASUREMENT OF TEMPERATURE AND SAR

We used two experimental setups: first, we performed temperature measurements on a PM lead tip inside a rectangular box phantom, using different types of contact positions between the probe and the lead tip. Second, we used a human-shaped phantom with a PM, and its leads exposed to a commercial MRI scanner.

PROBE POSITIONING

A PVC box (28 × 20 × 26 cm) was filled with a gelled saline (gel) solution. A grid was submerged in the phantom gel to support the implant and maintain consistent separation distances between the implant, phantom material surface, and temperature probes. The phantom material gel is composed of the following materials in percentages by weight: 2% hydroxy-ethyl-cellulose (*HEC*), 0.36% sodium chloride, and the rest, water. The gel has a conductivity of 0.59 Sm^{-1}, a permittivity of 79 at 64 MHz, and a heat capacity of 4178.3 J $Kg^{-1}K^{-1}$ (ASTM, 2004). SAR and temperature measurements were performed on the tip of a 62 cm-long monopolar lead (S80TM, *Sorin Biomedica CRM*, Italy). A radiofrequency (RF) signal was injected into the lead tip through a coaxial cable, connected to the lead. The outer conductor (signal ground) was connected to a 1x20x10 mm silver plate located on one side of the PVC box, so that the current flows in the gel from the lead tip to the plate. The lead was arranged in the phantom material 5 cm below the gel surface, simulating an implant in the human body. The distance between the silver plate and the lead tip was set at 7 cm. The temperature measurements were performed using a fluoroptic® thermometer (*Luxtron*, Model 3100, USA), with resolution of 0.1°C, operating at eight samples per second. Three sinusoidal excitations were applied: 25, 64, and 128 MHz, which nearly correspond to the RF field used in 0.5, 1.5, 3 T static field MRI systems. Signals were generated by a RF generator (*Rhode & Schwartz*—SMT 06), and then amplified (*RFPA*—RF 06100-6, France); a power meter (*Rhode & Schwartz NRT*—Z14) was connected to the output of the amplifier, in order to measure the average power and the reflection coefficient. Four configurations were studied (Figure 2):

- Transversal contact between the side of the probe and the circular surface of the lead tip (Figure 2, reference contact);
- Transversal contact between the tip of the probe and the side surface of the electrode (tip-to-side);
- Axial contact between the tip of the probe and the circular surface of the lead tip (tip-to-tip);
- Axial contact between the tip of the probe and the side surface of the electrode (side-to-side).

The effect of the position of the probes on the temperature measurements was expressed as the percentage error, in respect to the configuration giving the maximum temperature increase:

$$\Delta T\ \%\ error = \frac{\Delta T_{probe} - \Delta T_{max}}{\Delta T_{max}} \cdot 100 \qquad (1)$$

where ΔT_{probe} is the temperature increase measured by the probes in different configurations, and T_{max} the maximum of these values.

Local SAR was estimated as the slope (*dT/dt*) of the line that best fits the initial temperature increase. This estimation was assumed valid when the Pearson coefficient r^2 was greater than 0.98 (IEEE, 1991). The underestimation in SAR measurement, due to the different contact configurations as expressed in terms of percentage error, in respect to the maximum value of SAR:

$$SAR\ \%\ error = \frac{SAR_{probe} - SAR_{max}}{SAR_{max}} \cdot 100 \qquad (2)$$

where SAR_{probe} is the SAR measured by the probes in different configurations, and SAR_{max} the maximum of these values.

Our experiments showed how the position of the temperature probe significantly affects the SAR measure: transversal contact between the side of the temperature probe and the circular surface of the lead tip (Figure 2, reference contact) is the configuration which leads to the highest measured temperature. We define the temperature measured with other positions than the one leading to the maximum value as an underestimation (1). The highest temperature underestimation was obtained at 25 MHz, and it decreases as the frequency increases, regardless of the temperature probe contact. The configurations "tip-to-side" and "tip-to-tip" resulted in a temperature underestimation ranging from 28% to 39%. The underestimation associated with the side-to-side contact was significantly lower (4%–7%). These differences can be explained by the position of the temperature active element within the probe tip. Different temperature probe placement configurations result in different orientations of the temperature active element in relation to the PM lead tip. Therefore, the temperature active element can be exposed to different temperatures, especially in areas with high spatial temperature gradients.

The underestimation associated with the estimation of local SAR at the lead tip showed a similar behavior: transversal contact between the side of the temperature probe and the circular surface of the lead tip (Figure 2, reference contact) is the configuration measuring the highest SAR (1444 W/Kg). The underestimation associated with other temperature probe configurations is reported in Figure 2, upper panel. In the worst case, the SAR underestimation can be up to 75%. The effect of the frequency on SAR underestimation was similar to that observed for the temperature.

HUMAN-SHAPED PHANTOM

Experiments in real MRI scanning system were performed using a human-shaped torso simulator made at the Department of Technology and Health of the National Institute of Health in Rome. The simulator consists of a torso-shaped transparent PVC phantom of the size of a 70 kg male. Internal volume of the torso is 32 litre (ASTM, 2004). A PVC grid is mounted inside the torso to support the PM, the PM lead, and the temperature probes. The torso was filled with the same gel as described above.

The actual lead geometry and PM placement can vary from patient to patient. The PM can be located in the left or right pectoral region. Since the length of the lead may not fit the patient's anatomy and size, the exceeded length is usually wrapped near or around the PM. In the experiments on the human-shaped torso simulator, the geometry of the implant reproduced left and right PM placements. For each implant, three lead paths have been tested (Figure 1): without lead loop around the PM (no-loop configuration), and with the lead forming one or two loops around the PM (one-loop

Figure 2. SAR and temperature underestimation: Comparison among measurements made by a temperature probe in transversal contact with the PM lead tip (reference contact) and underestimation obtained with other contact configurations ("tip-to-side," "tip-to-tip," "side-to-side")

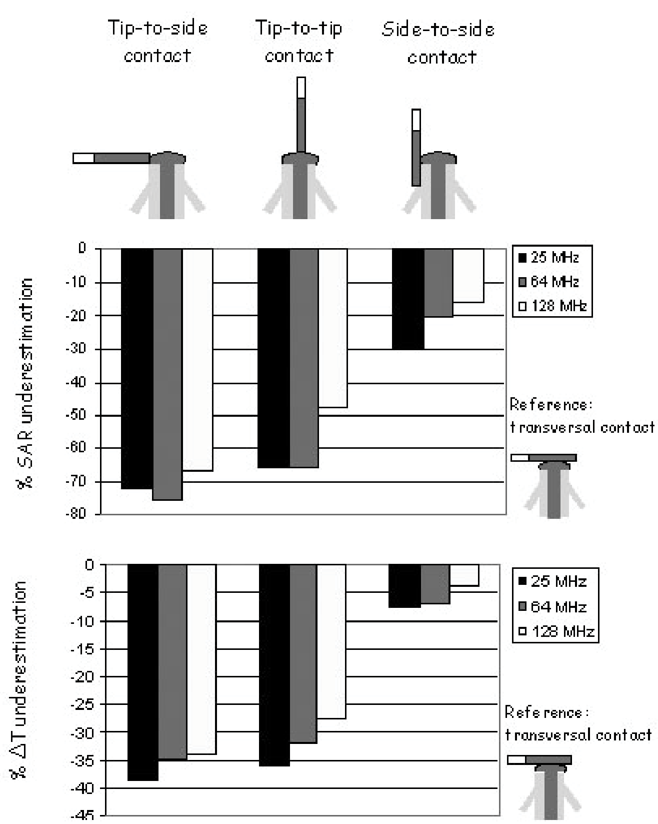


Table 1. Main parameters of the MRI clinical sequences used during the human-shaped phantom experiments

Siemens sequence name	Sequence type	TR (ms)	TE (ms)	Flip Angle	Length (s)

configuration and two-loop configuration, respectively). For each lead path, the length and the position of the linear section of the lead, as well as the lead tip position, were kept constant. Only the PM was moved from the left to the right pectoral location. Experiments were performed on a 1.5 T (static field) *Magnetom Sonata Maestro Class* scanner (*Siemens*, Germany). The main parameters of the sequences used are summarized in Table 1. The MRI parameters (TR, TE, and Flip Angle) were adjusted to reach a WB-SAR of 2 W/Kg, estimated by the scanner. The temperature increase and local SAR values for the experiments using a real MRI scanner are reported in Table 2. As for the clinical sequences, the gradient echo did not induce detectable temperature increase in all the configurations tested. Sequences with relatively high whole body SAR, led to a temperature

increase up to 12.3 °C. For left pectoral PMs, the lead area appears to be the major factor relevant for the heating. A high implant area (no loop) showed always a higher temperature increase than the one-loop and two-loop configurations.

Surprisingly, in right pectoral implants, the lead path seems to play the major role: no-loop configurations showed always a temperature increases significantly greater than the one- and two-loop configurations. In addition, the temperature increases observed were greater than those of the left implants. In both configurations (left and right), the temperature increase and local SAR were proportional to the whole body SAR reported by the scanner.

The comparison between short and long sequences showed that the major temperature increase occurred within the first minute. Experiments were repeated, changing MRI parameters such as the centre of view (chest, abdomen, and pelvis), and the field of view (200, 300, and 400 mm), without significant changes in the heating.

FUTURE INVESTIGATIONS

Our experimental measures showed the large number of variables which may be involved in the amount of heat generation and measurement of temperature increase. There are still some elements, such as the cooling effect of the blood around the leads, or the evaluation of the temperature and SAR errors yielded by other temperature probe types (e.g., surface and remote style probes), that need further investigations.

Moreover, this study investigated only the in-vitro heating of MRI on pacing leads. Other potential risks of MRI in PM recipients, such as fast pacing, inhibition of stimulation, or direct stimulation of the heart caused by the RF or gradient fields need further evaluation.

Owing to the large number of factors that influence the degree of heating, and that make it difficult to perform extensive and exhaustive experimental measures, the development of numerical models may represent a very useful approach to investigate the potential effects of MRI on PMs, ICDs, and other active implantable medical devices.

CONCLUSION

Fluoroptic® thermometry has become the most popular method to measure heating of metallic objects, due to MRI RF exposure, although some methodological issues have found limited attention so far. Among them, the positioning of the probes, as well as the estimation of the error in temperature and SAR measure, need to be investigated and standardized. Thin linear structures such as PM leads may generate temperature gradients which cannot be neglected, with respect to the physical dimension of the probes. As a consequence, specific methods and protocols are required to obtain accurate estimations of the maximum temperature and SAR in the region surrounding the lead tip.

Using temperature measurements on a physical model of a PM lead, we found that the positioning of temperature probes strongly affects temperature and SAR results. Due to the comparable dimension of the temperature probes with the PM lead tip, and due to the large spatial temperature gradient around the lead tip, temperature probes tend systematically to underestimate the real value of local temperature and SAR. In particular, using the SMM Luxtron fluoroptic® probes, we found that a transversal contact of the temperature probe with the lead tip always gives the highest temperature and SAR values. Using this configuration as reference, the underestimation yielded by other configurations may be as high as 39% for temperature, and 75% for SAR. Furthermore, we found less underestimation as the frequency increases. A deeper investigation of this issue was beyond the aim of this article.

The different contact configurations between fluoroptic® probes and the lead tip may explain, at least partially, the large variability of previous studies (Achenbach et al.,1997; Rezai et al., 2002; Roguin et al., 2004; Sommer et al., 2000).

Temperature and SAR measurements on the human-shaped phantom showed how the lead geometry affects significantly the amount of induced heating. In most cases, PMs are implanted in the left pectoral region. In this case, in the implant area (i.e. the area formed by the lead), the PM can, and a straight line connecting the PM tip to the PM can, plays a significant role on the lead tip heating. Implants with relatively large lead area (250-300 cm^2) exposed to a SAR of about 2 W/kg may experience temperature increase at the lead tip up to 12°C, and local SAR up to 3000 W/kg. Right pectoral implanted PMs cover smaller areas than left pectoral ones, but the temperature increases observed were higher, suggesting that the coupling to the electric field may also contribute to the heating. To explain such behaviour, resonance phenomena in various kinds of linear metallic leads and wires has been hypothesized by various groups (Duru, Luechinger, Scheidegger, Luscher, Boesiger, & Candinas, 2001; Nitz et al., 2001).

KEY TERMS

Fluoroptic® Thermometry: A trademark patented by Luxtron's researchers in the 1970s; the fluoroptic® thermometry determines the temperature of the sensor by measuring the decay time of the emitted light. It is a persistent property of the sensor that its decay time varies precisely with temperature.

Implantable Cardioverter Defibrillator (ICD): A device that is implanted under the skin of patients that are at risk of sudden cardiac death, due to ventricular fibrillation. The rudiments of cardiac arrhythmia detection and treatment are incorporated into the implantable device. The device was designed primarily to deal with ventricular fibrillation. Its current use has, however, extended to include atrial and ventricular arrhythmias, as well as the ability to perform biventricular pacing in patients with congestive heart failure, and to pace, should there be any marked bradycardia.

Magnetic Resonance Imaging (MRI): An imaging technique based on the principles of nuclear magnetic resonance.

Pacemaker (PM): A medical device designed to regulate the beating of the heart. The purpose of an artificial pacemaker is to stimulate the heart when either the heart's native pacemaker is not fast enough, or if there are blocks in the heart's electrical conduction system preventing the propagation of electrical impulses from the native pacemaker to the lower chambers of the heart, the ventricles.

RF Field: Electromagnetic field generated during MRI procedures. RF is absorbed and re-transmitted by hydrogen nuclei. Re-emitted energy is used to obtain the image. RF field is measured as Vm^{-1}. The RF frequency is related to the static field; in most commercial systems (1.5 T), the frequency is 64 MHz.

Specific Absorption Rate (SAR): A measure of the rate at which radio frequency energy is absorbed by the body when exposed to radio frequency electromagnetic field.

Static Field: Strong static magnetic field used in MRI systems to align the magnetization vector of the hydrogen nuclei. It is measured as Tesla (T). In most commercial MRI system, the static field is 1.5 T.

Multi-Dimensional Modeling in the Health Industry

INTRODUCTION

Today's information-rich and knowledge-based business society relies heavily on information technology (IT) and information systems (IS) design to enable the business to operate effectively and create a competitive advantage. Firms must align their IS design and performance with the core business competencies and business goals of the firm. There are multiple paths toward this end, and inefficiencies and conflicts may arise when the firm's IS strategies diverge from the business goals. There is no difference in the health industry, where conflicts exist between IS infrastructure and development, and business goals. The existence of inflexible mainframe IS unable to support modern technology such as the Internet, telemedicine, wireless technology, and real-time management software has compromised the business goals and business development in the health vertical to the extent that it has now fallen behind other comparable knowledge industries.

Where reference is made to more cohesiveness among IS capability, independence of the IS department, and the alignment of business goals, there is no mechanism or detail given on how this is achieved. Grover and Segars (2005) claim that while there have been studies that examine the "what" questions in strategic information system planning (SISP), particularly concerning the issue of IS business alignment, there has been little on the "how" questions.

A multidimensional cohesive model for IS planning and measurement of IS effectiveness has been developed as a means to more integrated planning and a simpler but more realistic means of assessing the effectiveness of the IS in business. The multidimensional cohesive model is applied to the selection and implementation of an information system in the health industry. The implications this has on the health industry include the opportunity to change to a more efficient business structure, a means to implement a modern technology- (Web-) based IS and an inherent capacity for change management.

BACKGROUND

Strategic information system planning (SISP) has evolved in method and style over the last decade on the basis that it is important because it emphasizes the need to bring information technology (IT) to align with and sometimes influence the strategic direction of the firm (Grover & Segars, 2005). In rich IT environments, this has a recognized relevance to competitiveness. However, although much has been studied with respect to business and IT alignment, little research has been undertaken into the mechanisms of SISP, including process planning.

Grover and Segars (2005) examined the evolution and maturing of SISP from the early 1970s and made several important observations. These were later supported by other researchers such as Earl (1993) and Sabherwal and King (1995). They found that many studies focused on planning content, with particular interest in methods and measurement of alignment between business and IS strategy (Burn & Szeto, 2000; King, 1998). They observed that these studies did little to illuminate the organizational aspects of planning.

Early studies by Pyburn (1983), in an attempt to identify institutionalized planning dimensions, actions, and behaviors, made field observations that noted the existence of both a *rational/structured* process and a *personal-informal* process. Earl (1993) made similar observations when he distinguished SISP approaches based on the degree of rationality and adaptability built into the planning process. Earl (1993), however, noted a hybrid organizational system of planning that seemed to be more effective than the highly structured and less adaptable rational approaches. This observation was ratified by the work of Sabherwal and King (1995).

More recent studies by Segars (1997) and Segars and Grover (1998) described and measured planning process dimensions and found that hybrid systems tended to be more successful and seemed to apply generally to a variety of industries. Through their research, Grover and Segars (2005) identified six important process dimensions of SISP: comprehensiveness, formalization, focus, flow, participation, and consistency. These dimensions are robust in describing the SISP design and extend beyond the methodological-based and less-generalizable descriptions of planning.

Wang and Tai (2003) add to the dimensions for success in SISP with their work on organizational contexts, commenting that most process-oriented research has recommended using integration and implementation mechanisms while not considering the possible contingent effect of contextual factors. They suggest that this may lead to the planning system being less adaptable to various organizational contexts and therefore be overly deterministic.

Wang and Tai (2003) acknowledge that although their work is generally supported by empirical data, a theory of IS planning is currently lacking. Their results did, however, support the contention that IS planning is a rational-adaptive process, supporting the claims of Earl (1993) and Grover and Segars (2005).

The link between strategic performance and planning has been found to be inconsistent by Grover and Segars (2005) and Premkumar and King (1992). Some indicators suggested for assessment of IS effectiveness have been IS usage, user information satisfaction (UIS), quality of decision-making, productivity from cost/benefit analysis, and system quality (Ein-Dor and Segev, 1978). The most commonly favored factors have been IS use and UIS. However, because of a lack of a theoretical framework for placing UIS within the greater context of overall IS effectiveness, its relevance as a performance measurement has been questioned (Grover & Segars, 2005).

Grover and Segars (2005) argue that successful SISP should achieve alignment between IS and business strategy; analyze and understand the business and associated technologies, foster cooperation and partnership between managers and user groups, anticipate relevant events/issues within the competitive environment, and adapt to unexpected organizational and environmental change. This multidimensional conceptualization approach is supported by Delone and McLean (1992).

However, further research is needed in order to define the construct space for effectiveness criteria. Delone and McLean (1992, 2003) have initiated research to this end with their IS Success model. Their model consists of six interdependent constructs, including system quality, information quality, use, user satisfaction, individual impact, and organizational impact (Delone & McLean, 1998). The measure of overall success should combine individual measures from these constructs to create a comprehensive scheme for performance.

Grover and Segars (2005) have developed a theoretically based construct space for IS effectiveness that complements the IS Success of Delone and McLean (1992). Their construct model provides a means of cross-validating the IS Success model and introduces a relative standard used for assessing performance.

To build a complete picture of IS effectiveness, evaluation must be conducted from both a macro (organizational) and micro (individual) view. Such evaluation is necessary because IS supports individual as well as organizational decision-making and can also provide competitive advantage.

From the organizational effectiveness literature, Brewer (1983) argues that there are three types of evaluation: process, response, and impact. Process evaluation involves the assumption that organizational members work to ensure efficient use of resources when resources are limited. This assessment is based on user dependence on IS, user perceptions of system ownership, and the extent to which IS is disseminated throughout organizational administration and operating procedure.

Response evaluation assesses the individual or the organization to the IS service or product. This assessment has significance in respect to user resistance to innovation and implementation. Any resistance or habitualization must be identified to ensure successful implementation. This assessment also considers complex variables such as user's beliefs and attitudes toward IS in general, which are important for fulfilment of IS planning (Grover & Segars, 2005).

Impact evaluation represents the most comprehensive and most difficult to assess evaluation. It is associated with the direct effects of IS implementation on the individual and/or the organization.

Grover and Segars (2005) model produces six classes of IS effectiveness measurement that define the overall construct space for IS effectiveness. As shown in Figure 1, the evaluation of IS is initiated by choice of the relevant evaluative referent. The first three classes of effectiveness measures are associated with macro (organizational) evaluation.

From their empirical work developing this model, Grover and Segars (2005) state, "It seems that both theoretical depictions strongly imply that IS effectiveness is multidimentional in terms of types of measures and level of analysis" (782). This supports their earlier stated contention and supports the argument by other authors (Earl 1993; Pyburn 1983; Sullivan 1985).

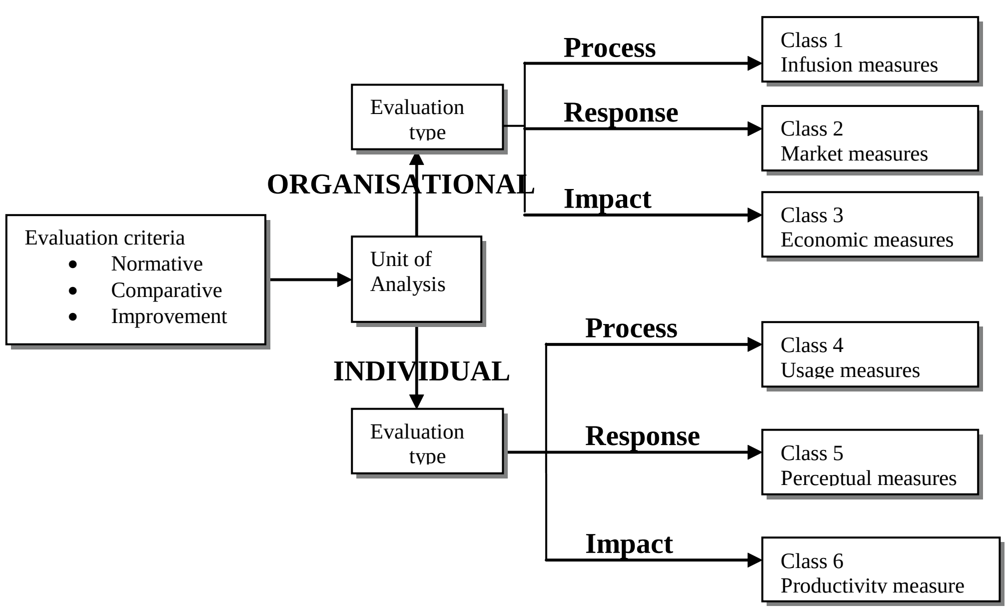
Further research by Grover and Segars (2005) on evaluation perspective raises questions asking from whose perspective the evaluation is being carried out. Although IS may be viewed as effective from one standpoint, it may be viewed as the opposite from another. Cameron and Whetten (1983) suggest that one reason no "best" criterion exists is because there is no "best" constituency. As such, Grover and Grover (2005) state that for the evaluation of IS effectiveness, the specific views of all groups should be considered because they help to increase awareness of the value of the IS and help the understanding of the multidimensionality of IS effectiveness.

MAIN FOCUS

The literature on the approach to measurement of IS effectiveness shows a great variation in the measurement techniques and the possibility of inefficiencies in the deployment of effectiveness measures through personal agendas or bias in the management team. Several authors exploring SISP, such as Pyburn (1983), Earl (1993), and Sabhewal and King (1995), agree that the planning process is most successful when rational and adaptive pathways are used in the design process. However, there is no mechanism suggested for possible pathways for this to happen. It is believed that there are several other shortcomings in the planning models presented in business: IT misalignment, no consideration for team member selection in either top-down or bottom-up situations, no consideration as to how people communicate to make plans (i.e., knowledge management/extraction and organizational learning), clear definition of business goals by thorough business analysis involving stakeholders from management to end-users required, and ensuring that the current IS hardware/software has the capability to handle the planned IS changes.

The literature cited on effectiveness measure is in a more confused state with so many criteria for measurement quoted. These criteria are clearly unidimensional and seem to be dissociated from what SISP is attempting

Figure 1. The construct space for IS effectiveness (Grover & Segars, 2005)



to achieve; that is, the original stated business goal(s) conjoined with the IS pathway during the SISP. The models presented by Grover and Segars (2005) and Wang and Tai (2003) are in themselves a demonstration of inadequacy. The arrows in Figure 1 representing direction and pathways are represented as being unidirectional. This implies that the models have a start and a finish. They are static, single event models. They would therefore be inconsistent with ongoing support and fine-tuning of SISP and maintenance of any competitive advantage gained with first implementation. Therefore, an alternative model is proposed based on a case study in medical pathology in Australia.

The case study is presented at two levels: the overall pathology practice and a specific pathology department. In the overall pathology practice, there was a merger of two pathology practices, one large and one medium into one practice. The workload for staff doubled overnight. The IT system of the larger practice was retained as the new group's IT platform. This was in theory totally inadequate and was proven to be so in practice in a short period of time post-merger. No business analysis premerger was performed to assess the existing system's capability to cope with double the workload. The IT platform consisted of an older mainframe computer that ran in-house developed software. The software was written in a totally unsuitable language for scientific applications (COBOL), and the storage capacity of the system was such that records could only be held on the system for one month before having to be transferred to Microfiche. The system was, in fact, solely a database and had no laboratory functionality to capitalize on the technology capability of the practice's analysers (applications that assist with quality control data and graphs, diagnostic graphics, work lists, and management statistics, and utilize LANs). This greatly compromised the functionality of the laboratory and the service to referring medical practitioners. There were personal agendas (software designer's claim: "We are the bigger laboratory so we know best") and cost considerations that determined the decision to stay with this unsuitable antiquated IT platform.

At the practice department level, the hematology department used analyses that were capable of extensive data and graphics generation for both diagnostic and quality control purposes. Each analyzer had a PC that acted as a controller for the analyzer and a data/graphics generator. The ability to disseminate the graphics would render the department paperless, saving time and consumables and increasing efficiency considerably. Incumbent mainframe systems were unable to accommodate this facility, and unless a supplementary graphics capable IT system was implemented, this great opportunity for efficiency improvement and consumable cost reduction would be lost. Management data from mainframe systems is statistically based on providing information as requested on types and numbers of tests performed, the number of tests from each referring doctor, and workstation performance. Enhancement of computer-based management performance, such as roster generation, reagent tracking, and supply chain management in real time, is not possible on existing systems due to lack of graphics capability. Many management functions are therefore still performed manually by department senior staff.

As in the example of the overall laboratory case, the drivers for decisions for choice of analyzers and IT systems are still made by top-level management with little consultation with end-users, and are cost based. The situation of the IT and business misalignment cited previously (Grover & Segars, 2005) is applicable, and the agendas also embrace self-preservation of employment.

Both examples presented in the case study show how inadequate planning (SISP) and personal agendas have and are still compromising the efficiency and adaptability to modern technological change in medical pathology. This is believed to affect the bottom line. Continuation with existing IT infrastructure in medical pathology is broadening the gap with modern technology and increasing the degree of difficulty for change. The realization of stakeholders of proper SISP and criteria for assessment of the effectiveness of IS other than cost considerations applies to medical pathology as rigorously as it does to any business. A change in attitude toward SISP and the adoption of processes based on the model proposed in this chapter could revolutionize the medical pathology industry by facilitating a major change in its business infrastructure from a pyramidal hierarchy to laterally linked self-funded business units. The models proposed in this chapter offer a mechanism for enhanced SISP and measurement of IS effectiveness, leading to the development of a cohesive business model.

The Cohesive Business Model (CBM) comprises two overlapping and coexisting units. The change source consists of two main functions. It is the innovation part of the CBM as it relies on the interaction of experienced people to capture ideas, knowledge through experience, and historical data. Through careful business analysis, the ideas and innovations are formatted into plans, models, and processes to carry them to implementation. The plans and models define team selection and project management as well as an absolute definition of the business goal(s) in the SISP. This process then provides the firm with an inherent facility for change management, as represented in Figure 1.

The process source also consists of functions. It is the integration part of the CBM as the models and processes from the change source are integrated into the business and the business change is effected. The end users provide feedback to the innovators, which give information regarding client issues as the perceptions are at the coal face. The process source unit is where quality management takes place through interaction and feedback at the client interface.

The change source (innovation side) of the CBM works closely with the IS department. This relationship differs from what is a common situation cited in the literature where the IS department is dominant in the relationship with the business managers. This model is driven by business and recognizes the IS department as a valuable, essential partner to advise on the best way to integrate the latest IT developments into the CBM. The IS department's facility for development of software and technical backup is defined in the plans, models, and processes of the innovation. The involvement of the IS department, together with the innovation and project management teams in staff training and alpha and beta testing of the developed IS, is imperative to the success of that project.

The CBM is multidimensional and is supported by provision for assessment of internal and external factors that may affect the implemented model in a positive or negative way. The links between components of the CBM, unlike other models cited in the literature, are bidirectional. The CBM is dynamic and fluid and has the facility to respond to potential influences quickly and effectively to ensure that the business maintains its functionality and competitive advantage.

FUTURE TRENDS

A review of literature on Laboratory Information Systems (LIS) and laboratory management systems relative to the case study in this article acknowledges a need for improvement in effectiveness and efficiency in clinical laboratories. In efforts to achieve this, several approaches by authors have been taken. These include the functional process approach of Goldschmidt, deVries, van Merode, and Derks (1998), the accountant's perspective of Revere (2004), the cost analysis approach of Mayer (1998), and the LIS requirements for the future work of Bender and McNair (1996). Bender and McNair's (1996) work supports and promotes the use of open architecture systems, which implies that the market will develop modular, scalable, and cost-effective LIS without the dependence on individual manufacturers and hardware/software systems that characterize current systems.

There is a marked diversity in these approaches with perhaps only the work of Bender and McNair (1996) considering the LIS as a whole. Their approach is truly significant when considering the IS management misalignment problems cited earlier in this article. Our planned future research centers on the implementation of a modular real-time management system designed by the researchers for the clinical laboratory using principles of the CBM. The possibility that the system will enable laboratories to change their business infrastructure as well as improve efficiency, introduce new technologies, and reduce costs will be investigated. The expected positive effect this approach will have on IS/business misalignment will also be investigated.

CONCLUSION

SISP is recognized as an event that results in the building of an IS to support a business goal. The ability of the IS to attain that business goal must surely be the measure of the effectiveness of the SISP. Many of the quoted measures of effectiveness of SISP and IS should be regarded as part of the planning brief so they are inherently achieved by the IS during the processes of alpha- and beta-testing, the user friendliness, usage, cost/benefits, and ROI.

The adoption of the alternative model and its approach to SISP introduces a multidimensional approach to SISP. The multidimensional approach is bidirectional in that it allows for an inherent change management facility in the SISP, which keeps the process abreast of changing internal and external influencing factors to the benefit of the firm. Competitive advantage is maintained through more rapid response to these changes. Future research will test the model presented in this article.

The multidimensional approach to SISP also allows for more standardization in design process by defining what is a design component of IS and what is an indicator of effectiveness of the IS. More research needs to be undertaken to fully elucidate these definitions to further enhance our understanding of this complex environment.

KEY TERMS

Bidirectional Modeling. A business or functional model in which data are exchanged to and from all components of the model in real time.

Cohesive Business Model: A multidimensional business model developed for information systems planning and measurement of IS effectiveness based on the clearly defined business goals of the firm and with an inherent capacity for change management. This model is fluid, dynamic, and ongoing.

IS Effectiveness: The ability of an IS to meet the success criteria as determined by the firm.

IT Misalignment: A difference in the developmental pathways of the IT department and the business goals and competencies of the (same) firm.

Laboratory Information System (LIS): An IS in a medical laboratory for data and record collection and storage, results handling and dissemination, and functional statistics generation.

Multidimensional Modeling: A process of business modeling based on rational/structured and personal/informal processes that are fluid, dynamic, and ongoing. This process considers the relationship among all components of the model bidirectionally and continuously.

Strategic Information System Planning (SISP): The planning of an information system based on many described and measured processes and aligned with the business goals and competencies of the firm undertaken to increase the competitive advantage of the firm.

Unidimensional Modeling: A process of business modeling based on rational/structured and personal/informal processes that are finite; it has a beginning and an end. This process considers the relationship among all components in one direction only and is a static process.

Myoelectric Control of Prosthetic Devices for Rehabilitation

Rami N. Khushaba
University of Technology, Australia

Adel A. Al-Jumaily
University of Technology, Australia

INTRODUCTION

Bio-signals patterns analysis problems have enjoyed a rapid increase in popularity in the past few years. The electromyography (EMG) signal, also referred to as the Myoelectric signal (MES), recorded at the surface of the skin, is one of the biosignals generated by the human body, representing a collection of electrical signals from the muscle fibre, acting as a physical variable of interest since it first appeared in the 1940s (Scott, 1984). It was considered to be the main focus of scientists, and was advanced as a natural approach for the control of prosthesis, since it is utilising the electrical action potential of the residual limb's muscles remaining in the amputee's stump (which still has normal innervations, and thus is subject to voluntary control) as a control signal to the prosthesis—in other words, it allows amputees to use the same mental process to control their prosthesis as they had used in controlling their physiological parts; however, the technology in that time was not adequate to make clinical application viable. With the development of semiconductor devices technology, and the associated decrease in device size and power requirements, the clinical applications saw promise, and research and development increased dramatically.

This control approach referred to as myoelectric control has found widespread use for individuals with amputations or congenitally deficient limbs. The methodologies used in this approach of control spanned the range from classical multivariate statistical and syntactic methods, to the newer artificial intelligence (symbolic and connectionist) approaches to pattern processing. In these systems, voluntarily controlled parameters of myoelectric signals from a muscle or muscle group are used to select and modulate a function of a multifunction prosthesis. The essential elements of a myoelectric control of prosthesis devices are shown in the block diagram schematic of Figure 1 (Merletti & Parker, 2004). The Myoelectric control system is based on the noninvasive interfaces designed for casual wear.

In the following sections, the details and related works to the research problem are given; after that, the methodology adopted is explained and discussed, followed by future work, and finalised with conclusion.

BACKGROUND AND RELATED WORK

Continuous myoelectric-controlled devices are one of the challenging research issues, in which the prosthetic is controlled in a manner proportional to the level of myoelectric activity. Although the success of fitting these systems for single device control is apparent, the extension to control more than one device has been difficult (Hudgins, Parker, & Scott, 1993), but, unfortunately, it is required for those with high-level (above the elbow) limb deficiencies, and the individuals who could stand to benefit from a functional replacement of their limbs (Englehart, Hudgin, & Parker, 2001). It has been proved that the MES signal exhibits a deterministic structure during the initial phase of muscle contraction, as shown in Figure 2 for four types of muscle contractions measured using one surface electrode. Based on this principle, a continuous myoelectric control strategy based on the use of pattern classifiers was the main focus during the last years for most scientists in related fields.

The MES patterns exhibit distinct differences in their temporal waveforms. Within a set of patterns derived from the same contraction, the structure that characterizes the patterns is sufficiently consistent to maintain a visual distinction between different types of contraction. Hudgins et al. (1993), and Lighty, Chappelly, Hudgins, and Englehart (2002) aligned the patterns using a cross-correlation technique, and showed that the ensemble average of patterns within a class preserves this structure. The myoelectrical signal is essentially a one-dimensional pattern, and the methods and algorithms developed for pattern recognition can be applied to its analysis. The myoelectric control, system-based pattern classifier consists of four broad system components, which are (Ciaccio, Dunn, & Akay, 1993; Lusted & Knapp, 1996) :

- Myoelectric signal acquisition using surface or implanted electrodes, mostly surface electrodes.
- Signal conditioning and features extraction.
- Pattern recognition algorithms to classify the signal into one of multiple classes.
- Mapping of classified patterns to interface actions that control external devices.

A general look onto the myoelectric control system components reveal that it operates at a few stages of machine pattern recognition or interpretation for biosignals that were proposed in Ciaccio et al. (1993), and Lusted and Knapp (1996). Also, specific features are extracted usually because the motivation is toward the evaluation of myoelectric signal features in ways which are not tied to accurate estimates of signal characteristics, but rather to the intrinsic quality of the features as control signals for a desired device, which have been usually a prosthetic hand robot for the purpose of rehabilitation.

The features extraction is considered as the most important part, because the success of any pattern classification system depends almost entirely on the choice of features used to represent the continuous time waveforms (Hudgins et al., 1993). Although the

Figure 1. Normal and myoelectric control system

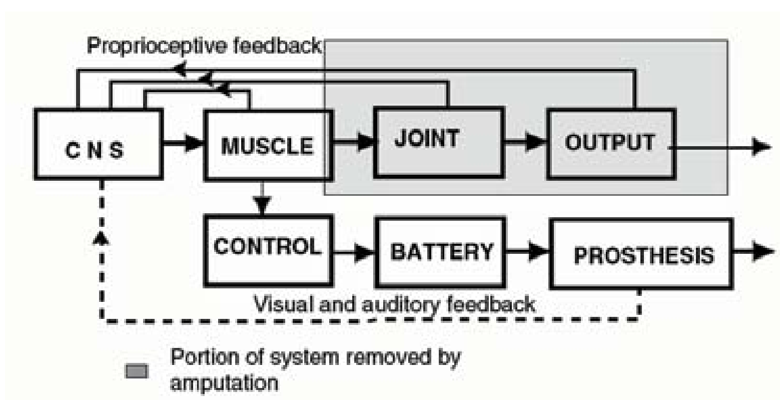

Figure 2. Patterns of transient MES activity recorded using a single bipolar electrode pair, placed over the biceps and triceps

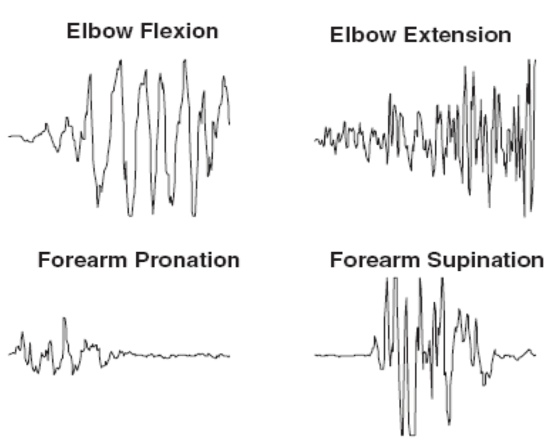


literature includes many papers which explore the extraction of features from the MES for controlling prosthetic limbs, there have been few works which make quantitative comparison of their quality. Overall, a high-quality MES feature space should have the following properties (Boostani & Moradi, 2003):

- **Maximum class separability:** A high-quality feature space is that which results in clusters that have maximum class separability or minimum overlap. This ensures that the resulting misclassification rate will be as low as possible.
- **Robustness:** The selected feature space should preserve the cluster separability in a noisy environment as much as possible.
- **Complexity:** The computational complexity of the features should be kept low, so that the related procedure can be implemented with reasonable hardware, and in a real-time manner

Raw MES offers us valuable information in a particularly useless form. This information is useful only if it can be quantified. Various signal-processing methods are applied on raw EMG to achieve the accurate and actual MES. Most of the researches on myoelectric control focused on the extraction of features that will best serve the purpose of controlling the prosthetic arm; the first attempts were made since the 1980s, when Doerschuk (Doerschuk, Gustafson, & Willsky, 1983) and Graupe (Graupe, Salahi, & Zhang, 1985) (that were both based on Graupe and Cline (1975)), used the parameters of some stochastic models, such as an autoregressive (AR) model, or auto regressive moving average (ARMA) model as features set for the myoelectric control system. Auto-regressive parameters (AR) were used as features for the MES signal (Karlik, Pastaci, & Korurek, 1994; Kocyigit, Karlik, & Korurek, 1996), as AR parameters can accurately estimate the power spectrum of the signal. It is worthwhile to observe some important advantages of modelling the signal in this way (Lamounier, Soares, Andrade, & Carrijo, 2002):

- Variations in the positioning of the electrodes on the surface of the muscle do not severely affect the AR-coefficients.
- The amount of information to be presented to the classifier is greatly reduced. Therefore, the total processing time is also reduced.

Recently, all attempts to extract features from the MES can be classified, in general, into two categories (Vuskovic, Pozos, & Pozos, 1995), although there are still many using the AR model for features extraction, and those two categories are:

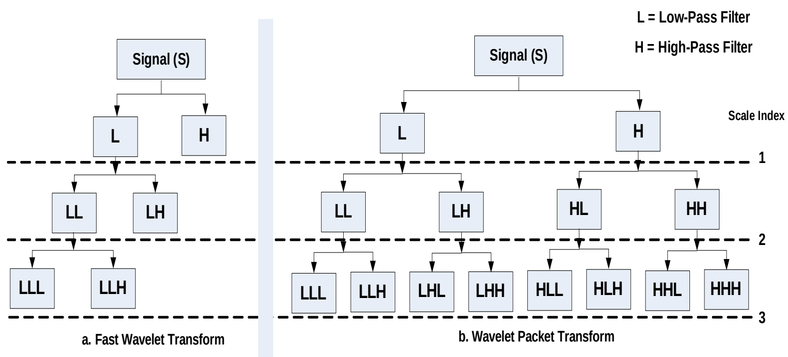
- **Temporal approach:** Identifies the attributes of the raw MES signal that characterize its temporal structure relative to a specific muscular function.
- **Spectral approach:** Uses information contained in frequency domain, which leads to a better solution for encoding the MES signal.

It was shown through literature that the spectral approach results were superior to that of the temporal approach, and that is why we adopted a spectral technique for features extraction.

METHODOLOGY

Due to the nonstationary behaviour of biosignals, the use of time frequency representations is highly desirable with the view to deriving meaningful features. These representations provide the means to regard the phenomenon simultaneously under two different points of view. The frequency characteristics, as well as the temporal behaviour, can be described with respect to the uncertainty principle. With multiresolution analysis, fast wavelet transform (FWT) leads to dyadic pyramidal implementation using filter banks and the corresponding Mallat algorithm (Mallat, 1989). FWT develops the two channel filter banks, through which the signal is split into two subspaces, L and H, which are orthonormally complementary to each other, with L being the space that includes the low-frequency information about the original signal, and H includes the high-frequency information. We keep repeating the decomposition of the low frequency subspace L. Compared to FWT, the wavelet packet (WP) method is a generalization of wavelet decomposition that offers a richer range of possibilities for signal analysis. The wavelet packet transform (WPT) not only decomposes the approximation coefficients, but also the details coefficients H as shown in Figure 3, in which the level of decomposition is to scale Index 3. The WPT provides a selective subbanding, which is the best for

Figure 3. Tree-like structure of digital signal processing by



Note: a) FWT analysis to scale 3; b) WPT analysis to scale index 3

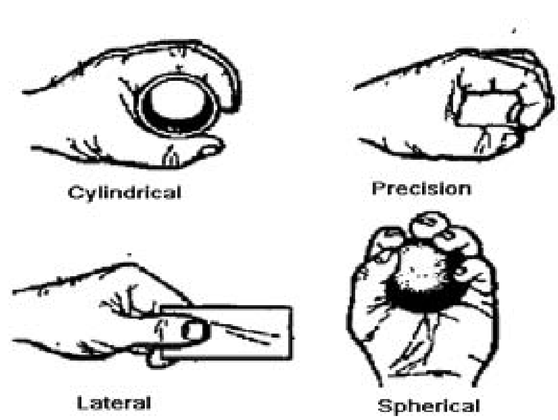
a given part of signals selected, such as in the case of the MES in which the most signal energy is positioned in between 35Hz–250Hz (Chan, Yang, Lam, Zhang, & Parker, 2000; Hudgins et al., 1993). The selective banding in WPT is determined by the order of low-pass and high-pass filtering from a tree-like structure using these filters (5).

Our proposed approach uses wavelet packet transform (WPT) for features extraction, with four levels of decomposition of the same database that is used by (Sijiang & Vuskovic, 2004) from the San Diego State University (focusing on the synergetic control of groups of finger joints that correspond to the basic prehensile motion), in which the MES signals of the four channels are sampled and recorded as the raw signal data. There are six categories of grasp types: small cylinder (SC), large cylinder (LC), small ball (SB), large ball (LB), small disk (SD), and a key (SK) as shown in Figure 4. Each of the six categories has 30 recorded grasp instances, respectively. There are 180 total recorded grasp instances, and the recorded data are used for feature extraction. Each instance generates a feature vector as the result of feature extraction by the WPT method. Four types of grasps are considered in this database, those are: cylindrical grasp, precision grasp, lateral key grasp, and spherical grasp, as shown in Figure 4. The input feature vectors are computed in two simple steps—first, each record of the database is decomposed using WPT with the fourth level (using two wavelets families: Daubechies, and Symmlet); second, features are extracted by simply determining every component of the feature vector ($f_1, f_2, ..., f_N$) using the Euclidean norm. Assuming the number of nodes in the fourth level is simply N , and that each node contains M elements, representing a row vector r_j for $j = 1, 2, ..., N$ the Euclidean norm is given by:

$$\left[f_j := \left\| r_j \right\|_2 = \sqrt{\sum_{i=1}^{M} v_i^2} \right] \qquad (1)$$

This means that each feature f_i is determined as the square root of the energy of the wavelet coefficients in the corresponding node, representing time and frequency information of the specific signal. A single feature especially describes a certain frequency range, which is equal to that described by wavelet coefficients underlying this feature. The method of computing the energy of wavelet coefficients was introduced in

Figure 4. Four grasp types



Pittner and Kamarthi (1999), but they used the FWT instead of WPT.

Because WPT possesses the useful property of identifying distinguishing characteristics from the original signals, we map the original signal into many WPT feature space. The number of valid decompositions increases exponentially with the number of decomposition level, so a problem found here is to compute the optimal decomposition. In our experiment, we found that the fourth level was very appropriate to deal with such a problem, as further decomposition is not necessary for our work. The number of features selected at the fourth decomposition level was also a matter of study for us, were we started with 12 features , and gradually increased the number of features extracted per channel (till 16 feature/channel), reaching to optimal results. The other part of our system was the classifier—to distinguish the six classes we have of movements in the database, we simply choose the Linear Discriminant Analysis (LDA), and achieved a high accuracy from the proposed system. The block diagram of the proposed system for classifying six categories of movements is shown in Figure 5, simply containing the extraction of features from the energy of WPT and followed by the LDA classifier.

The proposed system is different from that proposed in Englehart et al. (2001) by Englehart and his colleagues, where they used records of data each with 256 sample, and later extracted features by WPT, due to the size of their feature vectors they used Principle Component Analysis to reduce the feature set dimension, and followed that was an LDA part for classification, achieving an average error rate of 0.5% for four classes of motion, and 2% for six classes problem. In our case, we used the records from SDSU, each containing 400 samples, and extracted a number of features from the Euclidean norm of wavelet coefficients, achieving 64 features for the whole four channels, thus not requiring PCA, and conveyed those to an LDA classifier, and the results were very successful, as shown in Table 1-1, consisting of the number of features per channel, the error rate, and the wavelet families that we used in our experiments.

Table 1. Practical results from our experiment

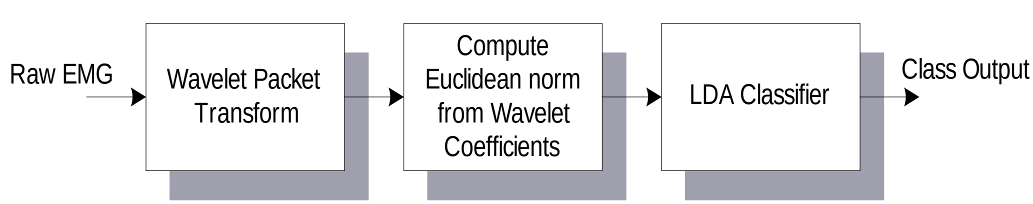
Features/Channel	Error %	Wavelet
16	0.56%	Symmlet
14	0.56%	Symmlet
12	1.11%	Symmlet
16	0.52%	db4
14	1.67%	db4
12	2.78%	db4

It is obvious from the table of experimental results that the case of 16 features per channel for Symmlet family of WPT, and Daubechies of WPT gave the best results; also, increasing the decomposition level to five gave 100% accuracy for the both families of wavelet. Our design was used to classify six classes of motion, achieving an error rate of 0.56% using Symmlet family, whereas in Englehart et al. (2001), the six classes problem reached only 2% of error rate.

FUTURE TRENDS

The fields of human-computer interaction and robotics emphasise the necessity of humanizing machine interaction, thus calling for more intuitive interfaces. The biocontrol systems technology had long served to provide the support required for people with paralysis, resulting from many causes, by focusing on noninvasive interfaces (those designed for casual wear). The EMG signal was utilised mainly in two applications in the last few years: those wearing controlling prosthetics devices for rehabilitations of patients, and in speech recognition that emerged recently. In both of the applications, the EMG signals were used to build a successful natural

Figure 5. Block diagram of the proposed system



controller with accurate results. Work in this field is a continuing one to achieve optimum results. Various methods have been utilised in literature in this field, but no one yet have used Type 2 fuzzy sets in myoelectric control; that is expected to achieve great results, as fuzzy set Type 2 is the extension to the fuzzy logic that has been used in this field, providing more accurate results than those based to statistical methods.

CONCLUSION

In this article, a simple and very effective wavelet-based approach has been explained for the problem of MES classification for the purpose of rehabilitation of patients after stroke. A simple method of extracting features from the wavelet coefficients was adopted and proven to be very effective in increasing the classification accuracy of the designed system. Although being simple, the accuracy of the classification system reached 99.44% for the case of six classes of motion, using the Symmlet family of the order five. The design described in this article represented a new promising approach for practical implementation of Myoelectric-controlled prosthetics, which we will be further enhancing for more applications, where we are currently investigating fuzzy approaches in feature selection as future work, and the application of artificial intelligence in pattern recognition rather than the LDA classifier.

ACKNOWLEDGMENT

The authors would like to acknowledge the support of Dr. Marko Vuskovic from the San Diego State University for supplying the database.

KEY TERMS

Biocontrol System: A mechanical system that is controlled by biological signals—for example, a prosthesis controlled by muscle activity.

Electromyogram (EMG): These are electrical potentials arising from muscle movements. They originate from the motor cortex when the brain sends action potentials along appropriate nerve tracts. They then transmit to the muscle groups, resulting in contractions of the muscle fibers, and are accessible as bioelectric signals under direct volitional control.

Grasp: To take hold of or seize firmly with, or as if with the hand.

Myoelectric Control: A man-machine control scheme in which myoelectric signals are used as control signals.

Noninvasive Interfaces: Those interfaces that acquire signals transcutaneously, using surface electrodes, which are preprocessed to reduce noise content.

Rehabilitation: The process of restoration of skills by a person who has had an illness or injury, so as to regain maximum self-sufficiency, and function in a normal—or as near normal—manner as possible. For example, rehabilitation after a stroke may help the patient walk again and speak clearly again.

Wavelet Transform: In mathematics, wavelets, wavelet analysis, and the wavelet transform refers to the representation of a signal in terms of a finite length or fast-decaying, oscillating waveform (known as the mother wavelet). This waveform is scaled and translated to match the input signal. In formal terms, this representation is a wavelet series, which is the coordinate representation of a square integrable function with respect to a complete, orthonormal set of basis functions for the Hilbert space of square integrable functions.

Nanorobotics: Applications in Bionanotechnology

Sourabh Bansal
Illinois Institute of Technology, USA

INTRODUCTION

Nanorobotics is a young and a challenging discipline of nanotechnology that is related to the design and simulation of robots or nonbiological machines on the scale of a nanometer (10^{-9} meter/1billionth of a meter). *Nanorobotics* is also termed as the science of studying nanomachines, commonly known as Nanorobots (nanobots or nanoids), which are in the range of 0.1-10 micrometres[1].

BACKGROUND

"There's Plenty of Room at the Bottom"[2]

This was the title of the first talk on nanotechnology given by the famous physicist, Nobel Prize winner Richard Feynman, in 1959.

Feynman offered $1000 to anyone who could either build a motor that would fit inside a 1/64" x 1/64" x 1/64" box, or write a page of text with letters that are small enough for the Encyclopedia Britannica to be printed on a pin head. As soon as Feynman announced these two prizes, the first one got claimed right away. Bill McLellan, who had really good hands, made a small motor almost immediately to fit inside the box of 1/64" x 1/64" x 1/64" without creating any new technology. However, the second Feynman prize did not get claimed until very late (1985). Tom Newman and Fabian Pease (Stanford University) used electronic beam lithography technique to write *A Tale Of Two Cities* at the length scale requested by Feynman. Hence, based on Richard Feynman's vision of miniature factories using nanomachines to build complex products, "nanotechnology" evolved over the years as the nascent, yet one of the most promising, fields of technology.

Nanotechnology is an extremely diversified field with its applications in numerous areas including medicine, chemistry and environment, information and communication, energy, and consumer goods. Out of these areas, medicine or life sciences is perhaps the most targeted application of nanotechnology. This area of study of nanotechnology in the field of biology and medical sciences is coined as *Bionanotechnology* or *Nanobiotechnology*. Nanotechnology led to the development of the novice field of Nanorobotics, which came into existence in 1980s. This area of study was majorly focused towards the generation of machines at nanoscale that would be capable of manipulating the nanoparticles.

In 1986, Dr. K. Eric Drexler[3] published his research on nanosystems, in which he discussed a field that would be derived largely from the macroscopic robots. Later, this field segregated into two parallel categories: one comprised the design and simulation of robots with nanoscale dimensions, while the other embraced the idea of manipulation or assembly of nanoscale components using macroscopic instruments.

The first technical paper on nanomedical device design was published in 1998 by Robert A. Freitas Jr., J.D. titled "A Mechanical Artificial Red Cell: Exploratory Design in Medical Nanotechnology," which was the first book-length technical discussion of the medical applications of nanotechnology and medical nanorobotics[4].

As of now, a major part of the study in nanorobotics is being conducted in the field of biology and life sciences (i.e., bionanotechnology). Therefore, medical technology will be the first one to extract the advantages of this upcoming technology.

ARCHITECTURE OF NANOROBOTS[5]

In manufacturing nanorobots, the ambient conditions under which a nanorobot is operating like temperature range, pressure, density, electromagnetism (including light, and so on) are taken into consideration. (Medically, in future, these conditions may be the considered inside the veins of a human body where a nanorobot will carry out its functions). To meet these requirements, signal processing, data transmission, power supplies, and so on are carried out using nanotechnology, along with the help of VLSI (Very Large Scale Integration) design. Moreover, it has also been noticed that VLSI design using CMOS (Complementary Metal Oxide Semiconductor) by the means of ultraviolet lithography tends to attain the highest degree of accuracy.

Likewise, Very High Speed Integrated Circuit Hardware Description Language, also popularly known as VHDL, which is one of the most common integrated circuits (ICs) in the industry, can prove to be a great help in the implementation of designs and simulation of nanorobots to achieve even a higher level of accuracy and sensitivity.

Nanophotonic and nanotubes jointly may accelerate further the actual levels of resolution ranging from 248nm to 157nm devices in the assembly process of manufacturing of nanorobots in a CMOS industry.

Chemical Sensor

Nanowires[6] (Figure 1) have two quantum-controlled directions, in comparison to other low-dimensional systems, with one direction left unrestrained for the purpose of electrical conduction. As a result of this, nanowires can be used as nanoconductors for numerous nanodevice applications. Nanowires possess splendid properties for applications in various filed like that of excellent electrical, optical, mechanical, piezoelectrical, and field emission.

Nanowires, due to their spectacular properties, are capable of decreasing drastically the self-heating and thermal coupling for a CMOS when used as a suspended array in silicon circuits. Consequently, this provides maximum efficiency for applications regarding chemical changes, enabling new nanomedical applications. Therefore, more than half of the power supply in a nanorobot can be decreased by use of nanowires in their various circuits while manufacturing it.

N

Energy Supply

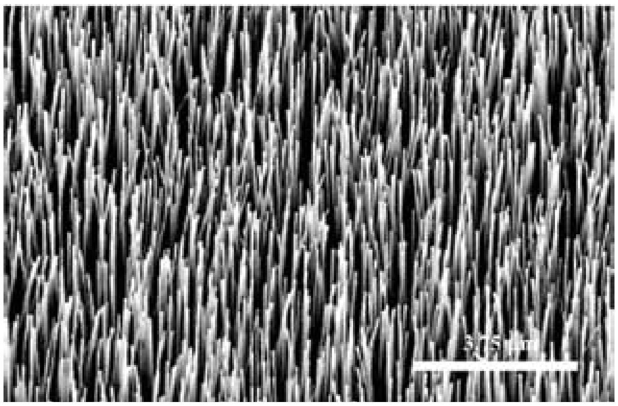
There can be a number of ways to supply energy to nanomachines from a human body itself. Inside a human body, temperature displacements can create potential differences, which can further be used as a voltage difference (Freitas, 1999).

The relation $E=hf$ can be well-used while using electromagnetic radiation, or light, where E is the energy generated by *photons,* depending on the frequency of light inside the body, f, encountering nanobots, and h is the Planck's constant (=6.626 x 10^{-34} Js). But these supplies of energy are not constant and may vary to a large extent. Thus, a wireless energy supply source may be used such as a microwave or a Radio Frequency wave generated from the patient's mobile phone to operate the transducers and *nanosensors* of nanobots efficiently inside a human body.

CURRENT DEVELOPMENTS IN NANOROBOTICS

Globally, several researches are being conducted in the field of nanorobotics in order to achieve the objective of synthesizing these miniature gadgets for human

Figure 1. SEM image of the zinc oxide (ZnO) nanowires grown by VLSI approach using Au catalyst (Courtesy: Liu, Wang, Kuo, Liang, and Chen (2007) "Recent Patents on Fabrication of nanowires")



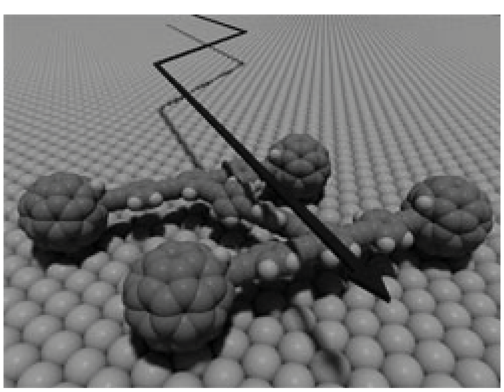
welfare. It is expected that within the next ten years, the development of nanobots will become comparable to the size of bacteria (Cavalcanti et al., 2004). Although nanorobots can prove to be a boon for the entire healthcare industry, the design of these nano miracles will be highly complex. Hence, the development of nanorobots in biomedical engineering can result in extremely complicated fabrication and control challenges. Also, a lot of research is currently being carried out all throughout the world using CMOS in VLSI design, with the help of VHDL in order to find a way to design and manufacture nanorobots. Quantum mechanics, thermal motions are also being considered in the design of nanobots.

Major development in the field of nanorobotics has been demonstrated by the Rice university scientists, which have constructed the world's smallest car—a single-molecule "nanocar" (Figure 2) that contains a chassis, axles, and four buckyball wheels.

According to Dr. James M. Tour, the Chao Professor of Chemistry, professor of mechanical engineering and materials science and professor of computer science, "*The synthesis and testing of nanocars and other molecular machines is providing critical insight in our investigations of bottom-up molecular manufacturing.*" [7]

The creation of the nanocar took over eight years. The entire nanocare[7] measures approximately 3–4 namometer, slightly wider than a DNA strand. It consists of a chassis and axles made of well-defined organic groups with pivoting suspension and freely rotating axles. The wheels are buckyballs, spheres of pure carbon containing 60 atoms apiece. This nanomachine is the first of its kind that actually functions like a car. It rolls on four wheels in direction perpendicular to its axles.

Figure 2. Nanocar (Courtesy: http://www.rpi.edu/~tsaiw/plans.htm)



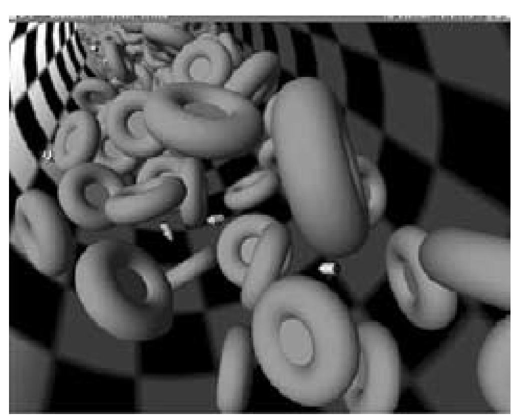
FUTURE APPLICATIONS OF NANOROBOTICS

In future, nanorobotics can prove to be extremely beneficial for the fields of information and communication, chemistry, environment, energy, and consumer goods, most of which will be reaped mainly by medicines and healthcare. However, there is still a lot to work that is to be done in order to meet the requirements of the synthesis of a nanodevice, which can be helpful to the entire healthcare industry, along with other areas of application. It might take a long time to realize all the theoretical concepts which are currently in the scene to manifest into reality.

By 2020, it is expected that nanobots will be used at a high level, and this technology may prove miraculous to the patients suffering from incurable diseases like diabetes (Figure 3). One may also be able to not only diagnose, but also control the BGL (Blood Glucose Level) by the use of nanorobots (Cavalcanti, Shirinzadeh, Freitas, & Kretly, 2007).

The two chief areas of applications of nanorobots, in future, may be categorised into Nanodiagnosis and Nanotherapeutics. Both these areas are briefly discussed in the following paragraphs:

Figure 3. Nanorobots in the diagnosis of glucose level in bloodstream (Courtesy: Cavalcanti, et al., "Medical Nanorobot Architecture Based on Nanobioelectronics")



- **Nanodiagonisis.** It is one of the most challenging aspects of nanorobotics. Continuous monitoring of patient's body condition can help in neurosurgery, detection of cancer at an early stage, and blood pressure control for cardiology problems. The same approach is quite useful in monitoring patients with diabetes. A RF wave transceiver like mobile phones can be of a great use in nanorobotic therapy, as these can be used for dual purposes including (a) a continuous source of energy for nanodevices, and (b) data reports can be transmitted to the mobile from nanodevices with a preinstalled software on the transceiver (Cavalcanti et al., 2007).•
- **Nanotherapeutics.** Cell herding machines are still a theoretical concept to stimulate rapid healing and tissue reconstruction along with cell repair machines to perform genetic surgery. These two areas of technology, if successful, will not only bring a revolution in the medical world, but also will prove to be a great benefit for the mankind. Nanorobotics will be able to diagnose, as well as the cure, the diseases quickly, efficiently, and effectively. Moreover, accurate and effective diagnosis of incurable diseases like cancer and HIV/AIDS at early stages will turn out to be a great relief for the coming generation from these deadly diseases.

CONCLUSION

Nanorobots can manipulate the objects at nanolevel or nanoscale. Nanorobotic instruments such as atomic force microscope can also perform manipulation at nanoscale. A lot of artificial nonbiological nanorobots are still in the developing phase, and will soon be a great benefit for the patients suffering from fatal diseases like Cancer, HIV/AIDS, and so on. Moreover, it will prove to be a milestone the medical world.

Nanorobotics has an enormous potential for phenomenal works in the fields of medicine and healthcare. In future, nanorobotics can help in the early and effective diagnosis of various diseases like cancer, HIV/AIDS, Alzheimer's, and so on.

The most important application of nanorobotics is in the field of medical technology. Currently, this technology is in its initial phase, and hence, more of theoretical concepts instead of practical are in scene as of now, in conjunction with a lot of research going on in this field worldwide. The theory of all these researches may be different but the goal is the same; that is, to promise the new generation a disease-free and healthy life with quick diagnosis and quick treatment, with the help of these miniature wizards called "nanorobots."

KEY TERMS

Blood Glucose Level (BGL): The concentration of glucose in the blood, measured in milligrams of glucose per 100 milliliters of blood.

Nanomachine: Devices, such as electronic circuits, from single atoms and molecules based on nanotechnology.

Nanoparticles: A microscopic particle whose size is measured in nanometres (nm). It is defined as a particle with at least one dimension <100nm.

Nanophotonic: The study of the behavior of light on the nanometer scale.

Nanoscale: Occurring on a scale of nanometers.

Very-Large-Scale Integration (VLSI): The process of creating integrated circuits by combining thousands of transistor-based circuits into a single chip.

VHSIC Hardware Description Language (VHDL): It is used as a design-entry language for field-programmable gate arrays and application-specific integrated circuits in electronic design automation of digital circuits.

Networks of Action for Anti Retroviral Treatment Information Systems

Elaine Byrne
University of Pretoria, South Africa

Roy D. Johnson
University of Pretoria, South Africa

INTRODUCTION

The South African government has an impressive constitution and legislative framework that recognizes the right of its citizens to quality health care (Government of South Africa, 1996). In South Africa, approximately 80% of the population relies on state-provided health care. Health workers in the public health sector provide services at the formal health facilities and to the various outreach programs in the community (i.e., immunization drives). The effective management and delivery of these diverse services requires regular reporting of routine and exceptional information by health care workers. These workers spend a significant amount of time collecting, recording, storing, and transmitting data in various forms.

With the commencement of the Anti-Retroviral Treatment (ART) program in selected clinics throughout South Africa in 2003 (Department of Health, 2003), treating and supporting clients attending ART clinics places great pressure on the health staff, not only because of insufficient human resources and time, but also with the associated severe emotional strain. Pressure is escalating as the number of clients requesting ART is increasing daily (Stewart, Padarath & Bamford, 2004). An effective Information System (IS) is needed to manage this increase in clients as well as support a variety of reporting requirements.

A national survey in South Africa of health personnel, ambulatory and hospitalized patients, and health facilities substantiates that a weak patient IS (a) was an impediment to ensuring ongoing and correct treatment, (b) increased staff workloads, and (c) led to unnecessary duplication of effort and time. Additionally, Shisana, et al. (2002) argue that ensuring that a single electronic IS is in place to assist in treatment of patients is an essential yet often neglected aspect of the health system.

In 2005, the clinical director of the Batho Pele clinic[1] in the Gauteng province in South Africa requested the assistance of the Department of Informatics at the University of Pretoria in addressing their IS issues. This request fitted the department's research interests in health information systems (HIS), as well the broader research focus and commitment to provide outreach services to the community. Knowing the problems of commencing projects without having planned for sustainability and scalability, the HIS research group elected to use the "networks of action" concept to partner and collaborate with the various role players, institutions, and other ART entities. This process of developing interconnecting networks of human and nonhuman entities in South Africa and beyond its borders raised a number of opportunities, challenges, and tensions in initiating this project.

To provide a background to this process, the next section introduces the concept of "networks of action" and a brief description of the ART clinic. The following section develops the main focus of this chapter, which is the process of developing these networks. The last section suggests the necessity of developing networks of action as a future trend for sustainable IS.

BACKGROUND

Networks of Action

In addressing why so many action research efforts fail in the long term, Braa, Monteiro, and Sahay (2004) argue that the two major challenges in the development of a successful HIS are the interrelated factors of sustainability and scalability. Sustainability refers to making the IS work over time through the institutionalization of routines and the development of local learning processes. Scaling concerns the spreading of a working solution to other sites (Braa et al., 2004). However, scalability is not merely a technical problem but encompasses a sociotechnical network, comprised of people, technology, and processes within an institutional context and relates to a process of specifically what is being scaled and how it is being scaled (Sahay & Walsham, 2006).

As argued by Braa, et al. (2004), scalability requires local interventions to be part of or connected to broader networks in order for sustainability to occur. They argue that local action research interventions need to be conceptualized and approached as one element in a larger network of action in order to ensure sustainability. Sustainability cannot occur just through action at a local level, and scaling needs to occur through the creation of multiple interconnecting networks. A flexible and adaptive process, which accommodates planned and unplanned events, or as Giddens (1984) would say, anticipated and unanticipated consequences, needs to be adopted in order for scaling to occur successfully.

Building on the Scandinavian-based action research's recognition of the need to perform action as part of a network rather than as a sole local venture (Chisholm & Elden, 1993; Elden & Chisholm, 1993), Braa, et al. (2004) argue that the need to develop an institutionalized and sustainable system is not a luxury but a necessity and needs to be part of larger interventions. Networking enables the sharing of experience, knowledge, and technology and thereby scaling the learning process. A key concept from this learning process is an alternative approach to action research; namely, the development of networks of action. These are characterized as:

1. "Abandoning singular, one-site action research projects in favor of a network of sites
2. Generating local, self-sufficient learning processes together with working mechanisms for the distribution of appropriately formatted experiences across sites in the form of vertical and horizontal flows
3. Nurturing a robust, heterogeneous collection of actors likely to pursue distinct yet sufficiently similar agendas
4. Aligning interventions with the surrounding configurations of existing institutions, competing projects, and effort, as well as everyday practices" (Braa et al., 2004, p. 359)

The development of networks of action is pivotal to addressing the challenges of sustainability and scalability and is especially important to the project described in this chapter, the Anti-Retroviral Treatment Information System (ARTIS) Project.

Background of ART Program

The Batho Pele ART clinic was recently established (2006) and is housed in a district hospital in the province of Gauteng. The clinic is part of the government's plan to improve the delivery of HIV/AIDS-related services (Department of Health, 2003).

Principally, there are three phases in processing a patient at this ART clinic:

- **Phase 1. Making an initial appointment.** This is based on the patient having a CD4 count <200 cells/mm3 or a WHO Stage IV disease (Department of Health, 2004). The patient has to be referred to the clinic from another clinic or medical practitioner.
- **Phase 2. Preprescription of ART.** Depending on the health and emotional status of the patient, acceptance for ART can occur, starting with the third visit or later.
- **Phase 3. ART prescription and follow-up.** Once accepted onto ART, there are regular return visits scheduled for pill counting, patient assessment, and prescription renewal.

Each visit requires the patient to check in with the ART administrator and register with the hospital administrator. Once registered, the patient is seen on each visit by nurses for tests (i.e., blood, weight, urine, blood pressure) and by the doctor, who reviews and analyzes the test results and prescribes the treatment regimen. The pharmacist dispenses the antiretroviral drugs. Consultations with the counselor, social worker, and dietician occur as the need arises (De Freitas, 2005).

Although there are official workflow processes for an ART clinic, these workflow processes are not adhered to stringently for a variety of reasons. Staff members are allocated to particular positions with clearly defined roles and duties, but due principally to shortages of staff, little segregation of duties occurs. When there is a shortage of staff or a staff member is experiencing a heavy workload, it is common for staff members to assist in completing the work tasks of their colleagues. For example, the administrator will assist the data entry operator when few patients are waiting at the reception. This implies that staff members are performing duties for which they have not received an adequate orientation, professional training, or supervised practice. This causes problems on many levels, such as security for accessing data and the quality of data entered incorrectly, incompletely, or duplicated (De Freitas, 2005).

Based on this background of the meaning of networks of action and the situation at the ART clinic, the next section describes our experience of developing these networks.

ESTABLISHING NETWORKS OF ACTION

From the preliminary review of the paper-based IS currently in place at the District Hospital ART clinic (De Freitas & Byrne, 2006), the IS does not meet the requirements of the staff and hence does not support the effective and efficient delivery of services to ART clients.

The IS at the ART clinic is a paper-based system and a partial computer-based system using an Excel spreadsheet. The paper-based system consists of a patient file, which contains all the necessary health-related documents on the patient's health condition and is stored in a filing room. The longer a patient stays on treatment, the bulkier and more cumbersome the documents become. The process of reviewing data in the paper file then becomes unwieldy, frustrating, and time consuming. The computer-based part of the system is an Excel spreadsheet originally designed at another ART clinic. These Excel spreadsheets contain basic demographic data, CD counts, and appointments.

In these initial stages of design and development, a conscious effort was made to establish networks of action. This process has been time consuming, frustrating, and confusing. However, the focus on sustainability overcomes these challenges. The various actors involved to date in the process of developing our network of actions are as follows:

- **Alignment of interests and focus.** In 2005, the Informatics Department established an HIS research group. The team meets regularly, and HIS has become one of three research focus areas for the department.
- **Memorandum of understanding.** A memorandum of understanding, which clearly outlines the role and responsibilities of the clinic and the university, has been established between the ART clinic and the Department of Informatics. The ART clinic agrees to give access at prearranged times; participate in IS requirements analysis, design, and implementation; and provide staff training on the system. The Department of Informatics agrees to perform an IS requirements analysis and develop a system; support the IS; assist in training health staff and students; and conduct research in IS design, development, and training.
- **User requirements.** A preliminary review of the IS requirements was obtained in 2005. In early 2006, an initial group meeting was held with all the clinic staff on the user requirements. However, at the following meeting, none of the clinic staff showed up. Later, they were evasive about the lack of support from the clinic staff but showed incredible interest in the documentation and insisted on keeping it.
- **Building upon networks.** The department has relationships with HIS research networks, such as Informatics Development for Health in Africa (INDEHELA) and Building Europe Africa collaborative Network for applying IS (BEANISH). INDEHELA is a Finnish initiative for collaborative research between Finland and Africa (Nigeria, Mozambique, and South Africa). Part of their research focuses on sustainability and contextual HIS design. BEANISH is a collaborative HIS initiative whose overall goal is to build networks of researchers and development between and within countries in Africa and Europe by studying practical applications of IS technology in the health sector.
- **Linking existing ART modules or systems.** One of the first steps of our project was a review of the existing ART modules or open source patient-based HIS. The Care2x hospital management system, the OpenMRS data model, the District Health Information System (DHIS) ver1.4 and 2.0, the Ethiopian ART module, and the Excel spreadsheet from another hospital have been explored to varying degrees. An ART module prototype has been developed and the possibility of exporting aggregated data to the DHIS, which is currently the official district HIS in South Africa

(HISP, 2006), and the potential of integrating as a module into Care2x is being investigated.

The most intensive review was a workshop in October 2006 on the refactoring of an existing ART module running in clinics of Ethiopia. The ART workshop was facilitated by the Open Source Centre from the Council of Scientific and Industrial Research in South Africa, and the refactoring process continued at the center the following week. Representatives from HIS networks in Ethiopia, Norway, India, and Vietnam attended the workshop. The development of the ART prototype took place during December 2006 and January 2007. Deployment of the system is still underway at the time of this writing.

This review of the process of developing the networks of action has implications for future IS development projects and are now discussed.

FUTURE TRENDS

From the review of the process of the development of the networks of action, it is apparent that this is a time-consuming process. However, developing such networks should be viewed as a necessity for the long-term sustainability of the systems. There is a number of implications of adopting such an approach, which surfaced within our process.

- **Time constraints.** There is a constant battle to deliver health services to implement an ART solution quickly, yet the need is not to reinvent the wheel or develop parallel systems. An agile and staged approach to systems development is appropriate, but the scope still needs to be delimited.
- **Various approaches.** Transferring tools and techniques from one sector to another may not be appropriate. Gaining user requirements from health practitioners may be more fruitfully done through participatory prototyping as illustrated in the development of DHIS rather than gaining all user requirements upfront.
- **Partnerships.** Within the health sector, there is a need to build relationships with the clinic staff, middle and top management, and across research groups, universities, clinics, hospitals, government departments, and NGOs. Cultural differences and different work practices across cultures also pose a challenge.
- **Understanding existing artifacts.** Given the number of patient-based HIS and ART modules, the review of existing artefacts could be paralyzing. This, however, raises opportunities for pooling resources (expertise and financial), which would otherwise not be possible.
- **Institutional building.** The institution in which the research is to be conducted needs to be clearly defined, establish institutional backing, and have a long-term commitment.

Insufficient attention to the process of establishing networks can severely impact the sustainability and scalability of the IS. However, the process of establishing these networks is not generally described in action research projects or in IS development initiatives. From our experience, this process has been time-consuming but needs to form a substantial part of any IS that wishes to be sustainable and scalable.

CONCLUSION

Within the IS discipline, there has been a movement away from the previously dominant technical orientation of systems developers, stemming primarily from a computer science tradition to include and actively recognize the needs, aspirations, and expertise of users and to understand IS as social processes (Cornford & Smithson, 1996; Roode, 2003). However, there is little focus on how to develop the networks of action within this sociotechnical process. Missing this vital process in terms of planning and allocating resources can have a negative impact on IS projects. This stage of IS design and development should receive more attention in project management and IS development methodology.

KEY TERMS

Action Research: A collaborative cyclical inquiry process that involves diagnosing a situation, taking action, and reflecting on the outcome before recommencing the process.

ART: The treatment of people infected with HIV/AIDS by incorporating antiretroviral drugs, counseling, and guidance on how to live a healthier life.

Developing Countries: Countries generally found in the southern hemisphere and characterized by low levels of human development.

Health Information Systems: Sociotechnical combinations of human and nonhuman artefacts for coordination and communication work, or social activities in the health sector.

Networks of Action: A term used in action research that involves the cultivation and alignment of groups of people, institutions, sites, and artefacts.

Scaling: The spreading of working sociotechnical solutions to other sites, including people, technology, and processes.

Sustainability: Involves a long-term working solution.

New Ensemble Learning Approaches for Microarray Data Classification

Ching-Wei Wang
University of Lincoln, UK

INTRODUCTION

A reliable and precise classification of tumors is essential for successful treatment of cancer. Microarray technologies allow the rapid and comprehensive assessment of the transcriptional activity of a cell, leading to a more comprehensive understanding of the molecular variations among tumors and, hence, to a finer informative classification. However, the major challenge in using this technology is the analysis of its massive data output, which requires powerful computational means for interpretation. Hence, the ability to interpret the information in gene expression data becomes a critical issue in Genetics.

One of the most active areas of research in supervised machine learning has been to study methods for constructing good ensembles of classifiers. The main discovery is that the ensemble classifier often performs much better than single classifiers that make them up. Recent researches (Dettling, 2004, Tan & Gilbert, 2003) have confirmed the utility of ensemble machine learning algorithms for gene expression analysis. The motivation of this work is to investigate a suitable machine learning algorithm for classification and prediction on gene expression data.

The research starts with analyzing the behavior and weaknesses of three popular ensemble machine learning methods—Bagging, Boosting, and Arcing—followed by presentation of a new ensemble machine learning algorithm. The proposed method is evaluated with the existing ensemble machine learning algorithms over 12 gene expression datasets (Alon et al., 1999; Armstrong et al., 2002; Ash et al., 2000; Catherine et al., 2003; Dinesh et al., 2002; Gavin et al., 2002; Golub et al., 1999; Scott et al., 2002; van 't Veer et al., 2002; Yeoh et al., 2002; Zembutsu et al., 2002). The experimental results show that the proposed algorithm greatly outperforms existing methods, achieving high accuracy in classification.

The outline of this chapter is as follows: Ensemble machine learning approach and three popular ensembles (i.e., Bagging, Boosting, and Arcing) are introduced first in the Background section; second, the analyses on existing ensembles, details of the proposed algorithm, and experimental results are presented in Method section, followed by discussions on the future trends and conclusion.

BACKGROUND

Ensemble methods are learning algorithms that construct a set of base classifiers and then classify new data points by taking a vote of their predictions. The spirit in ensemble machine learning is to combine a number of rough "rules-of-thumb" into a more accurate aggregate class prediction rule. The learning procedure for ensemble algorithms can be divided into the following two parts. The first stage is constructing base classifiers/base models. The main tasks of this division are (1) data processing: prepare the input training data for building base classifiers by perturbing the original training data; and (2) base classifier constructions: build base classifiers on the perturbed data with a learning algorithm as the base learner. In this project, the C4.5 decision tree algorithm (Quinlan, 1996) is employed as the base learner. The second stage is voting, which combines the base models built in the previous stage into the final ensemble model. There are various kinds of voting systems. Two main voting systems are generally utilized; namely, weighted voting and unweighted voting. In the weighted voting system, each base classifier holds different voting power. On the other hand, in the unweighted system, an individual base classifier has equal weight, and the winner is the one with the most number of votes. Figure 1 illustrates the structure of the ensemble machine learning approach.

There are three types of generally adopted ensembles (i.e., Bagging, Boosting, and Arcing). Bagging algorithm, which is introduced by Breiman (1996), constructs base classifiers with inputs generated by the bootstrapping technique. The construction process of every base classifier is independent of each other. It perturbs the training set repeatedly to generate multiple predictors and combines these base classifiers by simple voting (classification) or averaging (regression) in order to obtain an aggregated predictor. The multiple input data for building base classifiers is formed by bootstrapping replicates of the original learning data.

Boosting was introduced by Schapire (1990) as a method to enhance the performance of a weak learning algorithm. Freund and Schapire (1996) proposed an algorithm called AdaBoost. There are lots of varieties of Boosting algorithms, and AdaBoostM1 is chosen as the Boosting method used in this project. Boosting adaptively reweights the training set in a way based on an error rate of the previous base classifier. The Boosting algorithm improves its behavior in reflection to the latest faults it makes. Moreover, if the error rate of a base classifier is greater than 0.5 or equal to 0, the sequential construction of base classifiers stops.

The framework of Arcing introduced by Breiman (1998) is similar to the one employed in Boosting. They both proceed in sequential steps. The major difference between Arcing and Boosting is that Arcing improves its behavior based on the accumulation of its faults in history. It examines all previous base classifiers' faults for construction of a new base classifier, while Boosting only checks the previous one base classifier. Apart from this, Arcing adopts unweighted voting system, whereas Boosting uses weighted voting. In addition, unlike Boosting, no checking procedure exists through the constructions of base classifiers.

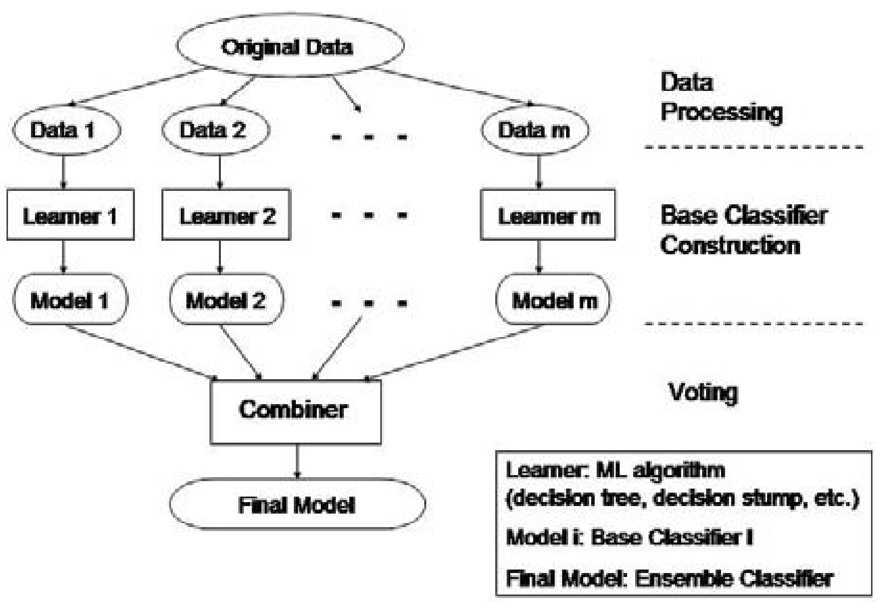
METHOD

In this section, the behavior and weaknesses of the existing ensembles are first analyzed, followed by presentation of the design and detailed algorithm of the proposed approach.

Behavior and Weaknesses of Existing Ensembles

1. **Boosting.** The accuracy of Boosting models will remain the same after specific numbers of base models are established, due to the checking mechanism following each construction of base classifiers. The specific criterion in Boosting stops further construction of base classifiers while its error rate is equal to 0 or greater than 0.5 (see Figure 2). Therefore, if the sequential construction halts after building six base classifiers, the same result will be obtained on evaluating over Boosting

Figure 1. Ensemble machine learning algorithm



models with any number greater than six, because fundamentally, these models are all identical. In other words, as long as the error rate of the first base classifier is equal to 0 or greater than 0.5, no matter how many base models specified, the whole construction terminates, and consequently, the entire ensemble model will be composed of exactly one base model.

This is an extreme case in Boosting, but it does happen very often in our experiments. As gene expression data consist of large amounts of genes, it helps learning methods to generate a more precise classifier that fits exactly on the training set. To sum up, due to the nature of gene expression data, the checking criterion seriously influences the diversity of boosted models by forbidding further construction of base models.

2. **Arcing.** The performance of Arcing models may deteriorate while more base classifiers are constructed. Unlike Boosting, without the checking condition interrupting, the other unwelcome situation may occur. The extreme undesirable result is an arced model with all identical base models. Without the checking criterion, Arcing may keep on producing the same base models. For example, once Arcing develops a base classifier that precisely fits the training data, there will be no misclassification value to be added in, and all misclassification values will remain the same. Hence, the instances' weights will stay the same as well. With the same data, the same instances' weights and the same base learner, the Arcing algorithm will produce exactly the same base classifier. As a result, due to the low diversity issue of base models, ensembles with self-optimization learning style may suffer from an over-fitting issue.
3. **Bagging.** Different from Arcing or Boosting, Bagging generates its base models by chance, because the constructions of the base models are independent of each other.

Design: Framework

The advantage of Boosting and Arcing is to refine their behavior based on previous learning experience. However, over-fitting the issue decreases the quality of these ensemble models. Hence, a data-perturbing technique is created for constructions of base classifiers in order to produce base models in higher diversity. Particularly, in construction of each base model, Boosting refines itself based on errors by the previous model, whereas Arcing learns based on errors by all previous models. It is found that the Boosting structure obtains higher accuracy (see Table I). The reason suggested here is that it is not necessary to pay attention to errors of all previous models since the errors have been corrected through construction of each base model. Figure 3 illustrates the overview of the proposed ensemble machine learning approach, which

Figure 2. Boosting: construction of base classifiers

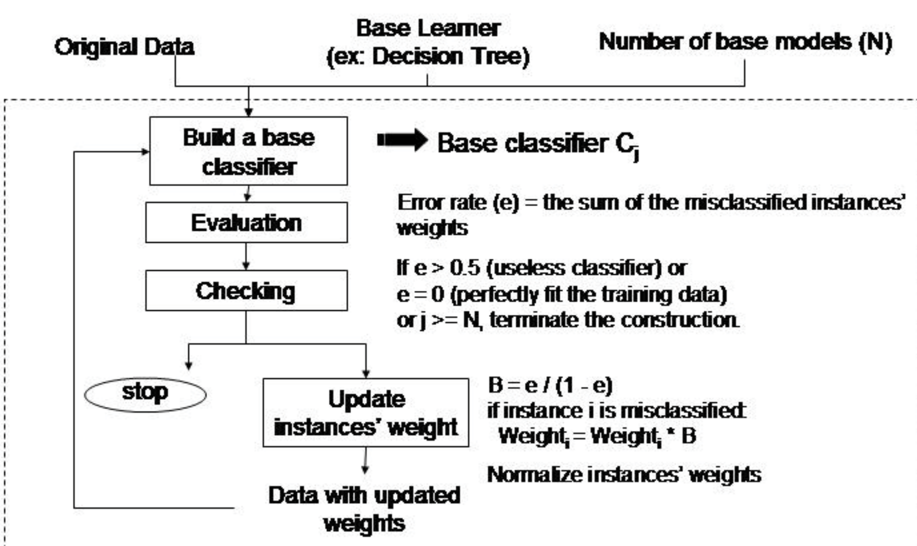


Figure 3. Behavior of the new ensemble machine learning approach

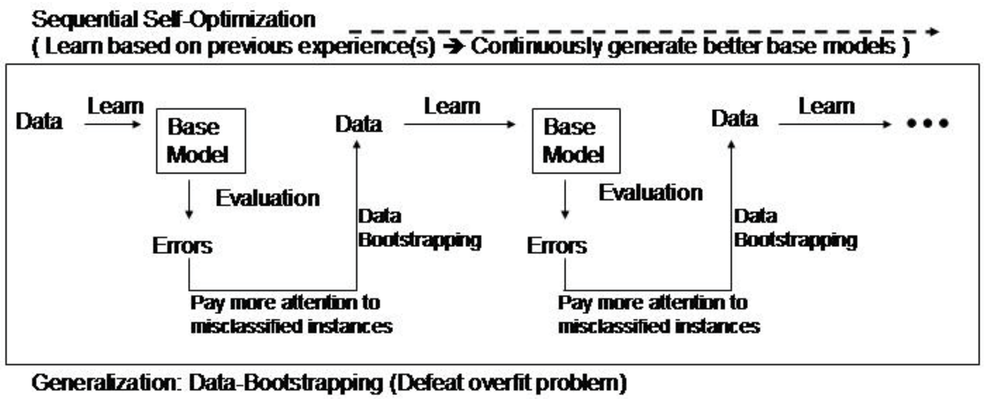

includes the sequential self-optimization structure and data-perturbing technique.

Design: Data Bootstrapping

The bootstrapping method is to generate a new dataset by sampling from the given dataset. Therefore, some instances may be selected several times, whereas others may be ignored. For every bootstrapping, a list of random floating numbers will be generated. The number of the random values is exactly the same as the size of input data set. These floating numbers are then processed into a list of accumulated probabilities, and the maximum value of this distribution is adjusted to the summation of instances' weights. Equation 1 presents the computation of each accumulated probability:

$$\mathrm{P(a)} = [\sum_{i=1}^{a} \mathrm{Random(i)} / \sum_{j=1}^{n} \mathrm{P(j)}] \cdot \sum_{k=1}^{n} W(k) \qquad (1)$$

Afterwards, the P(a) value is compared to the accumulated weight value ΣW(b).

$$\sum W(b) = \sum_{i=1}^{b} Weight(i) \qquad (2)$$

If the P(a) < ΣW(b), then add instance b into the result bootstrapped dataset, and the next comparison will be made between P(a+1) and ΣW(b). Otherwise, do not select instance b, and the next comparison will be made between P(a) and ΣW(b+1). Thus, one instance may be selected many times, and the higher its weight is, the greater the accumulated weight's value becomes, contributing to a bigger chance to be selected. The algorithm is devised in Figure 4.

Design: Main Algorithm

The proposed method is composed of the sequential self-optimization structure from Boosting and the data-bootstrapping technique. Figure 5 presents the details of the main algorithm.

Experimental Results

Cross-validation is deemed an objective and commonly used tool in model selection. Especially, cross-validation is markedly superior for datasets with a small number of samples, which exactly matches the gene expression data case; this fact is demonstrated in (Goutte, 1997). In this paper, tenfold cross validation is utilized for evaluation. Moreover, the experiments are conducted in a linux-based cluster (ScotGrid). Twelve gene expression datasets are obtained from published research works (Alon et al., 1999; Armstrong et al., 2002; Ash et al., 2000; Catherine et al., 2003; Dinesh et al., 2002; Gavin et al., 2002; Golub et al., 1999; Scott et al., 2002; van 't Veer et al., 2002; Yeoh et al., 2002; Zembutsu et al., 2002), and the C4.5 decision tree algorithm (Quinlan, 1996) is employed as the base learner. Three existing approaches (i.e., arcing, boosting, and bagging) and two new proposed methods (i.e., (New1) Data Bootstrapping + Arcing Skeleton and (New2) Data Bootstrapping + Boosting Skeleton) are tested.

Table 1 presents the percentage of accuracy in classification over 12 gene expression datasets by the

Figure 4. Data Bootstrapping Algorithm

Input: A dataset with n instances
Output: A bootstrapped dataset with the same size of the input dataset
Assumption:
Each instance has a weight, representing the relative level of importance in the dataset.
Process:
1. Generate n random numbers: R_1 to R_n.
2. Compute n accumulated probabilities: $P_i = \sum R_i$, where i =1 to n.
3. Normalize probabilities' values: $P_m = [P_m / \sum P_i] * \sum W_i$, where m, i = 1 to n
**Initialize two indices for iteration through two lists.
4. k = the index of the first probability in probabilities' list
5. x = the index of the first instance's weight in weights' list
** Iterate through lists of probabilities and instances' weights
6. Check if k <= n & x <= n. If both true, go to step 6.1
    6.1 $sumW(x) = \sum W_i$, where i = 1 to x
    6.2 Check if k <= n & P_k < sumW(x). if both true, go to step 6.2.1
        6.2.1 add instance x to the output dataset
        6.2.2 $W_k = 1$
        6.2.3 plus 1 to k.
    6.3 plus 1 to x.
7. Terminate with the output dataset

Figure 5. New ensemble machine learning algorithm

Inputs:
1. A training set T < X, Y >, where T: $\{<x_1, y_1>, ..., <x_n, y_n> \mid x \in X, y \in Y\}$.
    X: a set of instances: $\{x \mid x = <a_1, ..., a_q>\}$, where a_i = attribute value, q = number of attributes.
    Y: a set of classes, where y = 1 to z
2. Number of base classifiers R
3. The limit value of bootstrap times L
4. Base Learner / Inducer: C4.5 decision tree is used in this paper.

Output:
The Final model: Function C*
Steps:
1.Initialise instances' weights: For i = 1 to n, Weight: $W_1(i) = 1/n$
2.Generate a copy of the training data: S
  (T is for evaluating base classifiers. S is for building base classifiers.)
3.Repeat 3.1 to 3.9 R times
    1.Bootstrap S dataset from previous round S dataset
    2.Build a new Classifier $C_r(X)$ using weighted S dataset (X, W_r) by base learner.
    3.Evaluate $C_r(X)$ with T. Error rate e = Sum of the weights of the misclassified instances by $C_r(X)$
    4.Check if e = 0 & the number of data bootstrap ≤ L. If both true, go back to 3.1 to do the bootstrap.
    5.If e > 0.5 or e = 0, go to step 4.
    6.$B_r = e / (1 - e)$
    7. Set sum of instance weights for next round to 0: $SumW_{r+1} = 0$
    8. Update instances' weights: For i = 1 to n, check if Cr misclassifies instance i.
        1.If true, $W_{r+1}(i) = W_r(i) * B_r$. Otherwise, $W_{r+1}(i) = W_r(i)$
        2.$SumW_{r+1} = SumW_{r+1} + W_{r+1}(i)$
    9. Normalize instances' weights: For i = 1 to n, $W_{r+1}(i) = W_{r+1}(i) / SumW_{r+1}$
4.Produce ***Function C*(instance)*** by Voting

continued on following page

Figure 5. continued

Auxiliary algorithm: Voting

Function C*(instance)
Input: instance
Output: predicted result y_i
Steps:
1. Initialise votes of classes to 0: For i = 1 to z, V(i) = 0
2. For j = 1 to R, V(i) = V(i) + log (1 / B_j)
(i: class index from base model $_j$ in classifying the input instance.)
3. a = Argmax V(i), where i = 1 to z
4. Terminate with the predicted result y_a

five ensembles. The experimental results show that the proposed ensemble classifiers stably achieve high accuracy over all 12 gene expression datasets in comparison to existing ensembles. Particularly, the combination of data bootstrapping and boosting skeleton (New2) performs best in classifying gene expression data among five models.

FUTURE TRENDS

Obtaining patterns and rules with high accuracy in classification and prediction, a further investigation is to extract information about sets of influential attributes/genes from the resulting patterns and rules, allowing advanced study in biological meaning of genes and drug discovery.

The aim of discovery influential genes in microarray data analysist is to explore the relative importance of attributes within the ensemble model. Considering the patterns and rules learned, the most important criterion in classification will be placed as the first priority. As the decision tree algorithm is employed as the base learner in this study, the attributes in the upper tier of a tree are more meaningful in the classifying procedure. Hence, to obtain a comprehensive view on the influential genes/attributes in classification of microarrays, a design is proposed here to exhibit the attributes' precedence among all base models. The design scheme first assigns a weight for each tree level, and the attributes gain

Table 1. Prediction performance by 10-fold cross validation

points related to the weight in the particular tree level. Afterwards, the score of the individual attribute in each base model is associated to the voting power of the base model, which is multiplied by log ((1- error rate) / error rate). By summing up an attribute's points gained in all base models, its total score can then be obtained. The design scheme is presented in Figure 6.

CONCLUSION

Accompanied with the sequential self-optimization structure, the entire ensemble model is inclined to refine its behavior in a correct direction. The experimental results on 12 gene expression datasets prove that the proposed ensemble classifiers are largely upgraded with the data-bootstrapping technique. The combination of data bootstrapping and boosting skeleton (New2) is able to obtain high accuracy stably, and hence, it is recommended for gene expression data analysis.

KEY TERMS

Attributes: A property of an instance that may be used to determine its classification.

Base Learner: The algorithm used for building base classifiers (e.g, decision tree).

Base Model: The model generated by the base learner. A base classifier.

Classifier: A set of patterns and rules to assign a class to new examples.

Gene Expression Data: A typical gene expression array is made up of x columns of sample tissues, whereas each sample tissue contains y number of genes values. Every sample has its own individual class label, which represents the condition it belongs to.

Machine Learning (Mitchell, 1997): A computer system is said to learn from some experience E with respect to some class of tasks T and performance measure P, if it improves its performance (as measured by P) at tasks in T after passing the experience E.

Supervised Machine Learning: Machine learning algorithms require training datasets with prior knowledge of class labels.

New Perspectives in Rheoencephalography

INTRODUCTION

One of the most important advances in biomedical engineering has been the ability to inspect inside the body without opening it. In this sense, rheoencephalography (REG) is an electromedical technique used to assess the cerebral blood flow (CBF) by noninvasive electrical impedance methods, using electrodes attached to the scalp surface. This technique was first proposed by Polzer and Schuhfried (1950), and emerged as an extrapolation of impedance plethysmography applied to the head.

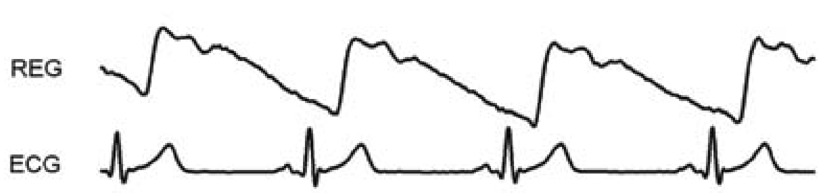
An electric current flowing through a biological tissue causes a potential difference between any pair of electrodes that can be measured. This potential difference depends on the amplitude of the injected current, the shape of the conductor, the arrangement of the electrodes, and the electrical characteristics of the tissue. For instance, the electrical conductivity of the lung tissue is much lower than that of the cerebrospinal fluid (CSF), since alveolar sacs are nonconductive. Furthermore, the electrical conductivity depends on the frequency of the electric current, the orientation of the tissue fibers relative to the current flow, and the amount of extracellular fluid that surrounds the cells. For example, electrical conductivity is higher in the blood than in most tissues, since plasma acts as a true-highway for ions (Malmivuo & Plonsey, 1995).

he ejected blood fills the arterial vascular bed, and a small and abrupt change in the electrical impedance of the tissues occurs, due to two reasons: the cross-sectional area of the tissue increases, and tissue effective conductivity rises. This is the physical principle of impedance plethysmography, and explains why the electrical impedance of any part of the body throbs synchronised to the heartbeat some tens or hundreds of milliohms around a basal impedance value.

BACKGROUND

By injecting an electric current through a pair of electrodes attached to the scalp surface, Polzer and Schuhfried recorded an impedance signal similar to that shown in Figure 1. Classically, these traces have been represented mirrored horizontally, so that the Y axis represents blood volume instead of impedance. They observed that, following the QRS complex, the REG trace increases abruptly suggesting a sudden blood inflow into the cranial cavity. Subsequently, a

Figure 1. Example of a REG signal and an ECG signal obtained in our laboratory



slow descent in impedance brings the REG trace back to its original value, and it is a result of the constant venous outflow. The morphological differences between the REG signals of pathological and normal subjects suggested that REG trace could be caused by the CBF pulsatility.

Nevertheless, despite the medical necessity of a device to evaluate the CBF, REG ability to evaluate the CBF was strongly debated. Detractors argued that the relative low electrical conductivity of the skull causes most of the current injected from the scalp surface to flow through the scalp tissue without crossing the skull. Accordingly, most of the REG information would be of extracranial origin.

The interest in the technique, and the disagreement about the origin of the REG signal, led to extensive research on the topic. For example, a review of the literature classified under the heading of rheoencephalography between 1959 and 1964 reveals some 150 articles, and one book (Namon, Gollan, Shimojyo, Sano, Markovich, & Scheinberg, 1967). Jenkner (1962) published a monograph summarizing his findings on more than 400 animal experiments, and well over 6,000 clinical records, and compared the results with those obtained by other authors. Some other exhaustive literature reviews can also be found in Lechner and Martin (1967), Lifshitz (1970), and Hadjiev (1972).

On the contrary, Perez-Borja and Meyer (1964) and Masucci, Seipel, and Kurtzke (1970) did not find significant differences in the REG signals recorded from normal subjects and from patients with cerebrovascular diseases and neurological deficits; Laitinen (1968) compared REG signals with intracerebral impedance traces, and found them to be substantially different; Masucci et al. (1970) applied the quantitative method proposed by Seipel (1967) to pathological and normal subjects, and found no clinical value of that analytical method; and, finally, Waltz and Ray (1967) analyzed the REG traces recorded from 96 subjects, some of them with partial or complete obstruction of an internal carotid artery or recent ischemic cerebral infarcts, and considered REG inadequate for the clinical evaluation of cerebrovascular disorders.

The interest in REG and its research flagged in the ‘70s at the same time as transcranial Doppler ultrasound appeared. Nevertheless, despite the lack of agreement on the REG signal origin, some other research groups have still contributed to REG knowledge during the following decades. For instance, Jacquy reported several findings about the use of REG in the study of regional CBF (Jacquy, Dekoninck, Piraux, Calay, Bacq, Levy, & Noel, 1974; Jacquy, Piraux, Jocquet, Lhoas, & Noel, 1977a; Jacquy, Piraux, Jocquet, Lhoas, & Noel, 1977b; Jacquy & Squelart , 1984), and Shender and Dubin (1994) used REG in the study of the CSF displacement on acceleration stress in military aircrafts. Meanwhile, Hatsell (1991) showed mathematically that regional impedance changes in the cortex are hardly observed by REG, whereas Basano et al. (2001) did not find significant differences in the REG signals recorded from brain-dead patients, and those obtained from living patients. In summary, research on REG ability to reflect the intracranial blood flow has coexisted with the use of REG in clinical studies.

REG MODELING

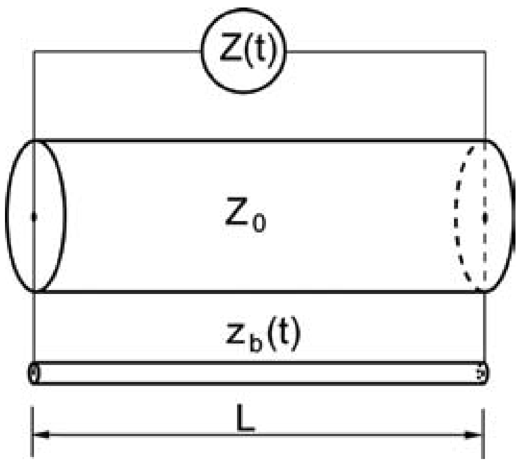
In engineering, models have been extensively used to study theoretical aspects involved in physical processes. In general, the more complex the model is, the closer to reality the results are. On the contrary, a simple model allows the study of each variable separately and independently from all the others. In this sense, only a few theoretical studies about REG ability to inspect the intracranial blood flow were published during the early stages in REG research.

To determine the changes in impedance caused by the blood inflow into an extremity, Nyboer modelled limbs as a cylinder with a constant impedance Z_0 connected in parallel to a second variable-diameter cylinder in such a way that impedance $z_b(t)$ is time-dependent. This second cylinder represents the net blood that flows in the extremity’s tissue along time (Figure 2). This simple model provides a relation between the blood volume increment (ΔV), and the impedance increment (ΔZ) as:

$$\Delta V = -\rho_b \left(\frac{L}{Z_0}\right)^2 \Delta Z$$

where ρ_b is the blood resistivity, L is the interelectrode distance, and Z_0 is the basal impedance of the limb (Geddes & Baker, 1989; Nyboer, 1970). Unfortunately, this simple model is not appropriate for REG analysis, since a portion of the current injected from the scalp surface crosses several tissue layers (e.g., scalp, skull,

Figure 2. Schematic diagram of Nyboer's model used in plethysmographical studies; the upper cylinder represents the impedance of the extremity, and lower cylinder corresponds to the time dependent impedance of the net blood flowing into the extremity



cerebrospinal fluid (CSF), and brain), whereas another portion flows through the scalp tissue only.

On the other hand, specific models for REG analysis have also been developed. For instance, Namon et al. (1967) and Seipel (1967) proposed the use of a multilayer sphere for head modeling, including regions corresponding to scalp, skull, cerebrospinal fluid, and brain. This simple head model is still being used in many applications, because it allows analyzing independently the influence of each geometrical parameter or electrode localization on the results, and even deriving the analytical expression of the solution (e.g., Reyhani & Ludwig, 2006). In addition, Lifshitz (1970) compared the distribution of the equipotential lines resulting from the use of different current injection electrode diameters by means of a two-dimensional head model consisting of three concentric circles of resistive Teledeltos paper. Today, powerful computer systems have allowed the development of multilayer spherical models of the head, providing the corresponding numerical and analytical solutions (Perez, Guijarro, & Barcia, 1999; Perez, Guijarro, & Barcia, 2000; Perez, Guijarro, & Barcia, 2004).

For a sound analysis of REG's theoretical principles, besides the geometrical factors of the head model, it is necessary to take into account how REG impedance is measured from the scalp surface. In practice, a pair of electrodes is attached to the scalp, and a small current is injected through them. Amplitudes of 1 or 2 mA and frequencies of 20 kHz to 100 kHz are usual values for the injected current. The diameter of the current injection electrodes is also of great importance, since the amount of current crossing the cranium can be significantly increased by using large electrodes (Namon et al., 1967). This current flow generates an electric field whose potential can be measured from the scalp surface. If the electric potential is measured between the current injection electrodes, the REG is said to be bipolar or REG I. This electrode arrangement is very sensitive to movements in the electrode leads and to noise, since most of the measured impedance is caused at the electrode-skin interface. Alternatively, a second pair of electrodes can be used to measure the electric potential difference created by the current injection, known as tetrapolar REG or REG II. Some other interesting REG electrode arrangements and techniques can be found in Namon et al. (1967) and Lifshitz (1967).

Based on geometrical head models, Perez et al. (2000) analyzed the ability of REG I and REG II to reflect the intracranial blood flow. They modelled the head as four concentric spheres representing, from the innermost to the outermost, brain, CSF, skull and scalp (Figure 3). The current injection electrodes were modelled as two high-conductivity cylinders attached to the scalp in such a way that the scalp volume intersected the electrodes.

This theoretical study only analyzed REG signal recoded from electrode arrangements totally symmetrical to the horizontal plane and for some electrode positions, in which the angle between the radial vector of the current injection electrodes (α) and the angle between the radial vector of the impedance reading points (β) (pickup electrodes) changed (Figure 3a). In this work, the head model was meshed and solved by the finite element method (Figure 3b). Observe that the electrode configuration studied there is a REG I when the current injection electrodes and pickup electrodes match (α=β); otherwise, it is a REG II.

The main results of the model used in Perez et al. (2000) are represented in Figure 4; the unitary contribution of the intracranial blood circulation to REG (M_1 ratio) is represented as a function of the electrode arrangement. Given a REG measurement, the M_1 ratio represents the amount of impedance per unit that can be attributed to the CBF. According to this study, most of

Figure 3. Geometrical head model used by Perez et al. (2000) to study REG ability to reflect the cerebral blood flow; (a) schematic diagram of the model; (b) meshed model

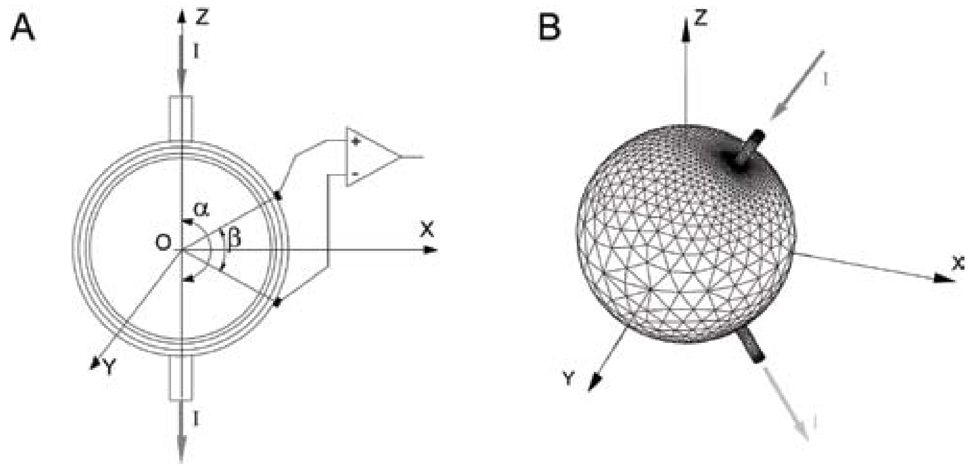


Figure 4. Relative contribution of intracranial circulation to REG (M_1); (A) M_1 ratio for REG I as a function of the injection angle α; (B) M_1 for REG II as a function of the pickup angle β

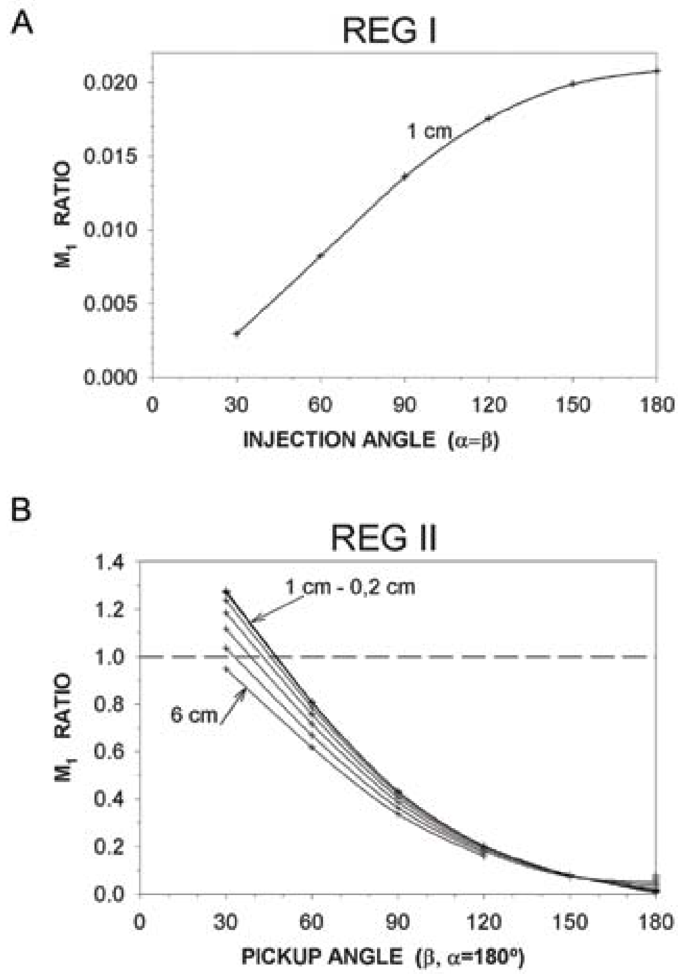


the REG I trace is caused by the scalp blood flow, since scarcely 2% of intracranial information may appear in the REG trace when the current injection electrodes are placed at diametrically opposite sites (α=180º).

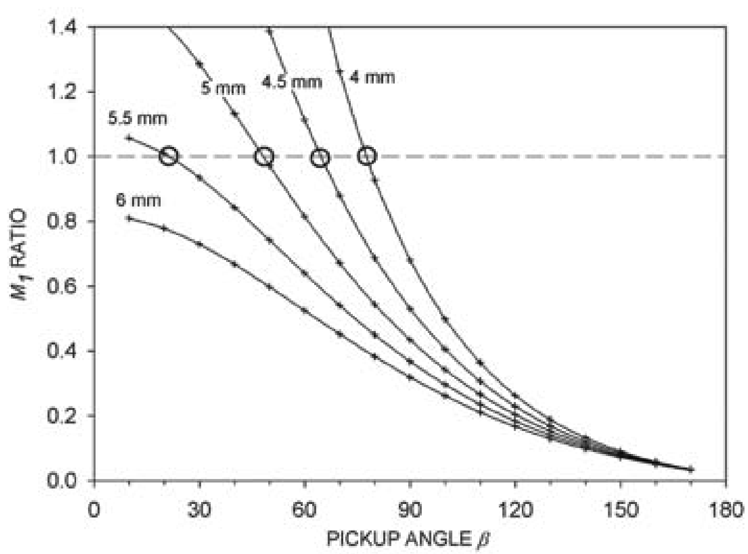
However, the analysis of the M_1 ratio in REG II reveals that, theoretically, there are some electrode arrangements from which a REG II signal free of extracranial contribution can be recorded (M_1=1). Obviously, the model is a simple approximation to reality, and hence, one should not expect to obtain a pure intracranial REG simply by placing the current injection electrodes at sites similar to those used in the model. However, these results suggest that the finding of an electrode arrangement to register a REG II free of extracranial contribution is physically possible, despite the fact that some of the injected current flowed only through the scalp tissue. Moreover, REG II signal results also show that the diameter of the current injection electrodes has only a small influence on M_1, and, in any case, it only slightly modifies the optimal electrode position. As a consequence, the use of large current injection electrodes in REG II experimental studies seems unnecessary.

In practice, a very high level of expertise is required to find an optimal electrode arrangement for a given subject to record a REG II free of extracranial contribution, only by inspecting the morphology of the trace. This is because the morphology of the intracranial REG component is unknown, and can only be observed by the detection of changes in the slope of the extracranial REG component, whose morphology is easily recognized.

In this work, the head model was solved by the finite element method, and although this method allows analyzing complex geometrical structures, any change in the geometrical parameters means the remeshing and resolution of the model again. Recently, this work has been extended to the study of the influence of the scalp thickness on REG II (Perez et al., 2004), and in this study, the analytical expression of the potential electric field created by the current injection for α=180º was derived.

The main results reported in Perez et al. (2004) are shown in Figure 5, in which the M_1 ratio is plotted as a function of the pickup angle β for different scalp thicknesses. Unexpectedly, the optimal electrode arrangement to obtain a REG II exclusively caused by intracranial circulation (M_1=1) depends strongly on the scalp thickness. Furthermore, a unitary M_1 ratio is not reached for scalp thickness values greater than 6 mm. This means that the search of an optimal electrode arrangement could be successful in some subjects, and fruitless in other subjects. Or, in other words, given an electrode arrangement, the REG signal recorded can either contain pure intracranial information, or be a course mixture of both extra and intracranial information, depending on the subject's physical constitution.

Figure 5. Relative contribution of intracranial circulation to REG (M_1) as a function of pickup angle (β) and scalp thickness, for a 180 º current injection angle (α)



The quantitative results reported in these works (Perez et al., 1999; Perez et al., 2000; Perez et al., 2004) cannot be directly compared to other experimental results, since they have been derived from simple geometrical models. However, they allow us to draw some interesting conclusions that agree well with earlier experimental works: (i) REG I mainly reflects extracranial information; (ii) the REG II signal is a mixture of information from intra and extracranial blood flow in unknown proportions; and (iii) there is no universal electrode arrangement to register a REG II free of extracranial contribution suitable for all individuals.

A close review of the literature shows comparative studies based on different electrode arrangements, and even different REG techniques. Furthermore, some reviews do not mention the REG technique used by other authors in their experiments. Both the comparison of results derived from different REG techniques, along with the unforeseeable amount of intracranial information contained in a REG signal, could be the cause of disagreement about ability of REG to reflect the intracranial blood flow.

FUTURE TRENDS

REG has not been included in the clinical practice yet, because the physical principles of this technique were not wholly understood. This caused the aforementioned disagreement that led to discarding further research on REG. Now, once the REG basis has been determined, the search of a method to eliminate the extracranial artifact from the REG signal can be addressed. For instance, Perez, Guijarro, and Sancho (2005) have recently observed that the extracranial component of the REG signal can be considered to be morphologically constant along the scalp surface. This means that the pattern of the extracranial artifact can be easily recognized by recording, for example, a REG I, and this information can be removed from a REG II signal to obtain a pure intracranial impedance signal (Perez, Guijarro, Sancho, & Navarré, 2006).

CONCLUSION

Despite the technological advances in tomographic imaging, the idea of a noninvasive, portable, and low-cost device to monitor the cerebrovascular system still seems attractive. REG signal was extensively studied and clinically used for this purpose some years after its proposal, but it was finally neglected because its theoretical principles were not firmly established. However, a deeper understanding of this technique would allow the recovery of REG to the clinical practice.

KEY TERMS

Bipolar Rheoencephalogram (REG I): Pulsatile impedance changes of the head, related to the cardiac cycle that is measured by injecting a small current between two electrodes attached to the scalp surface, and reading the electric potential difference generated between them.

Electrical Conductivity: Measure of the ability of a material or substance to conduct an electric current.

Electrical Impedance: Measure of the opposition to the flow of a sinusoidal alternating electric current.

Engineering Model: Simplification of the reality to address a complex problem by simple rules that can be described by means of equations.

Finite Element Method: Mathematical technique to solve complex problems in which a physical domain is spatially discretized (meshed) and solved by numerical methods.

Rheoencephalography: Electromedical technique used to assess the cerebral blood flow (CBF) by noninvasive electrical impedance methods using electrodes attached to the scalp surface.

Tetrapolar Rheoencephalogram (REG II): Pulsatile impedance changes of the head, related to the cardiac cycle that is measured by injecting a small current between two electrodes attached to the scalp surface, and reading the electric potential difference between another pair of electrodes.

A Non-Invasive Approach to the Bionic Eye

INTRODUCTION

According to the World Health Organisation definition for blindness, that is, visual acuity bellow 3/60 for the best eye on the Snellen scale, there are thought to be 38 million blind people worldwide (Delbeke et al., 2004). This figure is expected to double over the next 25 years due to combination of an increasing population and aging worldwide. There are additionally 110 million people who have severely impaired vision and are high risk of becoming blind. The most common causes of blindness are: cataract, trachoma, glaucoma, diabetic retinopathy, age related macular degeneration (AMD) and retinitis pigmentosa (RP). In the west countries, cataract and glaucoma make up only 11% of the total causes of blindness. In these regions AMD and RP are prevalent eye diseases. AMD increases dramatically with age, so that (with about 2million cases in the USA) it is the leading cause of blindness among Americans of European descent (Friedman et al., 2004).

The AMD and RP result in the loss of photosensitivity primarily due to destruction of the rod and cone photoreceptors. Medical intervention to date has been disappointing. There is no known mechanism by which the eye can self-repair. Anti-angiogenesis drugs can significantly slow down the progression of wet type AMD, but in most cases there is very little treatment. Even more significantly, none of the drugs are capable of restoring lost vision. The idea of using stem cells in therapies is still complex and may be many decades away from potential treatment. Prosthetic implants are therefore the only method at present by which we can offer a return of some of the lost vision. Here we present a special type of vision restoration based on the optical stimulation of retinal ganglion cells (RGCs), which remain operational.

BACKGROUND

Most of current concepts for a visual prosthesis are based on neuronal electrical stimulation. Several different locations along the visual pathways have been proposed and examined so far for visual prosthesis:

- Retinal implant (which is either epiretinal or subretinal)
- Optic nerve implant and
- Visual cortex implant

A nice historical perspective regarding electrical visual prosthesis can be found in Lovell et al. (2007). There is a number of very good reviews of the artificial vision and visual prosthesis, such as Dowling (2005), Loewenstein, Montezuma, and Rizzo (2004), Margalit et al. (2002), Zrenner (2002), and so forth. The most favoured approach is the intraocular electrode array, since the retinal implant seems to be the most convenient for surgical intervention and it is easier to retinotopically map individual pixels on the light sensing array with points on the retina.

In most forms of retinal dystrophy, the photoreceptors are lost, but the RGCs, the output neurones of the retinal network, survive and project to the retinorecipient areas of the visual cortex. There have been numerous attempts to stimulate these cells as a prosthetic strategy. The implants to date have come in two forms: subretinal and epiretinal. Subretinal implants are placed underneath the retinal layers and usually consist of a microphotodiode array which attempts to stimulate the remaining signal processing layers in the retina (U.S. Patent No. 5,024,233, 1991). The epiretinal chips are positioned on the surface of the retina, and try to stimulate the retinal ganglion cell layer (U.S. Patent No. 5,935,155, 1999). In this case, additional image processing is required to replicate that of the bypassed retinal layers.

The retinal prosthetics that have been implanted to date have several problems (Dowling, 2005). Both types of implants have to be implanted inside the eyeball (and subretinal structures need to be placed under the retina, requiring more delicate surgery) and the stimulating electrodes have to be in good physical contact with the cells which they stimulate. The invasive electrodes can cause further degradation of remaining functional tissue. The curved nature of the eye makes it very difficult to cover any significant portion of the retina, though there have been attempts at more flexible substrates. Furthermore, power consumption issues are highly significant. Introduction of power cables is difficult, and power transmission through an RF link, for example, does not always provide sufficient power to power a significant quantity of stimulation points. Additionally, the position of the electrodes is fixed once they are inserted, and precise positioning on the micrometer scale is hard to control.

To date, epiretinal implants have used small numbers of electrodes and thus the patient has seen light flashes known as phosphenes. It has been possible for patients to interpret some basic shapes from these phosphenes (Humayun et al., 2003). However, if the stimulation matrix is to be scaled to allow detailed analysis of the visual scene, then the image processing component will become increasingly important.

There has been substantial progress toward an electronic retinal prosthesis, but fully functional, long-lasting devices are presently limited largely by power consumption issues.

PHOTONIC RETINAL PROSTHESIS

Optical Stimulation of Neuron Cell

Recent advances in biochemistry have generated a novel neuronal stimulation technology that is based on light. Using light to stimulate neuronal signals has many advantages. First, in contrary to electrode based stimulation, light does not require mechanical contact and can enable noninvasive remote control on the cell activities. Second, since light beams can be easily scanned, the stimulating point is flexible and does not require a prior decision on the stimulation location. Third, using conventional optics light can be focused to very high spatial resolution.

The feasibility of using light instead of electricity to trigger neuronal signals was first demonstrated in 1971 by Richard Fork who used high power laser to stimulate action potentials in the abdominal ganglion of the marine mollusk Aplysia California (Fork, 1971). Since then scientists have been exploiting developments in Nanotechnology and Genomics to realize various photostimulation tools that would revolutionize biology and neuroscience. The impartment of light sensitivity, also known as photosensitization, is achieved by either:

1. Photolysis of blocking moiety attached to neurotransmitters
2. Expression of natural photosensitive proteins and ion channels
3. Attachment of a photoisomerizable switch next to the active site of ion channel or membrane receptor.

Photolysis of Caged Neurotransmitter

The photolysis of caged neurotransmitter approach is based on disabling the neurotransmitter activity by attaching a photoremoveable blocking compound. This idea was first introduced in 1978 by Kaplan, Forbush, and Hoffman (1978), but the utility of the caged compounds tool became widely apparent to the neuroscience world just in 1986 when an NB-caged-acetylcholine agonist, carbamoylcholine, was used to study the kinetics of nicotinic acetylcholine receptors (Walker, McCray, & Hess, 1986). Since then photolysis of caged molecules has gained a wide use as a remote control means of stimulating cellular responses. Since all CNS neuron cells express glutamate receptors, caged glutamate is the most widely used caged neurotransmitter (Callaway & Katz, 1993).

The uncaging process has very good temporal resolution. A temporal spike jitter, which is the time between stimulus and the first single spike, was reported to be reliably evoked with 1-3 ms (Shoham, O'Connor, Sarkisov, & Wang, 2005). The spatial resolution is more limited since it is influenced by the diffusion of the uncaged molecules. However, recently were reported spatial patterns of up to 5 μm (Shoham et al., 2005).The remarkable resolution of the caged neurotransmitters technique enables the studies of single dendrite interactions and mapping of neuronal connectivity (Yoshimura, 2005). The downsides of the technique are:

- The stimulation of unintended sites and reduction of the repeatability of the process due to diffusion of the neurotransmitter,
- It is difficult to target single subpopulation in heterogeneous tissue due to the wide sensitivity to glutamate,
- The process requires continual supply of the caged molecules,
- The UV excitation reduces the biocompatibility of the approach and hinders stimulating in volumetric tissue.

Expression of Natural Photoreceptive Protein

Expression of natural photoreceptive proteins is probably the most straight forward approach to render light sensitivity in cells. Here we also include direct addition of photosensitive proteins, such as Photosystem-I (Greenbaum et al., 2002). Natural photosensitive proteins have the advantage of being optimized by evolution over millions of years and they have good quantum efficiency. Most of the photosensitive proteins in the eukaryotic cells are in the same family as rhodopsin, the protein found in the retina rods and cones cells. Rhodopsin and its relatives all have an apoprotein (opsin) and covalently linked a photoisomerizable chromophore (a light sensitive molecule such as 11-cis retinal). The *cis-trans* photoisomerization of the chromophore triggers a conformational change in the protein that signals downstream cellular events through G protein-coupled cascade (Kramer, Chambers, & Trauner, 2005). The feasibility of using a natural (invertebrate) light sensitive system was first demonstrated in 2002 (Zemelman, Lee, Ng, & Miesenbock, 2002). They showed that non sensitive cells can be converted to respond to light by expressing only three proteins of the phototransduction cascade: rhodopsin, arrestin-2, and α subunit of G-protein. However, this approach had poor control (jitter length in the order of seconds/minutes) and bad reproducibility. Since then, two additional photosensitive proteins have been developed to render neural cells light sensitive.

The first one was melanopsin which is a photopigment that was discovered in small subset (~2%) of intrinsically light-sensitive retinal ganglion cells that are not involved in the image formation process, but instead regulate the circadian system and the pupil constriction (Foster, 2002). The phototransduction in the melanopsin is based on an invertebrate type G-protein cascade. Melyan, Tarttelin, Bellingham, Lucas, and Hankins (2005) showed that when melanopsin was expressed in mammalian cell lines it enabled light-evoked depolarization responses. The spike jitter of the melanopsin can be seconds to minutes long (Qiu et al., 2005). Melanopsin has a sensitivity maximum at 480nm, and the threshold light intensity required for producing responses is near 1012 photons cm-2s-1. For comparison, the thresholds for the rod and cone photoreceptors are about 106 and 1010 photons cm-2s-1. The advantage of the melanopsin is that it is bistable due to its intrinsic capability to reisomerise the retinal molecule back to its cis state after the photoisomerization (Melyan et al., 2005).

The second photosensitive protein is the algal Channelrhodopsin-2 (ChR2). When expressed in animal cells ChR2 forms small-conductance, nonselective cation channels that can be activated by exposure to blue light (Boyden, Zhang, Bamberg, Nagel, & Deisseroth, 2005). Its photosensitivity is based on photoisomerization of all-trans retinal to a cis conformation. Like melanopsin, the retinal in ChR2 can be reisomerised to back to its *all-trans* state alleviating the need for external enzyme (Bi et al., 2006). Expression of ChR2 in the surviving inner retinal neurons of mice with photoreceptors degeneration restored the ability of the retina to detect light signals and transmit it to the visual cortex (Bi, 2006). ChR2 has a sensitivity peak in blue 470nm wavelength. Its activation threshold was reported to be between 1015 photons cm-2s-1 (Bi et al., 2006) and 1018 photon cm-2s-1 (Zhang et al., 2006). Contrary to melanopsin and rhodopsin, the phototransduction in ChR2 does not involve any amplifying signalling cascades, since the ChR2 is sensor and ion channel combined. Hence, cells that express ChR2 respond very fast. The channel is opened within just 50 µs from illumination and first spikes are expected after 1-3 ms. Boyden et al. (2005) used this unique kinetics to demonstrate for the first time a reliable millisecond timescale triggering of single action potentials (Boyden et al., 2005). Further investigations of the kinetics of ChR2 were published in Nikolic, Degenaar, and Toumazou (2006).

Synthetic Photoswitch

Photoswitching is also possible by coupling a synthetic photoisomerizable nano compound to an ion channel or a receptor protein. The azobenzene molecule is an example for such a compound. It shows a *trans*-to-*cis* photoizomerization upon absorption of a photon of the energy 3.4eV (λ = 365nm) and *cis*-to-*trans* at 1.95eV (λ = 420nm). This property has been recently used to form light controlled shaker channel (Banghart, Borges, Isacoff, Trauner, & Kramer, 2004). The uniqueness of the photswitch approach is its versatility since the photoswitch is not limited to a specific ion channel. At present, several limitations hinder the success of the technique: higher energy *cis* state is thermally isomerised to *trans* state disabling the bistable switch, the switching involve UV light, the photoswitch hyperpolarizes the cells and hinder action potential and the current method involves considerable genetic engineering.

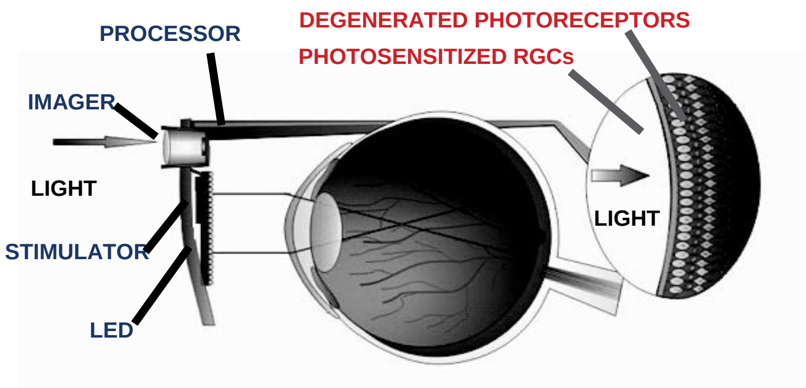
Description of the Prosthesis

The photonic retinal prosthesis, shown in Figure 1, is based on photosensitization of the residual retinal ganglion cells. The device comprises an image capturing component, light producing component, and control electronics to process the captured image and control stimulating waveforms of the light emission system (Degenaar et al., 2006). The light sources may be LEDs or lasers, for example, vertical cavity lasers. Each emitter will require individual control thus dedicated optoelectronic systems are required (Yan, Drakakis, Toumazou, Nikolic, & Degenaar, 2006), rather than typical raster scanned displays. The choice of the array will therefore depend on integration with processing electronics and power consumption.

The image processing is similar to that required for epiretinal devices, as the bypassed retinal processing needs to be replicated. Typically Laplacian filtering of the image is sufficient to replicate spatial processing (Banks, Degenaar, & Tournazou, 2005), but the full spatiotemporal processing will be more complex. Once the image is converted into the required retinomorphic format, individual points on the image matrix will need to be convolved with a stimulating transform to acquire the required stimulating waveform matrix. This will then be used to control the LED components which will emit the required optical waveforms to stimulate the RGC's and thereby the visual cortex.

Electrophysiological recordings of ganglion cells reveal diverse spiking patterns with maximal frequency up to several tens of kHz (Rullen, 2001). Additionally, ChR2, which is presently the most advanced candidate for photosensitization, will also have a variance in expression. Thus, the optical stimulation system will need to be tunable to cope with this variance. There is still a variance in the published literature about the required light intensities required for ChR2 stimulation. These vary between 0.1 and 100 mW/cm2. Given that

Figure 1. Outline of photonic retinal prosthesis device



functional vision restoration will require about 1cm2 of retinal stimulation, then assuming 5% LED quantum efficiency and 10% coupling efficiency, and negligible relative power consumption of the control circuitry, the final device will consume between 20mW and 20W. The former will last about 150 hours on a typical mobile phone battery, the latter about 10 minutes. It is thus crucial to maximize the photosensitivity of the RGCs and the efficiency of the light emission system.

FUTURE TRENDS

Optoelectronic vision restoration is presently in its infancy. As highlighted previously, there is still research to be done on maximizing the photosensitivity of the Retinal Ganglion cells. Additionally, the optical stimulation systems and control electronics will need development. The present potential directions are with flip-chip GaN based arrays on CMOS chips and organic/CMOS hybrid emissive systems that are used in present OLED displays. The latter is much more efficient, but may not be able to obtain the required brightness.

CONCLUSION

As this research progresses from the Petri dish to the animal models to humans, much will be learned not only about vision restoration but about the nature of communication with the visual cortex, and the adaptability of the visual cortex to new forms of image interpretation. Thus, the clinical implementation of this technology is around a decade from becoming commercial reality, but nevertheless provides exciting hope for the future.

KEY TERMS

ChannelRhodopsin/Melanopsin: proteins that can make cells light sensitive.

Implant: device made to replace or act as a missing biological structure.

LED: Light Emitting Diode.

Photosensitization: making neurons light sensitive.

Photoreceptor cells: retina cells that convert light into a change of cell membrane potential.

Retina: a very thin, multilayer network of neural cells at the back of the eyeball of vertebrates.

Retinal Ganglion cells: neural cells in the retina which receive the signals from the bipolar and amacrine cells (the cells that process the visual information passed by the photoreceptors) and send action potentials to the brain down axons, which form the optic nerve.

A Novel Blind Wavelet Base Watermarking of ECG Signals on Medical Images Using EZW Algorithm

Mohammad Saleh Nambakhsh
King's College London, UK

M. Shiva
California State University, USA

INTRODUCTION: NECESSITIES, METHODS, AND ALGORITHMS CURRENTLY USED

Exchange of databases between hospitals needs efficient and reliable transmission and storage techniques to cut down the cost of health care. This exchange involves a large amount of vital patient information such as biosignals and medical images. Interleaving one form of data such as 1-D signal over digital images can combine the advantages of data security with efficient memory utilization (Norris, Englehart & Lovely, 2001), but nothing prevents the user from manipulating or copying the decrypted data for illegal uses. Embedding vital information of patients inside their scan images will help physicians make a better diagnosis of a disease. In order to solve these issues, watermark algorithms have been proposed as a way to complement the encryption processes and provide some tools to track the retransmission and manipulation of multimedia contents (Barni, Podilchuk, Bartolini & Delp, 2001; Vallabha, 2003). A watermarking system is based on an imperceptible insertion of a watermark (a signal) in an image. This technique is adapted here for interleaving graphical ECG signals within medical images to reduce storage and transmission overheads as well as helping for computer-aided diagnostics system. In this chapter, we present a new wavelet-based watermarking method combined with the EZW coder. The principle is to replace significant wavelet coefficients of ECG signals by the corresponding significant wavelet coefficients belonging to the host image, which is much bigger in size than the mark signal. This chapter presents a brief introduction to watermarking and the EZW coder that acts as a platform for our watermarking algorithm.

EZW

The EZW algorithm was originally developed by Shapiro (1993) to find the best transmission order of the wavelet coefficients, which is the absolute value of decreasing order. This algorithm has already been applied to medical images and the electrocardiogram with good success (Nambakhsh, Ahmadian, Ghavami & Dilmaghani, 2006).

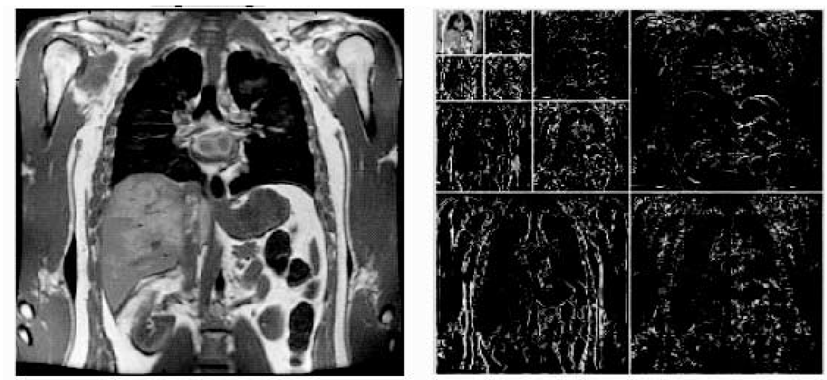
EZW in Image

The wavelet transform is a dyadic decomposition of an image (Nambakhsh et al., 2006) achieved by a pair of quadratic mirror filters (QMF). In two-dimensional separable dyadic discrete wavelet transform (DWT), each level of decomposition produces four bands of data, one corresponding to the low pass band (LL), and the other three corresponding to horizontal (HL), vertical (LH), and diagonal (HH) high pass bands (Figure 1).

Two distinct properties of the EZW algorithm make it an effective means of compression, as compared to traditional approaches. First, the EZW algorithm exploits the hierarchy of the wavelet coefficients and establishes a connection between coefficients from corresponding subbands in different levels of wavelet decomposition, allowing multiple coefficients to be encoded simultaneously. Second, coefficients are encoded in order of importance using bit prioritization (Mallat, 1989). After performing the 2-D DWT on the image, the resulting wavelet coefficients are coded by using a decreasing sequence of thresholds; that is, $T_0, T_1, \ldots, T_{N-1}$, where:

$$T_i = \frac{T_{i-1}}{2}, \qquad T_0 = 2^{\log_2(\max|\gamma(x,y)|)} \qquad (1)$$

Figure 1. Levels of decomposition



Here $\gamma(x,y)$ is the amplitude of wavelet coefficients and T_0 is the initial threshold value. The algorithm executes recursively two successive passes by considering significant coefficients in each pass related to the current threshold only (i.e., absolute value is higher than current threshold).

In the first pass, called the dominant pass, we look through significant coefficients related to the current threshold according to a scan order given in Figure 2(a) using the hierarchy given in Figure 2(b).

The algorithm then provides positions and signs of the significant coefficients in a predefined path that associates the absolute value of the parent coefficients with respect to their children ones. Two kinds of predefined paths are depicted in Figure 3.

Coefficients according to equation 1 and the way of scan that is illustrated in Figure 3 turn into four different symbols in the every step. In other words, they will be coded to P, N, Z, and IZ by the every pass process. Table 1 shows complete instructions of the coding process.

EZW in Signal

The EZW algorithm can be applied on signals similar to image. In this case, decomposed signal coefficients have dyadic tree instead of quad tree (Barni et al., 2001). This is illustrated in Figure 4.

It is obvious that each coefficient has two correlated coefficients in lower scale and so forth. We will use this similarity between images and signals to embed a signal inside an image, which is the topic of the next section.

PROPOSED WATERMARKING ALGORITHM

The multiresolution watermarking with multi secret key algorithm, which is developed in this chapter, is blind, because during the EZW decoding, only the multiparameter's secret key, which includes the header information and many parameters defined by the user, is used to extract the embedded information. There are

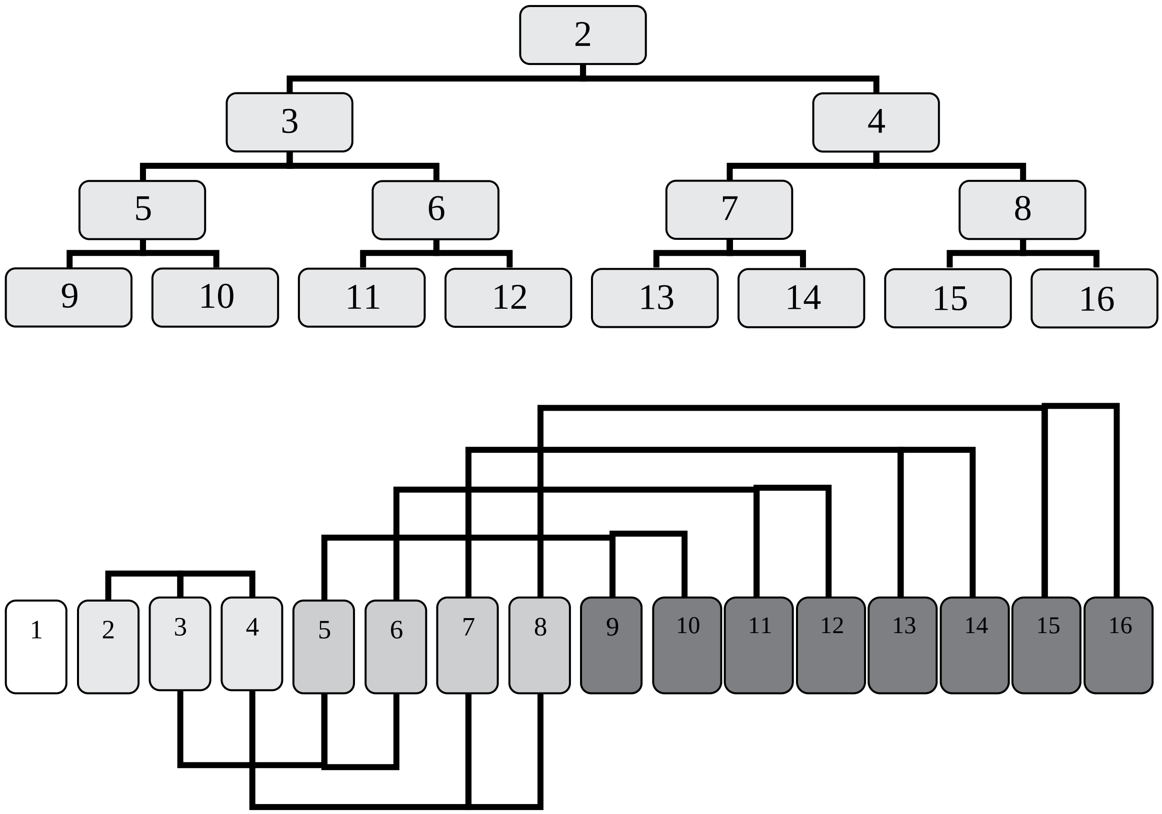
Figure 4. continued



two processes for embedding the mark signal during EZW coder:

The first is insertion process, and the second is extraction process, which is presented in sections 1 and 2.

The following notations will be used:

- INT_i : Thresholds interval $[T_i, T_{i+1}]$
- T_{sig} : Maximum threshold of matrix of signal decomposed signal
- T_{imag}: Maximum threshold of matrix of image decomposed image

Watermark Insertion Process

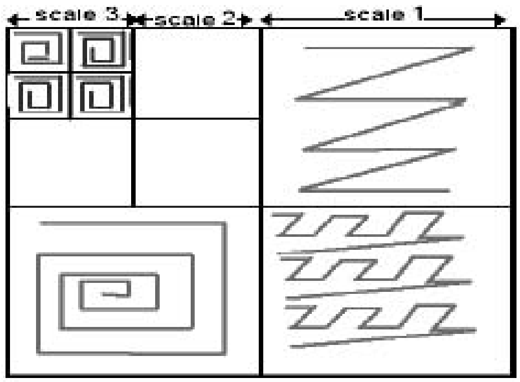
We performed up to five level of wavelet decomposition using Db2 (Wang, Doherty & Van Dyck, 2002) as mother wavelet to obtain matrixes of wavelet coefficients of host image and signal. Then, we specify maximum threshold of both matrixes (Eq.1). In the encoding process of the EZW coder, the image starts to be coded. After this, we look for the dominant pass with a threshold the same as the maximum threshold of the signal (T_{sig}).

After this, we look for the dominant pass with a threshold the same as the maximum threshold of the signal (Tsig). At the beginning, those belonging to this interval (INTi) are replaced with similar coefficients belonging to the last scale of the image matrix in current interval (INTi) according to a predefined path (scan order) of the matrix (Figure 2).

This means that once the coefficients of D4 are replaced with coefficients of image at scale 4 (Figure 6), then the rest of replacement at lower scales can be done by using the child-parent tree (Figures 2 and 4). Note that this predefined path can be changed by the user. In order to better comprehend, Figure 5 shows three different paths.

Subsequently, subtrees (coefficients in the lower scale according to Figure 4) of the embedded signal coefficients are replaced with subtrees (see Figure 2(b)) of image coefficients in a lower scale. Figure 6 illustrates replacement in the algorithm in a general way.

Figure 5. Three predefined paths of embedding

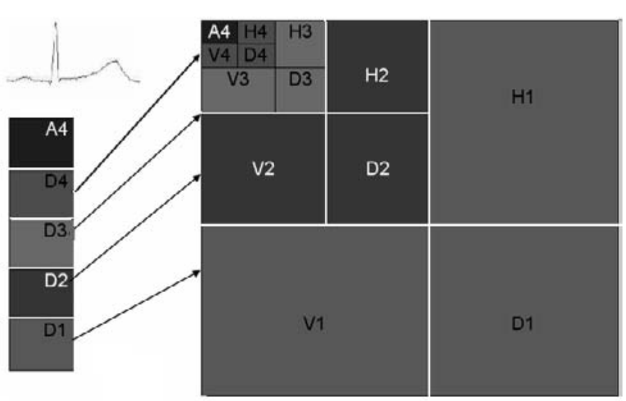


According to Human Visual System (HVS), coefficients located in lower scales are less sensitive than those in higher scales and details (H, V, D) are also less sensitive than approximation (A). Therefore, more significant coefficients are embedded inside a less sensitive region of an image.

HVS has at least two advantages: First, there must be a minimum amount of contrast between the areas of the image to be perceived as different by human eyes. Second, the HVS is less sensitive around edges than in smooth areas of an image. This effect is referred to as "spatial masking" and can be exploited for watermarking by increasing the watermark energy locally near the edge (Voloshynovskiy, Herrigel & Pun, 2000).

As part of the implementation of the algorithm, we use the perceptual model for varying the watermark based on the host image content (Noore, Tungala & Houck, 2004; Podilchuk & Zeng, 1998). An amplifying factor array, α, is computed for different scales and subbands according to human visual system (HVS). In other words, α is an array of amplifying factors for different subbands in different scales. It varies the watermarks coefficients such that a maximum amount of information can be hidden in the host image depending on luminance and contrast properties of the embedding region with least distortion to host image. In other words, the correlation between the original watermark, w_m, and the embedded watermark, w_a, is made maximum, while keeping the perceptual distance between the original image and watermarked image constant. The best value of α is found by iteratively computing the just noticeable difference (JND) for the watermarked image and reducing this difference to a target value. The embedded watermark is finally obtained using the best value defined in Eq. (2):

Figure 6. Correspond scales of replacement



$$Wa_s^d = \alpha_s^d W_{ms}^d \quad (2)$$

Where d is detail subbands that d={1,2,3} is equal with {H,V,D} and s is scale. For example, $\alpha_3^2 = V_3$, Wa_3^2 is watermark stream which would be embedded into V_3.

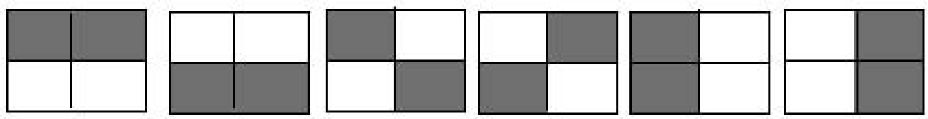
It is important to know that α for the last scale is equal, first because the extraction process has to be able to find coefficients of last scale of signal automatically. Accordingly, we have blind watermarking.

We perform the following process, which tries to insert the wavelet coefficients of the watermark:

1. **Initialization:** A multisecret key is used to select the embedding locations parameterized and randomly to secure the original watermark from tampering. Specifying the multisecret key includes:
    a. Way of scanning in EZW coder; for instance, Morton scan
    b. Prioritization of detail subbands of image for embedding (H, V, D, or V, D, H, ...)
    c. Selecting one way of embedding dyadic tree of the signal inside a quad tree of the image out of six ways (Figure 7)
    d. Maximum level of decomposition for signal and image
    e. Size of the signal
    f. Maximum threshold of the signal
    g. Way of selecting coefficients of signal for embedding in every pass

Figure 8. Block diagram of watermarking embedding process

Figure 7. Six ways of replacing two signals' coefficient with four possible images' coefficient



h. Coordinate of start point of embedding in wavelet matrix of image
i. Definition of mother wavelet.
j. Matrix factor α_S^d in Eq.2

2. **Encoding:** Making list of mixed symbols P, N, Z, IZ:
   i=0;
   $T_{imag} = T_{MAX-of-iaage}$
   $T_{sig} = T_{MAX-of-Signal}$
   $T_i = T_{imag}$

   While i>=0
   $INT = [T_i - T_{i-1}[$
   Check Threshold (Ti);
   If $T_i \leq T_{sig}$
   Find$\{S_i\} \in INT$ in signal detail last scale (n=number of coefficients);
   Find $\{C_i\} \in INT_i$ in image details last scale (H,V,D);
   Replace S_i with C_i;
   Replace sub-tree of S_i inside sub-tree of C_i;
   End;
   EZW (Dominant pass & subordinant pass);
   i=i+1;
   $T_i = T_{i-1} / 2$;
   End;

   This process is nearly similar for the embedding of signal approximation within the image approximation.

3. **Decoding:** The final watermarked image is obtained when the embedded subbands are reconstructed by passing EZW decoders, which turn symbols into wavelet coefficients by refining algorithm with the help of multisecret key information and eventually a five-level inverse discrete wavelet transform (IDWT).

The block diagram of embedding process is illustrated in Figure 8 to clarify different aspect of this section thoroughly.
According to the symbols generated during the encoding process in EZW algorithm, we present a formula for the first time, which represent percentages of redundant data inside images. It will be a comparing measure for considering effects of watermarking in contrast with mark size.

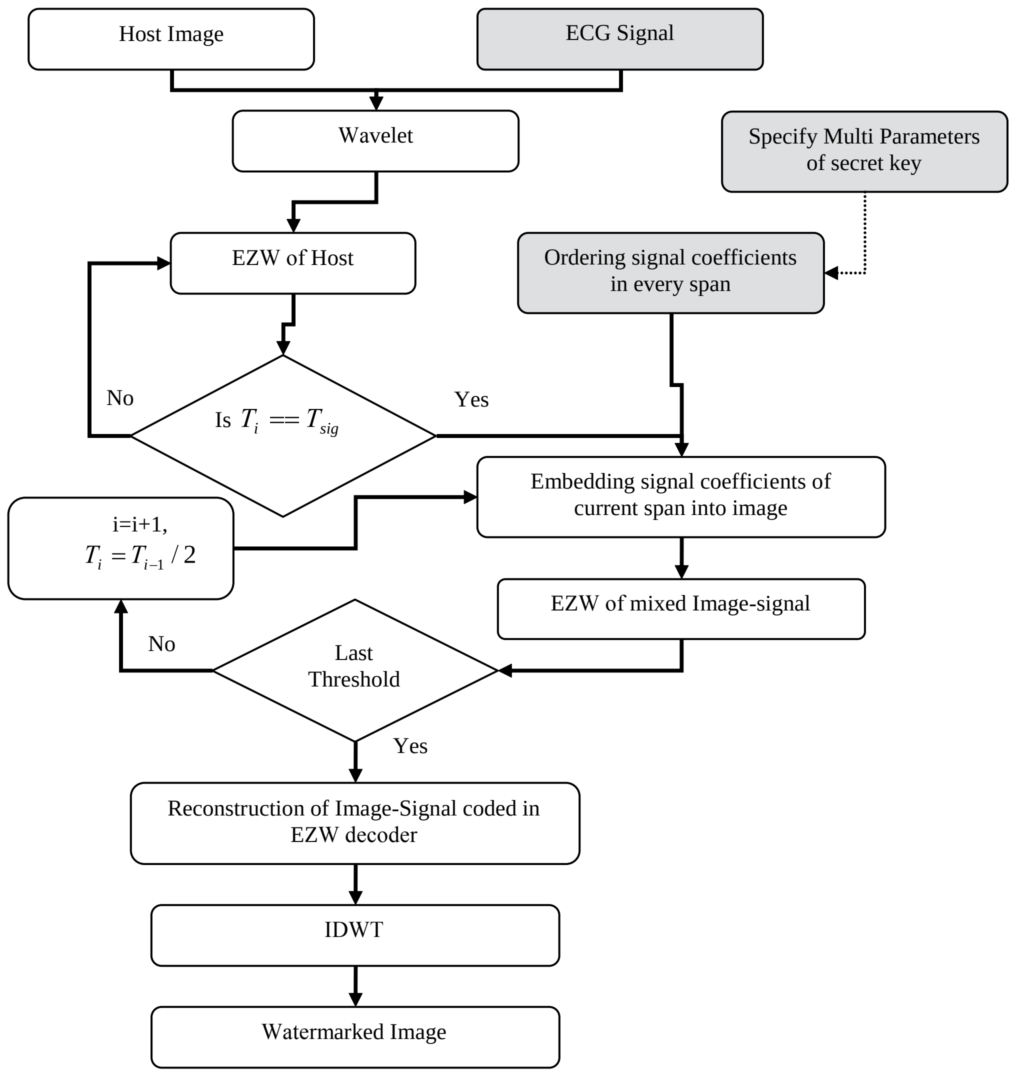
$$RD = \frac{Z+T}{Z+T+P+N} \times 100 \qquad (3)$$

while Z,T,P,N are numbers of symbols that have been defined in Table 1. RD is the percentage of redundancy for each image.

Watermark Extraction Process

In the extraction process, we nearly repeat most of the steps in the insertion process but in the reverse order, and the wavelet coefficients of the compressed watermarked image are constructed. Then, scanning is performed on the matrix in a predefined way using the initial multiparameters' secret key to find signal coefficients. In this step, we only need the wavelet coefficients matrix of the watermarked compressed image to construct the extracted wavelet coefficients of the ECG signal. By using the multiparameters' secret key highest details matrix coefficients (in Figure 6, D4 will be constructed from H4, V4, D4 by the secret key) and then according to their position, other coefficients in the lowest scale will be extracted. Finally, matrix of wavelet coefficients of the ECG will be constructed, and then 1-D and 2-D inverse discrete wavelet transform (IDWT) is applied to the matrix in order to reconstruct the extracted watermark and the compressed watermarked image, respectively. Block diagram of the extraction process has been illustrated to better observation of the process (Figure 9).

Figure 8. Block diagram of watermarking embedding process



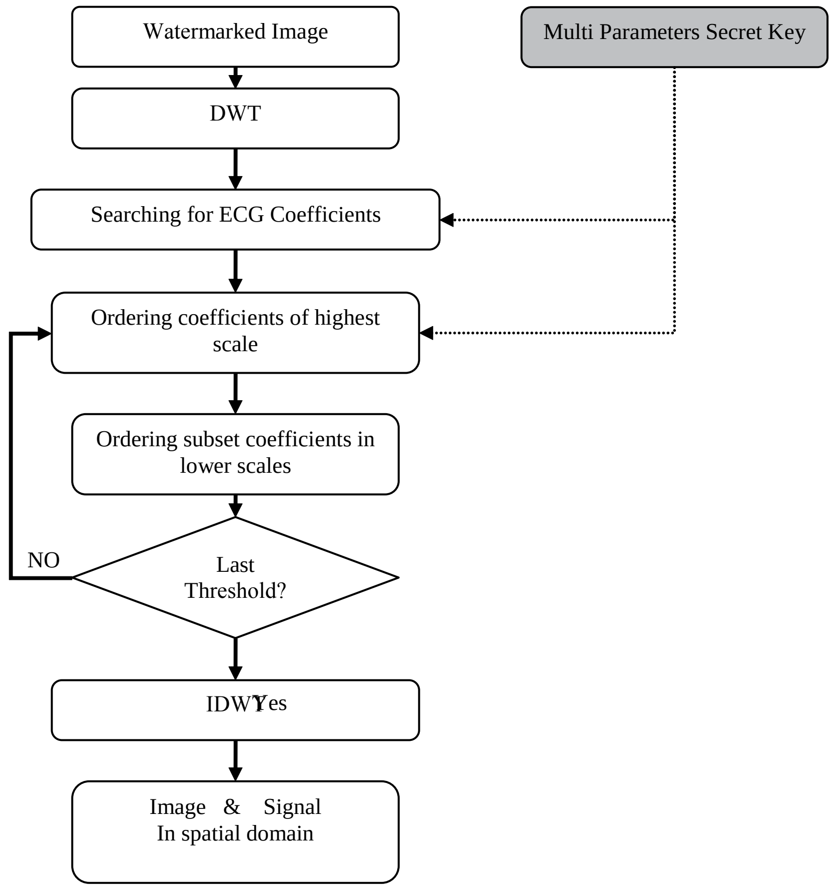
EXPERIMENTAL RESULTS

Several grey-scale MRI and CT images of size 256 × 256 and 512 × 512 pixels have been watermarked by embedding two different watermarks of size 512 and 1024 bytes (Figure 10).

As it is shown, the watermarked images are perceptually or visually acceptable. The original mark ECG signal (1KB) together with its reconstruction after extraction are shown in Figure 11.

We have used several mother wavelets such as Db2 to Db6 and different Cohen filters and found out that Db2 and Db6 are the best for our experiments (Wang et al., 2002). The PSNR calculated between the original image and the compressed watermarked and original signal and extracted one is more than 35 dB for all experi-

Figure 9. Block diagram of extraction process



ments as shown in Figure 12 and Table. 3. This proves the imperceptibility of the embedded watermarks, the property of unchanged remaining extracted signal, and the ability to find the signal accurately.

Beta factor (β) is for evaluation of the degradation of details or edges throughout the image. A β close to one shows less degradation. We have calculated β of the watermarked image as shown in Figure 13 and Table 3 using the following equation:

where ΓI is the high-pass Laplacian filter of the original image, $\overline{\Gamma I}$ is its mean value and wI is the watermarked image.

To compare results of β with amount of RD, we have depicted Table 2 to show the relation of RD with variance (σ^2) of one of the details in scale4 in every image. Obviously, it has inverse relation with variance and direct relation with β, which is resulted after watermarking.

Note that variance in other subbands and scales have direct relation with variance of H4. Therefore, we only show the variance of H4.

From the Figure 14, it is obvious that increase of redundant data in images will provide more space for embedding so that changes in edges are less sensitive.

The proposed method of selecting the insertion sites ensures both watermarking constraints: imperceptibility, since the watermark coefficients of highest scale are almost identical or even equal to those with which they are replaced; robustness since the substituted

coefficients are significant, and they will not be lost in the quantization step. Moreover, if the watermark extraction process does not find the considered approximation coefficients in the watermarked image matrix at the location indicated by the key, it will search an equivalent value somewhere else. And blindness because extraction algorithm must find the highest detail and approximate according to the information of multisecret key. Cross correlation (CC%) have been calculated between the original and extracted signals for evaluation of percentage of the unchanged signal. S/I (signal/image) is the percent of signal embedded within the image as shown in Table.3.

CONCLUSION AND FUTURE TRENDS

The proposed watermarking algorithm is blind because it only needs an initial key in the extraction process. We have included two processes in the EZW coder; the first one uses embedding the ECG signal in the host image after the decomposition step. The second process intervenes after the decomposition of the compressed watermarked image in order to extract watermarks.

The proposed algorithm has proved its imperceptibility since the embedding process here means a substitution of original coefficients by the equivalents (in the sense of EZW significance) from the watermark. The great advantage of this method is to decode the host image and the mark signal, progressively. This enables extracting the mark signal in a progressive approach from low to high resolution.

The outcome of this proposed method is to make an optimum balance between the resolution of host image and the size of the mark by controlling the maximum scale to be scanned in EZW algorithm. This presents a novel resolution controlled watermarking. Also it is possible to embed biosignals and demographic texts of a patient inside his or her related medical images to reach high integrity between related medical information of each patient and prevent mismatching of information in medical databases. To optimize the proposed method, we are going to use Hermit coefficients of ECG signal instead of its wavelet coefficients. Thus, one can raise capacity of watermarking with almost a factor of six.

KEY TERMS

ECG: Electrocardiograph signals that are recorded from heart activation.

Embedding: Fixing information in other information firmly and deeply.

EZW: Embedded zero-tree wavelet.

Medical Image: Digital images from different parts of the body that are acquired by MRI, CT, Mammography, and so forth; their role here is host in the watermarking process.

Watermarking: Inserting or embedding a kind of digital information inside other kinds or similar kinds of digital information.

Wavelet: A kind of transform domain.

A Novel Radiotherapy Technique

Maria F. Chan
Memorial Sloan-Kettering Cancer Center, USA

Yulin Song
Memorial Sloan-Kettering Cancer Center, USA

INTRODUCTION

Cancer is the second leading cause of death behind heart disease in the United States (National Center for Health Statistics, 2006). Various caner treatments are available now, but the three most common types are surgery, chemotherapy, and radiotherapy. Radiotherapy uses radiation—in the form of a special kind of x-rays, γ-rays, electrons, or protons to kill cancer cells. The advance of modern radiotherapy is closely linked to the evolution of computer and information technology. Intensity-modulated radiation therapy (IMRT) is an advanced form of three-dimensional conformal radiotherapy (3DCRT). It has become today's standard for state-of-the-art radiation treatment. IMRT is based on the concept of inverse treatment planning. By optimizing a constrained objective function, IMRT can modulate the shape and intensity of radiation beams to create a dose distribution highly conformal to the target volume. In this article, we report the results of our investigation on the feasibility and potential benefits of combining electrons with intensity-modulated photons, called IMRT+e, for selected types of caner, particularly for superficial tumors with critical organs underneath. The aim is to deliver high radiation dose to the tumor while sparing all the surrounding normal tissues, thereby minimizing radiation induced side-effects.

BACKGROUND

IMRT uses nonuniform beam intensities within a radiation field to provide more degrees of freedom for dose shaping and dose escalation, resulting in dose distributions that conform more tightly to the tumor shape. As a novel treatment modality, IMRT consists of three major components: a CT-based simulation system, an inverse treatment planning system with computerized optimization, and a computer-controlled linear accelerator delivery system. Unlike traditional IMRT, IMRT+e incorporates static electron fields into photon IMRT fields, taking advantage of electron beams' shallow penetration depth. The novel feature of this approach is that the optimization takes the exiting electron dose distributions into account, resulting in a treatment plan superior to a composite plan whose component plans are optimized independently. Our earlier study (Chan, 2006) has quantified the potential benefits of IMRT+e using established dosimetric parameters for malignant pleural mesothelioma (MPM). Details of various radiation techniques for MPM, such as photon and electron matching (Kutcher, Kestler, Greenblatt, Brenner, Hilaris, & Nori, 1987; Yajnik, Rosenzweig, Mychalczak et al., 2003), intraoperative radiotherapy (IORT) (Hilaris, Nori, Kwong, Kutcher, & Martini, 1984; Lee, Everett, Shu et al., 2002; Rosenzweig, Fax, Zelefsky, Raben, Harrison, & Rusch, 2005), IMRT (Ahamad, Stevens, Smythe et al., 2003; Baldini, 2004; Forster, Smythe, Starkschall et al., 2003; Munter, Christian et al., 2005; Munter, Nill, Thilmann et al., 2003), and intensity-modulated arcs (Tobler, Watson, & Leavitt, 2002), have been published. The first three techniques have been implemented clinically. As demonstrated by our data (Chan, 2006), IMRT+e provided superior target dose coverage compared to the conventional techniques. In addition, IMRT+e also improved critical organ sparing. Here, we present the results of IMRT+e for the treatment of various superficial tumors.

To further explore its potential benefits, IMRT+e was used on a patient with extensive lesions of the scalp covering the entire forehead and both temporal surfaces (Chan, 2006). Traditionally, these lesions have been treated with various electron beams. The relatively high skin dose provided by the electron beams, as well as the limited particle range, allows for adequate dose to the superficial target volume while sparing the underlying normal tissue, principally the brain. To eliminate the field-matching problem with electrons for extensive lesions, several investigations have been attempted by adding photon fields (Akazawa, 1989; Tung, Shiu, Starkschall et al., 1993). Electron arc techniques can also be used although designing an arc to deliver a sufficient dose to the target is difficult. The use of arcing photon fields was also reported (Kinard, Zwicker, Schmidt-Ullrich et al., 1996). Energy- and intensity-modulated electron beams have been investigated (Bedford, Childs, Hansen et al., 2005; Karlsson, Karlsson, & Zackrisson, 1998; Klein, 1998; Locke, Low, Grigireit et al., 2002; Ma, Pawlicki, Lee et al., 2000; Yaparpalvi, Rontenla, & Beitler, 2002). IMRT is able to modulate the photon fields, thereby customizing the dose distribution more specifically to the target. Locke et al. (2002) evaluated the use of tomotherapy with the Peacock system (NOMOS Corporation, Sewickley, PA) for this type of problem. It was found that IMRT provided improved dose homogeneity in the planning target volume (PTV) compared with the more conventional techniques, but resulted in higher doses to the brain and lens. More recently Bedford et al. (2005) further examined the possibility of using IMRT for extensive scalp lesions. They compared photon IMRT with either two or four matched electron fields and arcing electron fields. Their results showed that IMRT offered a feasible alternative to electron techniques for the treatment of extensive scalp lesions. Although it was considered to be clinically acceptable, the brain dose was higher with photon IMRT. In our study, the IMRT+e plan produced a more desirable dose distribution in terms of the dose reduction to the brain with the same dose conformity and homogeneity in the target volumes.

We also employed the IMRT+e technique to treat a patient with Merkel cell carcinoma of the left upper eyelid. A complex IMRT+e plan was computed to cover the left upper eyelid and the left lateral periorbital soft tissues, as well as the facial, periparotid, and cervical lymphatics. The plan consisted of three 6 MV IMRT fields and one enface 6 MeV electron field, delivering a total dose of 54 Gy in 30 fractions.

IMRT+e METHODOLOGY

The key concept of IMRT+e is to incorporate existing static electron fields into the photon beam inverse planning optimization. The goals are to improve the target dose conformity, boost the skin dose, and spare the distant critical organs. Although the photon beam IMRT has been shown to be an effective treatment for deep-seeded tumors, it is not suitable for treating very shallow targets like skin cancer, certain types of MPM, and breast cancer. This is due to the low surface dose and deep photon beam penetration. The slow attenuation of photon beams can still deliver a significant dose to the distant critical organs. The rapid dose falloff of electron beams makes electron therapy a viable treatment modality for these shallow targets. In addition, electron beams have negligible scatter radiation, compared to photon beams. Furthermore, electron beam therapy uses normal incidence; it is, therefore, less affected by patient's respiration than photon beam IMRT, particularly beamlet-based IMRT.

Prior to optimization, the PTV is delineated on CT images by a radiation oncologist. An appropriate margin is added to the PTV to account for patient setup uncertainty and internal organ movement. Critical structures are also delineated by either a medical physicist or a radiation oncologist. The IMRT+e plan is computed on a planning system developed at the Memorial Sloan-Kettering Cancer Center. The photon-only IMRT plan is computed first using six MV photons with several beam directions. Depending on disease sites, the beam configuration varies with the target and critical organ geometry. To create an IMRT+e plan, one or two electron fields using 6-16 MeV are added to the computed photon IMRT plan. The IMRT plan is then optimized again. This new round of optimization takes the existing electron dose distributions into account. Therefore, for those voxels with exiting electron dose, the photon IMRT fields will deposit less of a dose there. Normally, enface electron field arrangement is sufficient to achieve the acceptable tolerance levels for critical structures. When these acceptable levels can not be met, alteration of electron energy or differential weighting of the electron plan is attempted. In general, the electron fields are manually optimized to contribute about 50% of the prescribed dose. The quality of the final plan is evaluated using dose-volume histograms (DVHs). The photon IMRT component of the plan is designed to be delivered using the dynamic multileaf collimator (DMLC) technique while the static electron component is treated with custom electron cutouts.

The IMRT optimization algorithm uses an iterative gradient search method to minimize an objective function (Chui & Spirou, 2001; Spirou & Chui, 1998). The objective function consists of terms corresponding to the targets and the organs at risk (OAR).

$$F = F_{t\arg e-1} + F_{t\arg e-2} + \cdots + F_{OAR-1} + F_{OAR-2} + \cdots \quad (1)$$

The term for the target is given by:

$$F_{\text{target}} = \frac{1}{N_t}\left[\begin{array}{l}\sum_{i=1}^{N_t}(D_i - D_{presc})^2 \\ +w_{t,\min}\cdot\sum_{i=1}^{N_t}(D_i - D_{\min})^2\cdot\Theta(D_{\min} - D_i) \\ +w_{t,\max}\cdot\sum_{i=1}^{N_t}(D_i - D_{\max})^2\cdot\Theta(D_i - D_{\max})\end{array}\right] \quad (2)$$

where N_t is the number of points in the target, D_i is the dose to point *i*, and D_{presc} is the prescription dose. The second and third terms inside the brackets implement the target dose homogeneity criterion: D_{min} and D_{max} are the desired minimum and maximum target doses, and $w_{t,min}$ and $w_{t,max}$ are the penalties associated with under- and overdosing. Θ(x) is the Heaviside function, defined as:

$$\Theta(x) = \begin{cases} 1 & x \geq 0 \\ 0 & x < 0 \end{cases} \quad (3)$$

Similarly, the term for the OAR is given by:

$$F_{OAR} = \frac{1}{N_{OAR}}\left[\begin{array}{l} w_{OAR,\max}\cdot\sum_{i=1}^{N_{OAR}}(D_i - D_{\max})^2\cdot\Theta(D_i - D_{\max}) \\ +w_{OAR,dv}\cdot\sum_{i=1}^{N_{dv}}(D_i - D_{dv})^2\cdot\Theta(D_i - D_{dv})\end{array}\right] \quad (4)$$

where the first term inside the brackets implements a maximum dose constraint D_{max} on the OAR and the second term implements a dose-volume constraint. The relative penalty weights are given by $w_{OAR,max}$ and $w_{OAR,dv}$, respectively. N_{OAR} is the number of points in the OAR and N_{dv} the number of points whose dose must be below the dose-volume constraint dose D_{dv}.

The dose to point *i*, D_i, is the sum of dose contributions from all rays:

$$D_i = \sum_{j=1}^{N_r} x_j a_j \quad (5)$$

where N_r is the number of rays, x_j is the intensity of the *j*-th ray, a_{ij} the dose deposited to the *i*-th point per unit intensity of the *j*-th ray, and the product is summed over all *j*. The goal of optimization is to find the set of ray intensities x_j that minimizes the objective function given by expression (1).

The described methodology is, in principle, applicable not only to intensity-modulated photons, but also electrons or combination of both. At this time, medical linear accelerators are not equipped with electron MLC (EMLC), thus intensity-modulated electron plans can not be delivered. As a result, inverse treatment planning is routinely performed for photon beams only. However, to fully take advantage of the finite range of electron beams, it is beneficial to combine electrons with photon IMRT for certain disease sites. This can be accomplished by optimizing photon IMRT over a manually planned electron dose distribution. In this case, D_i in the above expressions is substituted with $D_i + D_{i,\,electron}$, where $D_{i,\,electron}$ represents the electron dose distribution. $D_{i,\,electron}$ is manually determined by the treatment planner and is not varied by the optimization algorithm. Figure 1 shows a representative photon IMRT field, where a low intensity region corresponding to the electron field was created to spare the kidney in an MPM patient.

Several dosimetric parameters from DVHs were evaluated to assess the significance of improvement of this new technique. The target coverage was measured by the dose covering 95% of the PTV (D_{95}), the volume of the target receiving at least 95% of the prescription dose (V_{95}), and the maximum and minimum target doses. The mean doses were used as the plan evaluation criteria for critical organs. The estimated normal tissue complication probability (NTCP) (Burman, Kutcher, Emami, & Goitein, 1989; Kutcher & Burman, 1991; Lyman, 1985) and fraction of lung subunits damaged (Fdam) (Jackson, Ten Haken, Robertson, Kessler, Kutcher, & Lawrence, 1995) were also used to evaluate the probability of pneumonitis for MPM patients. Thermoluminescent dosimeters (TLD), diodes, Gafchromic EBT films, and optically stimulated luminescence (OSL) dosimeters were used to verify the accuracy of the IMRT+e dosimetry. Figures 2, 3, and 4 show representative dose distributions of three different IMRT+e plans.

Figure 1. A BEV of a photon IMRT field (MLC aperture in green) shows a low intensity region (50% intensity level in white) corresponding to the electron field cutout. Kidneys and liver are in pink and light blue, respectively. The yellow mesh represents the shape of the PTV. The distance between grid points is 2 cm.

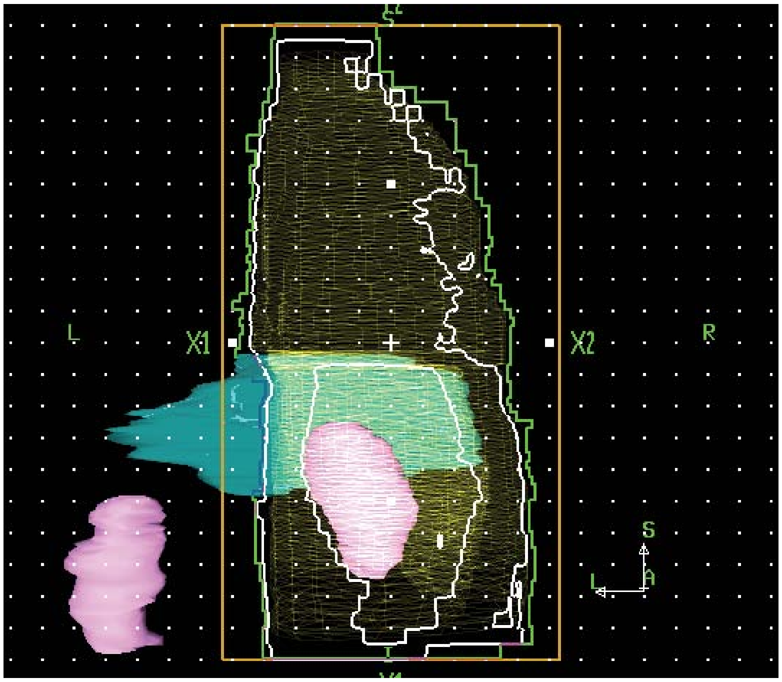

Figure 2. Isodose distributions of a representative transverse image at the level of the kidneys/liver of an MPM patient (PTV in yellow)

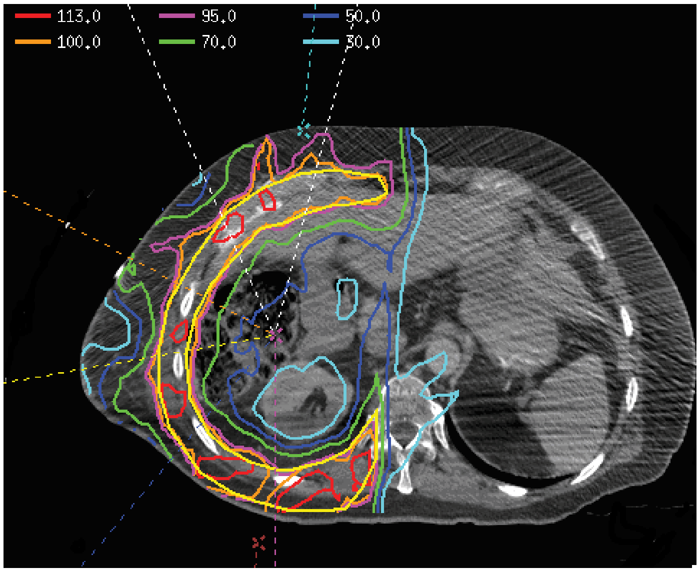

Figure 3. Isodose distributions of a representative sagittal image of the patient with extensive lesions of scalp (PTV in yellow)

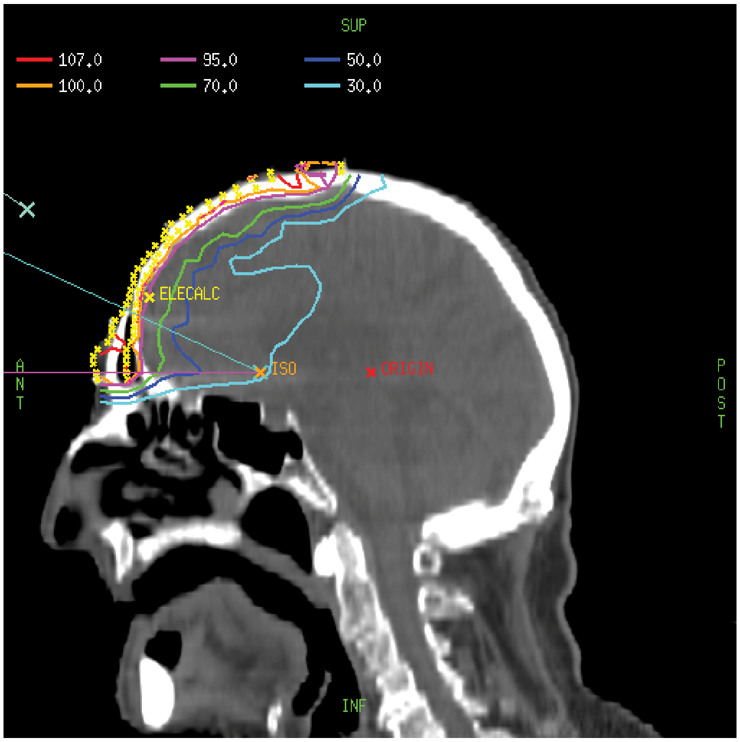

Figure 4. Isodose distributions of a representative transverse image of the patient with Merkel cell carcinoma of the left upper eyelid (PTV in yellow)

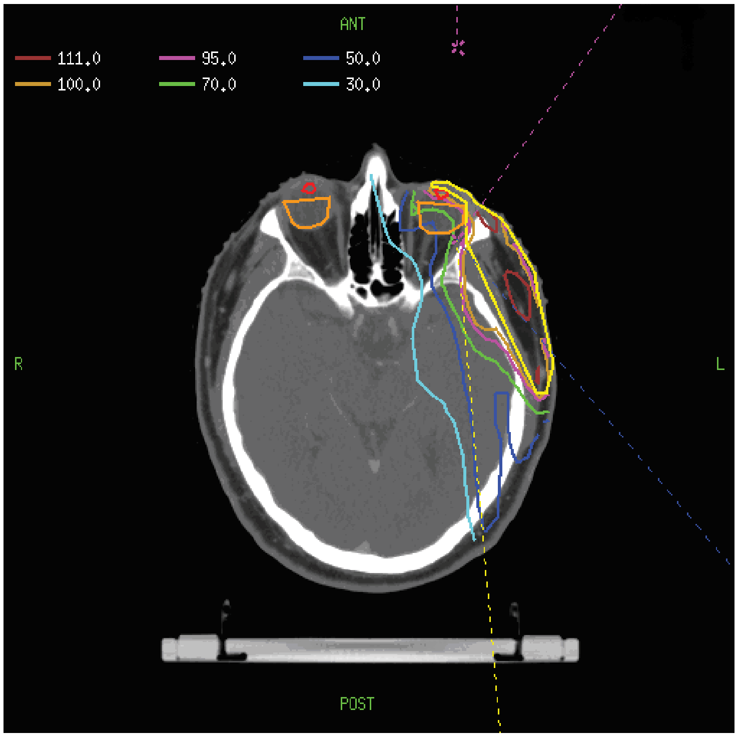

FUTURE TRENDS

Recently, there has been a strong interest in using photon IMRT to treat mesothelioma (Ahamad, Stevens, Smythe et al., 2003; Forster et al., 2003; Munter et al., 2003; Munter et al., 2005; Zierhut, Gutwein, Munter, Woger, & Debus, 2004). IMRT has shown great potential to produce a highly conformal dose distribution around the concave-shaped target volumes and a steep dose gradient near the OAR. These characteristics can spare radiosensitive normal structures and reduce complication rates. Therefore, IMRT may improve local-regional tumor control through dose escalation while maintaining acceptable levels of normal tissue complications. However, the high photon exit dose and low surface dose make it suboptimal for treating very shallow targets such as certain portions of typical pleural mesotheliomas.

Extensive scalp lesions also present a challenge to radiotherapy due to the fact that they are superficial and surround critical structures (e.g., brain and optic structures). To search for the best treatment option, a variety of planning techniques has been developed and tested. Bedford et al. (2005) proved that IMRT offers a feasible alternative to electron techniques for the treatment of extensive scalp lesions. The PTV dose distribution with IMRT does not suffer from problems of matching static electron fields and is considerably more homogenous than with either static or arcing electrons. However, the brain dose is higher with IMRT, but it is considered to be clinically acceptable. With IMRT+e, the brain dose can be further reduced, thus minimizing radiation-induced complications.

In theory, tumors with both deep and superficial extensions can be best treated with a combination of photon IMRT and modulated electron radiation therapy (MERT) (Song, Boyer, Pawlicki et al., 2004). Unlike photon IMRT, MERT can provide both intensity and energy modulations. However, the delivery of MERT plans requires an EMLC, which is not available on current commercial medical linear accelerators. Thus, IMRT+e is a promising alternative approach by which a conventionally delivered electron contribution is incorporated into the inverse treatment planning process. The rapid dose falloff of electron beams makes them a preferable treatment modality for the shallow parts of the PTV. Conceptually, such a combined modality plan would consist of multiple photon beams with the same low photon energy and electron beams with different energies, depending on the tumor depth. Dose conformity in the depth direction would be achieved by the use of different electron energies. Dose conformity and uniformity in the lateral directions would be achieved by photon beam intensity modulation using DMLC. Through both intensity and energy modulations, this combined approach is capable of delivering highly conformal doses to targets with complex shapes like mesotheliomas and of improving normal tissue sparing, particularly the distant critical structures. This technique, although not yet clinically mature, might present an opportunity for further dose escalation to the target and could potentially lead to improved local control. Adding the electron beams takes an experienced planner using our planning system approximately 30 minutes longer than IMRT planning alone. Our experience is that IMRT+e treatment time will be 15 minutes longer than IMRT alone.

CONCLUSION

We explored the feasibility of treating mesotheliomas, extensive squamous cell carcinoma of the scalp, and Merkel cell carcinoma of the eyelid using IMRT+e. This approach combined photon IMRT and static electron beams into a single plan. The optimization of the IMRT fields accounted for the existing electron dose contributions. Based on our initial experience, we believe that this new technique is straightforward and clinically viable. It improves target dose coverage compared to conventional non-IMRT methods and increases normal tissue sparing compared to photon-alone IMRT. Further refining of the IMRT+e technique will offer opportunities to escalate tumor dose without increasing normal tissue complication.

KEY TERMS

Three-Dimensional Conformal Radiotherapy (3DCRT): A complex process that begins with the creation of 3D digital data sets of patient tumors, and normal anatomy. These data are then used to generate 3D computer images and to develop complex treatment plans to deliver a highly "conformed" 3D radiation dose while sparing normal adjacent tissues.

IMRT: Intensity-modulated radiation therapy is an advanced form of 3DCRT. It uses sophisticated software and hardware to modulate the shape and intensity of radiation beams targeted on different parts of the treatment area.

Linear Accelerator: The most commonly used device for external beam radiation treatment for cancer patients. It delivers radiation dose of high-energy photons and/or electrons to the region of the patient's tumor.

PTV: Planning target volume is a composite margin of subclinical margin of gross tumor volume, internal margin accounting for variations due to organ movement and respiration, and set-up margin accounting for all the uncertainties in patient/beam positioning.

DMLC: IMRT plans can be delivered with a conventional multileaf collimator (MLC) in the dynamic mode. The MLC leaves continuously move while the beam is on. DMLC delivers intensity-modulated beam profiles previously determined by plan optimization algorithms.

Online Nurse Education

ABSTRACT

In many countries, healthcare professionals are required to participate annually in compulsory continuing medical education (CME). The effort involved in providing wide-scale training led the Italian Ministry of Health to support pilot courses using online distance learning. This article reports the results of a short survey which aimed to gauge the potential of online CME for nurses in Italy. Most of the 152 respondents, all of whom had completed an online course, supported the inclusion of some form of collaborative learning. Three possible market segments for online learning emerged from the study: nurses who prefer to study alone, those who would appreciate collaborative activities well-integrated into course design, and those who would prefer courses that include online collaboration of any kind. The authors conclude that online learning is a suitable mode for enabling participation in CME for accreditation, but caution that further research is required to confirm that the preferences of nurses who have experienced online distance learning are shared by those who have not.

INTRODUCTION

Rapid developments in medical knowledge have been accompanied by increased attention to continuing medical education (CME) for doctors, nurses, and other healthcare professionals. To ensure practitioners' knowledge remains current, professional organizations or national bodies, or both, typically establish a minimum number of hours or CME credits which a healthcare professional must attain in a year to maintain their accreditation to practice. Given the extent of training required, several national governments have supported pilot studies that use information and communications technologies (ICT) in different ways to enable healthcare professionals to participate in CME from their home or place of work, or while mobile, "on the road."

There is little literature on CME in the information systems field, but some recent studies have examined aspects of interaction by medical workers with Internet and mobile technologies. Studies of adoption of the Internet and Internet-based systems to gather data for evidence-based practice in the United Kingdom in the late 1990s indicated that voluntary use of such systems was limited by the busy day-to-day working life of the staff of medical practices (Abdulrasul, 2001; Howcroft & Mitev, 2000; Klecun & Cornford, 2003). The studies of mobile systems indicate that adoption of mobile technologies in medical contexts is complex, and related at least as much to organizational issues such as control, and extra-organizational issues such as the individual's perceived role as a professional and member of society, as it is to the interface between the user and the technology (Scheepers, Scheepers, & Ngwenyama, 2006; Wiredu & Sorenson, 2006). To this extent, these studies touch on some of the problems that online CME aims to address.

Nurses, like other healthcare workers, are faced with the challenge of combining education with practice, and their lives as professionals, family members, and members of society. In many countries, nurses obtain formal qualifications or keep up to date with developments in theory and practice part-time, juggling study with the demands of their day-to-day work and family life. Since 2002, the Italian government has required health professionals to obtain a minimum number of credits through participation in CME. In 2006, the minimum number of credits, for example, was 50, the equivalent of more than a week of full-time education (Ministero della Salute, 2000). It would be impossible to rely on classroom-based education to implement a nation-wide initiative on this scale. Instead, the Ministry for Health took advantage of the opportunities for distance learning offered by the Internet. In this article, we report on the preferences of nurse participants in one of the pilot courses supported by the Ministry. The course was conducted within the ambit of a research project that sought to evaluate the role of social learning, and in particular, online collaborative learning in motivating participants and reducing dropout rates in online professional development, so we were particularly interested in the participants' preferences for social and collaborative approaches to online learning.

BACKGROUND AND LITERATURE

The Internet permits busy professionals to participate in continuing professional education (CPE) from their offices or homes at times that are convenient to them. Most Internet-based or "online" courses for healthcare practitioners involve delivery of material prepared by professional teachers and trainers in computer-based training packages. These packages typically involve pages or slides that present foundation information and exercises and assessments that enable the learner to practice and test their understanding of the delivered information (Ricketts, Price, & Chamberlain, 2005). Some courses may include multimedia simulations. In many cases, an online tutor is available to answer participant questions and, in some cases, to stimulate involvement and participation in the course (Diekelmann & Mendias, 2005).

One of the problems associated with online courses is that dropout rates are high, even when tutors are available (Parker, 2003). Online social interaction among learners appears to reduce the sense of isolation that is often felt by learners taking courses at a distance from the teacher and other learners (Contreras-Castillo, Favela, Perez-Fragoso, & Santamaria-del-Angel, 2004). Participants in courses that incorporate such online social interaction have been found to have higher satisfaction and higher completion rates than participants in courses that afford no opportunity for social interaction (Renzi & Klobas, 2002). Collaborative learning activities that incorporate social interaction are also believed to improve learners' engagement with the course material and their learning from participation (Rudestam & Schoenholtz-Read, 2002).

A question mark hangs over the value of online social interaction in courses for nurses, however. Platzer, Blake, and Ashford (2000) found that British nurses did not necessarily enjoy group work for CPE in a face-to-face setting. They identified several barriers to learning from group work, including the ways in which the nurses interact with one another and group members' commitment to shared learning. On the other hand, Buckingham (2003) found that Canadian bachelor's degree participants studying at a distance from one another appreciated online discussions, which improved a number of skills, including time management and critical thinking. The differences in the settings of these studies, as well as the differences in the results, make it difficult to conclude if online collaborative learning is a suitable CPE method for nurses, or if nurses who participate in CPE would enjoy such an approach. Indeed, nurse educators have noted the lack of research on Web-based learning, and called for further research in this field (Howatson-Jones, 2004; Kenny, 2000).

In this article, we examine nurses' views of online learning in general, and online collaborative learning in particular. Working with Italian nurses who had just completed an online CME course, we asked two questions:

1. What are the perceived advantages of participation in online professional development courses for nurses?
2. What are nurses' attitudes to participation in courses that involve social and online collaborative learning?

We used the answers to these questions to draw initial conclusions about the nature of online courses that would offer a satisfactory distance learning experience for nurses.

METHODS

The research questions were addressed in a questionnaire survey of nurses who participated in a pilot online CME course supported by the Italian government.

The Course

The course concerned accreditation and measurement of the quality of health services. It was offered by an e-learning provider, TILS SpA, in partnership with the Tor Vergata University Hospital Clinic (Azienda Ospedaliera Universitaria Policlinico Tor Vergata), the Lazzaro Spallanzi National Institute for Infectious Diseases (l'Istituto Nazionale per le Malattie Infettive Lazzaro Spallanzani), and a consulting firm, SI-IES Istituto Europeo Servizi. As a pilot for the national CME initiative, the course was offered free of charge to participants. Participants who successfully completed the course were awarded 12 CME credits (just over 20% of their annual requirement).

The course was delivered entirely online over the World Wide Web (WWW) in the TILS Learning Management System (LMS). Trainees used their web browser to access the course on a site mounted by TILS (http://www.tils.com/ecm). Each of the course's three modules consisted of a lesson presented over a series of screens and supported by a glossary, documents such as copies of relevant directives, and references. The course environment also included an open forum where trainees could discuss the course and course-related issues in general. Trainees could take the course autonomously at any time of day, and could take as much time as they liked to complete each module and the course as a whole, provided they completed the course by the closing date two months from the date that the course was mounted. A tutor was available from within the course environment to answer questions and discuss the course material, although interaction with the tutor was not required to complete the course. Participants also had access to a secretary to help with administrative matters, and a help desk to discuss and resolve problems associated with accessing and using the course technology.

Successful course completion required reaching a minimum standard in a multiple choice test. Of the 554 nurses who commenced the course, 334 completed the test, and 229 passed it.

Data Collection

Once a participant completed and passed the test, the course tutor invited them by e-mail to respond to a postcourse questionnaire. The questionnaire was sent as a Word file attached to the invitation. Questionnaires were returned by e-mail to the course provider, so were not anonymous.

Instrument

The questionnaire (available, in Italian, from the authors) consisted of 13 questions with closed response choices. It was designed to identify reasons for a trainee's choice to participate in an online rather than a classroom-based course; preferences for the times of day in which courses and tutors might be available, print- or screen-based courses, and courses with or without a tutor; and options for inclusion of collaborative learning activities.

Sample

Of the 229 nurses who successfully completed the course, 152 replied to the questionnaire, a response rate of 66%. The sample consisted of 52 (34%) males, and 100 (66%) females. Most completed the course (including the final test) within nine days of commencing. Almost 50% were aged between 31 and 40, 25% were between 41 and 50, and 10% were over 50.

FINDINGS

Participation Patterns

The majority of the respondents (99, 65%) participated in the course most often from home, while 27% (41) participated most often from their place of work. Most worked on the course in the afternoons or evenings (59, 29% between 2:00 p.m. and 8:00 p.m., and 65, 39% between 8:00 p.m. and midnight). A smaller number participated in the mornings (22, 14% between 7:00 a.m. and 2:00 p.m.) and very few in the late night/early morning (6, 4%).

Perceived Advantage of Online Courses

Almost all participants (90%) reported that a significant advantage of an online course was the convenience of studying at times that suit them (Table 1). Over a third of participants (38%) also believed that completing an online course would save time, and a similar proportion (34%) thought that online courses provided easy access to information.

Preferences

The majority of participants (111, 73%) rated online courses as their preferred method of acquiring the necessary CME credits. Most of the remaining participants (34, 22%) would prefer a mixed mode course, with some classroom sessions as well as online learning. Very few of these online course participants (6, 4%) would prefer to attend courses held entirely in the classroom.

Only a small proportion of participants preferred to follow course contents only online on screen. The majority preferred to print all or part of the material. See Table 2.

There was strong support for the availability of a tutor. Most respondents (128, 85%) were unequivocal in their support, a smaller proportion (22, 14%) were indifferent while very few (2, 1%) saw no need for a tutor at all. Most respondents (119, 78%) preferred to communicate with the tutor by e-mail rather than other means, but nearly 20% (29, 19%) would like more interactive methods (such as chat or videoconference) in addition to e-mail.

Attitudes to Collaborative Learning

Most participants would accept some form of collaboration with other participants in their online courses (Table 3). While just over a third (53, 35%) expressed unconstrained interest in collaboration, a higher proportion (85, 55%) was more circumspect, expressing interest in collaboration "only when necessary." A small proportion (13, 9%) did not want courses to include collaboration under any circumstances.

Those participants who expressed an interest in collaboration were asked which online techniques they would prefer to use for collaboration. Their responses are summarized in Table 4. 10% (15) of the respondents were not familiar with the techniques. Among the remaining 90% of respondents, the most favoured technique was the discussion forum (74, 49%), followed by chat (43, 28%) and virtual classrooms (36, 24%), and finally, videoconference (31, 20%).

While participants were interested in some form of collaboration with other nurses, the respondents were divided over the role of collaboration in activities that required practice of a given technique or method. About a third of respondents (59, 38%) would prefer to complete such activities individually, while a similar number (54, 36%) would prefer to collaborate with other participants. The majority of the remaining respondents (33, 22%) would prefer to interact only with the course tutor.

Participation in the Course Forum

Trainees posted 19 messages to the course forum over the two-month life of the course. Half the messages were questions that were answered by the tutor. Five messages were about administrative issues that were resolved by the tutor. Six messages were from participants expressing their pleasure at successfully completing the course and expressing their appreciation of the way the course was structured and run. Seven messages over 15 days toward the end of the course period discussed the quality of documentation for health professionals working in issue.

DISCUSSION

Before considering the results in detail, we need to consider the sample of course participants who responded to this study. The respondents consisted of two-thirds of those who had successfully completed an online course. Their views probably represent those who successfully negotiated the online course well, but we do not know if their views are representative of those 220 nurses who commenced the course but did not complete it, or of the 105 who completed the course but did not pass it. In discussing the results, we will, therefore, consider what we can learn from participants who successfully completed a course before considering what research still needs to be done.

The strong preference expressed for online courses among those who completed the course indicates that online learning is appropriate for at least some nurses. While there was some demand for classroom-based courses and for courses that involve a blend of online and classroom discussion, such demand may be lower among participants who have been able to successfully complete a course online than others. Initiatives (such as the Italian pilot courses) that promote online courses, therefore have an important role in educating participants about the possibilities of online learning, and should be designed not just to test technology or market, but also in such a way that participants are motivated and supported to complete successfully.

Table 1. Relative advantage of online courses

Potential advantage	*n*	%
Convenience of studying at times that suit me	137	90%
Time saving	58	38%
Ease of access to information	52	34%

Table 2. Preference for print or screen

Preference	*n*	%
Print everything	59	39%
Print only what interests me	49	32%
Save the parts that interest me on my PC	39	26%
Read all on the screen	6	5%

Table 3. Preference for collaboration with other participants

Preference for collaboration	*n*	%
Yes, with pleasure	53	35%
Yes, but only if necessary	85	55%
Not under any circumstances	13	9%
No response	1	1%
Total	152	

Table 4. Preferred technologies for collaboration

Preferred technology	*n*	%
Discussion forum	74	49%
Chat	43	28%
Virtual classroom	36	24%
Videoconference	31	20%
None of these	7	5%
I am not familiar with these techniques	15	10%
Total responses	152	

Although there was little opportunity for collaborative learning in the pilot course described here, 90% of participants declared some interest in collaboration, more than a third of them without qualification. Nonetheless, more than half the participants pointed out that they would participate in collaborative learning activities only if they were "necessary." If collaborative learning is included in online courses, the reason for its inclusion and the value of participation in collaborative learning activities should be clear to the participants. We do not believe that the mere provision of a forum or "café" for discussion is sufficient to motivate the majority of participants to engage in social learning. Rather, collaborative learning activities should be incorporated in the curriculum in such a way that the relationship between the collaborative activities and the learning objectives for the course is clear.

There are also differences in preferences for forms of collaboration. Around half the participants in this study expressed an interest in participating in asynchronous discussion forums, but only a quarter expressed an interest in synchronous methods such as chat, virtual classrooms, or videoconferencing. This preference for asynchronous over synchronous communication is consistent with the participants' appreciation of online learning for the control it gives them over the time when they study. What do we do about the approximately 10% who would prefer never to engage in collaborative activities online? If, even when faced with clear learning objectives for collaborative activities, these people would not participate, the online collaborative activities of other participants would be disrupted.

These differences in preferences for collaborative learning may point to three different market segments for online CME: nurses who would prefer a traditional online course in which material is delivered directly to a learner working alone; nurses who appreciate collaborative opportunities that clearly add to the learning offered by the course, but who prefer those collaborative opportunities to use asynchronous methods that permit them to participate in courses at times that suit them; and nurses who would appreciate courses that use synchronous technologies that provide greater opportunity for collaboration. Even for this last group, we suspect that synchronous technologies would be most useful if they allowed the maximum flexibility in the timing of the student's participation in the course. For example, activities could be designed to permit participants to initiate chat and videoconferencing sessions at times that suit them. Virtual classroom sessions would compel participants to attend class (albeit at a distance) at the time the classes were offered, unless a system (such as Lectopia, http://lectopia.uwa.edu.au/) for recording and replaying the class is made available. Given the preference for asynchronous collaboration, and the range of hours in which participants prefer to study online, courses that include virtual classroom sessions should be designed to include recording and provision of any time access to the virtual classes.

There remains the issue of what type of course would be suitable for those participants who did not enroll in the online course, complete it, or pass it. Here, in the absence of further research, we can only speculate. Evidence from other courses suggests that lack of access to, or familiarity with, course technology can act as a significant barrier to participation (Buckingham, 2003). We can speculate that some potential participants did not enroll and others commenced, but did not continue simply because they were unable to overcome technological barriers (or felt they were unable to overcome them). Online learning might still be appropriate for these participants, but the introduction of online learning should include assistance with and orientation to the technology, not just the course itself. Why did 40% of those who began the course not finish it? Again, the literature offers some suggestions. If it is true that many learners are motivated by learning socially (Levy, 2007), a course that offers no more than a series of screen-based modules with optional tutor assistance and forum participation may not have been sufficiently motivating. The qualified interest in collaborative learning expressed by those who, in any case, completed the course suggests that inclusion of collaborative exercises may assist with participant motivation. Would formalized collaborative learning have improved the pass rate in the course? Again, the general literature on collaborative learning suggests that this would be the case (Rudestam & Schoenholtz-Read, 2002), but further research specifically among nurses undertaking CPE is needed to confirm the role of collaborative learning, both in motivating and improving the learning of participants.

CONCLUSION

This small study confirmed that online distance learning is a feasible, and even preferred, option for some

Italian nurses. Since all health professionals in Italy are required to participate annually in continuing professional education, online distance learning is likely to be an important—and appreciated—way to learn and to meet accreditation requirements. Moreover, many participants value social contact, both with the tutor and with fellow participants. There appear to be three market segments for online CME for nurses: nurses who prefer to study alone, those who would appreciate collaborative activities well-integrated into course design, and those who would prefer courses that include online collaboration of any kind.

How large is the demand for online distance learning in a system where some form of compulsory CPE is required for continued accreditation as a healthcare professional? While we know the preferences of those who already have successfully experienced online learning, we need to confirm that these preferences are shared by nurses who do not have similar experiences. Future research will need to include nurses who have not participated in online learning before we can find out.

KEY TERMS

Collaborative Learning: Learning that occurs through the exchange of knowledge among learners.

CME Credits: A system for calculating the amount of CME a healthcare professional has undertaken. In many countries, or for many professional bodies, a minimum number of CME credits must be obtained in a given period to retain accreditation to practice.

Continuing Medical Education (CME): Postqualification professional development, education, and training activities undertaken by doctors, nurses, and other healthcare workers in order to keep their knowledge up to date.

Continuing Professional Education (CPE): Postqualification education undertaken by professionals to ensure they keep up to date with developments in their field.

Online Collaborative Learning: Learning that uses the Internet and Internet-enabled software tools to support social and collaborative learning among students at a distance from one another and from their instructor.

Online Learning Activities: Learning activities in which students interact with resources, or other students, or both, using the capabilities of the Internet or other computer-based communication networks.

Social Learning: Learning through social interaction with other people.

Optimization of Medical Supervision, Management, and Reimbursement of Contemporary Homecare

INTRODUCTION

The concepts of health, sickness, and illness are subject to the specific sociocultural conditions under which they are considered, and, on the basis of which medical care is provided (Spyropoulos & Papagounos, 1995). The concepts and the methods involved in diagnosis and treatment are subject to the prevalent at the time theoretical model of disease. Hospitals, as a social institution, emerged as a response to particular needs and corresponded to the specific level of the understanding of health and disease. About 2,500 years ago, the temples of Asklepeios, the god of medicine, were probably the first well organized houses of refuge for the sick and training schools for physicians. Hospitals also existed in India under Buddhist auspices as early as the 3rd century BCE. The number of hospitals grew in the first centuries of the Christian era. In the 4th century AD, hospitals were founded in Caesarea and in Rome. Throughout the Byzantine time, the Middle Ages, the Arab and Ottoman dominance periods, the Renaissance, and even later, hospitals were almost entirely run by religious Christian or Islamic groups. During all these centuries, home care remains the main and usually the unique mode of treatment for the majority of the people world-wide. Only during the 18th century, hospitals ceased to be purely philanthropic institutions and they started to assume the character of a social institution where a systematic and theory-infused approach to disease prevailed. From the middle of the 19th century on, the number of hospitals, particularly in Europe and in the USA, increased, principally because of the discovery of anesthesia, aseptic surgical techniques, and, by the end of the century, the introduction of the x-rays. The demand for hospital services expanded further with the spread of prosperity, and with the introduction of various forms of hospitalization insurance, especially in England and in Germany, where the first obligatory and generalized social insurance system is introduced. It is the first time in the human history that home care ceased to be the main way of providing healthcare, and hospital treatment became gradually an important social right.

The modern hospital emerged gradually and successively, during a very long historical development, from a religious philanthropy institution to the contemporary managed care Establishment. The civil structure, the social demands, and the individual performance were always and are still reflected, on the hospital, throughout the centuries. Therefore, the 21st century hospital will provide a radically different professional activity environment, and a quite different professional-patient interaction modus; it will increasingly encourage telemedicine (De Leo, 2002) supported home care because of the increase of mean life expectancy, and the hospital care cost avalanche (Wipf & Langner, 2006; Woolhandler, Campbell, & Himmelstein, 2003). Its mission will be completed by a network of various associated Institutions, providing care rather closer to home care, than to that of the traditional hospital-care (Brazil, Bolton, Ulrichsen, & Knott, 1998).

Adapting medical and managerial decision-making (Spyropoulos, 2006a) in the modern home care environment is a cardinal prerequisite, in order to ensure, first, an economically sustainable development of the aging population healthcare (Scarcelli, 2001); second, the rehabilitation services required for impaired persons; and finally, the psychosomatic support necessary in the developed countries, during the next decades. Thus, a strategic question emerges that is how home care will be medically supervised and financially reimbursed. The present study attempts to describe the present situation and the contemporary technological trends in home care; more specific, it is focused on a system developed by our team that intends first, to enable the optimal documentation of the provided home care, and second, to facilitate the acquisition of all relevant financial data, leading to a fair remuneration of the services offered.

BACKGROUND

Contemporary home care is evolving on the foundation of a variety of applications in healthcare support services, and we argue that a qualitatively new "mobile" home care is presently emerging out of the combined employment of, first, the modern wireless mobile telephony networks and equipment, second, the contemporary digital entertainment electronics, and third, the commercially available computer hardware and software. This new mobile home care allows us for to be optimistic about the reduction of patients' unnecessary hospitalization in the near future, as well as, the dramatic reduction of the home care costs. It is essential to summarize the most important emerging innovative aspects of modern home care before describing in detail the developed therefore Management System.

Adapting medical decision-making and treatment in the home care environment begins with the effort to carry out periodically preventive examinations, as a kind of ambulant and emergency home care. The miniaturization of equipment, and the falling prices trend that could be developed by the opening of Biomedical Technology to the immense population of potential consumers, if combined with a "smart" home environment, then it may result in periodical, individually adapted, preventive medical examinations, and, consequently, a decreasing number of patients in hospitals and other costly traditional ambulatory services. Diagnosis and Treatment of an emergency patient at home is inevitable, in order to reduce morbidity, following acute pathological reasons or an accident, and it is paramount that the patient is first evaluated and stabilized on site. In such cases, there are two complementary ways to intervene: First, the continuous monitoring of high-risk groups suffering from chronic cardiovascular, respiratory, and other diseases; and second, equipping and training the "first responder" with appropriate hardware and standardized guidelines (Spyropoulos, 2006b). These two main options allow for an improvement of the efficiency of ambulant emergency services, especially if supported by telematics.

Concerning home-based in vitro diagnostics, "Dry Clinical Chemistry" offers today a variety of products, covering the whole range of important parameters, like metabolites, enzymes, electrolytes, and so on. Although diabetes every-day strip-based monitoring (Lewis, 2001) is a routine for the last two decades, a little has been done to establish a "home- based" in vitro diagnostics laboratory that would be very useful, especially in facilities offering housing and some kind of medical care for elderly people (Gill, 2002). In vitro testing, combined with biosignals monitoring at home, provide for a safe and pleasant living environment for sensible populations. Concerning home imaging, although several mobile systems have been developed, most of them, with the exception of ultrasonic equipment, will remain for the near future the "status symbols" of the hospitals. However, external patient-imaging, together with high-quality biological sound processing and transmission capabilities, are already available.

Although surgery will remain more or less the "monopoly" of the hospital, the postoperative hospital stay will be further dramatically shortened and replaced by home care in a familiar and pleasant room, instead of the impersonal, sterile ward. This becomes feasible, first, because of the recently developed minimally invasive surgical techniques, and second, as a result of decentralizing postoperative care to general practitioners and nurses, and finally, due to the emerging option of, the acquisition at home of vital-signs, postoperative wound images, and so on, and their transmission to the specialized surgical center, if necessary.

Although "home-ICU" sounds like a joke, there are always circumstances that may lead to interim intensive care settings, for instance on an uneasily accessible site after an accident. Virtually, within a telematics supported home care environment, the patient's monitoring, until safe transportation becomes possible, is not a major problem. Even Cardio Pneumonary Resuscitation (CPR) and defibrillation are feasible options. However, the access to specialized human and material resources will keep the ICU, as a hospital dedicated department, for the years to come. Furthermore, in cases like Chronic Obstructive Pulmonary Disease (COPD), Chronic Asthma, and other such diseases that cause air-flow limitation, leading to inability to carry out daily activities, an appropriate home care environment may contribute, first, to home-treatment patient-customized programs, aiming to improve the subject's performance and, thereby, the quality of life; second, to the evaluation of preceding pharmacological or surgical treatment; and third, to the definition of optimal selection criteria for home-based assisted ventilation (Simonds, 2003).

Several entertainment and medical electronics features already developed or under development, can easily be adapted to serve persons with limited mobility, poststroke patients, patients suffering from certain neurological and/or mental disorders. Such features include, among others, first, Web camera-supported presentations on interactive high-definition monitors, creating the feeling of being together, when physically separated from relatives and friends; second, every-day life equipment remotely controlled, third, electrical stimulators, developed by pacemaker manufacturers that improve poststroke incontinence control, reduce tremor on Parkinson's disease patients, and so on. Finally, interactive Internet and TV could contribute, first, to the reduction of the enormous rehabilitation costs, by providing online instructions to home-based post-traumatic or poststroke rehabilitation exercises; second, to the restriction of the agoraphobic symptoms, and of the self-respect-less behavior of depressive patients; and finally to the continuous home-treatment and/or to the special education of patients, especially young ones. However, the presently major difficulty is not the hardware and telecommunication infrastructure, but the development of appropriate content and user interfaces, serving reliably the aims mentioned.

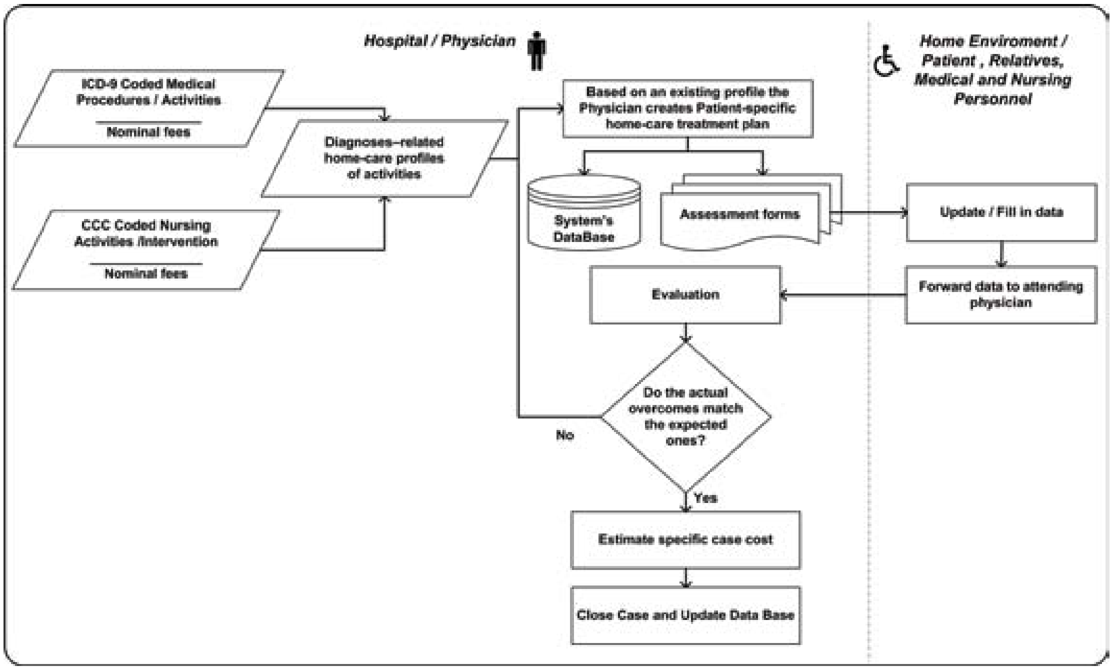
MEDICAL SUPERVISION, MANAGEMENT, AND REIMBURSEMENT OF CONTEMPORARY HOME CARE

The developed system attempts to relate home care to the Diagnosis Related Groups (DRGs) based Reimbursement (Botsivaly, 2006) by introducing an innovative adapted Continuity of Care Record (CCR). The proposed solution consists of a typical CCR-system, equipped with an extension that, first, acquires and processes an individually designed structured set of data to be employed during the post-discharge home care period, and second, allows for the estimation of the homecare cost vs. the DRGs code issued at discharge from the hospital, supporting, thus, a more accurate DRGs-related home care remuneration. Medical records are indispensable in home care, and are also used in a variety of ways, serving a multiplicity of purposes (Papagounos & Spyropoulos, 1999). A major problem of the contemporary health services, including home care, is the scarcity of resources. Patients' records provide information concerning the expenses incurred and the resources allocated for the treatment of the individual patient within the healthcare system. Home care resources consumption must also be monitored, and we argue that the most efficient and time saving way is through the employment of an appropriately adapted Continuity of Care Record (CCR).

The Continuity of Care Record (CCR) is a standard for exchanging basic patient data between two care providers, in order to enable the second one to access relevant patient information. It is intended to foster and improve continuity of patient care, to reduce medical errors, and to assure at least a minimum level of health information transportability when a patient is referred, transferred, or otherwise goes to another provider. The standard was proposed and developed by the E31 Committee on Healthcare Informatics of ASTM, an American National Standards Institute (ANSI) standard development organization (ASTM E2369-05, 2005).

The CCR is being developed to cover the need to organize and make transportable a set of basic patient information consisting of the most relevant and recently facts about a patient's condition. These include, first, patient and provider information; second, insurance information; third, patient's health status such as, allergies, medications, vital signs, diagnoses, recent

Figure 1. Details of system's flow chart



procedures; fourth, recent care provided, as well as recommendations for future care (that is, a care plan); and finally, the reason for referral or transfer. The structure of the CCR perfectly fits to the needs of homecare, both, the administrative and the medical ones, because it is designed to be technology- and vendor-neutral for maximum applicability. It is being developed on the extensible markup language (XML) platform in order to offer multiple options for its presentation, modification, and transmission.

Through XML, the CCR can be prepared, transmitted, and viewed in a browser, in an Health Level Seven (HL7) Clinical Document Architecture (CDA) compliant document, in a secure e-mail, or in any XML-enabled word processing document. This makes it possible for recipients to access and view the information in the manner that they prefer (electronic or paper), to extract the data as required, and even to store them on a portable storage device for use as a personal health record. Because the CCR will be a simple XML-document, different Electronic Health Record **(**EHR) systems will be able to, both import and export all relevant data to and from the CCR document, and enable automated transmission with minimal workflow disruption for individual caregivers. Thus, the CCR will increase interoperability between different EHR systems, with minimal or no custom programming. Finally, in countries with minimal EHR and healthcare networks infrastructure, the CCR is the only advisable interim operational mode.

We have designed and developed a first version of a CCR-extension for comprehensive payer-specific information. The developed model consists of various related databases, and allows for every user, first, to select one of the available DRG-codes; second, to create a typical CCR that contains the appropriate demographic and administrative data, as well as, the relevant clinical information; third, to set up for each DRG code a custom-made typical profile of home care activities; and fourth, to attach them either a nominal fee, proposed by the system, which is based upon realistic, empirically collected data, or to independently price them. The developed system employs the Australian Refined DRGs (AR-DRGs).

Starting point is the loading of a number of well established medical classification systems, like the International Classification of Diseases Version 9 (ICD9), the Australian Refined DRGs (AR-DRGs) and the Nursing Interventions Taxonomy of the Clinical Care Classification (CCC) databases (Saba, 2002). The AR-DRGs database figures out about 660 diagnosis-related groups, classified within 25 Major Diagnosis Categories (MDC), 30 Specialties, and three major groups (medical, surgical, and other). From this root databases, every user is able to individually assign an appropriate set of care activities to specific diagnosis codes that are coded according to AR-DRGs. These activity sets consist of diagnostic, monitoring and treatment activities that can be actually performed in a home environment, together with an appropriate nursing—activity treatment plan. These profiles of care activities are custom-made and every user (i.e., every physician responsible for discharging a patient from the hospital) is actually able to set up his own profiles. During the formation of these profiles the user can attach to each activity a set of nominal fees. This later is estimated by another already developed software tool (Botsivaly, 2003), and allows for a rational approximation of the effective mean cost for several elementary medical activities, over different medical specialties. Thus, the developed system ignites, when relevant, the corresponding revision of an implicitly associated latent financial record that allows for an approximation of the individual case-cost.

Once the modified database for specific homecare activities has been created, the program constructs a custom-made Structured Query Language (SQL) file, appropriate for Medical and administrative use. The user can interactively modify any description on this database, and it is possible to add any information for specific instances, in order to adapt the home care profile to emerging new needs. This interactively modified database is further used to create each time a typical CCR that contains all the necessary patient information. The appropriate patient and administrative data, as well as, the relevant medical information, are acquired, either by using an already installed EHR system or even manually, if no EHR is available. Then, the individual CCR is completed, by selecting the needed home care activities, which are automatically inserted in the CCR-section of Care-Plan. Simultaneously the CCR-system latently combines each of them to the predefined "cost."

However, the system, apart from producing, electronically or in paper-format, the CCR, it also produces a number of additional forms, including advisory and informational notes for the patient himself, or for his relatives, and diagrams of physiologic measurements, such as glucose, blood pressure, and so on that the patient should monitor. The system also provides for forms that will be filled by the nursing personnel during the care-visits, in order to document their activities.

Plan Of Care

Plan	Procedure	Scheduled For
Rehabilitation	X-Ray	Schedu
	Physical therapy	Scheduled 10/03/2006

The filled forms, both the ones regarding the nursing activities and interventions, and the ones regarding the monitoring of physiological parameters, are returned to the responsible physician who evaluates them and, depending on his evaluation, can modify the care-plan of the specific patient, in any suitable way. The structure and data of the produced CCR are complying with the ASTM E2369-05 Specification for Continuity of Care Record, while XML is used for the representation of the data. The XML representation is made according to the W3C-XML schema proposed by ASTM. The CCR that is produced by the system, is currently automatically transformed to HTML format, using the Extensive Stylesheet Language (XSL), in order to be viewable and printable.

FUTURE TRENDS

The previously described employment of some kind of records, as the main instrument for the management of home care, assigns them an additional dimension, which is related to the nature and function of technology. The development of patients' records exhibits the state-of-the-art Biomedical Technology, the dominant—at the time—medical knowledge and practice, and it reflects the existing value system of a given society. The assimilation of new technologies is a complex phenomenon, which is affected by the wider sociocultural, epistemic, and axiological parameters at work, within the specific social context in question.

In other words, the Technologies employed presently in the construction of medical records, were developed to satisfy concrete social needs. The availability of these technologies permitted new questions to be asked and new needs to arise, and this procedure will determine the future trends of the structure, the content, and the technological substratum of the medical records of the future.

CONCLUSION

The employment of this method enables the formation of a CCR, that is intrinsically, however latent, related to the costs caused and the expected reimbursement. Thus, the updating of the patients' relevant medical data, ignites, when relevant, the corresponding revision of an implicitly associated financial record, that allows for, both, first, a good approximation of the individual "case" cost, and second, the follow-up of cost evolution of a hospital-based or freestanding home care group. Thus, the developed system introduces a nondisturbing method for the home care personnel, to combine the collection of the necessary CCR information, and the creation of the associated documentation, with a latent simultaneous acquisition of important financial data. The correlation of these data to the DRG-coded principal diagnosis, allows for the estimation of the home care cost vs. the DRGs code issued at discharge from the hospital.

In view of the fact that there is a clearly higher discharge to home care incidence, for specific DRG-coded principal diagnoses, the developed system is now being tested with an EHR system that has been developed by our team under virtual home care conditions, and is being fed with financial data related to home care activities for some of the most frequent cases. The implementation indicates, so far, that the system, whether interfaced to an EHR or not, is stable enough for practical use, and it actually provides a simple, effective, and expandable tool for the formation of both a CCR and a home care plan, offering at the same time a good approximation of the individual case cost and a flexible HTML-format for data representation. The system allows for the improved approximation of the home care cost vs. the DRGs code issued at discharge from the Hospital supporting, thus, a new more accurate DRGs-related home care remuneration modus. Finally, the system constitutes an effective educational tool, supporting personnel training in operational cost management.

KEY TERMS

American Society for Testing and Materials International (ASTM): An international voluntary standards organization established 1898 in the United States by Charles Benjamin Dudley. ASTM develops technical standards for materials, products, systems, and services, and maintains presently more than 12,000 standards that have been incorporated into or are referred to by many federal regulations.

Clinical Care Classification (CCC): A categorization system that consists of interrelated terminologies—the CCC of Nursing Diagnoses and Outcomes and the CCC of Nursing Interventions and Actions—with both classified by 21 Care Components, that classify, and track care based on the six steps of the Nursing Process Standards of Care recommended (1998) by the American Nurses Association (ANA): assessment, diagnosis, outcome identification, planning, implementation and evaluation.

Clinical Document Architecture (CDA): An XML-based markup standard intended to specify the encoding, structure, and semantics of clinical documents for exchange. The CDA tries to ensure that the content will be human-readable and hence is required to content narrative text, yet still contain structure, and most importantly, allows for the use of codes to represent concepts.

Continuity of Care Record (CCR): A health Record standard (ASTM E2369-05) specification that constitutes a patient health summary and contains the most relevant and timely core health information to be sent, usually in electronic form, from one care giver to another. It contains various sections such as patient demographics, insurance information, diagnosis and problem list, medications, allergies and care plan, representing a "snapshot" of a patient's health data that can be useful or possibly lifesaving, if available at the time of clinical encounter. The CCR standard is expressed in the standard data interchange language known as XML and can potentially be created, read and interpreted by any EHR and EMR software applications. A CCR can also be exported in other formats, such as pdf, doc, and so on.

Diagnosis Related Groups (DRGs): A system that classifies hospital cases into one of approximately 500–600 groups, which relate types of patients treated, to the hospital resources they consumed. It was first developed by Robert Barclay Fetter and John Devereaux Thompson at Yale University, in the slate 1970s. The DRGs are assigned by a "grouper" program based on ICD diagnoses, procedures, age, sex, and the presence of complications or comorbidities.

Electronic Health Record (EHR): A personal medical record in digital format, typically accessed on a computer or over a network. An EHR almost includes information relating to the current and historical health, medical conditions, and medical tests of its subject. In addition, EHRs may contain data about medical referrals, medical treatments, medications and their application, demographic information, and other nonclinical administrative information.

Extensible Markup Language (XML): A general-purpose markup language designed to be reasonably human-legible, and therefore, abruptness was not considered essential in its structure. Its primary purpose is to facilitate the sharing of data across different information systems, particularly connected through the Internet, and to allow for diverse software to understand information formatted in this language.

Health Level Seven Inc. (HL7): HL7 is a not-for-profit organization, established 1987, involved in the development of international healthcare standards, accredited by the American National Standards Institute (ANSI). HL7 is currently the selected standard for the interfacing of clinical data for most hospital information systems worldwide.

Homecare: Healthcare provided in the patient's home by healthcare professionals or by family and friends. Homecare aims to enable people to remain at home rather than use institutional-based nursing care. Care workers visit patients in their own home to help them with daily tasks and supervision of treatment. Homecare is generally paid for by private health insurance, by public payers, or by the family's or patients' own resources.

International Statistical Classification of Diseases and Related Health Problems (ICD): The ICD is published by the World Health Organization (WHO), and provides codes to classify diseases and a wide variety of signs, symptoms, abnormal findings, complaints, social circumstances and external causes of injury or disease. Every health condition can be assigned to a unique category and given a code, up to six characters long. Such categories can include a set of similar diseases. The ICD is used world-wide for morbidity and mortality statistics, reimbursement systems and automated decision support in medicine. This system is designed to promote international comparability in the collection, processing, classification, and presentation of these statistics. The ICD is the core classification of the WHO; it is revised periodically, and is currently in its tenth edition (ICD-10).

Medical Classification: The method of transforming descriptions of medical diagnoses and procedures into universal Medical code numbers. These diagnosis and procedure codifications are used by health insurance companies for reimbursement purposes, they support statistical analysis of diseases and therapeutic actions, they are employed in knowledge-bases and medical decision support, and in a variety of other uses.

PACS Contribution to Hospital Strategy via Improved Workflow

INTRODUCTION

Since Strassman's (1990) exposition of the "productivity paradox," there has been increased attention paid to justification and evaluation of investments in information technologies (IT) and information systems (IS). Observed outcomes from practice have called for theoretical explanations in order to construct a generalized view of IS. In the hospital environment, we see that there is a pressing need for frameworks adequate to the tasks of evaluating increasingly expensive implementations. Because hospitals have multiple stakeholders and multiple strategic goals, in order to be adequate, a framework needs to address these multiplicities. One promising framework is Kaplan and Norton's (1992), the Balanced Score Card (BSC).

BSC has been used to evaluate hospital performance and the implementations of IT/IS in hospital and medical contexts by several authors (Curtright, Stolp-Smith & Edell, 2000; Gordon & Geiger, 2001). However, Picture Archiving and Communication Systems (PACS), which is one of the most important system implementations in the past few years in the area of e-health and the transmission of health data, have not been evaluated using BSC. Rather, most evaluations of PACS have tended to focus on single issues like clinical communication, quality improvement, image availability, speed of service, and workflow simplification and automation, and the associated gains that are important to the patient's overall journey (Peer, Peer, Walcher, Pohl & Jaschke, 1999). The focus on single issues within PACS implementations has made it difficult to gain a clear understanding of the overall workflow impacts of a PACS implementation. Moreover, the literature does not relate well to the intangible value created for the patient by the patient care benefits of PACS, which is an important component of the hospital's strategy overall and as it relates to IS strategy.

Therefore, this chapter investigates the adequacy of BSC for a holistic evaluation of the workflow impacts of a PACS implementation. It asks whether a theoretical model such as BSC adequately captures the reality of how such technology is used. The approach taken is radical in that it is built on a consideration of the fundamentals of hospital strategy. The BSC is then modified to incorporate qualitative themes rather than performance measures to reflect the fundamentally qualitative nature of the clinical values of hospital strategy. In so doing, this chapter develops a framework that is relevant to a hospital's not-for-profit and clinical strategies.

BACKGROUND

The BSC is a set of measures that provides managers with a comprehensive framework that translates a company's strategic objectives into a coherent set of performance measures. As originally developed by Kaplan and Norton (1992), the BSC includes performance measures from the following four perspectives, supplementing the financial perspective with those of the internal business process, the customer, and learning and growth within the organization:

- **Financial perspective.** "How should we appear to our shareholder?" Performance measures include operating income and return-on-investment.
- **Internal business process perspective.** "At which business processes must we excel?" Performance measures include rework rates, cycle times, and process costs.

- **Customer perspective.** "How should we appear to our customers?" Performance measures include customer satisfaction and retention.
- **Learning and growth perspective.** "How will we sustain our ability to change and improve?" Performance measures include employee skills, retention, and satisfaction.

The comprehensive view drawn from these four performance measures can then be presented as a single management report that reflects many of the elements of a company's competitive agenda: becoming customer oriented, shortening response time, improving quality, emphasizing teamwork, reducing new product launch times, and managing for the long term (Kaplan & Norton, 1992). Not only does the BSC provide a measurement framework that improves alignment of actions to the strategic goals of an organization, but it also provides a platform for identifying priorities (Mooraj, Oyon & Hostettler 1999). These priorities can then be used to guide management in the achievement of objectives.

However, the BSC is not a template that can be applied to business in general or even industrywide. Rather, it is intended that different market situations, product strategies, and competitive environments employ different scorecards, differing in terms of performance measures. Each organization's unique reason for an IT/IS implementation and therefore different perspectives on measuring success is reflected in the use of a BSC that includes appropriate performance measures. BSCs are particularly appropriate for organizations in industries such as health care, where there is a more diverse set of performance measures than in the business and academic sectors (Voelker, Rakish & French, 2001). Therefore, the BSC's design flexibility makes it applicable to the evaluation of a broad range of organizations and implementations, and suitable to evaluation within the health sector. A range of perspectives has been used to generate performance measures used in BSC applications within the health sector, such as patient satisfaction, clinical outcomes, functional health status, and cost to evaluate outsourcing (Schriefer, Urden & Rogers, 1997) . We argue that these adaptations of the BSC to health care are successful because the modifications are in line with the organizational strategies of the health sector; consequently, there is a value in a BSC that is specifically targeted toward PACS.

PERFORMANCE MEASURES THAT FIT HOSPITAL STRATEGY

"Strategy" in the corporate sense, popularized by Porter (1996), is "the creation of a unique and valuable position, involving a different set of activities … different from rivals." Following from Porter's earlier work, three fundamental strategies for competitive advantage are identified: low cost, product differentiation, and niche market (McFarlan, McKenney & Pyburn 1983). Willcocks, Petherbridge, and Olson (2001) expand these to six strategic uses of IT: breakthrough unit costs for customers, service-based differentiation, micromarketing management, shorter time to market, transfer of experience, and new level of partnership. The idea of strategy as a way of positioning the organization so as to attract customers and compete with rivals is central to these approaches.

However, the relevance of corporate strategy to hospitals that have a commitment to clinical excellence and a commitment to public responsibility has been questioned (Liedtka, 1992). Where clinical and not-for-profit considerations are fundamental to organizational strategy, Liedtka (1992) suggests that Andrews' concept of strategy is more relevant: "A pattern of decision in a company that determines and reveals its objectives, purposes, or goals, produces the principal policies and plans for achieving those goals … and the nature of the economic and non-economic contribution it intends to make to its shareholders, employees, customers, and communities" (Andrews, 1987, p. 56).

Given this richer concept of strategy, Andrews (1987) argues that there are four elements to be considered together to determine strategy:

1. What the market wants in terms of industry opportunities and threats—what might we do?
2. The organization's competence—what can we do?
3. The aspirations and values of executives in charge of the organization—what do we want to do?
4. The organization's obligation to society—what should we do?

Liedtka (1992) argues that in the health context, it is clinical as well as executive preferences that must be considered. Liedtka (1992) summarizes these elements emphasizing the fact that the elements of strategy may be classified as either market-driven or nonmarket-driven, and as internal or external (Figure 1). According to Liedtka (1992), the incompatibility of Porter (1996) and his followers' concepts of strategy for hospitals lie in Porter's exclusive focus on market-driven elements.

Clinical excellence and service to the community are key factors for public hospitals (Firth & Francis, 2004). These factors are important determinants of clinicians' acceptance, use, and "ownership" of IT/IS in hospitals. Clinicians' appropriate technologies to the extent that they support and enhance workflow in ways that improve the patient's clinical journey. Attempts to impose IT/IS that do not result in such positive workflow outcomes for patients lead to poor morale and resistance.

Consequently, BSC evaluations of IT/IS implementations in hospitals need to incorporate a wide range of nonmarket performance measures because they reflect the nonmarket elements of the hospital's strategic perspectives. Thus, a model for the evaluation of health systems based on Andrews' (1987) approach seems more appropriate.

In order to develop an appropriate set of performance measures for the BSC in the PACS environment and to understand those measures in a practical context, a study was undertaken of a PACS implementation in a large public hospital in Australia (identity withheld) offering the full suite of medical inpatient and outpatient services.

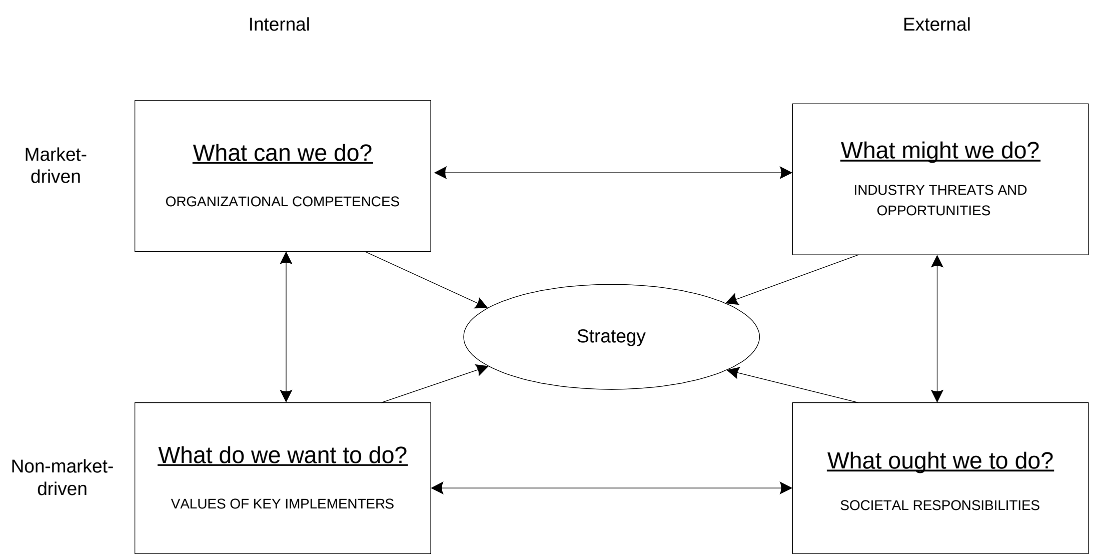
The study involved in-depth, semistructured interviews with users of PACS in several locations throughout the hospital covering three interrelated issues:

1. The goals and strategies of the hospital
2. The importance of workflow to those goals and strategies
3. How well they believed the PACS implementation helped to improve the workflow and subsequently to achieve those goals and strategies

Four measurement perspectives were found. The first two are directly analogous to two of Kaplan and Norton's (1992) original perspectives (internal business processes and customers, respectively). The latter two are more radical modifications to reflect the nonmarket context of the hospital environment in which PACS is implemented:

- A clinical business process perspective that captures the major clinical impacts on workflow has been included, because the outcome—speed of service—is of central importance to workflow analyses. The workflow implications of PACS impacting clinical business processes not only relate to automation but also to the productivity of radiologist, technologist, and clerical staff; report-turnaround times; and changes in communication between radiologist and clinicians. This perspective is consistent with the original

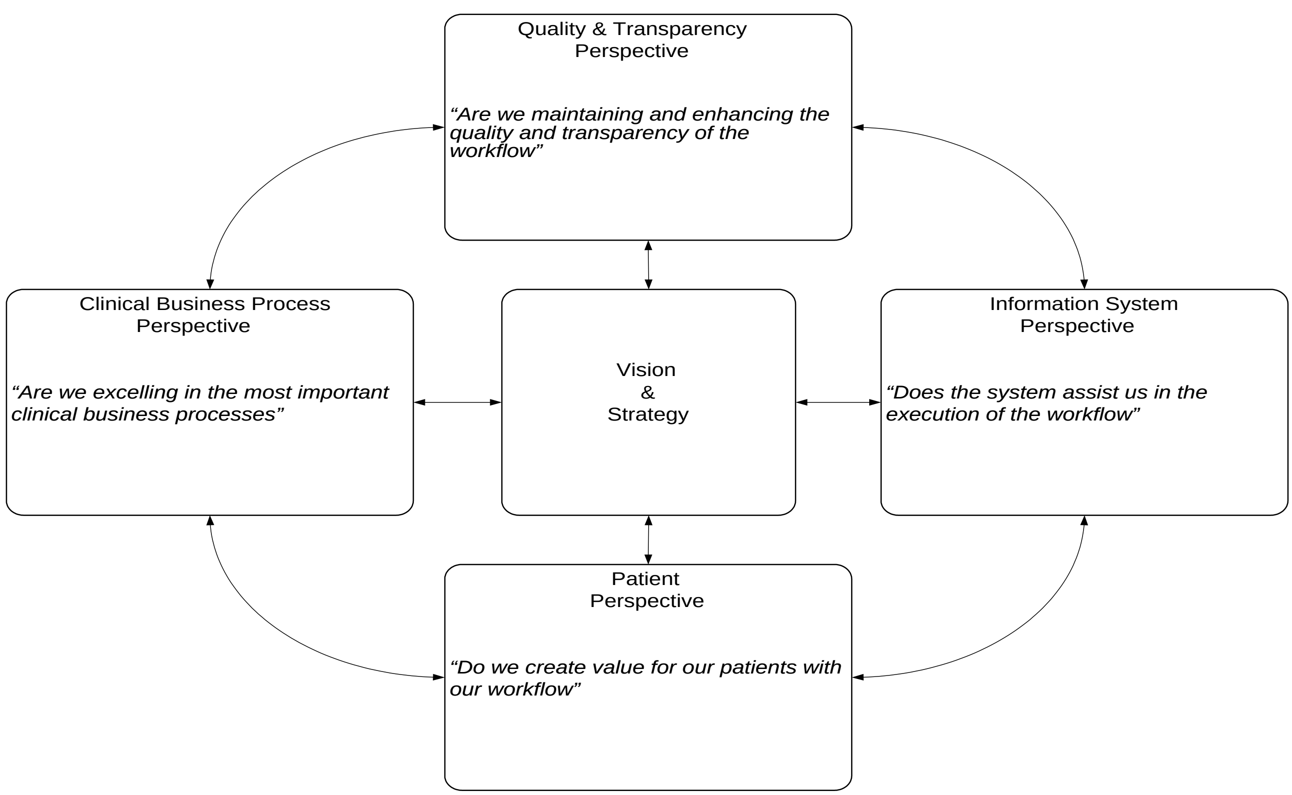
Figure 1. Andrew's model of the strategy formulation process (Liedtka, 1992)



BSC perspective: "At which business processes must we excel?"

- A patient perspective that captures the impact of PACS on the production of value for the patients along the workflow is included, because queues and bottlenecks are symptoms of poor patient throughput. The workflow implications that are directly patient-related include reduction in delays and an increase in timely care, as well as throughput time of patients (Andriole, 2002). This perspective is consistent with the original BSC perspective: "How should we appear to our customers?"
- A quality and transparency perspective that captures the level of monitoring and status checking possible in the system is included, because the literature suggests that improved workflow quality and transparency give higher diagnostic value. This radical departure from Kaplan and Norton's (1992) original four perspectives reflects the fact that hospitals not only need rapid workflow, but they also must have quality checks that imply a quality and transparency of workflow. It reflects an emphasis on Andrews' (1987) perspective of "what do we want to do" and "what should we do?" when hospitals are focused on workflow as a way of enhancing patient care. This perspective asks, "Are we maintaining and enhancing the quality and transparency of our workflow?"
- An information systems perspective that captures the impact that PACS has on the enabling power of the information system is included. This is because the literature suggests that PACS impacts upon the information system's potential to contribute to workflow execution. This is a somewhat radical departure from Kaplan and Norton's (1992) original four perspectives. This perspective provides an aggregated view of these issues and asks, "Does the IS assist in the execution of the workflow?" This change was made to reflect the fact that PACS typically does not stand alone. Rather, in its relationship with existing systems, it can be integrated to streamline processes, or it can slow processes through parallel systems.

Figure 2. PACS-BSC model



These perspectives indicate another radical deviation from Kaplan and Norton's (1992) original BSC in which the perspectives indicated performance measures. While performance measures with their essentially qualitative implications are relevant to financial and corporate internal business process perspectives, it has been found that they may not be adequate for some enterprisewide applications (Goldszal, Bleshman & Bryan, 2004). When it comes to hospital goals of clinical excellence, the outcomes may be difficult to quantify because they have aspects that are essentially qualitative. It is hard to measure the intangible value created by PACS to patients, radiologists, and clinicians in terms of quantitative measures. It requires a broader understanding.

Therefore, the perspectives outlined here should be considered as incorporating qualitative themes rather than performance measures. This makes it necessary to have a qualitative method for understanding the values of the outcomes associated with many elements of the perspectives.

FUTURE TRENDS

This chapter highlights an important issue in health that will become increasingly important in the future: the multiple goals of health care providers requires a context-specific concept of strategy and appropriate evaluation techniques. The finding that fundamentally BSC is appropriate as a starting point, although not adequate to capture the complexity of public hospitals' multiple goals, suggests that conventional models from business system evaluation may be able to be modified meaningfully and valuably for health. This is good news, as it avoids the need to start from scratch in order to avoid the misleading application of "off the shelf" conventional models that are inadequate to evaluate health contexts. The trend toward evaluation using appropriate models and techniques heightens the prospect of greater accountability and system success in health. With the growing trend to see health information systems as integral to combating ill health and breaking in ill health/poverty nexus in the least developed nations, the need for appropriate evaluation is pressing.

CONCLUSION

Given the four perspectives that were found to capture the strategy in the particular case at hand, the proposed BSC to evaluate the impact of a PACS implementation on workflow in a hospital are as follows:

1. Clinical business process perspective
2. Patient perspective
3. Quality and transparency perspective
4. Information system perspective

These have been identified as consistent with the hospital strategy, as indicated by the users of PACS, other hospital officials, and the documents reviewed. These measures are consistent with the literature on workflow associated with the patient's clinical journey. Taken together, these perspectives give the following framework: the PACS-BSC model as seen in Figure 2. The PACS-BSC model enables the holistic investigation of PACS impacts in that it captures the essential impacts on workflow.

The model demonstrates interdependency of the four perspectives and the relationship with the vision and strategy of a hospital. This is in accordance with Kaplan and Norton's (1992) original intentions in that the four perspectives complement each other, and there is not one perspective that alone represents strategy; yet it is a significantly improved approach for specifically evaluating PACS. Moreover, the PACS-BSC invites qualitative assessment that reflects the qualitative nature of not only the perspectives, but also of the strategy and vision of hospitals.

The Balanced Scorecard allows adaptation to the specific needs of hospitals in order to evaluate organizational performance and IT/IS implementations. Because the implementation process is undertaken for reasons consistent with IS and organizational strategy that is largely nonmarket, it should be evaluated in nonmarket terms. Clinical goals and not-for-profit components should therefore be primary when evaluating IT/IS implementations in hospitals.

Our approach is radical in that it is built on a consideration of the fundamentals of hospital strategy, and valuable in that it results in the PACS-BSC model. Consistent with the qualitative nature of major aspects of hospital strategy, the new model incorporates qualitative themes rather than quantitative performance measures. While changing the perspectives to fit the hospital context and changing the quantitative focus of the performance measures to qualitative themes may be radical, there is no change to the essential nature of the BSC model. Rather, the new model retains Kaplan and Norton's (1992) intention to evaluate outcomes from the perspective of the organization's strategy and to be flexible to whatever those outcomes and strategies may be. Thus, the PACS-BSC model is a holistic method to evaluate PACS impact on workflow that is relevant to a hospital's not-for-profit and clinical strategies.

Retaining the original robustness of the BSC with regard to a radical review of organizational strategy and to the evaluation of qualitative outcomes, the PACS-BSC will be used to evaluate the impacts of PACS on workflow within hospitals. The authors argue that valid outcomes require a radical review of models in terms of purpose, concepts, and structure, and are currently undertaking empirical research to test the new model.

The application of the BSC framework and theories of strategy to PACS within the hospital environment has enabled both a richer understanding of the workflow outcomes and a refinement of the BSC. The PACS-BSC, as developed, has enabled a more diverse understanding of outcomes from the staff's various perspectives. The use of qualitative interview methods in conjunction with quantitative survey methods has enabled an unearthing of outcomes as observed by the staff. Therefore, it is concluded that the academic tool kit with various theories and methods enables a clearer view of reality, while reality enables the appropriate refinement of theory.

KEY TERMS

Balanced Scorecard (BSC): BSC is a framework that measures organizational performance along various perspectives in accordance with the organizational strategy and vision.

Evaluation: The systematic acquisition and assessment of information using an overarching perspective to provide useful feedback about some sort of object/subject.

Hospital Strategy: An integrated set of actions with a focus on increasing the long-term prosperity and strength of hospitals relative to its environment and (strategic) goals.

Information Systems: A system that comprises people, machines, and/or methods organized to collect, process, transmit, and disseminate data that represent information.

Not for Profit: Not for profit is the concept of which the primary objective is to support some issue or matter of private interest or public concern for non-commercial purposes.

PACS: A Picture Archiving and Communication System (PACS) is an (workflow) integrated system that is designed to streamline the processes of acquiring, storing, distributing, and displaying medical images throughout a hospital's enterprise.

PACS-BSC Model: A Holistic Method. Based on the BSC, to evaluate PACS impact on workflow that is relevant to a hospital's not-for-profit and clinical strategies.

Strategy: A pattern of decision in a company that determines and reveals its objectives, purposes, or goals; produces the principal policies and plans for achieving those goals; and defines the range of business the company is to pursue, the kind of economic and human organization it is or intends to be, and the nature of the economic and noneconomic contribution it intends to make to its shareholders, employees, customers, and communities.

Parallel Architectures for MEDLINE Search

INTRODUCTION

It is often extremely difficult in clinical practice to find answers in a timely manner to specific questions that arise in the management of patient health issues. The central repository of medical research is the MEDLINE database. The time needed to search and *review* results from MEDLINE may range from 20 minutes to 2½ hours (Lucas et al., 2004); this greatly exceeds the two minutes that clinicians typically have available to answer questions during clinical care (Ely et al., 1999). Consequently, clinicians rarely use MEDLINE (Ely et al., 1999); when they use MEDLINE, they do not use it well (Hersh & Hickam, 1998).

In 1997, the National Library of Medicine launched PubMed, which gave the first public and free access to MEDLINE with links to full texts of articles (Free Web-based access to NLM databases, 1997). To reduce the time needed to search and review results, SUMSearch was developed by Badgett, Paukert, and Levy (2001) to automatically examine the results from an initial MEDLINE search and revise queries multiple times to extract more relevant information. Thus, each query from a user may result in up to eight queries by SUMSearch of MEDLINE and other resources. An overview of SUMSearch and other search techniques may be found in the companion article (Badgett, Chalasani, Boppana & Pugh, 2007). However, owing to the restrictions on the access to MEDLINE by the National Library of Medicine, the refined queries need to be issued sequentially, and the rate of queries needs to be throttled. Due to Internet delays accumulating during multiple searches, SUMSearch's response time to a query can be as much as 30 seconds. This delay prevents adding to SUMSearch additional searches that are needed.

In this chapter, we describe a parallel architecture for MEDLINE database integrated with search refinement tools to facilitate accurate and fast responses to search requests by users. The proposed architecture, to be developed by the authors, will use low-cost, high-performance computing clusters consisting of Linux-based personal computers and workstations (i) to provide subsecond response times for individual searches and (ii) to support several concurrent queries from search refinement programs such as SUMSearch.

BACKGROUND

Several commercial companies have implemented fast search engines that run on a cluster of computers and sift through a large volume of content to find relevant information. For example, there are more than 20 billion Web pages registered with the Google search index as of 2006. Google uses sophisticated and proprietary techniques to find and return relevant Internet documents requested by the user. Fast searching can be accomplished by distributing the problem of searching among multiple computers that search simultaneously in various parts of data. Distributed processing and distributed databases have been significant research topics in past years. However, special techniques to optimize the response time of searching are required. For example, loading data to be searched into memory before any searching begins has been explored (Chalasani & Boppana, 2005). Constructing index trees based on keywords to speed up searches has also been explored by several researchers (Melnik, Raghavan, Yang & Garcia-Molina, 2001; Yu, Cuadrado, Ceglowski & Payne, 2003). Searching in the context of clinical setting was studied by Hersh and Hickam (1994), who showed that simple word searching is an effective means to search for medical literature. Hersh, et al. (2001) showed that Boolean searching and vector space searching are almost equally effective in the context of medical searches.

However, no comprehensive implementation that combines all these various techniques for fast searches has been reported in literature. Most such implementations are commercial and, hence, proprietary in nature. In this chapter, we will combine techniques such as (a) indexing large databases using keywords and content, (b) in-memory loading and searching of databases, (c) distributing content to be searched on multiple computers, and (d) increasing the precision of searches using finite refinements to achieve fast searching of MEDLINE data.

The rest of this chapter is organized as follows. Section 3 describes parallel architectures for the MEDLINE database. Section 4 discusses performance implications for the parallel MEDLINE implementation. Section 5 discusses directions for future research in this area. Section 6 concludes this chapter.

PARALLEL ARCHITECTURES FOR THE MEDLINE DATABASE

Proposed MEDLINE Database Architecture and Implementation

The proposed architecture for a parallel MEDLINE implementation is illustrated in Figure 1. This architecture exploits two types of parallelism:

- **Temporal parallelism.** The incoming requests are distributed equally among the application servers (Appservers). An incoming request is handled completely by a single Appserver.
- **Spatial parallelism.** The MEDLINE database is equally distributed among all database servers (DBservers). In response to an incoming search request, the documents corresponding to that search are retrieved from one or more DBservers.

In this architecture, the application server (Appserver) receives the search request. Each application server has the complete index tree for the MEDLINE database. The incoming requests are evenly distributed across application servers by the Gateway server (Sprayer machine). The application server quickly searches its index tree for the keywords contained in the request. The index tree search identifies the documents relevant for those keywords and the database servers (DBservers) on which those documents reside. The Appserver then requests the DBservers for the identified documents. DBservers return the documents to the Appserver, which then combines the results from various keywords and sends a response to the requestor. This procedure is indicated in Figure 2.

We need to address three critical issues for successful implementation of MEDLINE and to facilitate subsecond search times: (i) implementation of the search engine, (ii) implementation of the database, and (iii) automatic revision of searches. These are discussed further in the next three subsections.

Search Engine Implementation

To facilitate fast and multiple concurrent searches, index lists are often created for a database. An index list is similar to the index at the back of a textbook and indicates the IDs of records that contain a given word. For example, when a request for a list of documents containing the words "hypertension" and "diabetes" is submitted, the index lists for these two words will be examined to identify records that contain both words. Alternatively, a document vector that indicates words (in dictionary order) contained in a document can be used. Given the large vocabulary used in medical publications, the index list approach is preferable for this implementation. The records so identified will be retrieved from the DBservers and composed to generate a response. Figure 3 shows an example index list in the form of a tree search structure. Each keyword (or search term) is a node in this tree. Each node is associated with a list of database servers and the document IDs on that database server that point to relevant documents for that keyword. In the example shown in Figure 3, the relevant documents for the term "diabetes" are documents with IDs 2, 100, and 215 on DBserver 1, and documents with IDs 625, 901, and 1576 on DB server 5. Even though this example indicates a tree search mechanism (to simplify the discussion),

Figure 1. Parallel Architecture of the MEDLINE module; the actual hardware can be a simple fast Ethernet based Linux cluster

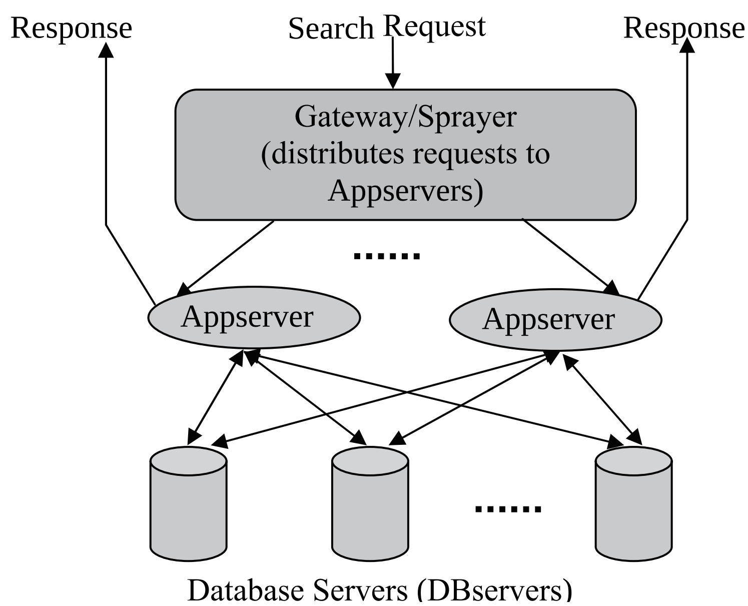

Figure 2. Process steps for handling a single MEDLINE search request

Process Steps for Servicing a MEDLINE Search Request by the Parallel Architecture
// Input to this process is the MEDLINE Search request including all the keywords.

Step 1: Gateway server (Sprayer machine) identifies an Appserver and forwards the search request to the Appserver.

Step 2: Appserver searches its copy of the index tree for each keyword and identifies the DBservers on which the corresponding documents reside. Appserver sends requests for those documents (it sends a unique request id, the keyword and the unique document ids for that keyword to the identified DBservers).

Step 3: Each DBserver which receives a request for the documents with document ids reads the corresponding documents from its memory and sends those requests to Appserver.

Step 4: The Appserver combines the resulting documents supplied by the DBservers and sorts the results by relevance. The Appserver then decides whether the search needs to be further refined; if so, it sends another set of retrieval requests to the DBservers. If the search does not need to be refined, it sends the results to the requestor.

the implementation in reality will follow a hash-map implementation so that searching for a keyword takes almost a constant amount of time, regardless of the search term.

Index lists will be created for the most frequently occurring words and phrases in the database. These index lists will be created at one time and stored (replicated) in the main memories of Appserver machines, which process the searches. We will write a multithreaded program to examine the index lists and identify the records that satisfy the search request. With multithreading, we can take advantage of multiple CPUs in each machine. To handle multiple concurrent searches, we can simply increase the number of Appservers.

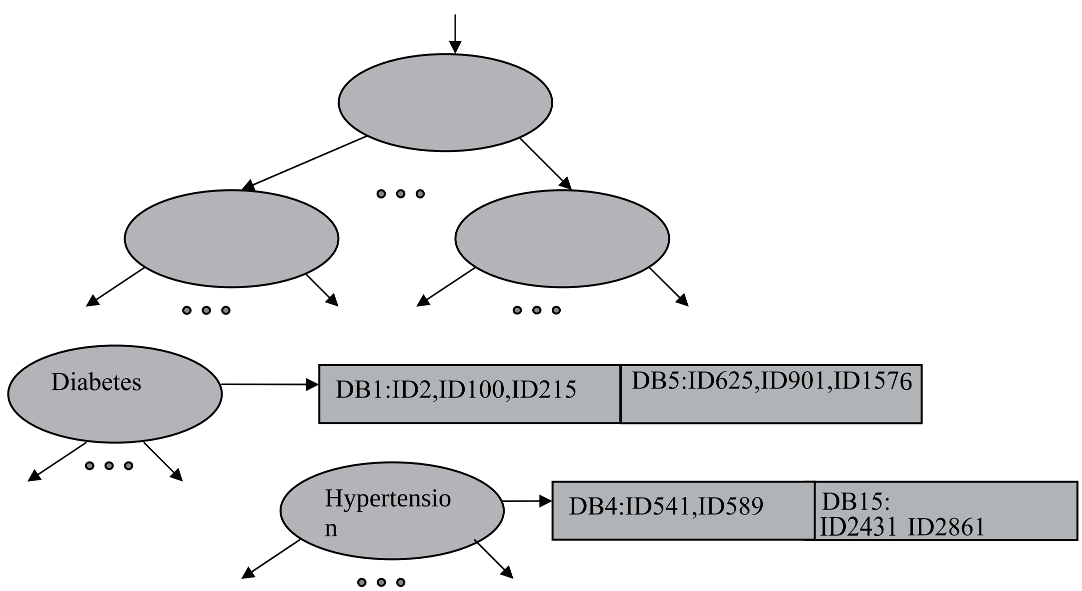
From the user's standpoint, a query is submitted to a Web server. For load balancing purposes, one machine can act as a sprayer or distributor of requests (see Figure 1) and distribute the request to an available Appserver. The Web server, which contains the controller module, acts as a conduit to pass the query request to a common gateway interface (cgi) program, programmed in C. This program will send the search request to an Appserver ensuring that all Appservers are evenly loaded with search requests. An Appserver in turn searches the index lists and retrieves appropriate records from DBservers. Then the Appserver examines the search results and combines it with results from other sources to format a response to the user. If necessary, to refine the search results, the Appserver will generate new search requests and process these new requests before it sends a final response to the user. This process is illustrated in Figure 2.

The size of the index list can fit easily in a few GBytes of memory. With 40 GB of data, it is reasonable to assume that there are a million documents in the MEDLINE database. Let us assume that there are 100,000 keywords used to search the database. Of these, 10,000 may occur frequently in the database. Such keywords are indexed by a binary string to indicate their presence in each document by a 1 or 0. Each such keyword requires a million bits, or 128 KB, of memory. In addition, the other less frequent keywords may occur in an average of 1,000 documents. In that case, each of the less frequent keywords requires 8,000 bytes (assuming each database record's uniquely located ID is 8 bytes long). The amount of memory required for all 100,000 keys is less than 800MB. For the 10,000 most frequent keywords, we will need 10,000 * 128KB = 1.28GB of memory. So the total memory requirements for keeping the index list in the main memory are slightly over 2GB. This is well within the scope of a moderately priced workstation.

Database Implementation

The database will be implemented using either the MySQL or PostGreSQL database engine. Both engines are high-performance engines that support multiprocessor hardware platforms. The MEDLINE database can be loaded into a sequential database from an XML format using software tools developed by Oliver, Bhalotia, Schwartz, Altman, and Hearst (2004). However, these tools need to be further modified to load the MEDLINE data into the parallel database architecture. The database can be searched using SQL syntax queries. To facilitate subsecond search times, we need to avoid searching the database from disk memory directly. To achieve this, we will split the database into nearly equal parts and allocate each part to a distinct machine (denoted DBserver). We will develop software that will let each DBserver (at boot time) read the database and store the records as Java objects in main memory. We will create a hash (mapping) mechanism to associate these Java objects with the unique IDs of the records they contain. To reduce the memory requirements, we will consider compressing infrequently used records. To improve

Figure 3. An example index list in the form of a search tree



performance, most of the data from the database will be loaded into the DBserver's memory. If there are 10 DBservers, each DBserver needs to load 4GB of data into its memory to load the complete 40GB MEDLINE database. DBservers with 8GB of memory can be purchased at a cost of $10,000 per server.

The MEDLINE database can be divided among the DBservers in two ways:

- **Strategy 1:** Distribute MEDLINE data equally among all DBservers.
- **Strategy 2:** Distribute MEDLINE data among DBservers so the overall load is approximately equally distributed at any given time.

Strategy 2 has the potential to improve the performance of our parallel implementation by distributing the load evenly among all DBservers. To implement this strategy, however, we need to estimate the probability with which each document in the MEDLINE database is accessed. For example, if document D_i is accessed with a probability of p_i, MEDLINE database documents need to be distributed among n DBservers such that the combined probability of all documents on any given DBserver is approximately 1/n. Probability p_i with which document D_i is accessed can be computed by looking at access trends of documents over an extended period of time. These trends likely can be predicted. For example, the publication date and nature of a document may predict frequency of access. Therefore, a database record that is a very old citation for a letter to the editor of a low-impact journal probably will be accessed infrequently. This strategy is difficult to implement in practice compared to Strategy 1 and will require quantifying correlated accesses of documents.

PERFORMANCE MODEL

As the number of users increases, more Web servers and Appservers can be added to handle multiple concurrent search requests. On the other hand, if the request load is not expected to be high, then we can combine the functionality of a Web server and Appserver into a single machine. We believe that our approach provides flexibility to scale up to handle larger databases and a larger request volume, if needed, and to scale down to facilitate a low-cost implementation if search time constraints are not stringent. We will use the Linux operating system with public domain MPI and OpenMP software packages to use multiple machines and multiple CPUs in each machine efficiently. For database implementation, we will use MySQL or PostGreSQL to implement DBservers. We will use Java and C to develop the search engine and other custom software as needed.

We will monitor the resulting MEDLINE Web service by observing its response times in response to queries from the search engine to the MEDLINE gateway. In addition to recording search times of the naturally occurring searches submitted by users, we also will submit automated requests every hour. The automated requests will be important during development when there are few requests for searches.

In addition, the static data from the MEDLINE database will be loaded into memory when the application starts and before any user request is processed. Our software will load the static data (data that does not change frequently) at the beginning of the application and store them in memory cache. As discussed in Section 2, we expect most of the data, including the MEDLINE data and the index trees, to reside completely in the memory; hence, no penalty for disk-reads is incurred in the parallel MEDLINE architecture.

Optimal Cluster Size

In this section, we present a simple analytical model to determine the optimal use of the cluster to speed up a single MEDLINE search. The response time of a query can be broken up into several components: (a) the time taken for a search request to reach an Appserver from a user machine; (b) the time taken for an AppServer to broadcast the search information to the Dbservers; (c) the time taken by DBservers to send data back to the AppServer; and (d) the time taken by the Appserver to format and send results back to the client machine. Of these, the time for tasks (a) and (b) are very small and are nearly constant for all searches; we can ignore these times in our model.

Let M be the average amount of data in bytes resulting from a single search. Let $M*t_a$, where t_a is the data format time per byte of data, be the amount of time it takes for an AppServer to format and send data to the client machine. Let $M*t_r$, where t_r is the retrieval time per byte of data, be the amount of time it takes to complete the search using a single processor. If n DBservers

P

are used to perform the search, then the search time is reduced to $(M*t_r)/n$. But this data need to be transferred from the DBservers to the AppServer. On average, each DBserver transmits M/n bytes of data.

The communication among servers in a cluster can be modeled as $t_s + m*t_b$, where t_s is the startup time required to format and prepare transmission of a message, t_b is the transmission time per byte of message, and m is the number of bytes transmitted (Grama, Gupta, Karypis & Kumar, 2003). So the total time taken to process a query, T_{search}, is the sum of the search time, the data transfer time, and the data format time.

$$T_{search} = (M*t_r)/n + n*[t_s + (M/n)*t_b] + M*t_a = (M*t_r)/n + n*t_s + M*t_b + M*t_a.$$

To minimize T_{search}, we need to differentiate the righthand side of this equation with respect to n, equate it to 0, and solve it for n.

$$-(M*t_r)/n^2 + t_s = 0$$

So, $n = (M*t_r/t_s)^{1/2}$ gives the optimal number of DBservers to be used to satisfy a single query.

The message startup time and computational time per unit data are dependent on the technology used. With fast Ethernet and standard Linux network protocol stack with parallel processing middleware such as MPI (message passing interface) (Gropp, Lusk & Skjellum, 1999), the startup time is about 100 microseconds. The retrieval time can be 100 nanoseconds (sufficient to execute about a thousand CPU instructions) or more per byte of data. If the average amount of data produced in a search is 100 Kbytes, then the optimal number of DBservers to be used is at least

$$(10^5 * 10^{-7}/10^{-4})^{1/2} = (100)^{1/2} = 10.$$

If the message startup overhead is reduced, for example, using more expensive Infiniband or Myrinet interconnects with optimized network software (Liu et al., 2003), then more DBservers can be used efficiently. On the other hand, if several queries need to be handled simultaneously, then more queries can be completed per unit of time if the number of DBservers is allocated proportionately to the amount of data to be generated by each query. We will incorporate this model to dynamically vary the number of DBservers used for efficient and fast completion of search requests.

FUTURE TRENDS

We intend to provide access to the MEDLINE database via the campus intranet initially and via the Web eventually to everyone else. The Internet presence includes a Web site that displays the user interface and also a Web service that exposes the MEDLINE database to remote searching by authorized collaborating Web sites. To facilitate easier user interface, we will incorporate user selectable clinical filters developed by other researchers in the medical field. The user may also access the MeSH browser to look up the canonical search term. Finally, the user will have the option to turn off automation if the user wants more control over the search strategy and making revisions.

The Web site will direct the user's query to the database and will receive the results from the database in XML. Scripting at the Web site will transform the XML into html, which is returned as a Web page to the user. The Web page of results that the user receives contains links to the full texts of the articles at the publishers' Web sites. To facilitate automated, high-volume queries by licensed third parties, we also will provide a direct query mechanism without going through the Web interface. In response to a query to the Web service, the search results will be sent as XML documents to allow the remote Web site to insert the results into its Web pages directly.

CONCLUSION

This chapter presented a parallel architecture for speeding up MEDLINE searches. The parallel MEDLINE architecture is based on constructing index trees for the MEDLINE database and storing this index tree in the memory of application servers. The index tree is replicated among all application servers, and the incoming requests for MEDLINE searches are evenly distributed among all application servers. However, the MEDLINE database is distributed among all database servers (or DBservers). In response to a search request, the application server (or Appserver) searches the index tree for keywords and identifies the DBservers on which the corresponding documents reside. The Appserver sends a request to read these documents to the DBservers and gathers the resulting documents from the DBservers and compiles a response. In some cases, the Appserver may further refine the searches based on the documents retrieved. This chapter presented an analytical model on the number of database servers needed and indicated techniques for performance improvement.

KEY TERMS

Cluster of Computers: Several personal computers or workstations interconnected by an Ethernet or similar local area network and having a common communication software such as MPI (message passing interface) to solve various parts of a problem concurrently.

Index List: A list that indicates IDs of records that contain a given keyword.

MEDLINE: Database of citations and links to much of the world's biomedical research. MEDLINE is maintained by the National Library of Medicine of the National Institutes of Health. More information is available at http://www.nlm.nih.gov/databases/databases_medline.html.

Parallel Computing: The execution of a single task using multiple processors in order to speed up the task. In parallel computing, a single task may be divided into multiple subtasks that are assigned to the available processors. The results from these subtasks often are merged together to complete the task.

Performance Model: An analytical model used to predict various performance metrics such as speedup of search request response time, number of computers needed for optimal search times, and so forth.

Search Engine: A special software designed to retrieve from a database the records relevant to the search terms given by the user.

Servers: A computer designed to accept and execute certain types of tasks. Types of servers used in this chapter include Web servers, which interface with user via a Web browser; application servers, which interpret the incoming search requests and dynamically construct the search results; and database servers, which retrieve records based on the IDs indicated by the application servers.

Patients and Physicians Faced to New Healthcare Technologies

Marie-Christine Thaize Challier
University of Grenoble, France

INTRODUCTION

It is increasingly recognized that, by introducing healthcare information systems, it may be possible to improve healthcare delivery. Yet, insufficient attention has been paid, in the context of the introduction and implementation of new technologies, to examine the issues concerning the reduction of the astonishing variations in medical (and surgical) practices across seemingly similar areas. This article studies the causes of the differences in healthcare practices by examining the agency relationship where the patients delegate decision making to the physicians. To do this, it first presents the consequences of two main informational issues: the asymmetric information, and the imperfect information. Under such informational inadequacies, practitioners could not act in the best interests of their patients, and unnecessary and inappropriate cares could appear. Second, this article derives from such informational problems the necessity of information and coordination systems to ensure a better healthcare delivery.

BACKGROUND

Health researchers identify amazing variations in medical and surgical practices across otherwise-similar market areas (Phelps, 1997, *Darmouth Atlas of Healthcare,* cited by Dranove, 2000). Small Area Variations (SAVs), defined as wide variations in per-capita rates of healthcare procedures among seemingly similar areas, have many sources. The reasons for these variations, as well as their magnitude, remain controversial. Possible sources of the variations, besides demographics and insurance coverage, are patient preferences, the demand inducement, as well as the role of the differences in the practice style of physicians.

1. A first explanation of SAVs is attributed to the *patient preference*; that is, to their power to increase the healthcare demand (Folland, Goodman, & Stano, 2001, pp. 219, 222; Phelps & Mooney, 1992).
2. A second explanation of such differences rests on the existence of an *informational problem* due to the "supplier-induced demand" (SID) (Pauly, 1988; Phelps, 1986). This phenomenon is a problem of *asymmetric information* occurring when physicians use their influence to make treatment recommendations and other clinical decisions that rise the costs, and are not in the best interest of their patients. In that case, *patient ignorance* provides physician financial incentives to increase healthcare supply, and to generate unnecessary or inappropriate care. There is thus a specific informational asymmetry, called "moral hazard," revealing the postcontractual opportunism that occurs when a party takes an inappropriate action or provides distorted information (Arrow, 1963; Milgrom & Roberts, 1992). In this context, the role of physicians' payments (in particular under their three major forms) can be examined. *(i)* Under fee-for-service (FFS) basis, each physician has a schedule of fees and is reimbursed for each unit of service. Benefit schedules indicate the maximum levels reimbursed by insurers for a specific service. However, given this reimbursement, physicians could prescribe inadequate services in order to increase their own incomes. FFS compensation provides no financial incentives for health suppliers to mitigate moral hazard. *(ii)* Physicians can receive salaries/fixed fees (i.e., capitation for each patient assigned). This capitation (fee per capita and per year) limits repetitive visits, testing, and referrals; moral hazard can be reduced. Physicians have no incentives to provide unnecessary care given that they will not receive any additional payment for any additional care. However, if capitation induces physicians to rein in the utilization of their own services, this prepayment system does not prevent moral hazard, in particular the

overuse of specialists. Nevertheless, this problem is reduced if capitation fee increases when primary care physicians bear the costs of their referrals (see e.g., Dranove, 2000, pp. 75–76). *(iii)* Other physicians gain a fixed salary: a prepaid fee whatever the inputs provided. Through such a prefixed remuneration (i.e., a salary whatever the number of patients—moral hazard can be avoided).

3. Yet, most of controversy has focused on a third explanation: the differences in the *practice style of physicians* and the question of unnecessary or inappropriate care, due to *imperfect information* (Folland et al., 2001). Practice styles often differ across markets but also within communities. Where Green and Becker (1994) argued that SAVs are not necessarily due to the practice style hypothesis, most researchers find that many SAVs are closely related to the degree of physician uncertainty concerning the diagnosis and treatment (Wennberg, 1984). Corroborating this idea of physicians' uncertainty, healthcare researchers showed that the practice styles of physicians underline their imperfect information about the technology of producing health (Folland & Stano, 1989). In other terms, physicians could be misinformed (Folland et al., 2001). Consequently, physicians' decision making is not always optimal even if they act as "perfect agents" (i.e., without voluntary misbehaviors). Finally, such informational problems create substantial quality losses and wastes through overuse, underuse, and misuse.

Faced to such problems, the growing recognition of a need for better data and understanding led to various efforts to improve the healthcare system. Most of these actions developed evidence-based medicine, and recommended the collection and evaluation of administrative data in clinical and surgical services. In order to implement a variety of practices to identify information about cost and quality based on evaluations of outcomes research, a new tool emerged in the United States, the so-called "utilization review." Utilization review agencies usually approve the proposed treatment plans, but also recommend lower cost alternatives and sometimes recommend more costly interventions (Dranove, 2000, pp. 82). Detractors argue that such practices reduce costs at the expense of quality and they accuse the utilization review agencies of using "simplified treatment criteria that ignore patients' idiosyncratic needs" (Dranove, 2000, pp. 82). Due to contested practice guidelines and standards to assess and assure the healthcare quality, utilization review was eliminated in late 1999.

REDUCING SAVs

How can one provide a better way to avoid the part of SAVs due to informational inadequacies? The first way is accurately to identify the patients' and physicians' lack of information, and then to eliminate or reduce them by appropriate incentives and tools. Let us examine the challenges information systems face to reduce SAVs. One do not forget that the physician-patient transaction is an agency relationship where one party (here the patient) relies on another party (here the physician) to make decisions. Physician-patient transaction reveals a complicated relationship where the emergence of contingencies leads the parties to find adaptations. Consequently, this introduces the possibility of opportunistic behaviors leading to inefficiency.

Reducing SAVs in the Case of Asymmetric Information

Two types of *asymmetric information* can cause SAVs.

1. An important type of informational inefficiency leading to SAVs is due to the so-called "*adverse selection*" problem. Adverse selection refers to the *precontractual opportunism* due to the fact that one party has a private (i.e., unverifiable) information before getting engaged in a contractual relationship, this information affecting outcomes (Milgrom & Roberts, 1992). For example, patients may have private information about other symptoms; physicians may have private information about the available treatments, the efficiency of alternative medicines.

   To reduce the problem of asymmetric information relative to the physicians, it is necessary to develop systems of coordination displaying *common knowledge* about the availability of treatments and the capacity of therapies or alternative medicines, among others. In order to deal with the asymmetric information relative to the patients, the latter will report more easily the truth about their (other) current own healthcare characteristics if the information system allows the provider to check the patient history.

2. The second source of inefficiency is the *moral hazard* problem. For example, after the treatment delivery, patients may take actions that affect the outcomes—such as not follow the prescribed treatment—or they may also have incentives to lie about their healthcare conditions by understating them; physicians may prescribe unnecessary tests and procedures in order to protect themselves from malpractice suits.

   To deal with moral hazard problem, effective information systems can give the following solutions: *(i)* increase the resources of monitoring and verification in order to catch inappropriate actions before their occurrence; *(ii)* provide incentives for good behavior through rewarding good outcomes—for example, assess, develop, and implement new payment schemes (in order to remunerate good advice, Dranove (2000, pp. 174) imagines a "fee-per-advice" system that would resemble existing fee-for-service payments as well as a "retainer" system that would resemble capitation). *(iii)* Moreover, because *asymmetric information* leads to conflicts of interest between patients and physicians, it is necessary to align the individual interests with the group interest. Indeed, fear of opportunism may jeopardize the players' trust and lead to imperfect commitment. It is thus a priority to restore trust in physician competence and trust in the ability of healthcare systems to coordinate the various resources. All this constitutes a part of the "information integrity and quality" developed by HCIS (see, e.g., Eder, 2000; Fadlalla & Wickramasinghe, 2004).

Reducing SAVs in the Case of Imperfect Information

Other informational problems occur without opportunistic behaviors.

1. The motive behind the delegation of authority between a patient and a physician is that the former is generally less well informed about some features or problems than the latter. The *patient lack of information* refers to the true patient healthcare, the available treatments, the most appropriate treatment, the need to carry out other tests, and the expected outcomes of the prescribed treatment, among others.
2. However, it is insightful to note that the physician him/herself can also ignore the same features. Such a *physician lack of information* is due to uncertainty and ignorance in diagnosis and treatment. In addition, the physician can also ignore the other patient's symptoms, the patient's well being after the therapy, and the availability of various treatments, and the patient's preferences about the desired form of medicine. Physicians' uncertainty and ignorance over the best medical practices can also lead to unnecessary care.

   The resolution of such wastes is crucial. Solutions can be provided through information systems that can: *(i)* identify inappropriate or unnecessary care (i.e., define and measure what could be an appropriate and necessary care); *(ii)* assess and develop the taking into account of patient preferences, including the traditional and alternative forms of holistic medicine (Ayurveda and Chinese medicines, homeopathy, and herbal medicine, among others); and *(iii)* examine the patient needs (i.e., idiosyncratic needs).

Principles and Aims

More broadly, to solve such informational problems, the main question is: how to assess the effectiveness of healthcare information systems? The answer depends on two levels of information (Milgrom & Roberts, 1992, chap. 4). In the case of healthcare delivery, the answer is the following. First, if all information is reported honestly and if the information process is perfect and costless, the system of coordination can achieve an efficient healthcare decision. If it is not the case, an effective system must study how much extra information or coordination the system requires. Second, under imperfect information (i.e., if some healthcare information is lacking or inappropriate) it is relevant to determine what is the loss of effectiveness of the system. Taking into account such aspects, it is worthwhile to add that an effective system should apply the six key aims defined in 2001 by the Committee on the Quality of Healthcare (cited e.g., by Wickramasinghe, 2007, pp. 10). Indeed, healthcare should be: (1) safe–avoiding injuries to patients from the care; (2) effective—avoiding underuse and overuse; (3) patient-centered—avoiding care centered on the interest of other people; (4) timely; (5) efficient—avoiding wastes; (6) equitable—avoiding personal or social exclusion. Moreover, in the context of the emerging area of the "information integrity," four key principles are significant for the implementation of an effective system. Clearly, "the information must: (1) meet the consumers information needs; (2) be the product of a well-defined information production process; (3) be managed by taking a life-cycle approach; and (4) be managed and continually assessed vis-à-vis the integrity of the processes and the resultant information" (Huang, Lee, & Wang, 1999; Wickramasinghe, 2007, pp. 9–10).

FUTURE TRENDS

Medical practices can use information systems in order to reduce SAVs. Nevertheless, the future lies in finding new ways to improve the relationship between physicians and patients, and to provide direction for coordinating the delivery of healthcare resources. This article has examined some of the issues that must be taken into account when studying the relationships between informational issues, medical practices, and SAVs. However, several questions need further development. First, the relationship between physicians and patients need to be scrutinize in order to improve better information systems. Successful studies will show how the optimal healthcare decision can be detected in an environment characterized by a growing number of diagnostics, tests, and therapies through the generation and implementation of sophisticated technologies. Second, the strengths and weaknesses of information systems need careful investigations. When medical information is missing or imprecise (i.e., under imperfect information), it is crucial to find the real information in order to implement the best treatment. This will ensure superior decision making and support quality in healthcare delivery.

CONCLUSION

The generation and implementation of new information and communication technologies is currently affecting healthcare delivery and, in particular, the physician-patient relationship. Achieving high levels of information and coordination is a permanent challenge. Some researchers have focused on the reasons for SAVs, and the issues and controversies presented in this article have developed the role of asymmetric and imperfect information in the context of physicians' practices in connection with the healthcare preferences and needs of the patients. Medical and administrative data (on patient history, treatment protocols, research finding on treatments, among others) settle the foundation for a better healthcare system. Although information systems are already effective, ongoing efforts to generate much more quality improvement and reduce SAVs through appropriate information systems will create substantial welfare gains for society.

KEY TERMS

Adverse Selection (or Antiselection): In economic theory, adverse selection refers to the precontractual opportunism that results from an asymmetric information. It occurs when one party has private information—about his/her own characteristics or on the environment—that can affect the outcomes of the contract.

Agency Relationship: Situation in which one party relies on another party to make decisions.

Asymmetric Information: This term refers to situations in which contractual parties have differing amount of relevant information. Such situations can be adverse selection situation or moral hazard situation.

Imperfect Information: This term refers to situations in which a contractual party ignores relevant information about the other party or the environment, or when he/she does not know the action of the other party.

Moral Hazard: In economic theory, moral hazard refers to the postcontractual opportunism that results from an asymmetric information. It occurs when the actions contractually required are not freely observable; for example, a party takes an inappropriate action or decision that can affect the outcomes of the contract.

Private Information: Relevant information known only by some parties involved in a contractual relationship.

Small Area Variations: The wide variations in the per capita rates of healthcare procedures across seemingly similar areas.

ABSTRACT

One of the challenges in intensive care is the process of weaning from mechanical ventilation. We studied the differences in respiratory pattern variability between patients capable of maintaining spontaneous breathing during weaning trials, and patients that fail to maintain spontaneous breathing. In this work, neural networks were applied to study these differences. 64 patients from mechanical ventilation are studied: Group S with 32 patients with Successful trials, and Group F with 32 patients that Failed to maintain spontaneous breathing and were reconnected. A performance of 64.56% of well classified patients was obtained using a neural network trained with the whole set of 35 features. After the application of a feature selection procedure (backward selection) 84.25% was obtained using only eight of the 35 features.

INTRODUCTION

Neural networks are very sophisticated modelling techniques capable of modelling extremely complex functions (Bishop, 1995). A simple network has a feed-forward structure: signals flow from inputs, forwards through any hidden units, eventually reaching the output units. Such a structure has stable behaviour. Neural networks are applicable in every situation in which a relationship between the predictor variables (independents, inputs) and predicted variables (dependents, outputs) exists, even when that relationship is very complex and not easy to articulate in the usual terms of "correlations" or "differences between groups."

The weaning trial protocols are very important in patients under mechanical ventilation. A failed weaning trial is discomforting for the patient and may induce significant cardiopulmonary distress. When mechanical ventilation is discontinued, up to 25% of patients have respiratory distress severe enough to necessitate reinstitution of ventilatory support (Tobin, 2001).

The respiratory pattern describes the mechanical function of the pulmonary system, and can be characterized by the following time series: inspiratory time (T_I), expiratory time (T_E), breath duration (T_{Tot}), tidal volume (V_T), fractional inspiratory time (T_I/T_{Tot}), mean inspiratory flow (V_T/T_I), and frequency-tidal volume ratio (f/V_T).

The variability of breathing pattern is nonrandom, and may be explained either by a central neural mechanism or by instability in the chemical feedback loops (Benchetrit, 2000). The study of variability in the respiratory pattern has been discussed in (Bruce, 1996; Caminal, Domingo, Giraldo, Vallverdú, Benito, Vázquez, & Kaplan, 2004; Khoo, 2000; Tobin, Mador, Guenter, Lodato, & Sackner, 1988).

The aim of the present work is the analysis with neural networks of the respiratory pattern variability in patients during weaning trials, in order to find differences between patients capable of maintaining spontaneous breathing and patients that fail to maintain spontaneous breathing.

As in many real situations, the suitable variables that describe the problem are partially unknown. When irrelevant variables are present, there may be many different models able to fit the data. But only some of them (those that do not use irrelevant variables) will lead to good generalization performance on unseen examples. However, in general it is not possible to control that irrelevant variables are not used during the training phase to learn the training set. This problem is shared by all modeling techniques, including neural networks. In this situation, feature selection techniques allow to search for a good subset of input features.

ANALYZED DATA

Respiratory flow was measured in 64 patients on weaning trials from mechanical ventilation (WEANDB data base). These patients were recorded in the Departments of Intensive Care Medicine at Santa Creu i Sant Pau Hospital and Getafe Hospital, according to a protocol approved by the local ethic committees. Using clinical criteria based on the T-tube test, the patients were classified into two groups: Group S (GS), 32 patients with Successful trials after 30 minutes; and Group F (GF), 32 patients that Failed to maintain spontaneous breathing and were reconnected after 30 minutes of weaning trials.

Respiratory flow was obtained using a pneumotachograph connected to an endotraqueal tube. The signal was recorded at a sampling frequency of 250 Hz during 30 minutes.

From each recorded signal the aforementioned time series were obtained: inspiratory time (T_I), expiratory time (T_E), breath duration (T_{Tot}), tidal volume (V_T), fractional inspiratory time (T_I/T_{Tot}), mean inspiratory flow (V_T/T_I), and frequency-tidal volume ratio (f/V_T).

METHODOLOGY

Data Preprocessing

Each one of the seven time series was processed by moving a Running Window (RW), with a width range from 3 to 100, consisting of several consecutive breath

Figure 1. Representation of 35 features for each patients obtained by Running Window (RW) with seven respiratory time series (TI, TE, TTot, VT, TI/TTot, VT/TI and f/VT and five statistics (mean, standard deviation, skewness, kurtosis and interquartile range) applied

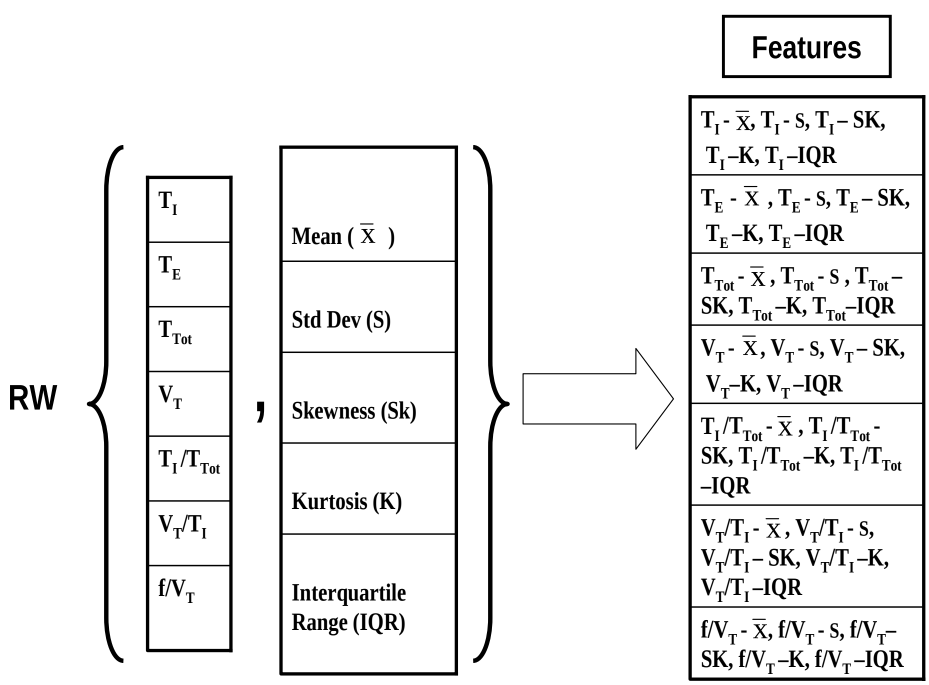

Figure 2. p-values total for all statistics parameters in all time series and for each window width. The best width was 15 (p < 0.001).

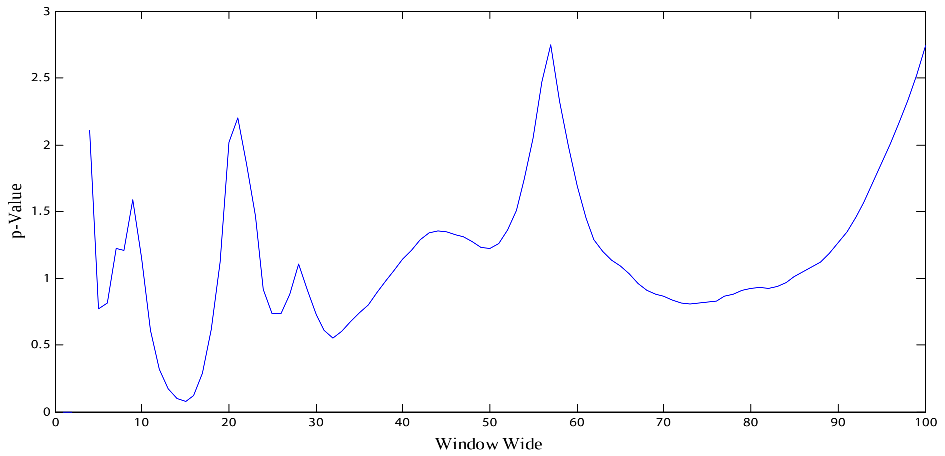


cycles. Five statistics were calculated for each window: the mean ($\overline{x}$), standard deviation (*S*), kurtosis (*K*), skewness (*Sk*), and interquartile range (*IQR*) of the value. In this way, 35 new time series were obtained for each patient (Figure 1), that are the features of the system. The optimal width of the RW was selected in the range from three to 100 by using a Mann-Whitney Test.

Figure 2 shows the total *p*-values for all statistics parameters in all time series and for each window width. The best width was 15, with $p < 0.001$ in all cases. Finally, this RW width was used to compute the 35 variables for each patient.

Next, with the RW width selected, the data of each patient were analyzed independently by applying a *k*-means clustering algorithm, which automatically determines the best number of clusters for all patients. The data of each patient are partitioned in *k* clusters mutually excluding. The partitions are defined by their centroides in each cluster, which represent the minimal distance between each data and this point. This cluster it must have a good cohesion (low intra-cluster variance). In this study, for all patients, there was a main cluster containing the most part of the patterns (i.e. data points). Table 1 shows the mean percentage of data points, represented by the main cluster for Group S and Group F.

Hence, this result was exploited to perform a dramatic data reduction, by which a single pattern of 35 features was associated with each patient. This pattern was computed as the mean value of the data points in the main (largest) conglomerate of the patient, using the *k*-means cluster algorithm.

As result of the data preprocessing step, the data set to be classified by the neural network included 64 patterns, one for each patient, 32 from Group S, and 32 from Group F.

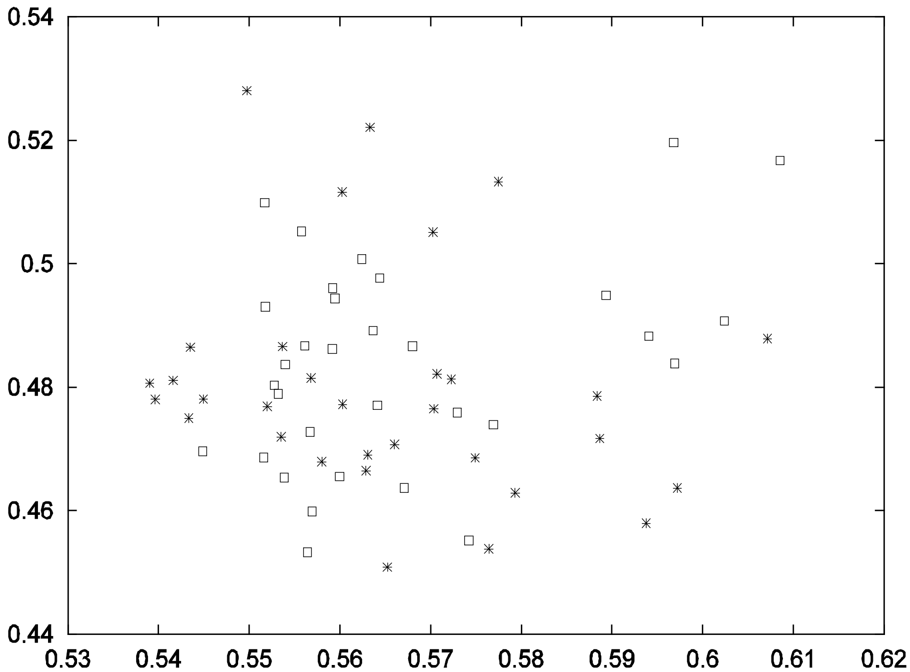
Data Visualization

In order to visualize the data, the 64 patterns were projected onto the plane with the Sammon mapping (Fiesler & Beale, 1997; Mao & Jain, 1995). Sammon mapping is a procedure designed to project high dimensional data onto low dimensional spaces preserving the original structure of the data. In particular, every point in the original space is associated to a point in the projected one, so that the distances between the original points are preserved in the projected space as much as possible. Figure 3 shows the results of the projection in this study (Sammon error = 0.053). As it can be seen,

Table 1. Percentage represented by the main cluster

	Mean ± SD (%)
Group S	
	96,081 ± 3,84
Group F	
	96,707 ± 3,58

Figure 3. Projection of the original data onto the plane with the Sammon mapping; different symbols indicate points of different classes



the data is not easily separable, and there are examples of different classes that are very near between them. This makes the data difficult to learn.

Neural Networks and Feature Selection

Neural networks are used for a wide variety of pattern classification tasks (Rumelhart, McClelland, & the PDP Research Group, 1986). A pattern is represented by a number of features that form a *d*-dimensional feature vector **x** within an input space $X \subseteq R^d$. A classifier therefore realizes a mapping from input space X to a finite set of classes $C = \{1,...,l\}$. A neural network is trained to perform a classification task from a set of training examples $S = \{(\mathbf{x}^{\mu}, t^{\mu}), \mu = 1,..., M\}$ using a supervised learning algorithm. The training set S consists of M feature vectors $\mathbf{x}^{\mu} \in R^d$ each labeled with a class membership $t^{\mu} \in C$. The network typically has as many outputs as classes and the target labels are translated into *l*-dimensional target vectors following a local unary representation. During the training phase the network parameters are adapted to approximate this mapping as accurately as possible (unless some technique, such as early stopping, is applied to avoid overfitting). In the test phase, an unlabeled feature vector $\mathbf{x} \in R^d$ is presented to the trained network, and the network outputs provide an estimation of the *a-posteriori* class probabilities for the input **x**, from which a classification decision is made, usually an assignment to the class with maximum *a-posteriori* probability (Bishop, 1995).

In this work, we used feed-forward two-layer perceptron architecture (i.e., one hidden layer of neurons and an output layer). For processing the full feature vectors, the networks consisted of 35 inputs, *n* hidden units and two output units, where *n* took different values from five to 30. Sine and logistic functions were used as activation functions in the hidden layer and the output layer, respectively. The networks were trained with backpropagation. A modified version of the Parallel Distributed Processing (PDP) simulator of Rumelhart and McClelland (Sopena, Romero, & Alquezar, 1999) was employed for the experiments. The weights were initially assigned randomly using a uniform distribution in the interval (-*w*range/2, *w*range/2). Some range values were tried and set independently for the hidden and output layers. Learning rates were adjusted for every architecture and range of weights. The momentum parameter was set to 0, with a maximum number of 1000 training epochs for each run.

For each network tested, 25 independent runs of an eight-fold cross-validation (CV) procedure were carried out, so that many different data partitions were generated, each including 56 patterns in the training set, and eight patterns in the test set. In some cases, eight patterns not used in the test set were reserved as validation set for early stopping the training phase (Romero et al., 2003). In this case, an internal seven-fold CV was performed with the training set of the eight-fold CV, so that six folds were used to train, one fold to validate and the remaining fold to test the model.

The network chosen at the end of the training phase was either the one that yielded the best classification result on the validation set among the networks obtained after each training epoch (when a validation set was used), or the one that yielded the best result on the training set (otherwise). Then, the chosen networks were evaluated on the corresponding test sets, and the test results were averaged for the different partitions and runs.

First, the experiments with the whole set of 35 attributes were carried out. As previously mentioned, 25 independent runs of an eight-fold CV (without validation set) were performed. After the experiments with the whole set of 35 features, we performed similar cross-validation experiments with different subsets of features, forming groups of five statistics related to each one of the seven time series collected. The number of inputs of the networks was set in this case to the dimension of the feature subset.

Finally, in order to determine the best possible subset of input features, feature selection was performed by carrying out several runs of a sequential backward selection method. Features were eliminated one by one, and the network was retrained each time a feature was temporarily removed. Again, eight-fold CV was applied and validation sets were used for early stopping and for selecting the features to remove. Once identified the feature subset providing the best result, 25 runs of an eight-fold CV (without validation set) were performed to obtain the final average test classification result using the selected variables.

RESULTS

Using all the 35 features, the average correct classification rate in the test sets was 64.56%. This result was improved in the case of using some fixed groups of the five statistics obtained from the original time series (Table 2), obtaining a best average result of 68.62%, using only skewness and standard deviation variables. However, a much more significant improvement in the average test result was achieved when applying the sequential backward feature selection process (in which features were not grouped but removed independently). Table 3 shows the three best average results after backward selection, being 84.25%, the best average of well classified patterns in the test set using only eight of the 35 features.

DISCUSSION AND CONCLUSION

Neural networks are very sophisticated modeling techniques capable of modeling extremely complex functions and feature selection techniques allow searching a good subset of input features.

Neural networks have been applied in order to analyze the respiratory pattern variability in patients during weaning trials, in order to find differences between patients capable of maintaining spontaneous

Table 2. Test classification results for several groups of selected variables using combinations of five statistics: Mean, standard deviation, skewness, kurtosis and interquartile range

Feature subsets	***Recall***		***Test result***
	GS	***GF***	***± SD***
Skewness (*Sk*) and Standard Deviation (*S*)	**69.75**%	**67.50**%	68.62% ±1.12%
Kurtosis (*K*), Skewness (*Sk*) and Interquartile Range (*IQR*)	65.75%	70.75%	68.25% ±1.21%
Standard Deviation (*S*), Skewness (*Sk*) and Interquartile Range (*IQR*)	67.75%	67.50%	67.62% ±1.24%
All 35 features	64.12%	65.00%	64.56% ±1.18%

Table 3. Test classification results for the best sets of selected variables obtained after sequential backward feature selection

Feature subsets obtained after sequential backward selection	***Recall***		***Test result ± SD***
	GS	***GF***	
$Sk(V_T/T_I), K(V_T), Sk(T_I/T_{Tot}), K(T_I), Sk(T_I), IQR(f/V_T), \overline{X}(V_T), IQR(T_{Tot})$	76.75%	91.75%	84.25% ±0.81%
$S(V_T/T_I), Sk(f/V_T), S(T_E), \overline{X}(T_I), IQR(f/V_T), Sk(V_T/T_I), IQR(T_I), Sk(T_I), K(T_{Tot}), K(V_T), Sk(T_I/T_{Tot}), IQR(T_{Tot}), \overline{X}(V_T/T_I), \overline{X}(T_I/T_{Tot})$	79.12%	83.00%	81.06% ±1.13%
$\overline{X}(f/V_T), IQR(f/V_T), Sk(V_T/T_I), Sk(V_T), IQR(V_T/T_I), IQR(T_I/T_{Tot}), \overline{X}(T_I/T_{Tot})$	79.75%	80.62%	80.19% ±0.87%

breathing and patients that fail to maintain spontaneous breathing.

The networks trained with the whole set of 35 features achieved a performance of 64.56%. After the application of feature selection, 84.25% was obtained using only eight of the 35 features. Although the groups were balanced, a greater facility of learning and generalization was observed in the Group F with 91.75% of successes compared with the Group S with 76.75%.

It is necessary to make a model with the most important characteristics and to prove the generalization of our system. Additionally, it could be interesting to increase the number of patterns used for training, in order to improve the generalization error, assuring the presence of the subgroup with the most important characteristics.

The optimal wide of the RW was computed with the complete set of characteristics, when selected characteristics are modified, this optimal wide could change.

Given the clustering results, it would be important to carry out a study to obtain the indexes that allowed us to decrease the temporary registry of data.

ACKNOWLEDGMENT

The authors would like to thank to Dr. A. Ballestero of the *Hospital Universitario de Getafe*, Getafe, Spain, by his collaboration in the signal database acquisition.

Planning and Control and the Use of Information Technology in Mental Healthcare Organizations

I.J. Baars
Maastricht University, The Netherlands

G.G. Van Merode
Board of Maastricht University Medical Center & Maastricht University, The Netherlands

INTRODUCTION

Demand for mental healthcare increases. Simultaneously, the need for more patient oriented processes increases and the market develops towards more competition among providers and organizations. As a result of these developments, mental healthcare organizations are becoming more aware of efficiency and effectiveness. Often, they choose to transform to more process oriented organizations, which require changes in planning and control systems and information technology (IT). However, little is known about the required planning and control systems and IT for mental healthcare.

We argue that IT for planning and control of mental healthcare organization needs to be adaptive and support short term planning. IT has to be adaptive to be able to support first and second order control which is needed for planning and control of mental healthcare processes. Short term planning or reactivity is needed to deal with stochasticity and variability as present in mental healthcare. These subjects are further described in the background.

This article reports the results of two studies on the use of standard care processes and IT for planning and control of mental healthcare processes. The results give insight in the needed functionalities of IT and planning and control of mental healthcare processes. The first study is a case study in a center for multidisciplinary (mental) youth care. This center implemented care programs and an automated planning tool. We studied the success of this implementation and particularly the fit between the care programs and the planning tool.

In the second study we studied the characteristics of ambulant mental healthcare processes and the actual and preferable use of planning and control models and IT.

BACKGROUND

Mental healthcare is often multidisciplinary and includes several professionals, disciplines, and departments within one or more organizations which all need to be planned and controlled. Consequently, the object of control is mainly professionals and patients, but also resources like rooms. We define planning as the determination of what should be done and control as the process that assures that the planned results are obtained (Van Merode, Groothuis, & Hasman, 2004).

According to Hofstede (1981), the way nonprofit organizations, such as mental healthcare organizations, can be planned and controlled depends on the type of processes. The type of process can be determined by answering the following questions: is the output measurable? Are the objectives unambiguous? Are the effects of management interventions known? And, can the activities be repeated? The type of processes determines the control model and instruments (e.g., protocols, case management and budgeting) that can be applied.

Hofstede (1981) defines six different control models, as shown in Table 1. The more standardized, well-defined, and structured the processes are, the more routine control can be used.

A mental healthcare organization consists of various processes. These processes are possibly different and thus need different control models. To select a control model that best suits a situation, processes have to be analyzed. Especially the distinction between routine and less routine processes is important here.

Routine processes can use standards and can be controlled by routine control or, when the activities cannot be repeated, by expert control. For routine control, and marginally for expert control and trial-and-error control, models that compare automatically what

Table 1. Control models

Control model condition	Unambiguous objectives	Measurable output	Known effects	Repetitive activities
Routine control	+	+	+	+
Expert control	+	+	+	-
Trial and error control	+	+	-	+
Intuitive control	+	+	-	-
Judgmental control	+	-	+/-	+/-
Political control	-	+/-	+/-	+/-

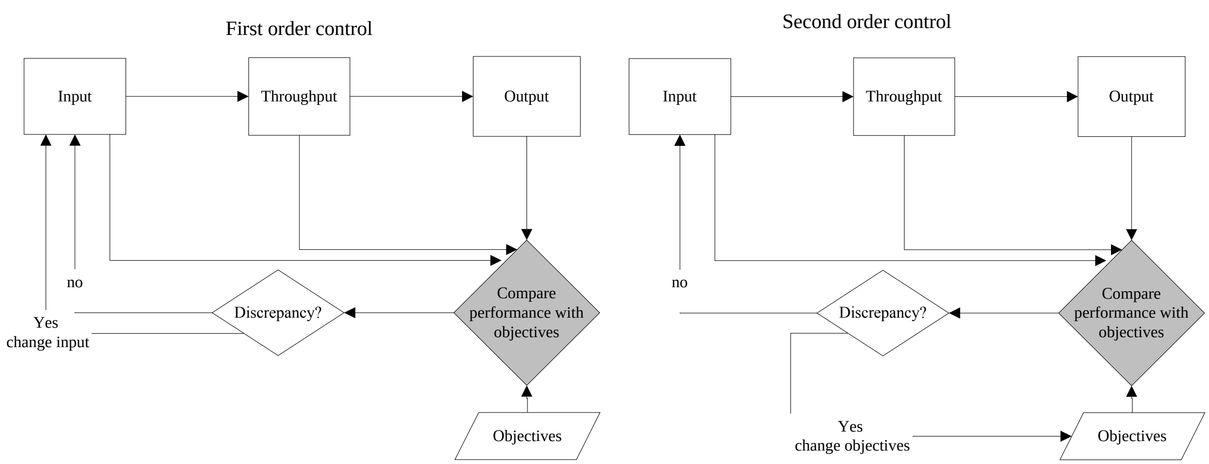
+ = condition is present
- = condition is not present

actually happens with the standards about what should happen apply. These models use feedback for control. The feedback from relevant indicators provides information that can be compared with targets. A number of care processes can be coordinated to a large extend by planning and control integrated in one system and by providing feedback from control to planning (Hofstede, 1981; Van Merode, Groothuis et al., 2004; Van Roth & Van Dierdonck, 1995). Moreover, for intuitive and judgmental and political control only vague models exist (Hofstede, 1981).

An example of control by feedback in mental healthcare is a protocol for the process of the treatment of depression. This protocol describes that the target of the indicator "number of sessions" is 15. If a patient receives 17 instead of the targeted 15 sessions, this is evaluated. Several actions can be undertaken to meet the target of 15. One such an action is adapting the input of the process so that the 15 sessions are not exceeded. This is first order control (Figure 1).

A problem with first order control can be that the aim becomes to keep the activity on target at any cost. To overcome this problem, a second order feedback loop that can periodically adjust the targets of the first order feedback loop is necessary (Figure 1). A second order feedback loop provides information (e.g., by new insights or outcome of evaluations) that enables decisions on the appropriateness of the target. By means of a second order feedback loop, the interventions of the first order loop can be overruled. With that, the targets of the process can be adapted so that the outcome better fits the targets. In our example of 15 sessions where the output did not meet the target of 15 sessions, the target of the standard can be changed to, for example, 17 sessions. An advantage of second order feedback is that it can cover more complex organizational control

Figure 1. First and second order control



situations. Furthermore, variability and stochasticity can be accounted for with a second order feedback loop.

Information Technology for Planning and Control

Planning and control by feedback on performances can be supported by IT. IT provides the backbone for collecting, compiling, and utilizing information on patients, activities, methods, costs, and results (Porter & Olmsted Teisberg, 2006). Because of the multidisciplinary care and the involvement of several professionals, disciplines, and departments that need to be planned and controlled, a central automated system for planning and control might be needed. In industry Enterprise Resources Planning systems are often used for this purpose. Enterprise Resource Planning (ERP) systems attempt to integrate all corporate information in one central database, and information can be retrieved from many different organizational positions and in principle they allow any organizational object to be made visible (Dechow & Mouritsen, 2005).

Likewise, for healthcare, ERP systems can integrate many functions such as patient scheduling, human resource management, workload forecasting, and management of workflow (Jenkins & Christenson, 2001). However, when implementing ERP systems in an organization, several implementation and structural problems can occur, for example, ERP may not fit the structure of the organization.

Implementation and structural problems may occur in healthcare because ERP systems require fixed, deterministic processes and ignore alternative processes (Van Merode, Groothuis et al., 2004). But in healthcare, stochasticity (e.g., patients not showing up) and variability (e.g., demands for care differ between several individual patients) exist. Because of the existence of stochasticity and variability, a more reactive decision making technology or short term planning systems as, for example, Advanced Resource Planning (ARP), better suit the less deterministic processes (Vandaele & De Boeck, 2003; Van Merode, Groothuis et al., 2004). Another possibility for planning and control in mental healthcare is to physically separate deterministic processes suitable for ERP from nondeterministic processes requiring a more reactive decision making, or short term planning, technology.

PLANNING AND CONTROL AND THE USE OF IT IN MENTAL HEALTHCARE ORGANIZATIONS

To study the possibilities of planning and control and the use in mental healthcare organizations, we performed two case studies. Here we present the results of these two case studies.

Case 1: Planning Tool and Care Programs

In the multidisciplinary youth (mental) healthcare center, processes were standardized by care programs. The aim of the care programs was to plan processes more efficient and effective, and also to improve the patient-oriented way of working. A care program is defined as a framework with which organizations, professionals, and patients should comply and it is used to get a patient-oriented organization of a well described target group. It integrates the activities between different disciplines, professionals, and departments and indicates the way the care should be given, by which professional, in which setting, and with what frequency (Berg, Schellekens et al., 2005).

Care programs consist of several standardized modules. The planning of a care program, that is, which modules will be performed, is done based on the demand of the patient. Further, for planning and control of the activities of a module, each module contains a Bill of Resources (BOR), which is described in the protocol of the module.

A BOR is derived from a Bill of Materials that is used by ERP systems. However, mental healthcare includes more than materials such as professionals and patients. Therefore, the use of a BOR is more appropriate for healthcare organizations (Van Roth & Van Dierdonck, 1995). In the center, a BOR defined the location, type of activity, professional, and patient.

Because of the multidisciplinary care, the coordination of the care programs was complex. Automated support might reduce this complexity. Therefore, IT, that is, the planning tool, was used for planning and control of activities of patients and professionals. The planning tool was a software application, intended to support working with care programs. The features of the care programs, such as the involvement of several professionals and departments and the standardization of modules, require certain functionalities of the planning tool. The planning tool contained the following functionalities: a BOR to plan activities, an event handler to react to ad hoc changes by revising timetables and re-arranging activities, an electronic organizer, and a control function for process control by first order feedback and second order feedback.

To test the functionalities in relation to the care programs, the planning tool was tested in a pilot. The evaluation of the pilot was done with a document analysis, interviews with all those involved, and analysis of e-mails to and from the planning tool helpdesk.

The results of the evaluation show that the fit between the standardized care programs and the planning tool was insufficient. The main cause was the noncompliance of the professionals with the standard modules because they feared inflexibility in performing their activities due to the standardization and first order control. However, the professionals did have some flexibility in planning. They could use the event handler to react to ad hoc situations and they had the possibility to deviate from the standards to react to variability which is second order control. But the results show that the flexibility possibilities were not known and not used by the professionals.

As the results illustrate, the characteristics of care processes and the functionalities of IT must fit to function. In this case, the IT demands a certain amount of standardization while in daily practice the professionals require flexibility in performing their activities. Therefore standardization and flexibility have to be balanced. Because the professionals did not comply with the standard modules of the care programs, and did not know of, or use, the possible flexibility, we do not know for sure that the care programs and the IT did not fit. It seems also due to implementation problems of the IT and care programs that professionals did not comply and did not have knowledge about the possibilities of second order control.

Professionals do need some planning freedom to be able to react to the present variability and stochasticity. A planning and control system, including the IT, need to support this in an efficient way. In the second case study, we studied the actual use and the possibilities of a planning and control model which is based on performance measurement and second order feedback.

Case 2: Optimizing Planning and Control in Ambulant Mental Healthcare Centers

Due to increasing competition in mental healthcare, planning and control based on performances is needed. Therefore routine control is necessary and processes have to fulfill the characteristics as described by Hofstede (1981). But as shown in the evaluation of the planning tool, also flexibility in planning is needed.

The case study of four ambulant mental healthcare centers presents information about characteristics of their processes and the planning and control models as used. These results are used for recommendations that can guide mental healthcare organizations in their planning and control and the use of IT. These are presented in the conclusion.

In this case study, we first described the present processes by using process mapping techniques. Next, we assessed these processes on the uncertainty of demand, supply, and the service process itself, complexity of coordination, and staff inflexibility. These three factors determine the efficiency and adaptation possibilities of a process (Van Merode, Molema, & Goldschmidt, 2004). These factors incorporate the conditions of Hofstede's (1981) model.

The results of this study showed that most of the processes were not planned and controlled in a consistence way. Three of the four ambulant mental healthcare centers hardly used performance indicators to monitor the processes. The uncertainty and complexity were high and instruments, like protocols or IT, to decrease the unnecessary uncertainty and complexity were hardly used. One center did use care programs. However, the opportunities for planning and control of these care programs were not used to their full extent. Besides, a planning and control system based on feedback did not exist. This center had the most extended IT software. Nevertheless, this software was not used to monitor the results of the processes with performance indicators. Therefore, planning and control based on feedback was not performed. IT use for planning and control was very minimal in all four centers.

FUTURE TRENDS

In mental healthcare organizations, we mainly see two developments. The first is that many mental healthcare organizations continue in their old ways in organizing their care, that is, that no standards or IT are used. However, a second development is that, because of growing attention for more efficiency in mental healthcare, more and more mental healthcare organizations standardize their processes by, for example, the introduction of care programs.

Standardization can be very fruitful in decreasing unnecessary uncertainty in care processes. However, mental healthcare organizations often do not change their organization structure simultaneously with the introduction of care programs. Additionally, IT with planning and control functionalities is underused. The use of IT for integrated planning and control will probably increase. But, what we observe in somatic healthcare is that (standard) ERP packages are implemented while they do not suit the situation. These ERP systems are often implemented without a change in organization structure. By the lack of the fit between the organization, processes, and ERP systems, this can result in many problems. New, adaptive, software is there but is not successful.

As we claimed in the introduction, first and second order control should be supported by IT. Therefore IT has to be adaptive and support short term planning or reactive decision making. However, mental healthcare organizations are not yet interested in this kind of technology. In the future, mental healthcare organizations consider IT more to profit from care programming and, as a result, work more efficient and effective.

CONCLUSION

Mental healthcare organizations are on their way to more efficiency in their processes; yet IT is still underused for planning and control.

As shown in the first case study, processes and IT must fit. In this center, the organization thought that planning and control was possible with routine control supported with information technology. The care programs met the conditions for first order control and second order control. However, in the pilot it did not work out as intended.

In the second study, we observe that almost no use is made of possibilities of standardization and feedback for control purposes. Moreover, IT is hardly used for planning and control purposes. As a result, the ambulant mental healthcare centers miss the possibility to direct the outcome of processes to a certain target, and efficiency is not optimal. As a result, the centers miss the opportunities to be competing on the (regulated) market.

The results emphasize the need to carefully consider process characteristics before introducing a planning and control system. Careful consideration is needed to avoid type I and type II errors. Type I errors occur when opportunities for routine planning and control (with standardization and IT) are not used by management. However, some processes are not deterministic and cannot be controlled with routine models. When they are controlled with routine models anyway, type II errors occur. To avoid either type I or type II errors, a fit between standardization and flexibility has to been found. Hofstede (1981) states that type I errors often occur in not-for-profit organizations because the concern for cost and effectiveness is often missing. However, mental healthcare is subject of social and political developments resulting in the need to be more aware of efficiency and effectiveness. Therefore we assume that type II errors may occur in future more often.

The results also show the necessity of balancing between process standardization and the flexibility of the working practice. Routine models can be applied for processes in mental healthcare in certain circumstances. Nevertheless, routine models need to use second order control because not all activities can be planned in advance due to variability and stochasticity. This balance between standardization and flexibility has to be considered carefully before fully implementing care programs and a central planning and control system integrated in IT. To be able to balance between flexibility and efficiency by means of care programs, the organization structure also has to be changed and IT has to be adaptive.

We recommend the following to develop more efficient processes in mental healthcare organizations. First, performance indicators should be developed to be able to compete in the (regulated) market. Simultaneously, time horizons should be distinguished in which planning and control on several different levels (e.g., establishing different care programs by board 3 years, planning of professional 6 weeks) can be defined. Next, processes need to be distinguished on uncertainty and complexity of the process. The difference in characteristics of a process (more or less routine) decides on the possibility of standardizing processes. After that, the processes that satisfy the possibilities for routine control need to be standardized and a BOR should be described. For the actual control on performances, a system based on first order control and second order control must be developed and adaptive IT that supports short term planning or is reactive is needed to support the planning and control.

The use of these recommendations helps in finding a balance between standardization, use of IT, and flexibility. In addition, IT interacts with the social system and the working practice and, therefore, it is necessary to tailor both. However, it is a process of trial and error and therefore requires adaptive IT.

KEY TERMS

Adaptive Information Technology: Information Technology that can be adapted to changing circumstances in finding a balance between processes and IT.

Care Program: A care program is a framework where organizations, professionals, and patients should comply with and is used for patient-centered organization of a well described target group. It integrates the activities between different disciplines, professionals, and departments (Berg, Schellekens et al., 2005).

Control: The process that assures that the planned results are obtained.

Enterprise Resource Planning System: Enterprise Resource Planning systems attempt to integrate all corporate information in one central database, and information can be retrieved from many different organizational positions and in principle they allow any organizational object to be made visible (Dechow & Mouritsen, 2005).

Feedback: Information about the output is fed back to the input.

Planning: Determination of what should be done.

Reactive Decision Making: Decision making based on reacting to unexpected situations due to variability and stochasticity.

Short Term Planning: Planning on short terms with data about monthly, daily, and hourly demand and meaning full statistical distributions to be able to deal with stochasticity and variability.

Populomics, an Emerging E-Health Response to Comtemporary Healthcare Realities

Michael Christopher Gibbons
Johns Hopkins Urban Health Institute, USA

INTRODUCTION

There is increasing interest in the role of technology in health care and public health. Several researchers have predicted a coming revolution in health care similar to the transformations that occurred in the finance and retail industries upon the widespread adoption of computer technology (Abrams, 2006; Crane & Raymond, 2003; Gibbons, 2005, 2006). In biomedical research, computer technology has catalyzed the emergence of whole new disciplines such as regulomics, proteomics, phenomics, and pharmacogenetics (Gibbons, 2005). Telemedicine, e-prescribing, Electronic Medical Records, and computerized physician order entry systems are emerging as important tools to improve the quality of health care even though the broad health care transformation historically envisioned has not yet occurred (Crane & Raymond, 2003).

Several important factors, however, are suggesting a need for significant changes in traditional health care and medical research systems. These include (1) the growing proportion of people living over the age of 65; (2) the increasing prevalence of chronic diseases; (3) increasing global urbanization; and (4) the increasing recognition of disparities (inequalities) in health and health care (IOM Committee on Quality of Healthcare in America, 2001). In the United States over the last century, many acute and communicable diseases have either vanished or become much less prevalent. Over the same time period, there has been a rise in the prevalence of chronic conditions and diseases. To date, approximately 60% of UK citizens and 50% of US citizens report having at least one chronic disease (IOM Committee on Quality of Healthcare in America, 2001; National Health Service, 2004). Cardiovascular disease is now the number one cause of mortality in developed nations. Although chronic diseases usually result in symptoms and/or death in the later decades of life, the origins of these diseases can often be traced to the first decades of life. To complicate matters further, the elderly often have more than one chronic condition at the same time.

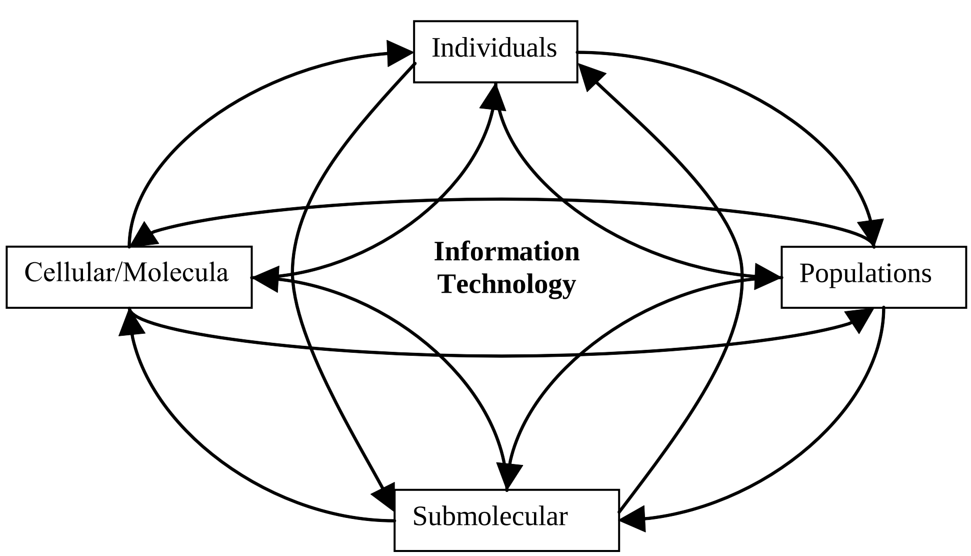
The rapid increase in urbanization that is occurring worldwide is increasingly causing many people living in the inner cities to experience an urban health penalty. This is due to the concentration of economic decline, job loss, and major health problems often found in urban centers (Andrulis, 1997). In addition, significant racial and ethnic disparities (inequalities) are often found in the urban environment. These disparities appear resistant to interventions and policies designed to reduce or eliminate them (Acheson D, 1998; Macintyre, 1997; Smedley, Stith & Nelson, 2003) Increasing evidence suggests that disparities arise as a result of complex interactions among socioeconomic factors; behavior, biologic, and environmental factors; and disease that are related to race and ethnicity (Smedley et al., 2003; Haynes & Smedley, 1999; Faber & Krieg, 2002; Amick, Levine, Tarlov & Walsh, 1995; Evans, Barer & Marmor, 1994). As such, multifaceted approaches that extend beyond the current medical model are needed to improve health status (Andrulis, 1997), particularly in the urban environment.

In general, the major health care systems of the world function as acute disease treatment systems. Chronic diseases, however, occur and progress over long periods of time, often without obvious personal health impact. They then slowly lead to progressive declines in health, punctuated by intermittent episodes of acute illness. Effectively managing the acute episodes of a chronic disease often does little to the natural progression of the disease or the prevalence of the disease in the population. Effectively preventing illness and promoting health among patients with chronic diseases will undoubtedly require a technological infrastructure that can enable the real-time monitoring of physiologic, behavioral, and environmental data simultaneously among large numbers of patients. All this will need to occur prior to the need for hospitalization and also during sometimes lengthy periods of time between acute episodes of illness.

To improve health in the community setting, many kinds of novel health technologies will likely be required. For instance, new spatial analytic, epidemiologic, and computational methodologic innovations will be required to support clinical decision-making by turning vast amounts of information and data into usable knowledge. Computer technology will be essential to the conduct of complex, large-scale clinical trials to objectively implement interventions and assess outcomes. To be successful, this technology infrastructure must also facilitate the transfer of culturally and linguistically appropriate health information to patients. The ability to tailor information to individual patient needs will be critical to adequately supporting patient health choices and self-care. Finally, computer-based innovations such as nanotechnology, distributed processing, RFID, and advanced sensor technology, will facilitate the ability to detect changes in the physical status of things, enable intelligent interactions between devices, and enable devices to make independent decisions based on collected data, devoid of prejudice, bias, or other "human error." "Smart devices" in health care include smart phones that can automatically communicate patient data to physicians, "intelligent" homes that can detect if a senior citizen has fallen and then notify Emergency Medical Services (EMS), "smart" vehicles that can minimize motor vehicle accident related trauma, and wearable "smart" clothing that can monitor and wirelessly transmit environmental and physiologic data to providers. Scientists are even attempting to develop intelligent ovens and online refrigerators that can be controlled through phones or the Internet (International Telecommunications Union, 2005). Such technology applications in health care will enable "smarter," behaviorally oriented, patient-centered, and therefore potentially more effective prevention, public health, and clinical treatment strategies.

Achieving this vision, however, will require a paradigm shift in the conceptualization and provision of health care services and the conduct of medical research. It will require less dependence on reductionism while increasingly relying on a more comprehensive multifaceted approach to scientific inquiry. The term Populomics has been used to articulate a new integrated, transdisciplinary approach to health research and practice (Abrams, 2006; Gibbons, 2005). The term is derived from the synthesis of the disciplines that comprise the field; namely, the population sciences, medicine, and informatics. More specifically, Populomics is defined as an emerging discipline focused on population level, transdisciplinary, integrative disease/risk characterization, interdiction and mitigation that relies heavily on innovations in computer and information technologies. Populomics seeks to characterize the interplay of pathways and mechanisms that work across levels of existence to impact the health of individuals and populations. Populomics focuses on the interrelatedness of "environments" and their complex codependence on each other, which in the aggregate either protect health or enable disease. On the other hand, a populomics orientation will also facilitate the development of transdisciplinary strategies and inter-

Figure 1. Populomics "web of disease/health causation"



ventions to develop socioenvironmental and cultural context-sensitive treatments and regulatory policies that will influence the "web of causation" and ultimately improve health outcomes (see Figure 1.0).

In summary, future health strategies and interventions, whether medical, behavioral, or public health, will increasingly need to rely on current and emerging Information and Computer Technologies (ICT) not only to understand complex health problems but also to help design, implement, and evaluate the solutions and health outcomes. ICTs can be seen as enablers of the discipline of populomics in the same way they catalyzed the development of other scientific and medical disciplines (e.g., regulomics, phenomics, etc.). In so doing, the promise of preventing disease and illness among individuals, promoting health among populations, and eliminating health disparities (health inequalities) may one day become a reality.

Prevalence of Bullwhip Effect in Hospitals

Kannan Sethuraman
Melbourne Business School, Australia

Devanath Tirupati
Indian Institute of Management, India

INTRODUCTION

Growing concern about health care costs in developed countries in the past two decades has spawned extensive research on the industry and, in particular, hospital management. The literature on the subject is extensive and covers a wide range of themes that include application of operational research-based tools, redesign/re-engineering of delivery systems and clinical procedures, and so forth. However, in our case studies, we found that hospitals in Australia are in early stages of adoption of emerging paradigms in operations management (e.g., coordination, lean principles) that have significant potential for enhanced performance. The purpose of this chapter is to describe one of the consequences of poor coordination—*bullwhip effect* in hospitals—and its impact on performance and to discuss initiatives to mitigate and manage it.

In their widely cited papers, Lee, Padmanabhan, and Whang (1997a, 1997b) define *bullwhip effect* as "the phenomenon where orders to the supplier tend to have larger variance than sales to the buyer (i.e., demand distortion), and the distortion propagates upstream in an amplified form (i.e., variance amplification)." The bullwhip phenomenon has been observed by many firms across a number of diverse industries.

Lee, et al. (1997b) state the impact of increased volatility as, "Distorted information from one end of the supply chain to the other can lead to excessive inventory investment, poor customer service, lost revenues, ineffective transportation, and missed production schedules." Although there is a growing body of research on managing the bullwhip effect in manufacturing-based supply chains (Baganha & Cohen, 1998; Chen, Drezner, Ryan & Simchi-Levi, 2000; Chen, Ryan & Simchi-Levi, 1997; Metter, 1997), little research exists on its presence in service chains, and we are unaware of any reported research on this subject. In this chapter, we present several examples of distorted information in hospitals resulting in variability amplification and causing inefficiencies similar to the bullwhip effect. We highlight the underlying causes for this phenomenon and propose actions that can mitigate the detrimental impact of this distortion.

BACKGROUND

The analysis of the bullwhip effect was originally initiated by Forrester (1958, 1961), who was also the first to simulate the demand amplification characteristic through the "beer distribution game." Taking a behavioral perspective, Sterman (1989) and Senge and Sterman (1992) attribute the amplified order variability observed in the game to players' systematic irrational behaviors or misconceptions about inventory and demand information and lack of "systems thinking" by management.

Unlike Sterman (1989), Lee, Padmanabhan, and Whang (1997a) demonstrated that even rational decision-making by individuals can result in the bullwhip effect. They identified four main factors as contributors and offered prescriptions based on four complementary themes: (a) data transparency and information sharing; (b) coordination and synchronization (e.g., demand and supply planning); (c) efficiencies at the operational level; and (d) inventory management for the entire supply chain.

A conspicuous characteristic of the literature on bullwhip effect is its focus on manufactured goods and the role of inventory. Comprehensive approaches for managing supply chain do involve service elements (e.g., interface between retailers and customers). However, consistent with its focus on manufactured products, the emphasis in bullwhip effect literature is on inventory-related service measures such as product availability, fill rate, and so forth.

Relatively very little or no research has been reported to highlight the existence of this phenomenon in service context. There are at least three reasons why research in this area has been relatively sparse. First, simultaneity in production and consumption of services often precludes use of inventory strategies, and thus, many of the results of bullwhip effect literature do not extend readily to services. Second, higher levels of demand variability in services due to seasonality and uncertainty are well recognized, and there exists extensive literature on demand and supply strategies for managing this variability. This literature, which predates emergence of supply chain management, includes research related to price and related incentives for demand and capacity adjustments for supply management. In contrast, service chains typically do not have inventory but only have backlogs that are managed indirectly through service capacity adjustments. Further, in many services, production and consumption happen simultaneously; the service chain comprises only one level, and the issue of amplitude propagation up the chain becomes irrelevant. However, it may be noted that materials and supplies required for the provision of services may exhibit variability amplification, and related results may have direct application.

The aforementioned suggests that the bullwhip effect phenomenon may not be as pronounced and relevant for managing services. However, in our study of institutions in the health care industry in Australia, we have observed several examples of variability amplification similar to the bullwhip effect. The purpose of this chapter is to highlight the existence of bullwhip effect in hospital operations, identify its causes, and prescribe ways to mitigate its detrimental impact.

RESEARCH METHODS

A case-study-based approach was employed to conduct the research. Our findings are based on in-depth case studies of three hospitals—two public and one private not-for-profit. Data were gathered through interviews, observations, and archival sources. Interviews with doctors, nurses, administrators, and other hospital staff were conducted in person. We used an informal, minimally structured, nondirective interview approach to minimize the influence of our assumptions.

Saint Mary's Hospital's Service Value Chain for Elective Surgeries[2]

In this section, we describe briefly the service value chain for elective surgeries at St. Mary's Hospital (SM), one of the hospitals in our case studies, to provide the necessary background for our presentation. It will become clear that other services such as emergencies and outpatients will only make the system more complex and accentuate the bullwhip effect.

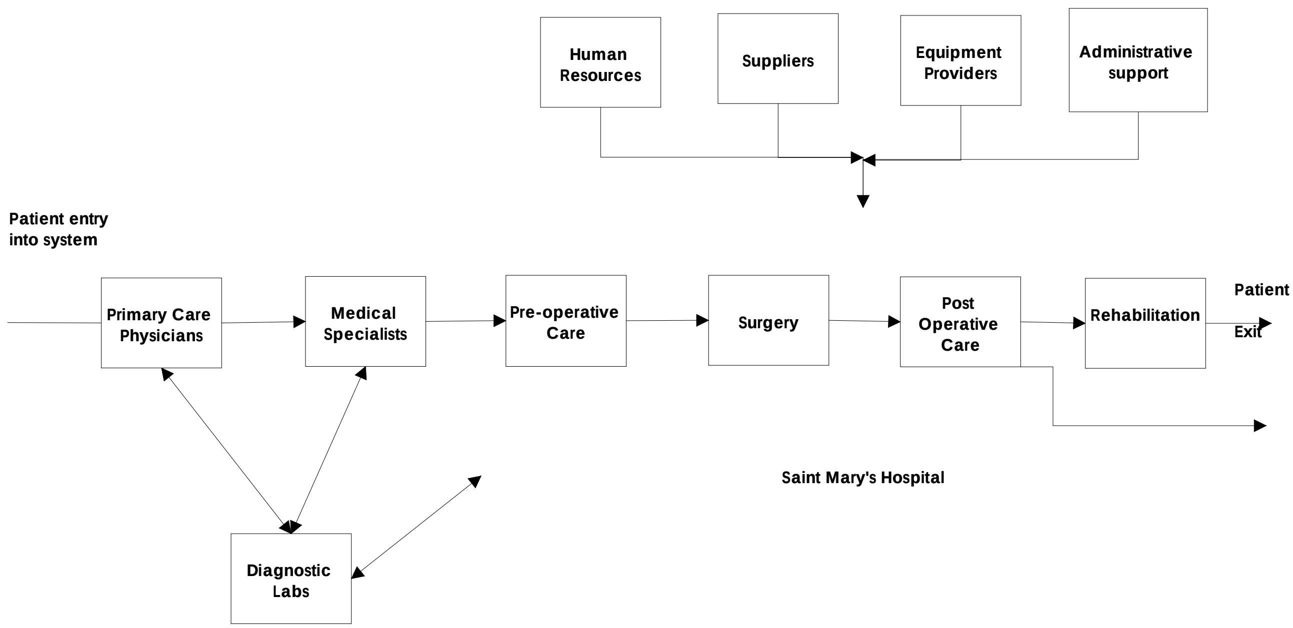
SM, a private not-for-profit hospital, essentially provides facilities comprising of operating rooms (ORs) with state-of-the-art equipment, wards for in-patients, rehabilitation unit for recovery of acute cases beyond normal postoperative care, and related ancillary services. The wards are organized by specialty and considered to be departments, as is the OR management. Hospital administration is decentralized with autonomy for the departments at the operational level. Thus, departments are responsible for nurse staffing and allocation of other resources. Regulatory requirements specifying threshold levels for nurse-patient ratios impose constraints in both ward and OR schedules.

SM does not employ any specialists/surgeons but has only a small group of physicians for overall supervision of the wards. Instead, it has arrangements with a large group of consultant surgeons who hold privileges to avail of the hospital facilities for treatment of their patients. SM derives its revenues from the fees charged for the use of its facilities. In most cases, these are borne by patients' medical insurance providers.

Figure 1 provides a schematic of SM's service value chain. The process begins with a consultation with the patient's primary care physician. If necessary, the patient will visit a specialist for further assessment. This stage may involve several visits to the specialist and diagnostic tests. The patient is added to the doctor's surgery list, if needed. Typically, specialist doctors have privileges at several hospitals in the area, and the choice of hospital is determined by several factors that include cost, patient preference, complexity, wait, facilities, and other services provided by the hospital. Following the choice of hospital, the patient is scheduled for surgery by being assigned a slot in one of the doctor's theater sessions at the hospital.

Surgery represents the third stage of the value chain, and the hospital is responsible for providing required support services, including pre- and postoperative care. Insufficient capacity and/or poor management

Figure 1. Service value chain for surgery patients at St. Mary Hospital



can result in delays for the patient and underutilization of resources. Postoperative care in the hospital and in subsequent rehabilitation, if necessary, represent the fourth and fifth stages before the patient is discharged and exits the hospital system.

Planning and Scheduling at Saint Mary's Hospital

Planning and scheduling at SM is similar to that in other hospitals in Australia with annual theater plans forming the basis for the hospital's activities. The plan involves assignment of theater sessions to surgeons and essentially defines the demand for the hospital's services. A half-day slot is considered the basic unit for this purpose, and thus, each theater has a capacity of 10 sessions per week, based on a five-day week. Surgeons expect hospitals to provide complete flexibility in organizing their sessions, and hence, assignment of a session commits the hospital for the operation and pre- and postoperative care, and thus determines the workload.

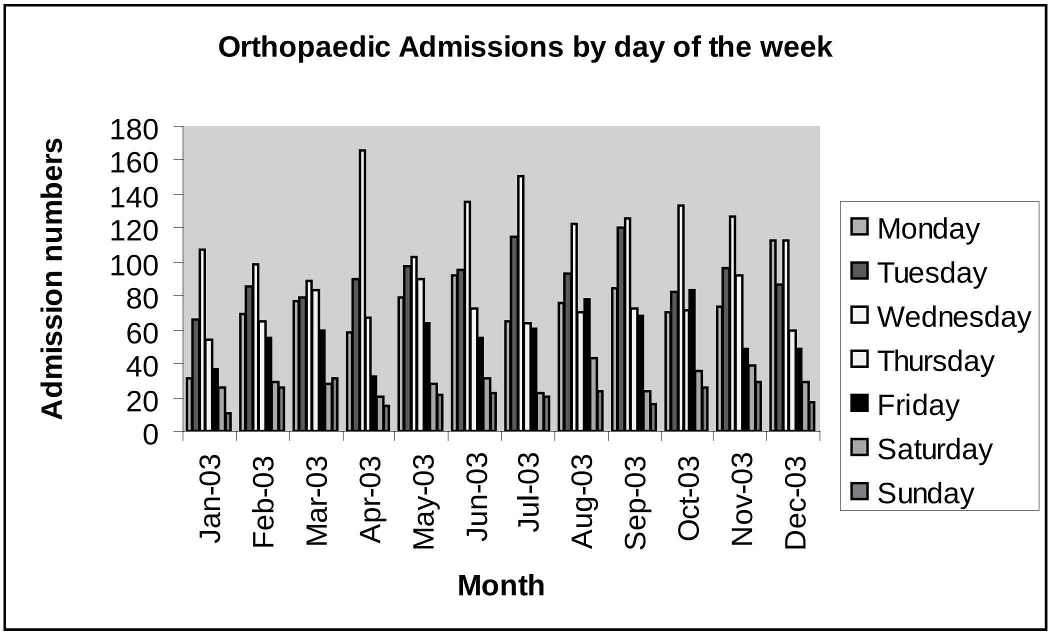
In practice, the annual plan is developed three months in advance, in consultation with the surgeons. The plan can be characterized as cyclic with effort to evenly spread out sessions assigned to individual surgeons. Further, to the extent feasible, weekly schedules are adopted. For example, a surgeon with 50 sessions would be assigned one session per week, usually in the same time slot every week. One feature of session plan at SM that merits mention relates to the practice of concentration of sessions assigned to particular specialty. As a result, sessions corresponding to various specialties peak on different days of the week. Such practices are quite widespread at other hospitals in Australia.

The annual session plan forms the basis for nurse and technician staffing in the hospital. The labor cost of nurses and technicians is perhaps the most significant controllable operating cost at SM and directly impacts the hospital's financial viability. Staffing plan for nurses in the OR theaters is prepared for each calendar month, two weeks in advance, to conform to regulatory requirements. The initial plan is developed on the basis of the session plan. The nurse schedule is revised and frozen only a day in advance, at which time the requirements are assessed based on surgery lists provided to the OR department. At this stage, due to the limited availability of permanent, full-time staff, the nurse scheduler relies on part-time agency nurses to meet the gap in requirements. Nurse staffing in wards exhibit similar trends, and schedules are frozen only a day in advance.

Observations and Comments

Our interviews indicated that in most specialties, there is no pattern in the demand for elective surgeries. This is

Figure 2.



in contrast to illnesses such as flu and hay fever, which exhibit pronounced seasonality. Thus, daily demand for elective surgeries (i.e., customer demand) can be assumed to be uniform displaying no seasonality (day of the week, month, etc.) and low variability. Figure 2 describes the pattern of admissions for orthopedic surgeries at SM by day of the week. It is based on data for one year and excludes the holiday period (mid-December to mid-January). It shows mild seasonality by month (admissions range from a low of 332 to a peak of 512 with a mean of 470) and high variability by day of the week. Excluding the weekends, the average daily admissions range from a low of 58 on Fridays to a peak of 123 on Wednesdays. The pattern is similar for other specialties, except for the location of the peak. Taken in conjunction with our premise that end-customer demand is fairly uniform, this strongly suggests the presence of a phenomenon similar to the bullwhip effect. In the remainder of this section, we discuss briefly its impact on performance—operational and financial.

First, increased variability in surgeries performed directly impacts the demand for postoperative services in the wards. Consequently, on peak days, shortage of beds makes the wards the bottleneck, thereby restricting the number of surgeries, reducing theater utilization and throughput.

Second, the demand for nursing in theaters and wards is affected adversely by higher variability. With SM's flexible strategy of meeting the nursing demand with a mix of full-time, part-time, and agency staff, this results in larger use of casual and agency staff. Higher wage rates for these categories increases operating costs, leading to lower profits.

Third, SM's reliance on flexible staff affects the hospital's operating performance in a more subtle but significant manner. Higher levels of temporary staff result in frequent changes in the composition of support staff assigned to each theater, thereby inhibiting development of cohesive support teams. This factor was mentioned repeatedly by consultant surgeons in our interviews as the primary cause of inefficiencies in the theater, requiring more operating time and reducing theater throughput. Furthermore, this factor influences the doctor's choice of hospital, prompting use of SM for more complex cases requiring its facilities. For simpler cases, the doctors tend to choose more efficient hospitals. As the more complex cases typically involve higher costs, this behavior has an adverse effect on SM's finances. Under the Australian system, the fees payable (to the hospital and doctor) are based on predetermined rates for each class and do not depend on the case complexity within each class.

To summarize, increased variability in the demand for elective surgeries at St. Mary's Hospital results in lower efficiencies, higher operating costs, and lower revenues, leading to lower profits.

CAUSES AND STRATEGIES TO COPE WITH THE BULLWHIP EFFECT

Next, we describe the causes of the bullwhip effect in hospitals and suggest appropriate mechanisms to cope with them.

Demand Forecasting and Updating

In services such as hospitals, where patient presence is an integral part of the service delivery process, using inventory to buffer the demand-supply gap is not possible, and service targets are met through capacity. Thus, in contrast to the manufacturing sector where forecasts are used to plan for inventories, their role in hospitals is to help plan for capacity. With facilities fixed in the short term, capacity is managed through provision of human resources.

At SM, nurse staffing in wards is based on targeted occupancy levels rather than on any forecast. Similarly, nurse staffing in OR theaters is based on annual session plan. Currently, these are developed two weeks in advance to conform to regulatory requirements. The actual daily schedules are determined one or two days in advance based on surgery lists for the ORs and patient status in the wards. Typically, these differ substantially from the plans, and the gaps are met primarily through temporary part-time and agency staff. Currently, 25% of the hospital's nursing requirements is met by agency staff with consequent increase in operating costs.

Batching

Some of the practices at SM are motivated by batching considerations and happen at two levels. First, consultants prefer half-day OR sessions (either morning or afternoon), leading to batches that correspond to fixed time slots. The batch size is variable, depending on the specialty and complexity of the case mix. Thus, consultants' preferences for half-day sessions may be interpreted as batching resulting from implicit setup costs of consultants associated with their visit to the hospital. Second, SM's session plans with concentration by specialty can be interpreted as batching. This practice may have had some justification in the past when volumes were low and theater management was simplified with economies gained in procurement/hiring of equipment from outside. However, this is unnecessary in the current environment and seems to continue due to organizational inertia, resulting in ward beds becoming a bottleneck and leading to lower throughput and related adverse consequences.

Lack of Information Sharing and Coordination

In this section, we present several examples of lack of coordination and information sharing both in planning and operations resulting in the bullwhip effect.

Operations

At SM, the admissions department is responsible for working with consultants' offices and obtaining the necessary details to ensure that adequate resources are available for patient care. The business office is responsible for completing administrative formalities and financial checks prior to the commencement of surgery. Appointments for elective surgeries are made several weeks in advance, and the doctor's office is expected to provide the surgery list to the hospital several days in advance. However, this list is considered tentative (changes account for less than 10%) and not shared with other departments until it is frozen, usually one or two days in advance. This delay in sharing information results in several adverse consequences. First, instead of scheduling patient arrivals in a staggered manner based on surgery sequence, all patients are given a common reporting time and processed in the order in which they arrive. Second, because of the delay in getting the information, the business office is not in a position to complete the checks in advance. Together, these factors delay patient preparation and start of surgery. Third, the lack of information increases the need for flexibility in providing the required nursing and technician resources, thereby increasing costs and leading to other inefficiencies in the theater operations.

Planning

We also observed lack of coordination at the planning stage. First, daily activity schedule and shift times in various departments of the hospital are not synchronized, causing avoidable delays and inefficiencies. For example, the change of shift for nurses in the wards coincides with the surgery times in the theater. Nurses, instead of preparing patients for surgery, are busy with shift change activities and causing patient to wait and delaying start of surgeries. Delayed start induces late arrival among consultants and encourages them to schedule shorter lists (relative to theater capacity) leading to lower throughput.

Second, a coordinated approach for session planning that explicitly recognizes the impact of theater assignments on wards and takes into account bed capacity offers significant potential for increasing the theater output and improving capacity utilization. An integrated approach for session planning is likely to result in a more uniform distribution of theater sessions assigned to one specialty, and implementation of such plans would require buy-in from the consultants. Such an approach can explicitly factor cost and revenue contributions of individual consultants in session planning and help in developing and maintaining a consultant pool consistent with the hospital's strategic objectives, both business and clinical.

Methods for Coping with the Bullwhip Effect

In this section, we outline strategies for mitigating the bullwhip effect (see Table 1 for a summary):

1. **Reducing uncertainty.** If patient information is centrally managed and all parties are provided with the latest data in a timely manner, it will help eliminate duplication of effort and ensure data consistency across all groups. Dynamic updating of this information will greatly help reduce uncertainty.
2. **Variability reduction.** Localized practices that cause increased variability should be eliminated through improved coordination. Use of good forecasting methods will also assist the reduction of variability.
3. **Reducing batching.** Avoiding concentration of theater session by specialty will reduce the batch size. Batching effect can also be reduced by considering shorter time slots for surgeries (e.g., two hours instead of four).
4. **Developing strategic partnerships.** Developing strategic partnerships with key stakeholders is critical. For example, alliances with medical specialists can change the way in which information is shared and help foster coordination.
5. **Realignment of incentives.** The evaluation and reward systems should be modified to stress cooperation across departments to facilitate integrated planning based on system-level objectives.

Table 1. Causes, contributing factors and countermeasures for the bullwhip effect in health care sector

Causes	Contributing Factors	Countermeasures
1. Demand Forecasting and updating	• Lack of willingness to forecast and share based on partial information • Lack of effective use of forecasts in planning and updating of plans	• Have a common database that will minimize inconsistencies across stages • Continual updating of data
2. Batching	• High transportation costs • High setup cost for surgeon's visit to the hospital • Economies in the management of operating theaters	• Modify the measurement and evaluation systems to facilitate the use of systemwide objectives • Reduce the setup cost or transaction cost using lean practices
3. Lack of information sharing and coordination	• Poor incentives for sharing information • No culture of sharing information • Inconsistent information technology platforms across links in the service value chain • Lack of willingness to share until complete confirmation of information	• Alignment of incentives to encourage data sharing • Developing strategic partnership with different links in the service value chain

SUMMARY AND FUTURE RESEARCH

In this chapter, we have identified and described a phenomenon in hospitals that is similar to the bullwhip effect observed in the manufacturing sector. The resulting demand distortion and variability amplification likewise causes performance degradation. However, the similarity with the manufacturing sector does not extend much further since the causes and the impact are somewhat different. For example, in hospitals, it results in lower levels of throughput, higher operating costs, and longer patient waits. While we provide suggestions for improvement based on the case studies, more research is needed to further investigate the root causes. Further, there is opportunity to develop planning tools and systems that recognize, counter, and minimize the impact of the bullwhip effect. Based on our case studies, we conjecture that a similar phenomenon may be present in other segments of the health care sector. Further research in the area can provide more insights into the phenomenon and has the potential for order-of-magnitude performance improvements similar to those realized during the past two decades in the manufactured goods industries.

KEY TERMS

Batch Size/Batching: Refers to the practice of processing several units together to take advantage of economies of scale. In the context of hospitals, the surgeons' preferences for long theater sessions with several surgeries scheduled in one session is an example of batching that is motivated by the time and effort involved in the surgeons' visits to the hospital.

Bottleneck: The limiting resource(s) that constrains the performance of a system. Typically, bottleneck(s) refers to the resource or the constraint that limits the output of the system.

Bullwhip Effect: Represents the tendency for demand variability to increase, often considerably, as you move up the supply chain (from retailer, to distributor, to factory, to raw material suppliers, etc.).

Coordination: Refers to managing the various entities in the value (supply) chain to optimize the performance of the value chain. While synchronization focuses on the individual processes of the system, coordination deals with managing the various entities of the chain. In the hospital service chain context, the surgeons, hospital departments, patients, pharmacists, and so forth are examples of entities whose activities/processes need to be coordinated to improve the chain performance.

Service Value Chain: Represents the chain of activities that generates value to the customer. In this chapter, the hospital service value chain captures the journey that a patient travels through the hospital in achieving the required care.

Synchronous Operations: Refer to management of the entire process together in harmony to achieve the goals of the system. Synchronization involves coordination of all resources, subsystems, and processes so they are in harmony in order to achieve the total system performance, not on local performance measures.

INTRODUCTION

The challenges faced by U.S. health care system are vividly explained in the U.S. Government's health information technology plan,

The U.S. health care system faces major challenges. Health care spending and health insurance premiums continue to rise at rates much higher than the rate of inflation. Despite spending over $1.6 trillion on health care, there are still serious concerns about preventable errors, uneven health care quality, and poor communication among doctors, hospitals, and many other health care providers involved in the care of any one person. The Institute of Medicine estimates that between 44,000 and 98,000 Americans die each year from medical errors. Many more die or have permanent disability because of inappropriate treatments, mistreatments, or missed treatments in ambulatory settings. It has been found that as much as $300 billion is spent each year on health care that does not improve patient outcomes – treatment that is unnecessary, inappropriate, inefficient, or ineffective. All these problems – high costs, uncertain value, medical errors, variable quality, administrative inefficiencies, and poor coordination – are closely connected to inadequate use of health care information technology. (U.S. Federal Government Health Information Technology Plan, 2004).

These challenges have resulted in formidable and compelling pressures on the U.S. Federal Government, professional bodies, and accreditation authorities to undertake measures to bring about significant improvements in the quality of health care in both inpatient and outpatients settings. Quality is defined by the Institute of Medicine as having three overlapping domains: safety of patients and practitioners, practice consistent with current domain knowledge, and patient centered care (Kohn, Corrigan, & Donaldson, 2000). In the current environment, one of the important measures undertaken to improve quality of health care is adoption and use of computers and information technology such as electronic medical records system (EMR) by health care providers and medical institutions.

Introduction of EMR has received considerable attention because of its potential effectiveness in (a) implementation of decision support, (b) reducing practice expenses, (c) increasing revenues by improving office efficiency, and (d) making health records more up to date, accessible, legible, and modifiable (Gill, Ewen, & Nsereko, 2001; Hippisley-Cox, Pringle, Carter, Wynn, Hammersley, & Coupland, 2003; Singh, Servoss, Kalsman, Fox, & Singh, 2004).

Even though a few studies in the literature have tried to examine the usefulness of EMR at organizational level (Gill et al., 2001; Hippisley-Cox et al., 2003; Miller & Sim, 2004; Singh et al., 2004), very little research has been done on examining the various components of EMR systems and the process level benefits of these systems. As Barua, Kriebel, and Makhopadyay (1995) point out, by attempting to relate IT implementation directly to output variables at the organizational level, the intermediate processes through which IT impacts are felt are totally ignored. When information technologies such as EMR systems are deployed effectively, they interact with intermediate organizational processes, and deliver value by building unique process level benefits, which finally result in organizational level outcomes. Therefore, there is a need for more granular studies that explicate the underlying linking mechanism (process) between IT implementation and organizational level impacts (Radhakrishnan, Zu, & Grover, 2007).

In this article, we pursue this line of thought and examine the various components of EMR and the potential process level benefits of EMR systems by presenting case summaries. This article contributes to the literature and practice in two ways: First, it provides insights into various modules of EMR system and how they interact with each other to bring out value to users. Second, we present six case summaries (based on qualitative case analysis and content analysis of Web sites) to illustrate the potential process level benefits of EMR systems. The remainder of this article is organized as follows. The next section provides an overview of EMR and its components. In the following section, we present six case summaries to illustrate the potential process level benefits of EMR systems.

OVERVIEW OF EMR

What is EMR?

Electronic medical records system (EMR) is defined as an interorganizational information system that captures the essential components of a patient's medical encounter with the medical provider, including storage and retrieval of subjective, objective patient information, and assessment and plans for patient care (Lenhart, Honess, Covington, & Johnson, 2000). EMR systems facilitate physicians and other health care professionals to:

- Monitor the health status of their patients with electronic medical charts.
- Support health care decisions with evidence-based guidelines.
- Expedite referrals to specialists and other health care providers.
- Computerize ordering of prescription drugs, laboratory tests, and radiology results.
- Store and retrieve patients' medical records from different locations.

Why EMR?

While conducting a field study involving hospitals in countries such as UK and USA, Lederman (2005) found that there are several problems faced by health care professionals while handling patients' medical records. These problems are listed below:

First, in many hospitals, only paper-based records are maintained. Management of paper-based records becomes a significant problem due to the possibilities of losing or misplacing records.

Second, data inconsistency and data integrity are other problems related to paper-based records. Patient files can be changed with no assurance that changes made would be incorporated into a central repository or vice versa. This could lead to a possibility of different, conflicting records being held for the same patient. This increases the probability of incorrect information being accessed.

Third, nonintegrated databases across hospitals pose a significant problem, providing a major impediment to collection, access, and ability to view patient records. The medical staff in each hospital manually enters patients' records into the system. This may cause potential problems like inefficient use of time, loss of productivity, and data entry errors.

EMR can help in overcoming these problems (Bria, 2006; Doyle, 2006; Simon & Simon, 2006). In a survey of 703 practicing family physicians in the U.S., Karsh, Beasley, and Hagenauer (2004) found that the physicians preferred electronic medical records to paper based records as they were up to date, modifiable to meet individual needs, accessible when needed that resulted in better record quality. These studies highlight the value of EMR systems.

Components of EMR

An EMR system has several different modules. Organizations can implement specific modules or all the modules depending upon their needs.

Patient Registration Module (PRM)

This module helps with patient's registration. It helps track and maintain relevant details on the patient (such as name, date of birth, address, contact number, financial class), health insurance plans (insurance company, type of insurance policy, and level of copay), and historical as well as scheduled appointments.

Appointment Scheduling Module (ASM)

This module helps with scheduling appointments. Appointment reservations are scheduled for specialists, general practitioners, and for other resources such as medical labs, emergency rooms, operation theaters, and so forth. It provides flexible appointment schedules where one can request convenient time slots. Patients and support staff can search and view availability of resources within various departments, specialties, and locations.

Medical Billing and Receivables Module (MBRM)

This module helps with "super-bill" (i.e., comprehensive bill) creation and collection of receivables. This module helps track charges associated with diagnosis, medical check-ups, medical procedures, surgical procedures, lab tests, and medical prescriptions. Then super-bills are created by bundling all the charges for a variety of services provided by different departments. The co-pay amounts from patients are recorded. This module retrieves patients' insurance details and sends medical claims to insurance clearance agencies. This module tracks all the accounts receivables from insurance agencies. If payments are not received from insurance agencies within the stipulated period, it rebills the customers for outstanding dues.

Ambulatory Care Module (ACM)

This module maintains patient's medical records. It maintains patients' family and social history, statistics on vital parameters, immunization records, allergies, surgical procedures, physical examination reports, diagnosis results, lab reports, radiology reports, EKG charts, MRI, CT scan reports, medication reports, and any other remarks from other physicians in a central repository. This module permits users to record and retrieve digital photos, transcriptions, drawings, radiology images, MRI, CT scan charts, texts, graphs, and voice. Physicians can have their dictated progress notes transcribed and imported into the EMR, or record handwritten progress notes using a tablet PC.

E-Prescription Module (EPM)

This module generates and tracks electronic prescriptions. Physicians can write prescriptions electronically, which are then transmitted to the associated formularies and retail drug stores. Physicians can even electronically order referrals and laboratory and radiology tests. Users can track test-order status and extent to which a particular prescription is filled by a drug store.

Workflow Management Module (WMM)

This module manages the workflow within a health care organization. This module creates work lists for various professionals such as Specialists, General Practitioners, Nurses, and Lab Staff. This module interacts with the Appointment Scheduling Module and creates work lists for various professionals who are working in a health care organization.

Knowledge Base Module (KBM)

EMR system maintains a repository of clinical references for various disorders, medical complications and tracks information on latest drug dosages and delivery systems. Medical professionals can search this repository for any reference information.

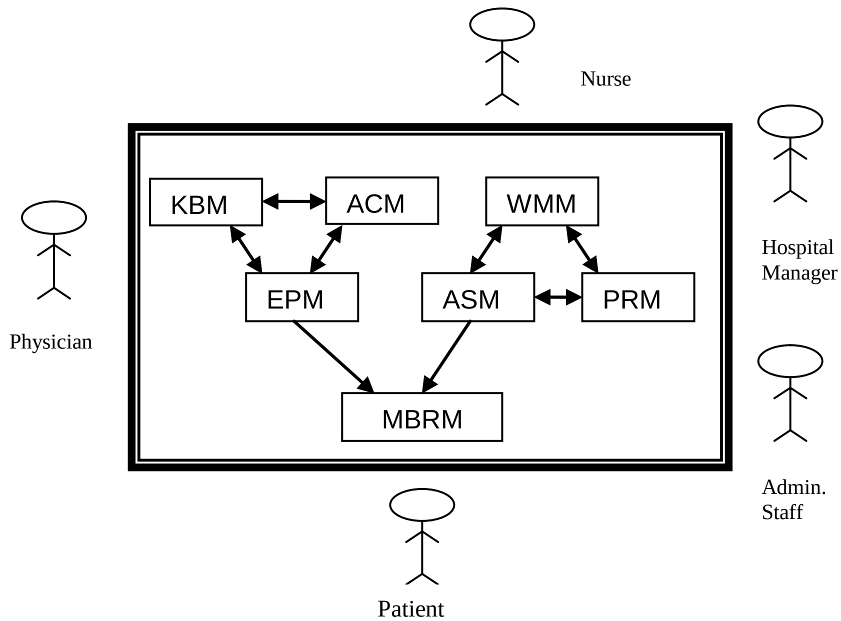
Figure 1 shows the different modules and their interaction. The appointment scheduling module (ASM), patient registration module (PRM) and workflow management module (WMM) frequently interact with each other while knowledge base module (KBM), ambulatory care module (ACM) and e-prescription module (EPM) frequently interact with each other. ASM and EPM feed into medical billing and receivables module (MBRM). As shown in Figure 1, physicians, nurses, hospital managers, administrative staff, and patients use EMR system.

RESEARCH METHODOLOGY

We conducted an exploratory case study on process level benefits of EMR systems. A case study is appropriate for an exploratory investigation like this (Yin, 2002). We employed a case study design using six organizations. We conducted interviews with EMR managers, physician champions, nurses, radiologists, and EMR vendors associated with a few hospitals and physician organizations that had adopted an EMR. We conducted the interviews during the period 2005-06. Using six different organizations allowed comparisons between them for more general research results (Benbasat, Goldstein, & Mead, 1987; Yin, 2002).

We triangulated qualitative data from multiple sources. As mentioned earlier, we conducted telephonic interviews with EMR managers, physician champions, nurses, radiologists, and EMR vendors. We relied

Figure 1. Modules of EMR system and their inter-relationship



heavily on the support of these experts. We used a structured interview guide for our interviews. This interview guide had both closed ended questions and open ended probing questions. Findings from closed ended responses were compared with answers to the open-ended questions. We verified answers by having interviewees review our notes on their responses. We also conducted several face-to-face meetings with representatives from one hospital who were willing to participate in our project.

We also reviewed reports from secondary sources such as trade journals. We also conducted content analysis of Web sites of organizations. We considered data associated with the period 2001-2006. Krippendorf (1980) defines content analysis as a technique wherein a researcher searches for structures and regularities in the content and draws inferences on the basis of these regularities. Here content refers to process level benefits. For consistency, the same researcher did content analysis of the various Web sites.

We conducted cross-case analysis and identified consistent patterns regarding process level benefits of EMR systems.

ANALYSIS AND DISCUSSION OF PROCESS LEVEL BENEFITS

We present six case summaries to highlight the process level benefits of EMR systems.

Case Summaries

Case #1: Oconee Memorial Hospital (http://www.oconeememorial.org/index.cfm?PageID=72)

Oconee Memorial Hospital operates in South Carolina, USA, and is considered progressive in the use of health care IT systems. In late 2003, they got interested in implementing an EMR system known as Practice Management Plus and Horizon Ambulatory Care. It is a part of a larger information network known as Foothills Health Information Network. They initially implemented the system in the radiology section in early 2004 before using it hospital wide. Radiologists used EMR to create and interpret images derived from a variety of modalities: radiography, ultrasound, magnetic resonance imaging (MRI), positron emission tomography (PET), and computed tomography (CT). EMR captures both analog and digital images. EMR also captures metadata concerning who viewed, annotated, printed, and sent specific data and when those activities occurred. This ability of EMR to capture and replay aspects of invisible work resulted in information richness as well as new accountabilities. The search and retrieval processes were enhanced in a digital environment. Now this hospital uses many modules such as appointment scheduling, billing and receivables, patient registration, ambulatory care, and workflow management. Based on the post-implementation evaluation, they have identified the following process level benefits: improved coordination among departments within the hospital, improved access to the patients' medical records from remote locations, improved throughput of diagnosis, treatment and consultation, reduced time taken for delivery of services, improved speed and accuracy of medical insurance claims registration, improved data integrity of patient's medical records, better control of employee work schedule and the institution's overall responsiveness.

Case # 2: Ogden Clinic (http://www.nextgen.com/images/pdfs/Ogden-FCG.pdf)

Ogden Clinic is a multispecialty group practice in Utah, USA. They implemented Next Gen EMR and enterprise practice management systems in 2005. Ogden Clinic began experiencing the following process level improvements: Patient check-in process gets completed in half the time and several reporting tasks associated with the receptionist function have been reduced by half. Using point-of-care documentation templates have allowed Ogden Clinic to eliminate 95% of its transcription use. Scanning and electronic storage of documents have reduced the volume of paper work by 75%. Electronic ordering and results management have been greatly streamlined—with an electronic interface to the laboratory information system, an EKG interface, and e-prescribing capabilities saving valuable physician and support staff time. With health maintenance reminders linked to its disease management programs and a robust set of online patient education materials, Ogden Clinic automatically generates patient recall reminders on a weekly basis, alert physicians when patient interventions are overdue, and provide comprehensive clinical information tailored to each patient's condition. As a result, the organization has recorded an annual increase in revenue of $72,000 attributable to the additional health maintenance visits. Whenever a national drug is recalled, Ogden Clinic generates a list of all its patients on that medication and sends them personalized letters with instructions, providing timely care and saving staff time.

Case # 3: Northwest Diagnostic (www.healthmgttech.com)

Northwest Diagnostic is a family practice clinic in Texas, USA. They implemented the clinical charting, ambulatory care, billing, and scheduling modules of the e-MD EMR system in 2005. Viewing capabilities of EMR system resulted in an up to date availability of data and charts, better data organization and legibility. Support staff reported that they spend less time finding, pulling and filing charts. Physicians reported that they spend less time in locating information. They were able to access and modify the records as and when needed. They reported that they are able to spend more time on assessment and patient care. Coding documentation (different medical procedures have different codes) also improved. Quality of preventive care and disease management improved because of use of electronic alerts on symptoms and allergy lists. Billing procedures also dramatically improved. All these resulted in a saving of a quarter of million dollars in the very first year after implementation.

Case # 4: Cayuga Family Medicine (http://www.healthmgttech.com/archives/1106/1106bridging_gap.htm)

Cayuga Family Medicine is a New York-based low volume practice that focuses on pediatrics and obstetrics. They implemented the patient registration, appointment scheduling and medical billing modules of EMR system in 2000. Cayuga realized the following process level improvements: reduction in the transcription and billing errors, improvement in the speed and accuracy of medical insurance claims registration, data consistency of the patient's medical records and overall productivity of the physicians and front office staff.

Case # 5: Newport Heart (http://www.alteer.com)

Newport Heart is a California based cardiology unit. It implemented the medical billing, clinical charting, and patient registration modules of the EMR system. They experienced the following benefits after implementation of the EMR system: improvement in cash flows, reduction in accounts receivables by 25%, reduction in the time taken for delivery of services to patients, improved ability to inform patients about their up to date financial account status, accurate patients' records, and reduction in the paper work by 90%.

Case # 6: Public Hospitals and Polyclinics under National Health Care Group and Singapore Health Services, Singapore http://www.zdnetasia.com/news/business/0,39047112,39189253,00.htm)

Seven public hospitals under National Health Care Group and 17 polyclinics under the Singapore Health Services share in-patient discharge summarizes including prescriptions, treatments, and allergies and out-patient records, x ray and lab reports through a centralized platform of EMR system. The hospitals and polyclinics have realized the following benefits: better coordinated care for patients moving across different providers, reduction in transcription errors, better clinical decisions with access to complete and legible clinical histories, cost savings through the avoidance of unnecessary repeat tests and investigations, 24-hour access to real time data for up-to-date results reporting, and improved data security with provision for audit trails.

In summary, we were able to identify several process level benefits from EMR adoption and use such as:

a. Improved coordination between departments in the hospital,
b. Better access to legible medical records from remote locations,
c. Increased throughput for diagnosis, treatment and consultation,
d. Increased speed and accuracy of medical insurance claims registration,
e. Improved data integrity of patient medical records,
f. Better work schedule management,
g. Improved data security and audit trails,
i. Better disease management and preventive care, and
j. Increased costs savings.

CONCLUSION

Electronic Medical Records system (EMR) is an enabling interorganizational information system for overall improvement in health care quality. In this article, various modules of EMR and the relationships between them were presented. There are several modules such as patient registration, appointment scheduling, ambulatory care, e-prescription, knowledge base management, work flow management, billing and receivables management modules. They all work synergistically to increase the value and benefits to all stakeholders.

The process level benefits of EMR systems were then examined by conducting qualitative case analysis of six organizations that had implemented EMR systems and content analysis of their Web sites. Assessment of benefits (at the process level) helps to explicate the underlying linking mechanism between EMR implementation and organizational level impacts. We were able to identify several process level benefits from EMR adoption.

While a few studies in the literature tried to examine the usefulness of EMR at organizational level, very little research has been done to examine the various components of EMR and process level benefits of EMR systems. We have set a stage for examining process level benefits of EMR systems to organizations. Researchers should further this line of research by conducting a longitudinal study involving several health care organizations and examine the process level benefits of EMR systems. Researchers could use theoretical lenses of Transaction Cost Economics, Resource Based View, and Digital Options theory to explain the process level benefits of EMR systems.

KEY TERMS

Electronic Medical Records System: An interorganizational information system that captures the essential components of a patient's medical encounter with the medical provider, including storage and retrieval of subjective, objective patient information, assessment, and plans for patient care (Lenhart et al., 2000).

EMR Process Level Benefit: A benefit measured at the process level after 2 years of adoption and use of Electronic Medical Records System in medical institutions (adapted from Radhakrishnan et al., 2007).

Health Care Information System: An arrangement of information technology, people, data, and processes that interact to gather, process, store, and disseminate health care information (adapted from Whitten & Bentley, 2007).

Production Management in the Elderly Care Services

Nora Ekroos
Helsinki University of Technology, Finland

Erkki Vauramo
Helsinki University of Technology, Finland

INTRODUCTION

In western countries, the so-called demographic time bomb, that is, the ageing of the baby-boom generation, has become one of the most challenging issues. Although it has become almost clichéd in health care planning, its effects are being felt rather acutely in reality. The situation in Finland, as in many other western countries, is compounded by the fact that as demand for *elderly care* is increasing, the service systems are suffering from severe labor and tax funding shortages. In fact, population in Finland is aging faster than any other OECD country (Antolin, Oxley, & Suyker, 2001). Elderly care centers have difficulties in hiring qualified professional staff. Nursing staff are also burdened by heavy workloads. The situation will worsen by time as the number of elderly people in our population increases further, leading to increased strain on health care resources. The present service structure is not going to be able to respond to this demand. Yet health care funding, which depends on public financing, will decrease as the number of taxpayers declines due to the aging of our workforce. "Elderly dependence ratio," a key demographic indicator, will approximately double over the next two decades (Eurostat, 2005).

We have approached this problem described above from a *production management* point of view. Some ideas from this concept can be implemented to improve elderly care, such as work-in- progress. This article reports on the findings of a case study using this approach in the field of elderly care in Helsinki City, 2004. A previous version of this article has appeared in the HCTM 2005 Conference proceedings.

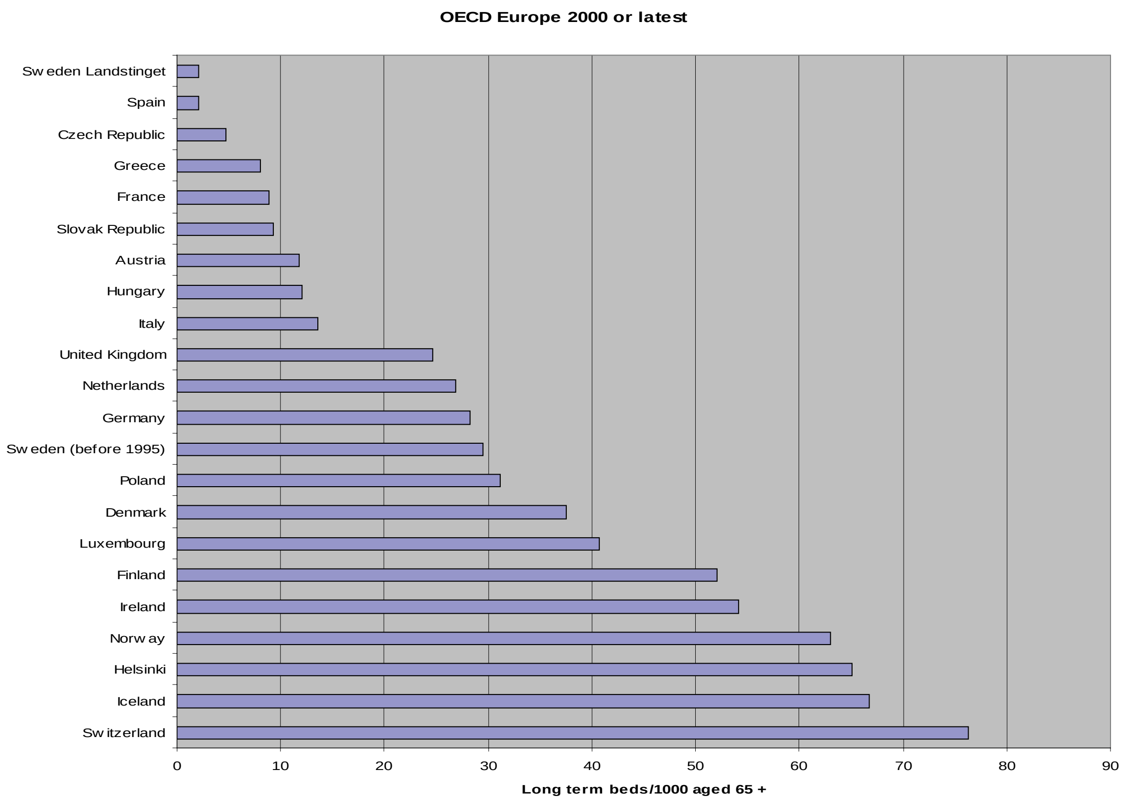
BACKGROUND

In the Finnish care system, the municipalities are responsible for providing health and social care services for all inhabitants including the elderly. This care is financed by local municipal taxation, although this can be supplemented by additional funding from central government.

The amount of long-term beds is relatively high in Finland (see Figure 1). In 2002, 5 % of the over 75s lived in service housing, 5 % in nursing homes, and 3 % were in-patients at health center long-term wards. In Sweden, the health care reform has accomplished a radical reduction in institutional care. Most of the Swedish elderly (96%) live in a single room with their own kitchen and toilet.

A shift towards the deinstitution of the elderly can be observed (Coleman, 1995; Eng, Pedulla, Eleazer, McCann, & Fox, 1997). A study performed in Italy (Tibaldi et al., 2004) suggests that severely demented elderly patients at home can benefit from the same level of care provided by a hospital ward. Stable support from family members of demented subjects can delay their admission to nursing home. Maintaining independence remains central to the quality of life of elderly persons with disabling chronic conditions (Ball, Perkins, Whittington, Hollingsworth, King, & Combs, 2004). A study performed in Australia (Allen, Glasziou, & Del Mar, 1999) reported that bed rest is not only used in the management of patients who are not mobile, but is also prescribed as a treatment for a large number of medical conditions. The researchers (Allen et al., 1999) reviewed available long-term care studies and concluded that bed rest does not help to treat any illness, but on the contrary actually worsens the

Figure 1. Long-term beds/1000 aged 65+ in Europe 2000 or later (OECD, 2000)



condition of the patient. Those who stay in the hospital for a very long time are usually those that consume the largest amount of hospital resources (Marshall, McClean, & Millard, 2004). In addition to the expense of long-term institutional care, it is also an inherently dependent way of living.

PRODUCTION MANAGEMENT IN HEALTH CARE

Health care has been perceived as different from any other type of service. The present requirement to improve efficiency is putting pressure on finding new approaches to service delivery. This has been given increased priority as a result of the increasing pressure on elderly care services in particular.

In recent years there has been increased interest in applying *production management* thinking to health care (Lillrank, Kujala, Kämäräinen, & Kronström, 2003; Thompson, Wolf, & Spear, 2003). The lessons learned from the industrial environment have guided innovations in health care service processes. With this in mind, the Department of Industrial Engineering and Management at Helsinki University of Technology has compiled a health care research team designed to transfer industrial engineering principles to the domain of health care.

The work-in-progress (WIP) measure in manufacturing has been introduced to health care through the patient-in-process concept (PIP) (Kujala et al., 2004). The focus in studying PIP is on patient episodes. In industry, process time has been divided into value-adding and nonvalue-adding components, but for health care the categorization needs to be more sophisticated. The proposal (Kujala et al., 2004) is to divide the duration of patient episode into three major components: diagnostic and care time, administrative time, and waiting time. The distinction between time categories is based on the expected change in a patient's medical condition, information management, the types of services provided and resource consumption. Cutting off nonvalue-adding time can lead to a remarkable improvement in a patient's condition and consequently provide savings for municipalities, other employers, and insurance companies.

Next we will be present how the production management approach and the work-in-progress concept were implemented to elderly care service production in our case study.

CASE HELSINKI

In Helsinki City, there are over 550, 000 inhabitants. The proportion of people over age 65 is 13.7 %, while 6.5 % of the population is over 75. There are several elderly care service providers: Helsinki City Health Department, Helsinki City Social Service Department, public and private foundations for elderly care homes, private enterprises, and others. The degree of institutionalization in elderly care is high (see Figure 1). The elderly care expenditure is also significant, €4260 per capita for those over 75, which is about twice as much as in the other cities/municipalities in Finland. This cost disparity can be partly, but note entirely explained by the higher employee and estate costs in the metropolis area.

Helsinki City has produced several analyses and evaluations on elderly care, the main conclusions of which are that some of the elderly are not currently located in the right category of care facility. Relatively healthy elderly people are laying in beds in hospital wards, although their quality of life would be higher in senior residential housing.

Taking cognisance of the challenges related to the optimization of a multi-organization service network, the City of Helsinki and the Department of Industrial Engineering and Management agreed upon a research project to analyze the processes and problems in 24 hour elderly care. This study focused on the processes between various service providers; in other words, the service system was examined from the perspective of the entire care path. The results of which will now be presented.

Research Objectives

The main objective was to analyze how the organizational structure and the service provision processes influence on the cost and quality of elderly care using industrial process analysis methods. The steps were as follows:

1. To describe the 24 hour service structure and operational environment;
2. To analyze the “selecting the next step facility” procedure after an acute care period;
3. To model patient flow by processes in the elderly care service system; and
4. To understand the mechanism driving extra costs incurred by this service system.

Research Methods

The elderly care processes were identified using the available data. The process perspective is a new approach in order to understand the care pathways and the supply-demand relationships of different elderly care services.

The data allowed us to do perform a number of quantitative analyses. The objective of which was to construct a process map to quantify the system structure and to identify possible bottlenecks or other problems in care pathways. The qualitative data was collected through semi-structured interviews of key persons.

Available Basic Data and Materials

Data for process analysis and reference materials were mainly gathered from databases of the Health Department and the Social Service Department of the City of Helsinki. The national registers of STAKES (The National Research and Development Centre for Welfare and Health) were used as reference materials. The financial statements of the Social Services Department and Health Department for 2003 were also used. The key person interviews were performed with a focus on the current service structure, collaboration between organizations, decision making, and follow-up procedures.

Findings

Service Structure and Operational Environment

The Health Department as well as the Social Service Department are responsible for the provision of 24 hour elderly care. Helsinki produces most of the care services on its own but also buys some nursing home beds and service housing beds from private provid-

Table 1. Elderly care providers in Helsinki

Provider	Amount of Locations
Health Department	*4*
Social Service Department	*20*
City owned Helsinki Nursing Home Foundation	*6*
Several Third sector of private care home	*89*
Helsinki Service Housing Ltd (org. for city owned residences)	*16*

ers and foundations (see Figure 2). The complicated administrative governance structure creates challenges in order to offer frictionless care pathways. There are five types of organization that provide 24 hour elderly care serves (see Table 1).

There are four different levels of care: acute hospital care, institutional care, service housing, and home care (see Figure 2). Long-term ward, nursing home and 24 hour service housing are all included in the 24 hour elderly care. The production expense of nursing homes is €93 per day, 24 hour service housing is €55 per day, while at €145 per day the long-term ward is the most expensive of these care locations. In long-term ward the care is mostly based on bed rest. For the elderly patient, the nursing home and service housing are the most independent places to live in the 24 hour care environment.

Selecting the Next Step Facility

After a period of acute care, the aim is to disband the patient as swiftly as possible. The selection of the patient's next facility is made by a committee consisting of representatives from open and institutional care. This decision making process is based on the patient's care needs as measured by the care index system. In principle the location of elderly patients will be based on the careful estimation of working order.

In the current system there are several problems associated with the effective disbandment of elderly patients. For example, there is no *rehabilitation* location that caters especially for the elderly. The only possible solution is to locate the not-yet-rehabilitated patients in institutional care. Despite the potential for the *rehabilitation* of elderly patients, all are placed in institutional care or service housing with the same protocols.

Care Pathways in Network

The process analysis (see Figure 3) illustrates the real patient flow and explains how bedridden patients are born. The data analysis confirmed that the service structure also interacts with the subsequent stage of facility location. As a result of over-capacity in the long-term hospital, as well as undersized service housing and nursing home facilities, elderly patients who so not require hospital care are located in the long-term ward. The occupation rate of which is mostly 100% or over (extra beds organized) in all 24 hour service levels. As has been established, the maximal capacity utilization does not always offer the most optimal cost effectiveness.

After a period in the long-term ward, it is difficult to get elderly patients up from their beds because their general condition will be weaker as a result of a prolonged period of bed rest. Some of the elderly have to stay in the hospital for many years, although for many of them bed rest constitutes a nonvalue-adding time. Furthermore, their quality of life would be better in a noninstitutional environment. Integrated care pathways do not function because several providers are involved and the service structure does not respond to the demand. This institutional oriented service structure leads to institutional care too early.

The difference between the required number of beds and the beds in use in the long-term ward is illustrated in Figure 4. Approximately 600 long-term ward beds can be closed while simultaneously increasing rehabilitation, service housing, and nursing home beds. If the service structure would response to demand, the resources required in the long-term ward would decrease. This care pathway cross-section analysis revealed one of the bottlenecks in the service system and explains partly the long-term ward periods.

Figure 2. The service structure and the division of service production between social service department, health department and other providers in Helsinki

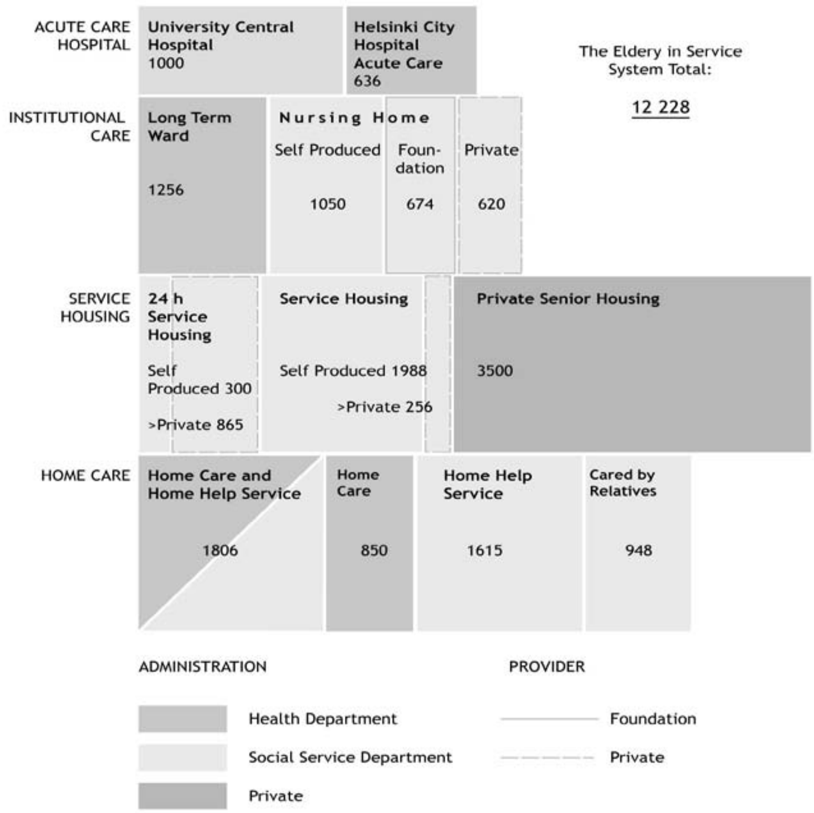


Figure 3. This phenomenon inflicts the long care periods in institutions in Helsinki; 09/2004

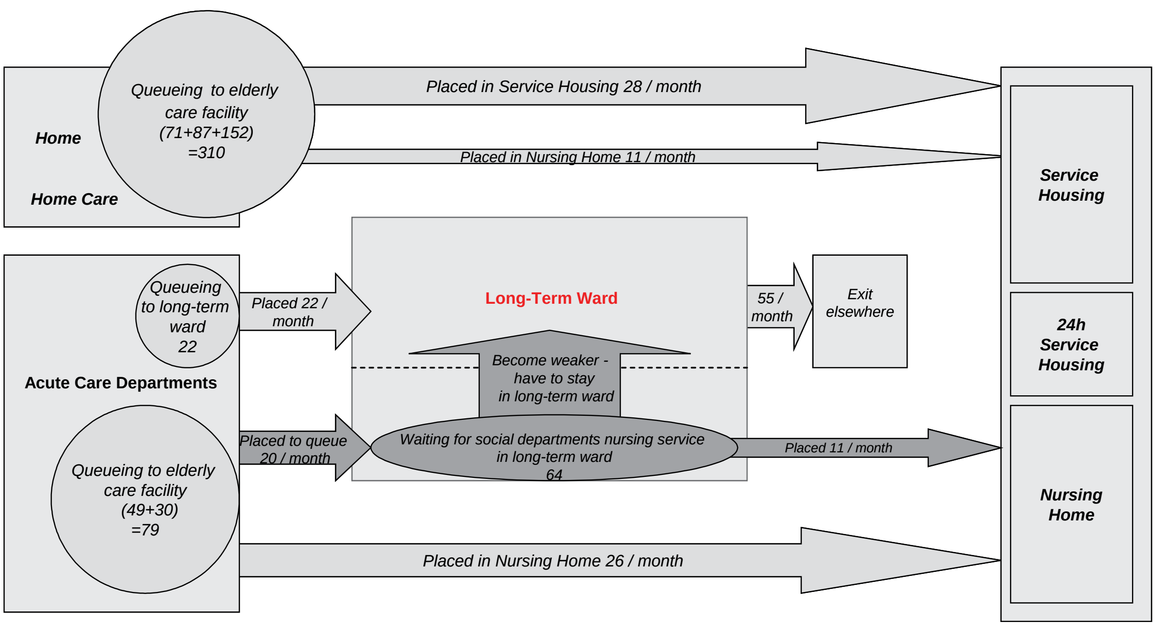

Figure 4. Differences between the beds needed and beds offered in the long-term ward in Helsinki, 2004

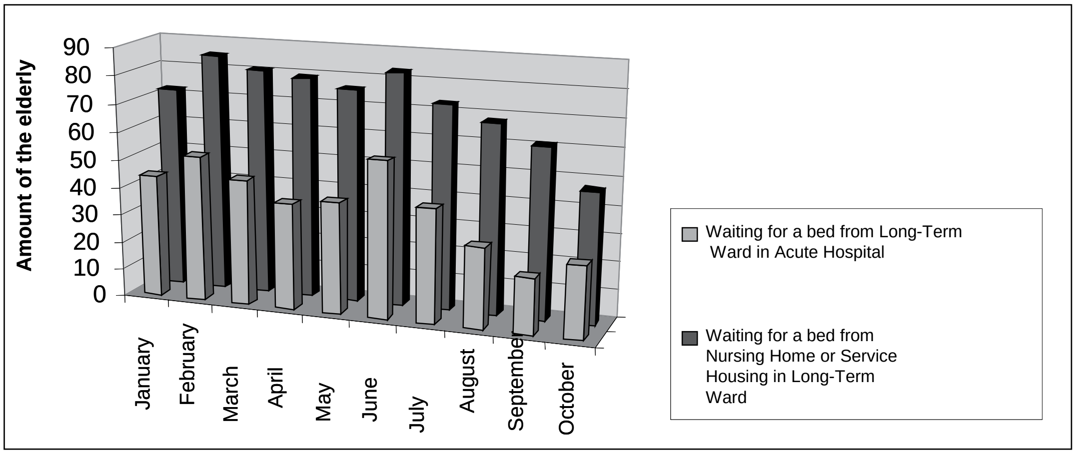

Processes Between Services

The study showed that the amount of possible care pathways, as indicated in Figure 2, is over 30 (between different providers and services). As an example, the Helsinki Nursing Home Foundation is owned by the city but is treated as a private provider creating an unnecessary border between services. The analyses of interface functionality were performed and the queues between providers were found out. Inoperative interfaces inflict bottlenecks in the process between services.

All administrative organizations in this case study produce their own budgets and follow-up reports. The entire care costs are not available, making it difficult to understand the cost factors in the service system from the perspective of the entire care path. Communication between organizations should be transparent in order to provide services more efficiency and offer frictionless care path to the elderly. Every interface should be under critical scope and with a systematic follow-up system.

CONCLUSION

It was speculated by the city that the "metropolis problem" was the principle cause of the significant elderly care expenditure. Data has showed that the problems are rooted in both the service system, nonfunctioning processes between the institutions as well as the lack of systematic process management. For example, timely rehabilitation of aged patients following an acute hospital admission is important in order to avoid several years of institutional care. The superfluous cost of elderly care in Helsinki is caused partially by the service structure, which due to the lack of rehabilitation places elderly people in institutional care often years too early.

The findings explain the reasons why the elderly are not always located in the correct facilities in Helsinki. The elderly care process can be categorized as the patient-in-process (PIP) in health care environment. The term "not-rehabilitated-in-process" (NRIP) as a new category can be used to analyze the elderly care processes and the caused costs. Patients that are located in care facilities of unwarranted cost intensity due to unrealized rehabilitation potential suffer from nonvalue-adding waiting time.

The possibility of rehabilitation in the prescribed time during and/or after an acute hospital visit is very important in order to avoid many years of institutional care. The extra costs associated with elderly care in institutional environments are caused often by the elderly people who are steered to institutional care sometimes even years too early as a result of the lack of rehabilitation services. Spending time in institutions does not add value to those elderly patients who still have the potential to rehabilitate. The patient's medical condition does not usually improve with bed rest. The diagnostic and care periods in acute care are completed but the care process is not finished. The administrative time might also be too long in the care process if the service structure does not respond to the demand. The problem is not caused because of a shortage of resources but as a result of the service structure and

Table 2. Care costs in different service levels in Helsinki

	Long Term Ward		Nursing Home		24h Service Housing	
Care Period	Patients +75	Care Cost (million €)	Patients +75	Care Cost (million €)	Patients +75	Care Cost (million €)
0-30 days	479	1,53	172	0,35	56	0,10
30-59 days	131	0,84	93	0,43	40	0,13
60-89 days	74	0,79	90	0,68	36	0,20
90-179 days	116	2,26	260	3,25	102	0,97
0,5-1 years	120	4,71	327	9,09	183	3,66
1-2 years	241	18,69	416	22,8	245	10,32
2-10 years	499	**109,56**	692	98,47	510	60,28
over 10 years	27	15,22	47	23,9	33	12,34
Total	**1687**	**152,92**	**2097**	**158,78**	**1205**	**87,95**

the "steering process" (which reflects the type of care for each elderly patient). As Table 2 illustrates, the 2-10 year care periods in the long-term ward are the most expensive ones. Therefore, the present service structure in Helsinki causes the extra costs because of the nonvalue adding long-term ward periods.

The costs of an unrehabilitated person can be considered analogous to the cost of work-in-progress in production management. Although the acute hospital has treated the acute illness, the patient is not fully rehabilitated. The importance of well organized rehabilitation is one of the key issues in order to avoid institutionalization too early.

FUTURE TRENDS

A process chart is a very illustrative way to analyze elderly care pathways in order to understand the relationship between supply and demand in service systems and also to identify bottlenecks in elderly care processes. Problems in organizational structure and process governance are also easily detected.

Not-rehabilitated-in-process (NRIP) is not only expensive, but also inflicts extra suffering on elderly patients. Service structures should respond to the demand, and follow-up procedures should be reviewed from a process perspective. The present unintegrated follow-up system does not support the frictionless care pathway. It is impossible to control the processes and optimize the resource usage without proper data. Resources should be re-organized and avoid the gratuitous institutional care that is expensive and leads to a dependent way of living.

In the future, as indicated in the study, more economical and user friendly care pathways can be produced. There will be more elderly people to take care of with less money from the tax payers. The importance of delivering well-timed 24 hour elderly care for the right person will increase in order to ensure that everyone in need of 24 hour care will receive it. Organizing the service structure and steering the elderly care processes in the most effective way will be a very important issue to improve the quality of care for the elderly, with optimal use of resources. It is possible to offer better quality of life to the elderly with fewer resources. From our experience, we believe the application of industrial process analyses to health care will be used in the future.

KEY TERMS

Acute Care: Short-term care in ward.

Care Path: Illustrates the patient flow through the different care services also over organizational boundaries.

Institutional Care: Long-term care in ward or in nursing home.

Not-Rehabilitated-in-Process (NRIP): The diagnostic and care periods in acute care are completed but the care process is not finished, for example, lack of rehabilitation.

Service Levels: In the elderly care environment, there are four different levels of care, including acute care, institutional care, service housing, and home care.

INTRODUCTION

The miniaturization and cost reduction of microelectronic devices have been leading to the development of new technologies. Wireless sensor networks (WSNs) are one example of these new technologies. A WSN is a distributed system that is composed of autonomous units with sensing capabilities (sensor nodes), interconnected by wireless communication. WSNs have been successfully applied in the monitoring of the human body. This development led to a new concept: Body Sensor Networks (BSNs).

According to Yang (2006, pp. 5), BSNs have specific requisites, when compared to WSNs. Among these requisites, we highlight the following:

- High level of security, in order to guarantee the confidentiality of information;
- Biocompatibility and biodegradability;
- Higher sensitivity to data loss, and the consequent need for mechanisms to ensure a minimum Quality of Service (QoS);
- Need for context awareness, as the physiological variations are strongly related to the changes in the context in which the user is in;
- Low number of sensor nodes, which should, however, be usually more precise than sensors for other applications of WSNs;
- Requirement of nodes with the capability of running multiple tasks.

Pervasive monitoring demands great adaptation capability from the BSN. Moreover, cases in which the decision made by the system can be different from the decision that would be made by a healthcare professional are frequent. Therefore, besides intelligent algorithms that allow autonomous operation, BSNs need mechanisms that allow changes in their behavior in order to become a clinically useful tool. According to Baldus, Klabunde, and Müsch (2004), "the BSN has to work automatically, but has also to be always under explicit control of any clinician."

Thus, specific models that include programmability as a functional requisite are important in a software architecture designed for BSNs. However, the greatest challenge is to allow the modifications to be made not only to the structure of the software, but also in its behavior, without excluding the capability for autonomous operation of the system.

According to Barbosa, Sene, Carvalho, da Rocha, Nascimento, and Camapum (2006), two important concepts related to programmability in BSNs are: (i) deployment-time programmability, and (ii) run-time set-up. The deployment-time programmability refers to the definition of software artifacts and algorithms that are embedded in the sensor node. In BSNs, the inclusion of this functionality requires a programming interface that is suitable for healthcare personnel, as well as intelligent compilers. Intelligent compilers should be capable of handling implicit functional and nonfunctional requisites of a program. As an example, the inclusion of mechanisms and policies for energy saving could be treated by these structures.

The run-time set-up refers to the capability for adjustments in run-time. The BSN should provide interactivity between the healthcare professional (the BSN manager) and the system. As a requisite, sensor nodes need mechanisms that allow a better control of the tasks that are being run. A possible solution is the use of data structures that allow preemptive multitasking.

The goal of this article is to present the current state of the art, regarding programmability in BSNs. Moreover, we want to present potential benefits of a paradigm shift in which healthcare professionals become the actual programmers and maintainers of the BSNs. With that in mind, we briefly present a software architecture that has been developed with the goal of allowing programmability at network and sensor node levels.

BACKGROUND

Many issues related to software for BSNs have not been discussed yet. Among them, we can mention: (i) the development of graphical user interfaces directed to healthcare personnel; (ii) the hardware abstraction layers (HALs); (iii) the standardization of services and information structuring (BSN ontology); and (iv) programmability at sensor and sensor node levels. The solutions to these problems can lead to improvement of the effectiveness of these systems.

Currently, the software used in BSNs has the following characteristics:

- They are composed of proprietary systems built based on a specific architecture (hardware), and designed for handling a single application. They have little or no modularization, and they are not committed to software development methodologies. In general, they do not employ multiprogramming. Sensor nodes are usually viewed just as sources of data, and all processing is performed in a gateway—an element that interconnects the BSN to other systems—or in a Local Processing Unit (LPU), which is an element to where the data are transmitted. Some examples of such systems are presented in Asada, Shaltis, Reiner, Sokwoo, and Hutchinson (2003), Valdastri, Menciassi, Arena, Caccamo, and Dario (2004), Linz, Kallmayer, Aschenbrenner, and Reichl (2006), Kara, Kemaloglu, and Kirbas (2006), and Chakravorty (2006).
- These systems are usually based on a generic, general purpose model. It is usually based on the NesC programming language (Gay, Levis, von Behren, Welsh, Brewer, & Culler, 2003), on the TinyOS Operating system (Hill, 2003), and on a network programming system, the Deluge (Hui & Culler, 2004). All of these systems are free of charge, and they were developed by the University of California, in Berkeley. CodeBlue (Welsh, 2006), WHMS (Jovanov, 2006), and UbiMon (ICL, 2006) are examples of designs that use the TinyOS framework. Other examples are presented in (Bauldus et al., 2004) and in (Farshchi, Nuyujukian, Pesterev, Mody, & Judy, 2006).

Regarding programmability, systems built based on TinyOS have the following limitations when applied to BSNs:

- The NesC programming language imposes a peculiar syntax, based on concepts emerged from software engineering. Without the knowledge of programming logic and the expertise in managing software components, it is virtually impossible for a nonspecialized user to use this system.
- The multiprogramming model used in TinyOS is not interactive enough. It offers little control over the activities (tasks) run by the sensor node, because there is no context switch. Tasks cannot be immediately interrupted or replaced in order to answer a policy established by the application, or to answer to a command issued by the user. Moreover, according to Han, Bhatti, Carlson, Dai, Deng, Rose, Sheth, Shucker, Gruenwald,

and Torgerson (2005), the execution of more complex tasks can be limited by the occurrence of deadlocks.

BSNs must be designed to operate in an autonomous manner. On the other hand, they should offer mechanisms that yield the control to healthcare personnel, since all the functionalities of the network should reflect their judgment and their clinical evaluation. Thus, a great challenge in BSN software design is to increase, in a transparent way, the access to the internal configurations of the network and its sensor nodes without damaging its capability for autonomous operation.

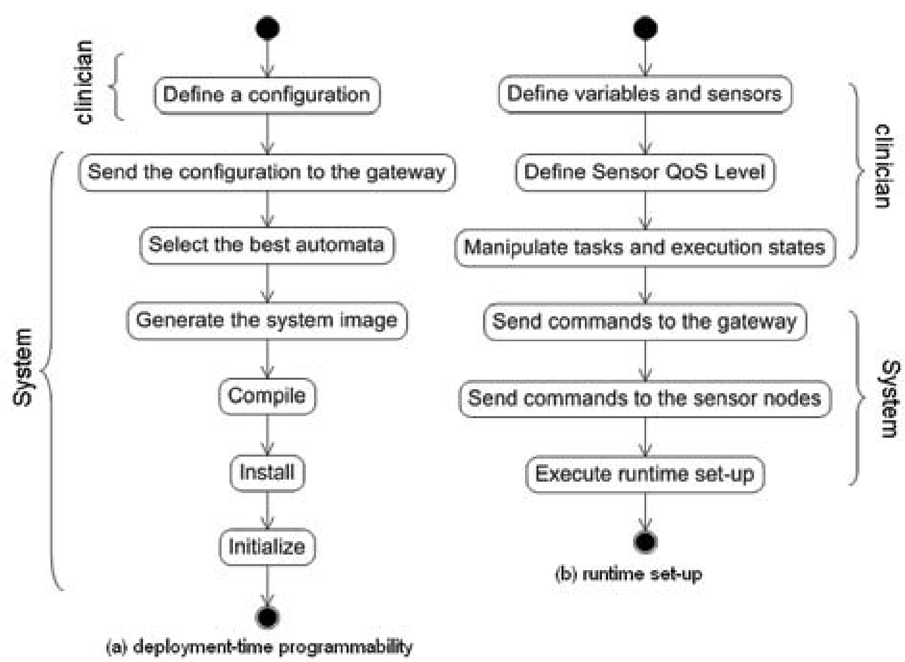
PROGRAMMING BODY SENSOR NETWORKS

Software Architecture for Body-worn Sensor Networks (SOAB) is a system that is being developed at the University of Brasilia to support BSN-based applications (Barbosa et al., 2006). SOAB incorporates the concept of programmability, presented in the introduction of this article, as functionality (service) offered by the BSN. Figure 1 presents a diagram illustrating the activities related to the method for programming BSNs proposed by SOAB. Part of these activities should be run by healthcare professionals (clinicians), and the remaining activities are run by the system itself.

Figure 1a refers to programming at deployment time. These activities are responsible for the definition of mechanisms and policies that are included in the sensor nodes to support a specific application. Figure 1b refers to the run-time set-up process, responsible for the definition and/or adjustments of applications and data sources. The detailed definition of these activities will be presented later, during the description of the layers of the proposed architecture.

SOAB is a modular system, divided into four independent functional layers: (i) a graphical interface, developed especially for healthcare personnel; (ii) middleware for interconnection of the BSN with the Internet; (iii) a server for handling the services related to the services requested by the programmers; and, finally, (iv) an operating system with support for preemptive multitasking, which will be installed in

Figure 1. Activity diagrams to describe the SOAB programming methodology



the sensor nodes. This operating system was named MedOS, and one of its main features is that it tries to increase the lifetime of the sensor nodes by means of proper scheduling of tasks, based on policies that are adapted to biomedical applications. In order to systematize these policies, an automata-based model has been used. Moreover, MedOS allows BSN managers to manipulate the states of the running tasks. Figure 2 presents an overview of SOAB.

In the first layer of SOAB (Figure 2), we have the BWSNET Configuration Tool. This graphical interface is responsible for providing means by which healthcare professionals can describe their algorithms in a way that is more intuitive, less time-consuming, and less error-prone. This interface also allows the possibility of including new sensors that were not initially specified, without the need to recompile the source code. An interface based on Java Reflection (Java Tutorials, 2006) was used to achieve this feature. The BWSNET Configuration Tool has also a simulator that acts as a virtual debugger for estimating the sensor node lifetime and other performance metrics. As a sample of the BWSNET Configuration Tool, Figure 3a shows a deployment-time programming interface for the acquisition of the electrocardiogram (ECG), while Figure 3b shows the run-time set-up interface.

Figure 3b also shows how an application is defined, and how it can be modified. As an example, the application "monitoring user stress" was defined by four variables: blood pressure, ECG, heart rate, and Blood O2. Each variable can also be defined by other variables of data sources, as described by Carvalho, Perillo, Heinzelman, and Murphy (2004). The "ECG" variable, in this case, has been defined by three data sources: ECG 1Lead 100 Hz, ECG 3Leads 500 Hz, and ECG 6Leads 1000 Hz. In order to support these functionalities, the tasks and the software artifacts have also been included at deployment-time (see Figure 3a).

In order to increase the lifetime of the network and, consequently, of the application, the system is responsible for determining how much time each data source should stay active, and how it should operate (the required precision). In order to do so, the system uses information regarding the application in order to execute policies that promote, for instance, energy saving. These policies act on the scheduling of the running tasks and on the adjustment of the bandwidth, and of the transmission power of the communication interface of the sensor nodes (Sensor QoS Level). By using the run-time set-up interface, the healthcare professional can alter the configuration that is usually chosen by the system, excluding and/or adding new data sources and variables, and can manipulate the Sensor QoS Level.

Figure 2. SOAB's four layer system

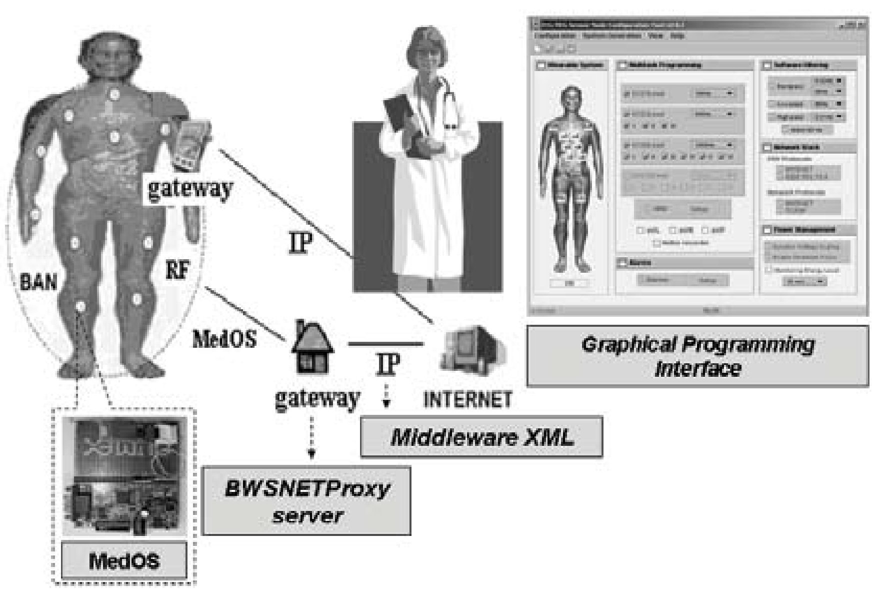


Figure 3. Examples of SOAB graphical interfaces

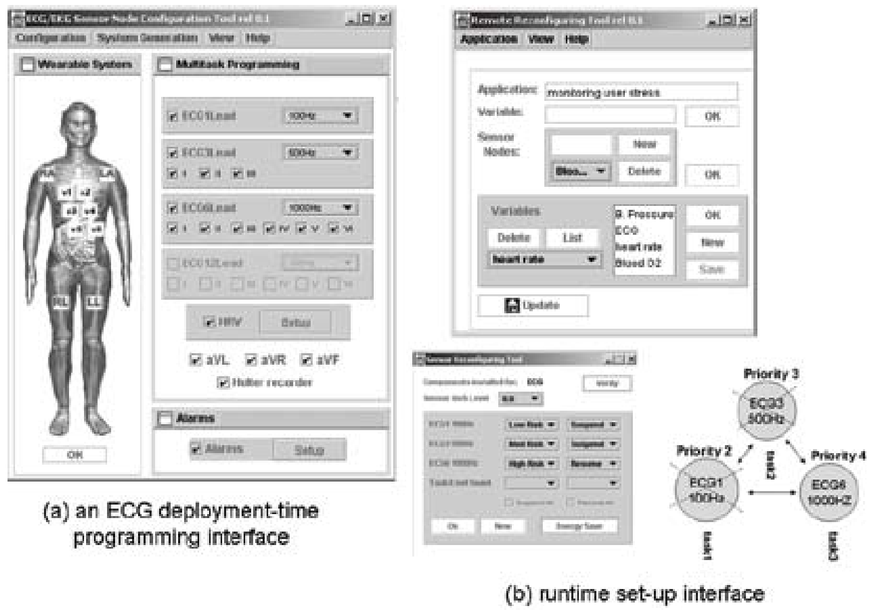


The user can also change the current values attributed to the priorities associated with the tasks, and also suspend and restart tasks.

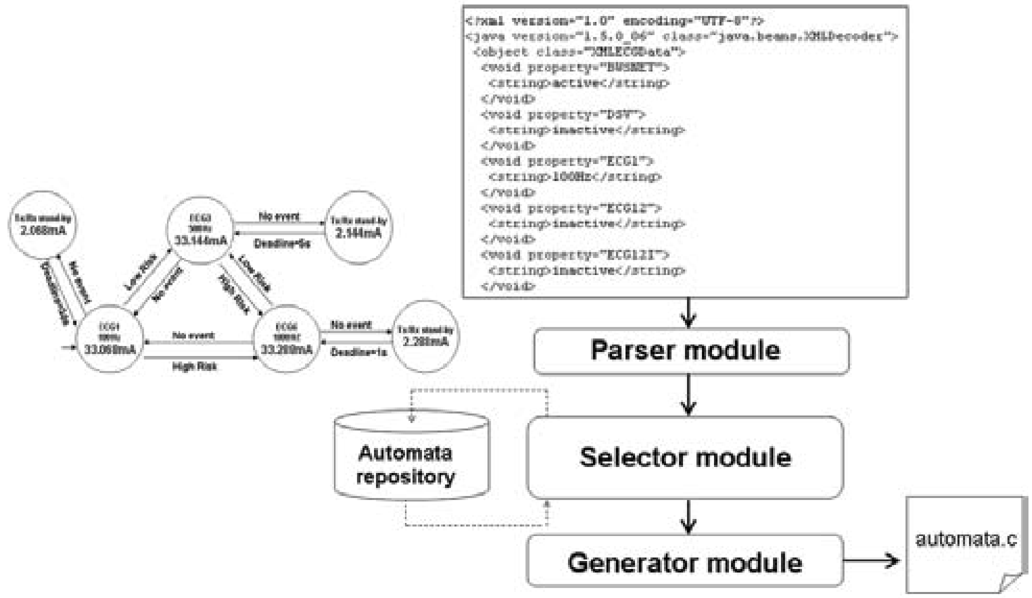
In order to provide support for the programming and reconfiguration of the sensor nodes from the Internet, a group of remote procedure calls (RPCs) has been implemented in compliance with the recommendations of the W3C Web Services (http://www.w3.org/TR/2004/NOTE-ws-arch-20040211/; http://www.w3.org/TR/wsdl20/). These RPCs represent the XML middleware layer in Figure 2.

In the third layer, we have the *BWSNET Proxy*. This software entity has been projected to operate in the gateway devices. It is responsible for the translation of the requisitions of the SOAP XML format (http://www.w3.org/TR/2003/REC-soap12-part1-20030624/) to commands that are understandable to the underlying layer. Besides, it has the responsibility of creating the real image of the system from the BSN manager's program and the correspondent automata, the selfadjustable binary code that will be executed by the sensor nodes. Another functionality of the BWSNET Proxy server that is equally important, is that it promotes the integration of the BSN with an external healthcare information system (HIS).

Figure 4 shows the module that is responsible for selecting the best automatum for a given configuration defined at deployment time. The automata generator is an intermediate-level intelligent compiler. It is composed of three modules. The "Parser" module is responsible for extraction relevant information for the "Selector" module. In practice, these informations are related to parameters, such as the objective of the application, the number of tasks, the types of tasks, and the selected alarms, among others. The values of these parameters are used for filling a table of parameters that will be used by the selector module. The "Selector" module chooses the automatum that maximizes the potential of each application, guaranteeing a greater lifetime for the system. In practice, the selector module is a decision tree (Cormem, Leiserson, & Rivest, 1997, pp. 173) that is responsible for the choice of the best automatum from a set of possible automata that are deposited in an automata repository. This choice is made based on the table of values that is made available by the "Parser" module. The definition of this three (selection algorithm) is based on the medical knowledge that influences the values of each parameter in the table.

After the choosing the best automatum, the "Generator" module can generate the "automato.c" file (see Figure 4), which will represent the program that will be embedded into the sensor node. For this task, a description of the necessary code libraries and necessary system calls should be used. This description is stored in the automata repository, along with the functional description of each automatum. During the automata

Figure 4 . The automata generator module



selection, this configuration file is used by the "Generator" module for assembling the "automato.c" file.

In the last layer of SOAB, there is an application-oriented operating system called MedOS. The main objective of MedOS is to provide support for the behavioral adjustment of the sensor-node at run-time, changing the priority values that can be associated with the tasks provided by the sensor-node. Figure 5 shows the main artifact of MedOS and their dependencies. The functionalities are represented by tasks created together using FreeRTOS libraries (Barry, 2006).

Besides the preemptive multitasking functionality, MedOS implements a set of device drivers, a set of library functions that are used by the automata generator module, and a command interpreter. The command interpreter allows programmers to alter the scheduling of tasks that is currently adopted by the system. This functionality may or may not be included during the generation of the image of the system. If this functionality is disabled, artifacts related to the library "interpreter.h" (Figure 5) will not be included. Thus, only artifacts related to the "policy.h" file (which represent the behavior of the automatum that has been chosen by the application) will be included in the "automata.h" file, which represents the image of the system that will be installed in the sensor nodes.

In addition to the code libraries of FreeRTOS, the MSPGCC code libraries (http://mspgcc.sourceforge.net/) have also been used for the implementation of MedOS.

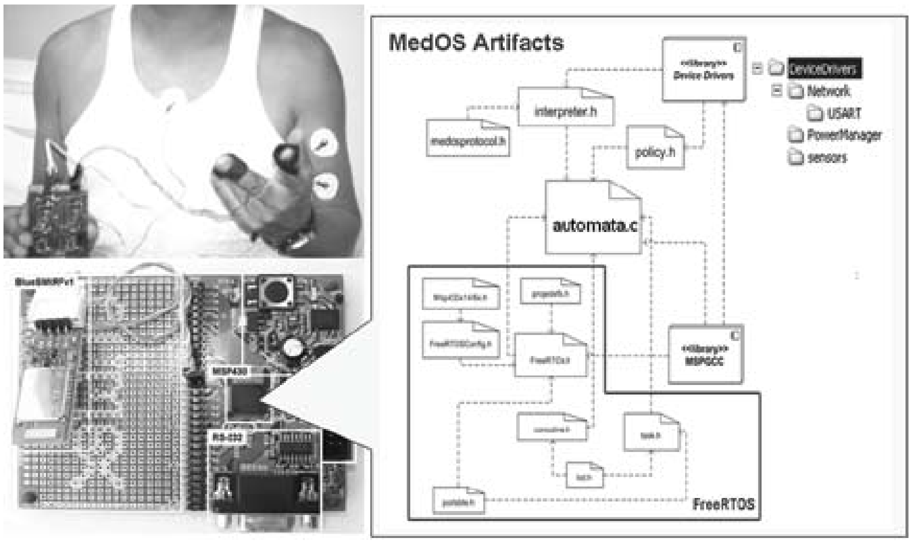
SOAB has been tested in the hardware platform presented in Figure 5. The sensor-nodes were built using the Olimex MSP-P149 kit (http://www.olimex.com/dev/msp-p149.html), with a bluetooth radio BlueSRMIFv1 (http://www.sparkfun.com/commerce/product_info.php?products_id=582). This system allows the monitoring of electrocardiographic and electromyographic signals, as well as skin temperature, arterial pressure, and galvanic skin resistance.

FUTURE TRENDS

The SOAB includes three main innovative features to the BSN research area: (i) a graphical interface for programming and reconfiguration of the sensor nodes; (ii) an application of the concept of preemptive multitasking to BSNs; and (iii) an intelligent compiler (which is also an automata generator). The authors believe that these three features will be pursued by future efforts in this area. Some other potential future trends may be highlighted:

- *The study of man-machine interfaces, and its repercussions on programming and reconfiguration models of BSNs*. A graphical user interface is

Figure 5. MedOS artifacts and sensor node architecture



an attractive and effective alternative, especially for remote access using the Internet. However, in some situations and environments, such as in an emergency room, other devices (hardware) could be used in a more effective way. Baudus et al. (2004) discuss the use of a infrared set-up pen, which works as a remote control, allowing the physicians and nurses to connect the data sources needed for patient monitoring. These data sources are implemented with sensor nodes that can be interconnected to form a BSN that is suitable for the desired application.

- *Smart compilers* that are capable of embedding, during the programming at deployment time of the sensor nodes, mechanisms and policies that increase the effectiveness of the application should also be targeted by new developments. These compilers must be based on a specialist's knowledge, since the medical expert is the one who should know how to schedule the resources according to each application, and should operate in a transparent way to the user.
- *Smart and adaptive algorithms* for task scheduling that take into account the dynamics of the applications should also be pursued. For instance, the health condition of the patient and the capability of the sensor node and of the network should be taken into account in the formulation of these algorithms. In this context, preemptive multitasking allows the computer system to guarantee for each process a regular "slice" of operating time in a more reliable way. It also allows the system to rapidly deal with important external events, such as incoming data, which might require the immediate attention of one or another process.
- *Stantardization of the software features* and of the process related to the development of sytem for BSNs will also be an important issue. In this subject, we can highlight: (i) the development of methodologies for evaluation of these systems regarding their usability and effectiveness; and (ii) the standardization of the interfaces and services as a tool for promoting the independency of hardware and for facilitating the integration of information with other networks and systems. For example, the definition of a BSN Sensor Ontology could establish a hierarchy that expresses the semantics associated to each type of sensor, group or relationship. This approach can increase the effectiveness in the use of BSNs facilitating the gathering of information, which could also be used for programming and reconfiguration of the network.

CONCLUSION

By using a modular software architecture that is designed according to the requirements of possible applications, it is possible to increase the capability for autonomous operation of the BSN, and still offer tools for programming and reconfiguration of these systems that can be used for people with little grasp on programming languages.

This text presented a proposal for a paradigm shift for the programming and reconfiguration of the BSNs. By making more suitable tools available—such as programming interfaces, intelligent compilers, and application-oriented algorithms—the goal is to allow healthcare workers to become the actual programmers and maintainers of this technology. The possibility of developing and/or testing new applications without the need of specific technical knowledge on programming languages and computational models can facilitate the popularization of this technology.

SOAB integrates concepts such as reflection, Web services, automata, intelligent compilers, and preemptive multitasking, with the goal of becoming a solution that is functional, portable, usable, effective, and easy to maintain. Also, this architecture can be extended into four levels, allowing its improvement and the implantation of other systems (services). This solution establishes a concept: application-oriented software architecture.

KEY TERMS

Application-Oriented Operating System: An operating system that is designed or customized for fulfilling the interests of an application or of a set of similar applications that share a significant part of the requirements. This kind of system must include specific mechanisms and policies, in order to effectively serve the interest of the applications.

Automata or State Machines: A mathematical model that can be used for representing the behavior of a computational system. A state diagram is used for its graphical representation. Basically, an automatum is composed of states that can be graphically represented by circles and edges, which indicate the actions that are responsible by changes of state. In WSNs, usually the states are associated with the tasks, and the edges are directly related to the events that are responsible by the changes in states.

Context Awareness: The capability of computational systems of determining circumstances and scenarios in which its users may be inserted, or simply determining information that is of interest to the system. To do so, the system uses rules (intelligent algorithms) and data that can be supplied by the user itself, or obtained by sensors. These data can also lead to probabilistic information. In this case, the context awareness is not exact, but instead, a hypothesis with an associated probability value.

Multiprogramming: The approach that allows several processes to run simultaneously in a system. In a multiprogrammed sensor node, several programs are simultaneously maintained and managed in the memory by resident software. These programs are organized as tasks. The execution of these tasks follows a policy that is defined during the design of the system, and it is coordinated by a mechanism called task scheduler. In WSNs, there are two kinds of multiprogramming: (i) event-driven run-to-completion single thread approach, and (ii) preemptively time-sliced multithreading model.

Ontology: A data model that represents the entities that are defined and evaluated by its own attributes, and organized according to a hierarchy and a semantic. Ontologies are used for representing knowledge on the whole of a specific domain or on of it. In WSNs, ontologies are included in software architectures as a way of facilitating the search for relevant information. For example, in a BSN an ontology could be used for sensing a specific context (context awareess).

Pervasive Monitoring: The capability of a system to keep itself operating under any condition. These conditions can be related not only to the location (space), but also to the time. They can also be related to technical conditions, such as connectivity, safety, and the amount of energy stored in the batteries.

Preemptive Multitasking: An approach of multiprogramming. The operating system can interrupt the execution of a task and initiate the execution of another, in order to satisfy the restrictions that are defined by the policy that is being used for the scheduling of tasks. It also allows the execution of a task to be suspended or interrupted by a command received from the application.

Quality of Service (QoS): The capability of the system of adjusting itself or of offering mechanisms that allow its adjustment in order to fulfill the requisites that are defined for each application. In WSNs the parameters that are commonly related to the quality of the service that is offered by this kind of system are application lifetime (which is related to energy consumption), connectivity, confidentiality, reliability, bandwidth, and transmission power.

Reflection: A concept related to software: programming languages, operating systems, middleware, and Graphical User Interface (GUI). A reflexive system offers mechanisms that allow its data structures to be inspected and/or modified during execution (at run-time). For this, the system must keep its selfrepresentation that is commonly organized as metadata. In nonreflexive systems, the metadata usually are lost or discarded during compilation, typically when the low-level codes (assembly language) are generated.

Web Services: Modular, independent, selfdescriptive programs that are designed to guarantee interoperability among systems that are developed with different technologies and that interact in a computer network. Typically, Web services are described by using the WSDL (Web Services Description Language), and they use SOAP (Simple Object Access Protocol) for message exchange.

A Prospective Observational Study of the Determinants of Current Cataract Surgical Selection

INTRODUCTION

The principal aim of this research proposal was to develop quality of life and relevant visual function criteria to provide a rational decisional framework to be used as a basis for individual and policy decisions on cataract referral and surgery. There are two key objectives within this overall aim. The first is to identify reliable and effective quality of life and visual function criteria to determine the threshold for surgery for each individual patient in which false positive and false negative errors are minimized. The second is to provide a decisional framework in which risk factors may be incorporated to assess the likely outcome benefits from surgery.

AIMS

The overall aim of the proposed project was the development of criteria, which would provide a rational decision framework as a basis of practical and policy decisions on cataract referral and surgery. The three key objectives within this framework are:

1. The development of reliable and effective criteria to determine the threshold for surgery for each individual patient in which error rates outlined are minimized.
2. To provide a decisional framework in which risk factors may be incorporated to assess the likely outcome benefits from surgery.
3. To produce a measure(s) in which likely outcome benefits (particularly quality of life) from surgery may be prioritized

BACKGROUND

Cataract surgery represents the single greatest highest number of surgical procedures in ophthalmology (Desai, 1999) and its positive health impact was clearly recognized in the UK Government's "Action on Cataract" initiative introduced in 1999 that was designed to streamline the steps, process, and systems of all stages in the patient care pathway. Technical developments in surgery now mean that earlier intervention is much more effective than it was a few years ago and this has lead to increased public expectations to minimize the impact of cataracts on vision related quality of life. Furthermore, the progressive ageing of the population means that there will be an increasing demand for cataract surgery for at least the next 20 years and, unless there are radical innovations to surgical procedure or intra-ocular lens design, it is also likely that referral for post-operative laser capsulotomies will increase proportionally. The clinical context to this project was to investigate factors that determine the process of care early in the cataract patient journey and how this influences surgical selection and subsequent management. Ensuring that there is equitable access to cataract services UK-wide requires some degree of standardization in surgical selection whilst preserving patient-centered care to meet the ophthalmic needs of individuals. Whilst hospital-based care may be more concerned with consequences further downstream in the cataract journey, that is, with increased numbers of patients listed for cataract outstripping surgical capacity, clearly the selection of patients presurgery is critical in the care planning process. The drive to reduce waiting times in cataract surgery has increased over the past several years following the Action on Cataract plan. This has led to initiatives for increasing cataract capacity becoming manifest in a number of public/private initiatives, for example, Netcare and Independent Treatment Centres. Concerns have been raised over "outsourcing" cataract surgical services, effectively unlinking the surgery from pre-assessment selection.

Following the "Action on Cataract" initiative, several fast-tract programmes of direct referral for cataract surgery from optometrists working in the primary care sector have been established (e.g., at the Gloucestershire Eye Unit, Cheltenham General Hospital, and Princess Alexandra Eye Pavilion, Edinburgh) where listing for day-case surgery is largely based on an estimate of potential benefits and complication risks made by the referring optometrist. While this procedure has been shown to work well at a local level where a good working relationship exists between the consultant ophthalmologists and local community optometrists, it has been difficult to implement such programmes on a national scale. This is due to a number of factors, the principal two of which are:

1. Large individual differences between ophthalmologists in what constitute criteria for cataract surgery (Mordue, Parkin, Baxter, Fewcett, & Stewart, 1994), and
2. Large individual differences in the referral criteria for cataract surgery used by optometrists (Latham & Misson, 1997).

Clearly, improvement in referral criteria can only be achieved once there are commonly accepted criteria for surgery. A consequence of these practical problems is that, in some areas of the country, there are high false positive referrals of patients with cataract and nationally there is no estimate of the false negative error rate. These issues are compounded by current practice. At present, the commonly accepted procedure for determining the false positive and false negative error rates is to assess the correctness of the referral in terms of whether an ophthalmologist will diagnose a patient as having a level of cataract that is visually disabling. Given the individual differences within ophthalmology in applying criteria for cataract surgery, and given that the appropriate validation criterion is not the diagnosis but whether the patient is likely to benefit from surgery, there is an urgent need to develop commonly agreed upon criteria used both by ophthalmologists and optometrists that will comprise reliable and effective measures and procedures for determining the threshold for cataract surgery for each individual patient.

The object of cataract surgery is to improve visual function and many reports demonstrate that the vast majority of patients benefit from surgery (Minassian, Rosen, Dart, Reidy, Desai, & Sidhu, 2001). For many years the emphasis has been on Snellen visual acuity performance both for referral and as an outcome indicator (Ruit et al., 2007). However, several studies have shown that the disabling effect of cataract is largely due to a reduced contrast in the retinal image due to intra-ocular light scatter. Not surprisingly, these studies on patients with cataract have shown that visual acuity measures correlate poorly with visual symptoms (Rubin, Adamsons, & Stark, 1995; Steinberg et al., 1994) and that changes in contrast sensitivity, especially in the presence of glare, give better predictions of the difficulties that patients face in daily situations (Elam, Graney, Applegate, Miller, Freeman, & Wood, 1988). Moreover, where cataract co-exists with another vision reducing pathology such as age related macular degeneration (AMD) (Armbrecht, Findlay, Kaushal, Aspinall, Hill, & Dhillon, 2000) or glaucoma (Nelson, Aspinall, Papasouliotis, Worton, & O'Brien, 2003), we have shown that functional measures of contrast sensitivity in the presence and absence of glare are more effective predictors of quality of life indicators than visual acuity.

A number of approaches have been developed that aim to assess visual symptoms and functional disability. These measures are able to identify those patients with significant disability due to their cataract and may assist in deciding whether cataract surgery is indicated. However they are poor at discriminating those patients with mild to moderate visual disabilities and in addition they have not been evaluated postoperatively. It has also been suggested that measures of vision related aspects of quality of life such as the VF-14 (Steinberg et al, 1994), the Activities of Daily Living Scale (Mangione, Phillips et al., 1992), or the Catquest Questionnaire (Lundstrom, Stenevi, & Thorburn, 2001) might be better indicators of the benefit of cataract surgery. It is worth noting however that the main applications of questionnaires are grounded in sampling theory so that the results between groups of patients can be compared and they are therefore more unreliable and less useful as a means of assessing individual needs (Armbrecht, Dhillon, & Aspinall, 2001). It remains the case that a properly validated scale of vision related quality of life, or a combination of such a scale and a relevant visual function test that may be used to assess who would benefit from cataract surgery, has still to be developed. The background literature suggests that the visual_function test will be one that demonstrates the disabling effects of veiling glare on contrast threshold performance. Unfortunately, the lack of any standardization and effective calibration of glare tests such as the Brightness Acuity Tester has meant that this approach has not gained clinical acceptance. At this point we had two choices. The first would be to use a functional test that is based on a practical daily task such as reading. We had developed such a test as one of the outcomes of our recent research on quality of life in patients with cataract having the comorbidity of AMD or glaucoma. This test was developed as part of an EPSRC award on practical problems arising from glare and could provide an estimate of the disabling effects of cataract (Hill & Aspinall, 2002). It has the advantage of being a simple and quick to use contrast visibility indicator. However, at the start of the project, the contrast visibility indicator test had not been evaluated. The second option arose from a research link with Dr. Tom Van den Berg of the Institute of Ophthalmology in Amsterdam. He had developed a new instrument (the C-quant) for assessing light scatter in the eye and presented early evaluations of the equipment at the ARVO conference in Florida in April 2004. Following discussion, it was decided that it was of mutual benefit to use this proven measure of light scatter within the project.

The problems relating to the lack of agreement on referral or intervention criteria for capsulotomies from postoperative capsule opacification are similar to those for the primary referral for cataract surgery itself. The development of any referral system incorporating decisional support on visual disability, quality of life, and patient awareness of risk for cataract surgery will, therefore, have practical relevance to establishing criteria for the management of secondary cataract from postoperative capsule opacification.

It was, of course, recognized that not all decisions about whether to refer for cataract surgery can be based solely on symptoms and a measure of reduced visual function. There are many risk factors that need to be considered by the surgeon and, consequently, these risk factors also need to be recognized by the referring optometrist if false positive referrals and unrealistic patient expectations are to be avoided. In order to aid estimates of surgical outcome, Moorfields Eye Hospital has recently taken the initiative to examine ways in which the risks of complications from cataract surgery may be used to prioritize patient management (Muhtaseb, 2004). They have highlighted the risks of ocular comorbidity but there are also several important nonocular risks. For example, the elderly and those with persisting cognitive impairments often do not show any recovery in daily activities post operatively from cataract surgery (Elam et al., 1988). It was desirable, therefore, that effective decisional support strategies be developed that will assist in the cataract referral process and that these will have wide professional acceptance. There are now many examples of the way in which decision models and strategies can be used to assist in clinical decision making in ophthalmology (Massof, 2002; Piermarochi et al., 2006) and we explored ways in which these could gain practical acceptance for the more effective management of cataract. A recent quality of life scale (VSQ, O'Donovan et al.) was included to complement the traditional VF14 (Sparrow, Bron, Brown, Ayliffe, & Hill, 1986).

Whilst Mordue et al. (1994) have used consultant interviews to explore variation in cataract surgical selection (Mordue et al., 1994), our approach using both interview and assessing selection in the *same* group of professionals is unique. In addition, we wished to extend further recent evidence from Lash, Prendiville, Samson, Lewis, Munneke, and Parkin (2006, pp. 464-467) that the interface between optometrist and patient is key to refining surgical selection.

PATIENTS AND METHOD

In developing the decisional framework, the relevant criteria and their associated Quality of Life (QoL) scales were piloted within the ophthalmological, patient, and optometry communities in Edinburgh. The main source of data collection was from the six cataract referral clinics at the Princess Alexandra Eye Pavilion in Edinburgh by the research team experienced in visual psychophysics, cataract grading, straylight measurement, and QoL measurement masked to the findings of referring optometrist and supervising ophthalmologist. Ethical approval was granted for the study and all patients had fully informed consent. The study dataset included:

a. **Visual function**—Snellen acuity, Logmar distance, and near acuity, Pelli Robson contrast sensitivity.
b. **Clinical**—objective grading of cataract morphology as assessed by the Oxford clinical cataract and grading system (Steinberg et al., 1994), Stray light meter test (C-quant).
c. **Quality of life**—VF14, Massof QoL scales, and VSQ for visually impaired people (Sparrow et al., 1986) developed at the Wilmer Eye Institute at Johns Hopkins University.

Within the constraints of the study period, follow up tests were performed at 3 months after surgery. The main interest here was a comparison of pre and post op quality of life indicators.

Following all data gathering, the research aim was to draw up a decisional framework and set criteria to summarize the views of the groups as a basis for further discussion. This 1-year study aimed to produce a prototype decisional framework. The longer view of the research will attempt to derive a consensus view initially using the Delphi technique, before summarizing opinion. The opinion of an expert ophthalmology group in conjunction with those of patients would provide a consensus towards the formation of an established norm (i.e., a "gold standard").

The data obtained from these sources will be used in conjunction with QoL scale questionnaire development for decision analysis. For example, the relationship between visual function data and the degree of change in scale items pre and post surgery will be examined. We need to know what level of functioning is impaired prior to surgery and what say 5% of improvement really means in relation to quality of life. Finally a prototype numerically based profile scale for quality of life outcomes would be drawn up for test evaluation.

The value of the research to Public health and patient care could be summarized as:

- Improving relevant referral criteria that relate to decisions about the likely benefit of cataract surgery for an individual.
- Use of common criteria nationally.
- Reduction of false positive error rates.
- Quantification of false negative error rates.
- Consensus of decisional criteria within and between the relevant professional groups in primary and secondary health care.
- Improved cost effectiveness of ophthalmology resources.
- Improved effectiveness of managing patient expectations from cataract surgery.
- Improved Quality of Life for patients.

RESULTS

Main Data Collection

105 patients referred for cataract surgery to the Princess Alexandra Eye Pavilion were given a series of tests. The clinical tests including the stray light meter test;

a series of tests of visual function including the LogMar visual acuity test and the Pelli Robson contrast sensitivity test; and interviews using three quality of life scales as described above. A brief overview of the demographic characteristics of the patients is shown in Figures 1 and 2.

Demographics

The mean age is 72 years with a standard deviation of 11 years. In addition there was an even gender split with 55% of patients being female and 45% male, while 78% of patients were referred for surgery. Of these latter patients, 77% of the patients listed for surgery were first eye patients. Around 20% of referrals were not listed for surgery.

Visual Function of the Total Patient Group

In order to help interpretation of this data for Snellen acuity, which is the most widely known, the two highest frequencies within which the mean visual acuity lies, correspond to acuities of 6/9 and 6/12 with 6/12 .

This distribution is at the better end (and therefore the more controversial and problematic end) of the acuity range where we had wanted it to be. Decisions about cataract surgery at poorer acuities (other things being equal) are obviously not problematic and therefore not the main focus of this study.

Listed vs. Non Listed Patients: The Differences

As the initial purpose of this project is to understand the factors which are currently used in practice to discriminate those who are listed for surgery from those who are not listed, the initial analysis was to determine these discriminating variables. In Table 1, a nonparametric statistical test (Mann Whitney U test) shows the discriminating variables for right eyes between those listed and not listed at a probability <0.05. The variables are presented in 3 major categories—first clinical data; then visual functional data; and finally quality of life data.

Out of the full variable list, the following variables were significantly different (1-tailed test) between patients who were listed or not listed.

Table 1. Difference between listed and non listed patients

Category	Variable	Mann Whitney	Probability
Clinical	Cataract asc	2.0	0.04
	Cataract waterclefts	1.8	0.06
	Cataract brunescence	2.6	0.009
	Cataract white scatter	2.2	0.02
	Cataract psc	2.1	0.03
	Cataract fibrefolds	1.7	0.08
	Iris colour	2.0	0.03
	Stray light meter	3.2	0.002
Visual Function	Snellen	4.1	0.0001
	LogMar (distance)	4.1	0.0001
	Log(pin)	2.6	0.009
	Pelli Robson	3.6	0.001
	PelliRobson (near)	3.6	0.001
Quality of Life	Massof (Gardening)	2.3	0.02
	VF14 Driving (diff)	1.8	0.08
	Vsq Glare (diff)	2.2	0.02

Right Eye

In the clinical data, ocular comorbidities are not significantly different between those listed and not listed which may reflect the small number of comorbidities in the group. From the range of cataract features ASC is significant while water clefts is just beyond the boundary of significance. PSC is significant while brunescence is highly significant and white scatter is also significant. These latter two are the most significant discriminating variables from the set of cataract graded features. Iris colour is also just significant. In the visual function category, Snellen acuity, LogMar distance acuity (including pinhole method) is highly significant, as is Pelli Robson contrast sensitivity. LogMar near reading acuity and the stray light meter are also highly significant discriminators between those listed and those not listed for surgery.

When we examine the QoL scales "gardening" reaches significance as does driving and glare. It should be noted that quality of life scales would be more likely to relate to binocular visual function rather than criteria for single eye surgery.

A particular focus of this research was to look at criteria for surgery in patients with relatively good visual acuity. The Snellen acuity of 6/12 is seen as a benchmark by ophthalmologists for different reasons including its critical role in determining whether someone is fit to drive. Surgery on patients with visual acuity better than 6/12 is currently a topic of much debate. In Table 2, the criteria discriminating those with acuities 6/12 or better who were listed or not listed for surgery is given.

Significant differences for patients listed or not listed.

Right Eye

Again within the patient group with better acuities, a similar pattern of discriminating variables between those listed and not listed for surgery is seen.

As an example for the subgroup of patients with acuities better than 6/12, the difference between those listed and not listed for surgery is shown below in Figure 1 for the variables brunescence, white scatter, LogMar acuity, and Pelli Robson.

Figure 1 shows two of the clinical and visual functional variables clearly discriminating between patients who are listed or not listed with acuities better than 6/12.

It is also interesting that for both right and left eye data there is no difference between the significant variables for listing for the six consultant teams.

Quality of Life Scales

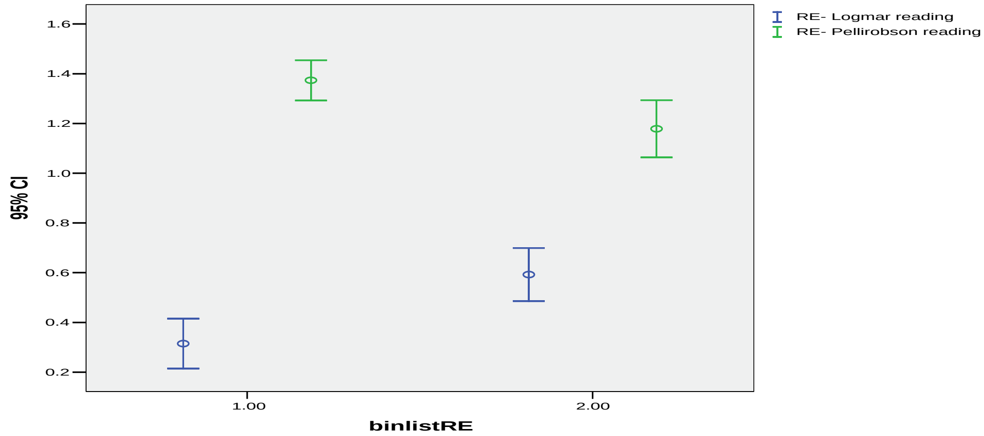
Quality of life, which is increasingly seen as a basis for all clinical intervention, has been measured using

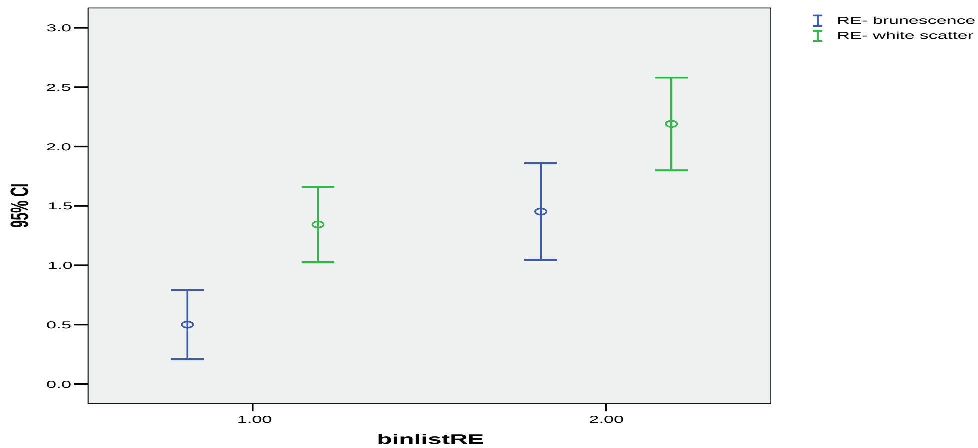
Table 2. Subgroup of patients with acuities better or equal to Snellen 6/12

Category	Variable	Mann Whitney	Probability
Clinical	Cataract cortical spokes	2.1	0.04
	Cataract Brunescence	3.2	0.001
	Cataract white scatter	3.1	0.002
	Stray light meter	3.3	0.001
Visual function	LogMar distance	3.4	0.0001
	LogMar (pin)	2.0	0.03
	Pelli Robson	2.6	0.01
	LogMar (near)	2.6	0.007
Quality of life	Vf14.10 sport	2.0	0.04
	Vsq 11 (recognising faces)	1.9	0.05
	Vsq12 (glare)	2.4	0.02
	Vf14.8 (writing)	1.8	0.08

P

Figure 1. Differences in LogMar acuity, Pelli-Robson contrast sensitivity, brunescence, and white scatter for listed (2) and not listed (1) patients





three different scales in this study. The VF-14 scale has been widely used while the VSQ scale and the Massof scale are more recent. The data presented above has indicated that there are elements of the scales which are different between those listed and not listed.

VF. 14 Scale

A frequency plot of responses on the vf14 scale showed half the sample not responding to questions 3,7, 9, and 10 (large print, fine handwork, card/board games, and sports, respectively). A factor structure of the remaining variables (excluding driving) showed from a principal component analysis a two factor solution which accounted for 57% of the variance in the data.

VSQ Scale

A similar analysis was carried out on the Vsq scale. The third question of the scale “which is your bad eye” was not included in the following analysis. Here, five factors accounted for 70 % of variance in the data.

The correlations between acuity data and quality of life scales are significant but moderate. In other words there is no question that binocular visual acuity on the Logmar or Pelli Robson tests is highly significantly related to quality of life scores on VF14 and Vsq scales. However the highest relationships in the table are correlations in the range 0.3 to 0.4 which means that the percentage of common variance between acuity and quality of life measures is between 9% and 16%, leaving at best around 84% of the variance unaccounted.

This is a case therefore of statistical significance with limited applied or practical benefit.

A clearer picture of the relationship between binocular visual function and quality of life is provided by mapping the two quality of life scales VF14 and Vsq against the two binocular visual function measures of Logmar and Pelli Robson contrast.

Two interesting aspects emerge. First, the relationship of the VF14 scale with the two measures of visual function is linear in both cases. On the other hand, the relationship of the Vsq scale is nonlinear and for the case of the Pelli Robson contrast test and the LogMar test, shows a threshold score beyond which quality of life falls. This requires further exploration but if confirmed provides useful evidence based practical criterion before which quality of life is relatively stable and unaffected and beyond which quality of life deteriorates. The Logmar criterion is around a score of 3 (or 0.19-0.30 on the test chart). The PelliRobson criterion is at a score of 2 (or 1.36-1.5 on the test chart). The nonlinear aspect of Vsq accounts for its slightly lower correlation than VF14 with visual function.

Quality of Life: Pre Operative vs. Post Operative

Perhaps the most important outcome measure in the study is the difference in quality of life indicators between a patient's situation before and after surgery. The number of patients available for this comparison was much smaller than the sample undergoing surgery. This was due to the limitation of the study (one year duration) and the waiting times before surgery and 3 months after surgery for follow up quality of life data. However, in spite of the reduced numbers available, there were highly significant differences in t scores in 10 of the 12 quality of life scales between the situation before and after surgery, with the differences being positively linked to surgical intervention. On quality of life indicators, surgery was clearly perceived as beneficial. A comparison of individual patient data shows that for all patients the score if not in the positive direction remained the same post surgery. In no instance did a patient report a worse quality of life score post surgery.

Clearly there is a high correlation between acuity level and difference in acuity between eyes – r=0.758 and r=0.817 for right and left eyes, respectively.

DISCUSSION

Towards a Prototype Decision Model

One of the central aims of the study was to make recommendations towards a prototype decision model. We are now in a position to do this but we need to emphasize two issues. First, there has been a significant limitation on the numbers of patients available for study in spite of accessing all cataract clinics in the Princess Alexandra Eye Pavilion. This limitation has been particularly severe on the follow up patients—for example, given a waiting time prior to surgery and a post operative minimum of 3 months post surgery we have only been able to see 28 patients before and after surgery. Nonetheless the significance of the findings point to particular conclusions. Second, the study has been based at one particular hospital across five consultant teams. We do not know how representative these consultants are with respect to the UK in general although qualitative interviews (results reported elsewhere) and the questionnaire data suggest that they may be typical of UK consultants. We need therefore to test the prototype more widely across the UK.

There were two initial tasks:

a. To find variables which best discriminated in current practice between those patients referred and not referred for cataract surgery.
b. By using the outcome benefits to patients from cataract surgery, to identify a rational basis for changing current practice.

We have identified the variables under (a) and will use these in the decision model. However, the issue under (b) of changing current practice raises an important question. The Edinburgh data clearly shows that current practice is working in delivering perceived benefits to patients. While a small number of patients indicate no improvement in daily tasks post surgery, there is no evidence of patients regretting their decision to go ahead with surgery or of reporting more negative quality of life scores post surgery. We have no information on the satisfaction or otherwise of patients who were refused surgery. In other words, given we have a group of very satisfied patients, we have no grounds from users of the service for changing current local practice.

We have approached the research by assuming that in ophthalmology in general, there are three categories of variables relevant to any appropriate decision model. These categories are clinical state, visual function, and quality of life. We believe it is important to preserve these categories in the final prototype model for cataract surgery. In the analysis that follows, eyes are considered as units for analysis rather than persons. So a particular eye has a functional and clinical profile which provides the evidence for or against surgery. The quality of life evidence is more problematic as its main basis is binocular visual function. In fact, in the study there are significant (though moderate) correlations between binocular vision and quality of life. The quality of life link with monocular vision would be expected to be weaker as the main criterion for quality of life would be vision in the better eye. As a consequence, quality of life criteria would be less likely to discriminate between referrals in current practice (and therefore be shown in regression analysis) irrespective of their low frequency of use.

Another important issue is the acuity level for surgery. We have taken the view that surgery on Snellen acuities greater than 6/12 is noncontroversial and consequently of little research interest. Far more important is the discovery of a rational basis for surgery at the better end of the acuity range.

A final criterion in the decisional model was ease of use in practice so that ophthalmologists and optometrists could be provided with relatively straight forward criteria for referrals.

ANALYSIS FOR PREDICTING CURRENT PRACTICE

The results in Tables 1 and 2 show the variables which are significant discriminators of current referral practice under the three categories described. The subset of these, which were most highly significant, was used in regression analysis. These were:

i. Clinical State
    Brunescence
    White scatter
    Stray light meter reading
ii. Visual Function
    Snellen acuity
    LogMar acuity
    Pelli Robson contrast sensitivity
iii. Quality of life
    Summed scores across vf14 questionnaire
    Summed scores across the vsq questionnaire

In addition, difference scores between right and left eyes were calculated for the three tests of visual function.

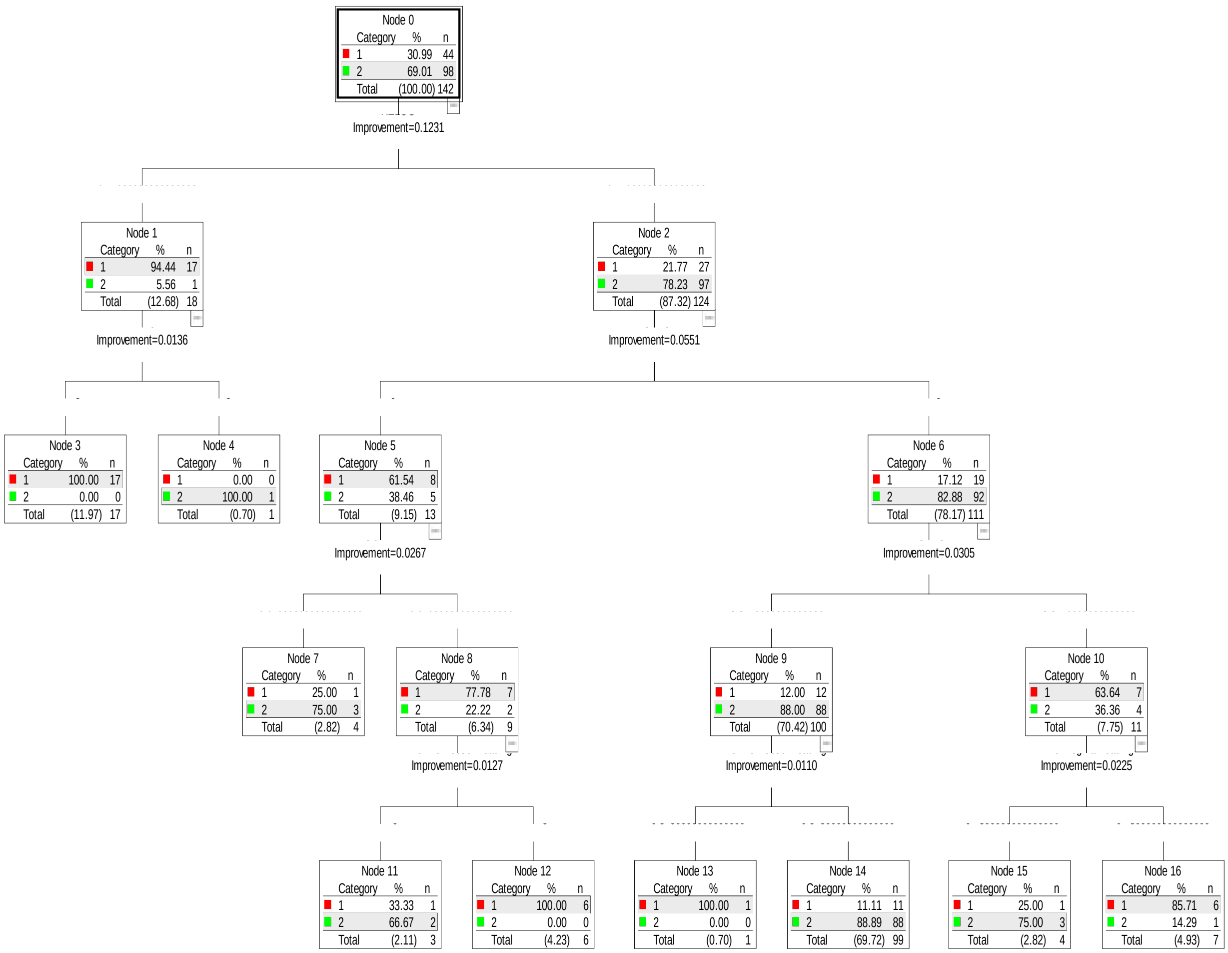
The chosen analysis was the decisional package Answer Tree—a module of SPSS. This has several advantages. First, it is an exploratory decisional which gives flexibility to the user. Users can manipulate the model to provide alternative criteria at different nodes of the tree and receive feedback on the impact of this change to the tree as a whole. This feature of local control should appeal to consultants and to local authorities with special concerns or needs. The analysis also has the advantage of being a nonparametric form of analysis and so able to cope with a variety of non normal distributions and nominal data. In addition it provides an optimal basis for a sequence of decisional nodes, and identifies the most efficient criterion point for critical paths at any node.

Predicting current practice with target variable surgery listing (all patients) and the algorithm classification and regression is shown in Figure 2. The strongest predictor is that at the first node of the tree and is LogMar acuity. By following the change in frequencies in each box as you move down the tree, it is possible to see the impact of the variable at that node on classification. Although not shown, the software provides a rank order of alternative predictors at each node of the tree and a measure of relative improvement in classification. Finally a misclassification matrix gives the overall accuracy of the model.

In summary, a tree made up of binary splits gives a good prediction of current practice. Key discriminators near the top of the tree are LogMar acuity, brunescence, and the stray light C-quant measure. Difference between eyes and binocular vision appear near the foot of the tree.

When a regression analysis is run on those patients with better acuities (i.e., <=6/12 Snellen), the relative importance of both the stray light measure and Pelli Robson contrast sensitivity as independent predictors of patient listing for surgery increases. In fact a simple three level tree with stray light at the first node and difference in contrast sensitivity between eyes at the second node produces a classification matrix at around 90% accuracy.

Figure 2. Regression tree for all patients



Analysis for Predicting Quality of Life

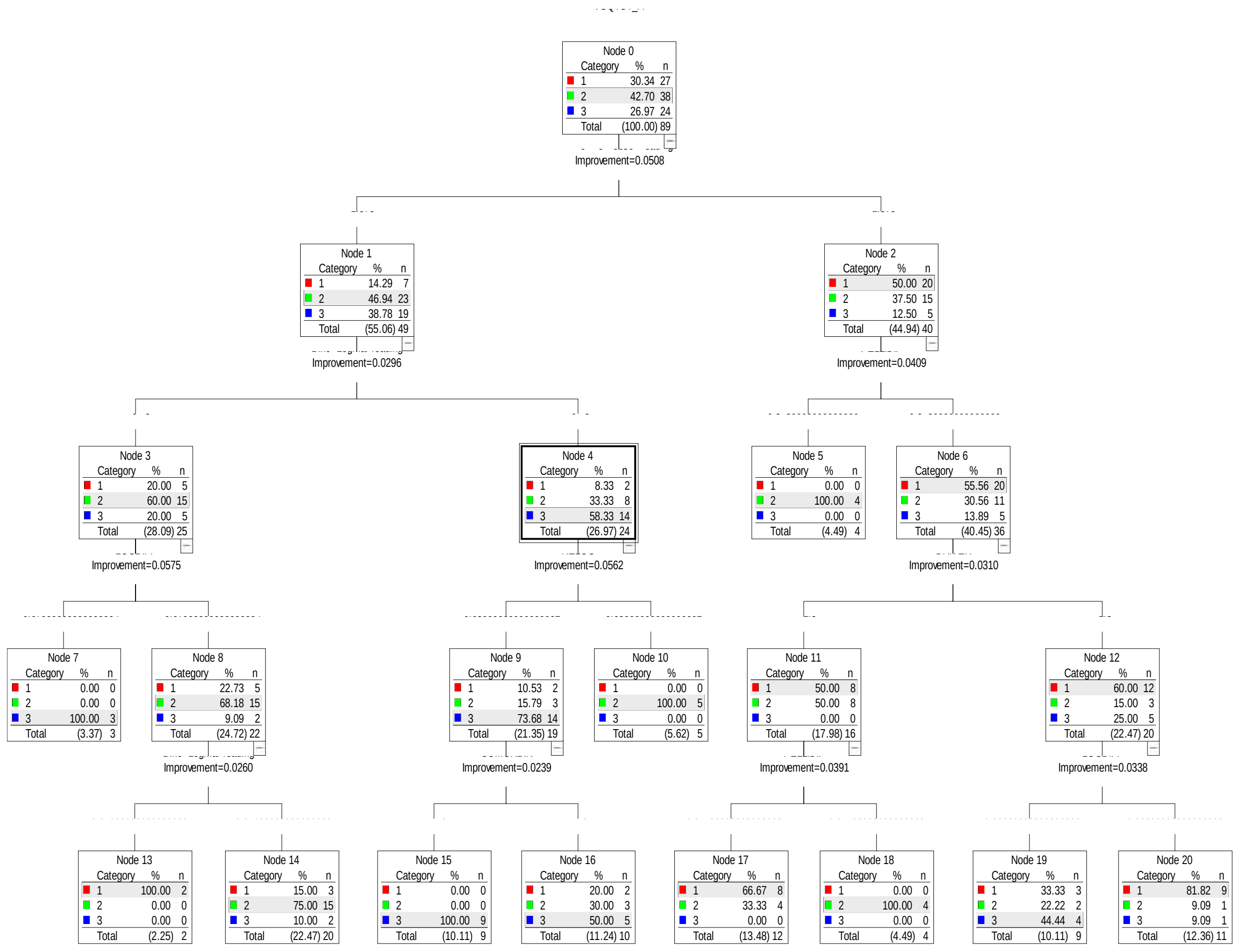
When the key variable for referral is changed to Quality of Life rather than current practice, Quality of Life is best predicted by binocular vision. In the case of the Vf14, scale binocular LogMar appears at the top and lower down the tree, and in the case of the Vsq scale, it is the binocular Pelli Robson contrast sensitivity test which is the best predictor. Once again brunescence and stray light measures feature very strongly.

Similarly if we examine the predictors of quality of life for the top acuity group (<=6/12 Snellen), then as in the total group of patients it is binocular contrast sensitivity which is the main discriminator for quality of life. This is shown in the regression tree in Figure 3. It is noticeable that difference between eyes is featuring strongly as an important variable in the trees. Driving and comorbidity also feature as relevant.

In summary, the regression trees show high prediction for current practice for all patients referred and for those in the top acuity group. When quality of life is made the key dependent variable, the model prediction is less good and binocular contrast sensitivity appears more strongly as a relevant predictor.

At this stage, we need more evidence from a wider based study of hospital practice. It seems to us unlikely that the relevant parameters in cataract referral will differ between hospitals, but it seems highly likely that the weightings given to these parameters may well differ between centers. As a consequence, until we receive further feedback on the Edinburgh weightings, the regression weights are not built into the simplified decisional outline scheme given below.

Figure 3. Regression tree for predicting quality of life for the top acuity patients



FUTURE WORK

Simplified Decision Structure for Cataract Surgery

Notes

1. RED indicates Refer (or for ophthalmologists) list for surgery, AMBER indicates maybe, and GREEN indicates no basis for referral on that measure.
2. The 3-way split (1, 2, 3) on scales would be based on proportions of patients in the best third (1), middle third (2), and worst third (3) of each scale.
3. Note that the risk scale is inverted and that the lower risk categories (1 and 2) are both given amber. In other words, low risk cannot of itself justify referral.
4. Similarly for patients views, which no matter how keen for surgery are not sufficient in themselves.
5. Any one RED appearing in the profile of a patient indicates refer. The challenge is to find the threshold for how many AMBERS indicates referral. We assume this will be arrived at in consultation with ophthalmologists (we suggest 3 AMBERS=refer).
6. The model assumes that all three major categories, and all measures are equally important in arriving at a decision. This is not true with respect to analysis of current practice but may be a useful starting position. The same assumption underlies tertiary splits for criterion points on each scale.
7. We have not as yet gone back to the data and looked at the consequences of implementing this or discovering the number of AMBERS meeting current practice.

Box 1. Simplified decision structure for cataract surgery

CONCLUSION

This study has described the determinants of current cataract surgical selection in a large teaching hospital. However, there is scope for improved concordance in referral criteria and selection. There is a need to expand the dataset to cover a wider spread of consultants working in different geographic locations in both teaching units and district hospital which tend to serve urban and rural populations respectively.

In addition, we have proposed a simplified yet flexible decision structure for cataract surgery designed to improve both equity of access to cataract surgery and increase the efficiency of the "cataract journey" by reducing false positive referrals from optometrist to hospital specialist. There is an opportunity to maximize further funding support by addressing this issue Scotland-wide in parallel with the Centre for Change and Innovation Programme for improving cataract services. With additional funding, we would aim to carry out a multisite study in Scotland to:

1. Test the decision model proposed,
2. Expand the dataset evaluation in second eye surgery,
3. Gather follow up data over a 2 year period.

ACKNOWLEDGMENT

The authors gratefully acknowledge the generous support of a BUPA Foundation Award, which funded the study, and to the Princess Alexandra Eye Pavilion consultants, nurses, and patients who made this study possible.

INTRODUCTION

Nowadays the world medical practice widely uses the method of extracorporeal shock wave lithotripsy for treatment of patients with urolithiasis bay means of pulverizing action of focused shock waves (FSW). In the early 1980s in Germany, the Dornier Medical Systems Company fabricated the first lithotriptor based on the electrohydraulic principle of shock wave generation. By 1988, practically all countries had applied lithotriptors developed by Dornier Medical Systems. Later, more than 15 countries started to fabricate their own lithotriptors, which use various methods of FSW generation, such as electrohydraulic, electromagnetic, and piezoelectric. These countries were Germany, USA, Russia, China, Italy, France, Israel, Turkey, Slovakia, Poland, Austria, Sweden, and so forth.

However, the given method of the physical effects can be used not only for the extracorporeal fragmentation of calculi. The biological effects of shock waves presume a perspective of their use for treatment and aftertreatment of the patients with other disorders and pathological conditions using their stimulatory and inhibitory actions.

BACKGROUND

The method of shock wave therapy (SWT) originates in the late 1980s and in the early 1990s. A number of investigations have proved that the influence of shock waves accelerates callus formation and fracture healing, faster healing of skin wounds, as well as intensifies the regenerative and reparative processes and stimulated metabolism in tissues and cells (Garilevich, Kudryavzev, & Dzeranov, 2003; Garilevich, Zakharov, Kudryavzev, & Kirpatovsky, 1997; Haupt, 1997; Valchanov & Michailov; Zubkov, Garilevich, & Olefir, 2005).

In 1988, SWT was for the first time successfully applied for treatment of fractures (Valchanov & Michailov). Thereafter, the method has been widely used in orthopedic and traumatic surgery and sports medicine. With accumulation of experience, the scope of application of this method has been gradually extended. So, its efficiency in treating Peyronie's disease, neuromuscular dysfunction in children with spastic cerebral paralysis (Siebert & Bush, 1997) has been proved. The investigations of the last years have exposed a perspective of cardiologic use of SWT at patients with ischemic heart disease (Nishida et al., 2004). The basic clinical effects of shock waves are: analgesic action, activation of microcirculation and neonangiogenesis, stimulation of the metabolic processes, resorption of healing connective tissue, anti-inflammatory, and antibacterial action (Garilevich, Kudryavzev et al., 2003; Garilevich, Zakharov et al., 1997; Gerdesmeyer et al., 2005; Haupt, 1997; Kudryavzev, Garilevich, Kirpatovsky, & Olefir, 2003; Mironov, Vasiljev, & Burmakova, 1999; Nishida et al., 2004; Zubkov, Garilevich, & Olefir, (2005).

Nowadays, there are a number of issues about the use of the inhibitory action of shock waves. The methods of cancer treatment through the influence upon them by ultrasonic waves of high intensity (U.S. Patent No. 3735755, 1975; U.S. Patent No. 4441486, 1986), and focused shock waves (W.O. Patent No. 86/05104, 1986) are well known. The cytotoxic action of shock waves upon cancer cells (Eisenberger & Miller, 1999; Kohri et al., 1990; Mastikhin, Nicolin, Teslenko et al., 1995) has been also described. The ability of FSW, besides the mechanical damage of cells, to break sulfide bonds and to form highly reactive free radicals makes possible the participation of the free radical mechanism in changing the membrane permeability of cells (Mastikhin et al., 1995).

However, these methods have a restricted application due to a high negative pressure of a shock wave impulse (SWI) provokes cavitation processes in the field of the diffusion of a wave beam that also damages healthy tissues and causes a decrease in the efficiency of tumor growth suppress.

Disadvantages of the known methods have been eliminated in the new offered method of treating malignant neoplasms based on a synchronous influence of SWI and pulsed electrical field of nano or microsecond range of duration (Andriyanov et al., 1999).

Nowadays, various firms produce equipment to be used for the treatment of patients with orthopedic disorders applying FSW. Disadvantages of the given equipment result from the fact that the parameters of SWI do not differ from those applied to the extracorporeal fragmentation of urinary calculi. That is to say, the focus of shock waves uses the pulverizing action of FSW, which is unacceptable for therapeutic influence upon internal body organs. Another disadvantage of the available equipment for SWT is that the diameter of the focus of a shock wave varies from 3 up to 12 mm that does not meet the size of the area of damage or pathological process and particularly organs' pathology. Thus, the available equipment does not essentially differ from lithotriptors, which are destined for extracorporeal lithotripsy, and hence, there is no essential difference either in cost or in maintenance charges.

NEW OPPORTUNITIES FOR THE METHOD OF SHOCK WAVE THERAPY

Experimental investigations in studying the biological action of shock waves upon organs and tissues have allowed establishing parameters of their stimulatory influence acting upon cell metabolism and reparative processes that has led to the development of a pilot sample of the shock wave device "Biostim" (Andriyanov, Yu.V., Garilevich, B.A., Cokhan, V.E., & Kudryavzev, Yu.V., 2000). Besides, the development of the lithotripter "Urat-P2" (Russia) has introduced modes of operation of the shock waves generator, which also have positive therapeutic effects. These devices use an electrohydraulic system for shock wave generation.

The first stage of the examination with regard to determining the parameters of stimulatory influence of shock waves has included experiments on animals. The influence of shock waves has been experimented upon the kidney at simulating acute and chronic pyelonephritis and wound surface.

The examination has found out that therapeutic action upon metabolic processes in tissues produces microsecond SWI varying from 3 up to 20 MPa in amplitude, and from 15^0 up to 60^0 in angulation of SWI front towards the time axis with a pulse duration at a half-height its amplitude varying from 0.6 up to 2.0 μsec. These processes are effective with pulse compression amplitude (i.e., positive phase of the pulse) less than 20 MPa and pulsing more than 500 pulses.

Experiments with a provoked skin wound have shown that the shock wave stimulation (SWS) made the wounds heal 5 to 7 days earlier than in the control group. Histological analysis of the healed wound has found out that the epidermis has been correctly formed having a normal position of the cell layers and well expressed dermal papillae. The control group of animals has shown a large area of the expansion of dense fibrous connective tissue, both in derma and in subcutaneous fatty tissues, as well as smaller integrity of smooth muscle fibers of derma.

Histological analysis of the kidney tissue after SWS has shown changes with evidence of metabolic processes activation. There has been present hyperemia of microcirculation blood vessels of the cortical and cerebral matter of the kidneys, mainly capillaries and arterioles. This specifies an increase in efficiency of extrarenal neurohumoral regulation of homeostasis due to the intensification of prostaglandin synthesis.

The experiments through simulation of acute pyelonephritis in animals have shown that 21 days after SWS the inflammatory infiltrates have been localized only in the submucous layer of the renal pelvis and have been of insignificant size. The control group of the experimental examination has shown massive leucocytic infiltrates present over the entire surface of the organ. The inflammatory processes have affected the cerebral substance by small peritubular infiltrates. Hence, a low-power shock wave influence acting upon the kidney at simulating acute pyelonephritis helps to reduce the inflammatory processes until their complete suppression. Besides, it has been found out that FSW with direct action upon microorganisms do not lead to the stimulation of their reproduction. On the contrary, the intensity of their reproduction reduces to a greater degree by direct influence of the focal area of a shock wave (Garilevich & Kudryavzev, 2003).

The experiment through simulation of chronic pyelonephritis (interstitial nephritis) and use of shock waves in a stimulation mode has proven that the kidney tissue has had a decrease in the amount of inflammatory infiltrates with prevailed macrophages and hystiocytes as well as activated fibroblasts in its cell structure. The amount of fibroblasts in the control group has been much lower. It has been found out that the sclerosis extent of the kidneys tissue in the control and experimental groups has been practically equal. Hence, low-power shock wave influence in case of chronic pyelonephritis has a sensible effect only on the suppress extent of the inflammatory reaction and does not have any essential action upon the extent of sclerotic changes in the kidney tissue (Kudryavzev, Garilevich, Kirpatovsky, & Olefir, 2003).

The results of the experimental examination of influence of microsecond electrical fields with amplitude varying between 1 and 7 kV/cm and shock waves with pressure up to 100 MPa upon permeability of the cell membranes of an ascitic tumor of mice in vitro have shown an intensification of the efficiency of irreparable pore formation under their synchronous action.

Under a simultaneous influence acting upon cell suspension of shock waves and electrical field of moderate intensity the survival rate of cells is 5 times less than under their nonsimultaneous action, and 10 times less in comparison with control parameters. Most sensitive to the influence of the investigated fields are cells in the phase of DNA synthesis, preparation for cell division, and in the phase of mitosis.

SWS of the area of a shinbones fracture (30 patients) has marked callus formation 9.6 ± 0.1 days earlier than in the group of patients where traditional methods of treatment have been used. In the experimental group of patients, the pain syndrome has been reduced 5 to 7 days in comparison with traditional methods of treatment. By the same term, the extent of movement in the contiguous joints has increased 10 to 15 degrees, and an improvement of regional blood flow has been marked. Stabilization of hemodynamics and microcirculation has promoted a restoration of the injured extremity function 8.7 ± 2.3 days earlier in 75% of the cases.

Taking into account positive results of the experimental and clinical examinations, we have used SWT method of therapy for treatment of the patients with chronic prostatitis (35 patients). SWT has been carried out using a lithotripter “Compact LGK” (Russia) with electromagnetic system of shock wave generation. The defocusing of shock waves has been constructively performed. The procedures were carried out every other day. A treatment course consisted of seven procedures. The control group included 15 patients who received a traditional physiotherapeutic treatment within a complex therapy.

All the patients of the experimental and control groups have shown a decrease in disease symptoms. In addition, the patients of the experimental group have felt a clinical improvement (inclusive according to the laboratory data) on the fifth day, on the average, while in the control group on the seventh day ($d<0.05$).

The control aftertreatment examination has statistically revealed a reliable improvement of uroflowmetry parameters that have been more expressed in the experimental group ($d<0.05$), as well as a decrease in disease symptoms evidence through a questionnaire survey using the NIH-CPSI scale ($d<0.05$).

Doppler color mapping has found a restoration of the symmetry of the prostate gland vascularization at 83.3% of the experimental group and at 80% of the control group. A transrectal ultrasonic examination in the grey scale mode has revealed a normalization of the prostate gland sonomorphology at 66.7% in the experimental group and at 60% in the control group. In addition, the most significant changes have been observed at the patients of the experimental group with fibrous changes in the prostate gland, who have shown after treatment a decrease in hyperechoic areas. The patients with dense calcifications have no improvement.

Thus, the preliminary results of use of SWT method on patients with chronic prostatitis have shown its efficiency that determines a perspective on the continuation of investigations. The best results can be obtained in the patients with fibrous changes in the prostate gland within lasting inflammatory processes, the treatment of which by traditional methods is insufficiently effective.

FUTURE TRENDS

Nowadays, there is a necessity to continue investigations oriented to the study of biological action of shock waves. It is necessary to optimize the parameters of shock waves, which can be used for extracorporeal fragmentation of calculi, stimulation of metabolic processes in organs and tissues, as well as for inhibitory action in case of malignant cell growth

With regard to extracorporeal shock wave lithotripsy, the problem has not been resolved by the present time, both concerning the quality of calculi fragmentation and injuring action of focused shock waves upon the kidney tissue. The achieved results of our investigations allow resolving this problem.

As regards the application of SWI stimulatory action, there is a factual opportunity to expand significantly the scope of application of the method in case of different diseases and pathological states.

The offered way to suppress tumors in the course of a complex treatment of patients with malignant neoplasms has prospects for development (Andriyanov et al., 1999).

The development and introduction in the clinical practice of a multibeam generator of shock waves (Andriyanov, Garilevich, Zotov, & Olefir, 2005) allow developing a multipurpose shock wave complex (for extracorporeal fragmentation of urinary and biliary calculi, shock wave stimulation of organs and tissues, as well as inhibitory action upon tumor cells).

CONCLUSION

On the basis of the data from articles and our own investigations, we have found that shock waves lead to an intensification of the reparative processes and metabolism stimulation in tissues and cells. SWT has found a wide application in orthopedic and traumatic surgery for treatment of patients with diseases of the locomotor system. It has been determined that the scope of application of the given method can be considerably extended, using stimulatory and inhibitory action of shock waves. Insufficient knowledge of biological action of shock waves upon organs and tissues and imperfection of the available equipment, which does not let shock wave pulses acting upon the internal organs, still impede.

The obtained theoretical, experimental, and clinical data allow continuing further investigations aiming at designing specialized equipment for SWT and expanding the scope of application of this perspective method.

KEY TERMS

Focus of the Shock Wave: Area with high-amplitude pressure up to 300 – 1000 atm.

Focused Shock Waves: Shock waves are focused by ellipse-formed reflector into definite area.

Metabolism Stimulation: The metabolism is improved on the level of organs and cells.

Shock Waves Parameters: Pressure amplitude and duration of positive and negative shock wave impulse phases.

Shock Wave Therapy: The application of shock waves' curative effect.

Reducing Patient Delays in a Day Surgery Unit of a Hospital

Victoria Hanna
University of Melbourne, Australia

Kannan Sethuraman
Melbourne Business School, Australia

INTRODUCTION

In this article, we illustrate the relevance of queuing theory principles to the healthcare sector through a case study of a day surgery unit in a hospital in Melbourne, Australia. The hospital has an acknowledged problem: patients are spending longer-than-anticipated periods of time in the day surgery unit, and they are facing excessive waiting times at all stages of their healthcare delivery process. The hospital is operated on a not-for-profit basis, and the executive board members are keen to understand the root causes of the problem, so they can direct their investment in the system to improve its responsiveness.

BACKGROUND

To reduce the time a patient spends waiting in the hospital system, a hospital needs to understand the implications of queuing and the theories that explain the causes and costs of congestion. Little's Law (Little, 1961) states that the average number of patients in a stable system (over some time interval) will equal the product of their average arrival rate and their average time in the system. In manufacturing situations, this law represents the critical link between the three key internal process performance measures: cycle time, work-in-progress (WIP) inventory, and manufacturing lead time (MLT).

- Cycle time characterizes the average time between completions of successive units. In the healthcare context, for instance, the cycle time could represent the average time between completions of successive procedures in a surgical unit.
- WIP inventory represents the number of units contained in the process at any given time. Patients-in-progress (PIP) will be the equivalent measure in the healthcare context, representing the number of patients who are currently being served, and who are waiting for service in the system.
- Manufacturing lead time stands for the total time a unit spends in the manufacturing process. In the healthcare context, the patient resident time (PRT) would be its equivalent. And it represents the total average time a patient spends in the hospital, from the time of his arrival, to his discharge time. This would include all the value-added time and the nonvalue-added time, such as waiting that the patient experiences in the system.

Using the average number of patients residing in the system at any given time, and the surgery throughput capability of the system, Little's Law helps us predict the average time a patient would reside in the system (PRT). In other words, the larger the number of patients waiting for treatment, the longer will be the wait for an arriving patient. An immediate implication of Little's Law is that, for a given level of throughput at any hospital, the only way to reduce the PRT is to reduce the number of patients in the system. For example, assuming patients arrive at the rate of 10 per hour, and stay an average of one hour. This means we should find the average number of patients in the system at any time to be 10. If the arrival rate rises to 20 per hour, the unit must either be prepared to host an average of 20 occupants, or must reduce the time each patient spends in the system to 0.5 hour. Naturally surgery cannot be sped up, so the unit must look to other components of the patients' stay to reduce their time in the system.

This relationship, however, is not obvious to hospital administrators or doctors. The system expects people to wait, and hence provides infrastructure to deal with patients waiting in the system, resulting in escalating costs and poor responsiveness. Long lead times are still accepted by patients, as they have no alternative. What the service providers are missing is an opportunity to simultaneously improve both patient responsiveness and cost effectiveness. Too many patients in the system can be costly in a number of ways. You need more room to hold them, more resources to engage them, monitor, and progress them through the system (hospital), and the excess number of patients in the system acts as a buffer, hiding the linkages between processes. It is critical to observe that the time spent delivering patient care should never be sped up (for example, time for anaesthesia to start working, treatment of wounds, recovery time, and so on), as it compromises quality of care to achieve responsiveness. The focus has to be on simultaneously achieving responsiveness and quality of care through the elimination or minimisation of nonvalue-added activities, such as waiting for service.

How Variability Increases the Time Patients Spend in the System

Variability robs a system of capacity. As a consequence, utilization is reduced, and this affects the time a patient spends in the system. The *Pollaczek-Khintchine* formula (Heyman & Sobel, 1982) provides the fundamental relationship between capacity utilization, variability, and inventory, and is represented by:

$$L = K \times \left(\frac{\rho}{1-\rho}\right) \times \left(V_a + V_s\right)$$

where K is a constant, ρ represents the capacity utilization, V_a characterizes the variability in arrivals, V_s characterizes the variability in the service process, and L stands for the queue length.

If patients undergoing treatment are a form of inventory (analogous to work in progress), the above relationship has important consequences for a hospital trying to reduce patient delays.

- In steady state, if a hospital system experiences higher levels of variability (either in the patient arrival process, or in the patient care delivery process, or both), it will essentially result in an increased patient queue length. From Little's Law, we can infer that increased patient queue length will lower responsiveness, or in other words, increase average patient resident time.
- In highly unpredictable environments (such as an emergency department), the patient queue length and the average patient resident time tend to increase exponentially with increased capacity utilization. If better information cannot be obtained to lower the level of variability in the patient arrival process, the system will need to operate at lower levels of utilization to achieve the target service levels. That is, they will need buffer capacity. Attempts to fully utilize capacity will result in extremely poor responsiveness—a situation unlikely to be acceptable to patients or healthcare providers.

Litvak and Long (2000) discuss how healthcare systems exhibit variability, and categorise them into three broad types: (i) *clinical variability,* which represents the differences in the patients' degree of illness, choice of treatment alternatives, and responses; (ii) *flow variability,* which captures the randomness in the arrival patterns of these patients; and (iii) *professional variability,* that describes the variability in the ability of the medical practitioners and healthcare delivery systems to provide treatment. The presence of clinical, flow, and professional variability results in a significant increase in complexity, and adds cost to healthcare systems. In addition to these natural variabilities, they also identify an artificial variability, which is an artefact of dysfunctional management and policies. They conclude that eliminating artificial variability in healthcare systems holds the maximum potential for reducing waste and improving responsiveness.

These theoretical underpinnings helped us to explain why the day surgery unit in our case was experiencing excessive wait times for its patients, and our analysis of the situation focused on the following:

1. **System design:** If the patient care delivery process is poorly designed (for example, redundant activities, activities occurring in sequence instead of in parallel, and so on), then the total time it takes for a patient to progress through the system will be longer than ideal.
2. **Waiting times at key stages of the process:** Even when a system is well designed, the wait times could be poor, due to constrained resources acting as bottlenecks. Since all systems exhibit some variation, queuing theory provides key insights

into why wait times deteriorate sharply in highly utilized systems.

3. **Variability:** Even well designed systems, without any limiting resources acting as bottlenecks, can still display poor responsiveness. This can be attributed to the level of variability in the system.

DATA COLLECTION

The case study of the day surgery unit was developed from direct observation of its processes, interviews with hospital staff, and review of secondary data. A total of 17 detailed interviews were carried out over a period of six weeks. The interviewees included the doctors, anaesthetists, nurses, technicians, middle managers, and the hospital executive team. Secondary data sources included a survey of surgeon satisfaction with the facilities, a survey of patient satisfaction focusing on the patient's experience at the day surgery unit and the extent to which it met their expectations (both of these surveys were deployed by hospital staff immediately prior to the involvement of the authors), internal project reports describing improvement activities undertaken in the previous five years, key performance indicator results, value and mission statements, and published material targeted at patients.

THE CASE

The day surgery unit handles only elective surgeries, and annually processes about 10,000 overnight admissions and 7,400 day surgeries. They offer a range of specialties, including orthopaedics, neurosurgery, urology, plastics, breast surgery, and dental surgery. The hospital provides facilities, equipment, and nursing staff. The hospital facilities consist of nine operating rooms (OR) with state-of-the-art equipment, and hospital wards for in-patients. OR equipment may either be owned by the hospital or be procured from outside on a loan/hire basis. The equipment that is owned by the hospital will usually be shared across theatres. Regulatory requirements specify threshold levels for nurse-patient ratios, and inability to provide adequate number of qualified nurses to meet the ratio requirements can result in "unused" beds and consequent underutilization of available capacity.

Scheduling Surgeries

Prior to interacting with the hospital, the patient will consult with his or her primary care physician. Upon receiving a referral from the general practitioner to visit a medical specialist, the patient will be assessed by the specialist. Once the need for surgery is established, the patient's name will be added to the surgeon's list of patients requiring surgery/hospitalization. Typically, specialist doctors have privileges at several hospitals in the area, and the choice of hospital for surgery is determined by a number of factors that include cost, patient preference, case complexity, wait involved, facilities, and other services provided by the hospital. The case hospital competes on location, range of services offered, and its reputation for quality and patient care. It is not uncommon for elective surgeries to be scheduled several weeks (even a few months) in advance. The day surgery unit receives information of surgeon lists as late as 24 hours prior to surgery. The surgeon's operating list is dynamic, with additions possible just a few hours ahead of surgery session start time. The hospital is expected to be responsive, and be able to provide the requisite support of staff, equipment, and supplies.

Similar to other hospitals, manually derived annual theatre plans form the basis of the hospital's resource allocation. The theatre plan involves assignment of theatre sessions to consultant surgeons, and essentially defines the demand for hospital's services. A half-day slot is considered the basic unit for this purpose, and surgeons expect hospitals to provide complete flexibility in organizing the activities within their sessions. The assignment of a theatre session to a surgeon commits the hospital for providing the necessary staff and equipment for surgery and postoperative care, and hence, the hospital workload is a direct consequence of the theatre plan.

Typical Patient Flow

When the patient arrives, they first go to the hospital reception. At this stage, they hand over any test results or medical notes they have brought with them, and complete the necessary information regarding private health insurance. They will also be advised of any additional payment necessary. Patients are seen on a first-come first-serve basis, rather than in the order their name appears on the surgeon's list. All of the patients

R

having surgery in the morning session (across all of the nine ORs) are requested to arrive between 6:45 and 7 a.m. There can be between 30–50 people attempting to access the reception desk at this time. Once the business office (behind reception) has completed all the necessary paperwork, the patient proceeds to the Surgical Admission Unit (SAU) reception. At the SAU reception, the patient's medical records are checked again, and any discrepancies are followed up. The patient is requested to change their clothes and proceed to the SAU waiting room. Most patients are accompanied by family members, and there is a small waiting room area adjoining SAU where they can stay. Unless they are accompanying a child, the visitors are not permitted to enter the SAU.

All patients are required to complete nurse education before being transferred to OR, and the majority of cases also require preoperative assessments by their respective anaesthetists. Nurse education involves meeting with one of the SAU nurses who will explain how the day will proceed. This could be done at the same time as admission, but when there are large numbers of patients waiting, it is often delayed to a later stage. Due to the congestion in SAU, these meetings occur on an ad hoc basis. Both anaesthetists and nurses can be observed searching for their patients, trying to ensure the first patients on the surgeons' lists are ready to enter OR on time. The anaesthetists are under even more time duress, because they want to see all their patients in a given session before surgery commences on the first patient. The reason for this practice is that the anaesthetists want to be physically present in the theatre for the complete duration of surgery, and they are also under pressure from surgeons to ensure fast turnaround between surgical cases. Another contributing factor is the physical layout of the theatres, which are not in proximity to the preoperative assessment rooms.

Once the surgery is complete, the patient is transferred to a recovery ward. Once fully recovered, he walks back to SAU and gets dressed. If no further payment is required, he is then discharged via SAU. If additional payment is required, he is directed back to the hospital reception, whereupon he will make final payment to the hospital, and is discharged by the business office.

The patients for the afternoon session all arrive between 10:30 a.m. and 11 a.m., repeating the chaos of the morning. Table 1 illustrates how long patients are waiting at various stages of their day. Some patients move rapidly through the system, but others can spend long periods of time waiting to enter both the SAU and the OR. On an average, a patient resides more than six hours in the system, where the actual value-added time is less than an hour in duration.

DISCUSSION

Through a detailed examination of the patient flow, several factors that contribute to delays were identified, and are presented in Table 2.

PROPOSED ACTIONS

The researchers, executive board, surgeons, anaesthetists, and nurses brainstormed various approaches that may help the situation and solve the problems identified in Table 2. Based on these discussions, the

Table 1. Typical patient wait times for day surgery cases

Description	Min Time (minutes)	Max Time (minutes)	Average (minutes)
Patient waiting at reception	1	54	13
Patient waiting for admission into the Surgical Unit	1	154	25
Pre-operative interview with anesthetists	1	18	4
Surgery duration	10	180	30
Time from entering SAU to entering OR	11	273	128
Total time in system	64	584	374

following priorities were developed for the hospital to focus on.

System Design

It was decided that it was not possible to make any changes to the physical design of the system, but was possible to modify how patients interacted with the system on arrival. It was agreed that when patients arrived at the hospital reception, their details would be noted, and they would be immediately asked to take a seat, rather than be admitted. The admittance procedures would be managed by calling patients in order of their position on the surgical list. The reception staff was briefed on the new protocol, and posters were put up to advise patients that they would not necessarily be called to the office in order of their arrival. The aim of this proposal was to reduce the number of times commencement of surgery was delayed, because the first patient on the list was not ready.

The second change focused on moderating the volume of patients in the system. Staged admission with risk stratification was proposed as a method to eliminate bulky arrivals. The major contributor to long patient lead time was the requirement by anaesthetists and surgeons for all patients in a given session to arrive at the same time. A staged admission process with risk stratification where patients did not arrive en masse was proposed. The practice is already established at several public hospitals. It requires the provision of complete patient information at the time of scheduling a surgery. In this scheme, patients are typically stratified into risk categories (low, high, very high) on the basis of institutional practices and management guidelines and known risk factors. All high-risk patients will be required to arrive at the hospital at the start of the day to ensure appropriate evaluation can be conducted prior to the start of their surgical procedures. This proposal is aimed at lowering the peak load of patient arrivals, and thereby reducing the pressure on resources, and considerably reducing the wait patient's experience.

Reducing Artificial Variability

The hospital also recognised the need to minimize all dysfunctional management practices that artificially escalate the impact of existing normal variability. This will require better information exchanges between doctors and hospital staff, as well as improved coordination across all stages within the hospital. Sharing accurate, real-time patient information to all parties would also aid in lowering uncertainty. Basic protocols for updating and transferring information were proposed, and responsibility for ensuring the consistent execution of these protocols was incorporated in the role of the unit's nurse-manager.

Table 2. Leading factors contributing to the poor performance of the day surgery unit

System Design	*Bulky arrivals*	The large numbers of patients arriving at once leads to bottlenecks, both at admission, and preoperative assessment.
	Physical design of facilities	The size of the unit does not accommodate the volume of patients being processed at the beginning of each theatre session. In addition, the ORs are separated by geographical distance, and insufficient time is given for the transfer and preparation of shared resources between theatres.
Waiting Times	*Resource bottlenecks*	Insufficient capacity of ward beds, recovery area, orderlies, and so on can result in blockage and starving of ORs. For example, if the recovery ward is full, the ORs cannot release their patients, and delays start to build.
Variability	*Lack of coordination and information sharing*	Missing information/test results, insufficient advance planning, due to lack of information and lack of prioritization, all lead to delays in patient flow. Information is updated in a decentralised manner, causing inconsistencies and duplication of effort. Data is also not updated in a dynamic fashion to reflect accurate information.

OUTCOMES

These simple changes to administrative procedures were helpful, and had an immediate impact. The staged admissions process was piloted with one surgeon and associated anaesthetists with positive results. The board was pleased with the improved performance, and has committed to examining all processes, not just those inside the day surgery unit, and has engaged outside consultants to coach the employees through a large-scale evaluation of their systems.

CONCLUDING REMARKS AND FUTURE TRENDS

This research has broader implications for strategic decision making and improved alignment between hospital priorities and their operational policies. Drawing on the insights of Lovejoy (1998) who noted the substitutability of inventory, capacity, and information (information acts as a surrogate for variability), to achieve a given service level, a hospital can achieve their desired responsiveness (expressed in terms of acceptable wait times for treatment) in one of two ways: (i) it could either hold surplus capacity when it is unacceptable to keep patients waiting or it is difficult to predict the arrival of patients or their needs, or (ii) it could invest in collecting enough in-depth and real-time data that would aid in lowering the variability in demand/services, and thereby using its available capacity more effectively without undue wait for its patients. Alternatively, they could relax the responsiveness requirement if the patients in their focused segment are not particularly time-sensitive, and are willing to wait for their treatment. In this situation, the hospital can continue to operate with high-capacity utilization and higher levels of variability in its demand/services.

The case also highlights how artificial variability adds complexity and costs to the healthcare system, and in the absence of perfect coordination and exchange of information between the various links in the healthcare value chain, the hospitals are forced to keep surplus capacity to be able to provide flexible and responsive services to their surgeons, resulting in higher costs. Also, the patients spend a much longer time in the system when there are capacity constraints within the system. It is essential hospitals understand the trade-offs that exist between (i) buffer capacity, (ii) collecting good quality information to lower variability in demand, (iii) standardisation of processes to lower variability in service provision, and (iv) patient resident time.

Through this article, we have also shown that operations management principles such as queuing theory, originating in the manufacturing sector, have far reaching implications for the healthcare sector. However, to make this application more readily acceptable to the healthcare audience, it is critical to translate the core components of operations management principles into a form that directly applies to this context. For example, if a hospital plans to use lean principles to lower the level of waste in their system, it would be first necessary to characterize what constitutes waste in a healthcare context. A taxonomy of waste as it applies to this sector would enable both healthcare practitioners and managers to better direct their efforts at targeting waste and improving the patient experience.

KEY TERMS

Artificial Variability: The direct result of the poor management of the processes used to provide care. This type of variability (dysfunctional management and policies) can be reduced through improved operational policies and system design.

Natural Variability: A source of great waste in the health care delivery system is excessive variability in the processes used to provide care. Natural variability is largely outside the control of a hospital, and it includes "clinical" variability (patients differ in the type and severity of their diseases, and patients with similar ailments respond differently to treatment), “patient demand” variability (patients arrive for treatment randomly over time), and “professional” variability (different surgeons treat similar patients in different ways), which has given rise to the development of approaches like practice guidelines and clinical pathways.

Patient Resident Time (PRT): The amount of time a patient spends in the healthcare system, typically measured from the moment they enter the system, until the time of their medical discharge.

R

Reforming Nursing with Information Systems and Technology

Chon Abraham
College of William and Mary, USA

INTRODUCTION

Much of healthcare improvement via technology initiatives addresses gaining physician by-in (Reinertsen, Pugh & Bisognano, 2005) and does not adequately address engaging nurses, despite the fact that nurses serve as the front-line caregivers and are a primary user group (Wiley-Patton & Malloy, 2004). However, the tide is changing, and visibility of nurses as information gatherers and processors in the patient care process is increasing (Romano, 2006). Nurses perform the majority of the data-oriented tasks involved in patient care and would benefit most from having access to information at the point of care (Bove, 2006). RADM Romano, Chief Professional Officer of Nursing and advisor to the U.S. Surgeon General concerning public health, recently addressed the American Informatics Nursing Informatics Association and stated, "This is the year of the nurse. The technologies that have the means to improve the efficiencies in patient care are in the hands of the nurses." Nurses need to embrace technology in everyday work or continue suffering the consequences of antiquated methods of computing that take us away from where we work—at the point of care (Abbott, 2006).

Healthcare can benefit greatly from use of a diverse set of technologies as facilitators of change to improve quality and safety of patient care by decreasing errors made because of the lack of faster, more comprehensive, and more accessible patient documentation at the point of care (IOM, 2000). Healthcare institutions abroad share similar sentiments according to international healthcare reports by the International Council of Nurses (Buchan & Calman, 2004). In light of these concerns and a severe U.S. nursing shortage (i.e., an estimated 400,000 shortage by 2020) (Bass, 2002), institutions are beginning to consider employing point-of-care IT as a means to promote patient safety, decrease medical errors, and improve working conditions for overtaxed nurses (TelecomWeb, 2005). This chapter provides an overview of nursing reform and novel ubiquitous computing integrating voice, hands-free, and mobile devices being researched or used to make nursing more efficient and promote the following:

- A decrease in laborious documentation aspects (i.e., decrease problems with access to information at the point of care, written errors or legibility issues precluding comprehension of medical regimens).
- An increase in recruitment and retention rates.
- Improvement in communication in which nurses are required to consolidate and process information during care.
- Promotion of involvement in systems analysis and design of information systems to increase the likelihood of technology acceptance.
- Baseline and continuing education in both professional training and on-the-job training to allay technology aversion and build computer self-efficacy.
- Development of standards for electronic documentation of patient interaction and processes for nursing that can be codified.
- Identification of role changes in the nursing community because of the use of information systems and technologies.
- More rigorous research concerning information research in the nursing community.

BACKGROUND

This chapter provides an overview of tactics to reform nursing sponsored by leading nursing healthcare information systems research in professional organizations such as the American Nurses Informatics Association (ANIA), Association of Medical Informatics (AMIA), and the International Council on Nursing (ICN).

The sociotechnical systems framework (STS) (Bostrom & Heinen, 1977) will be employed to categorize tasks, technologies, people involved, roles, and structure of aspects of the reform. STS emphasizes workplace interactions with various technologies and is espoused as a realistic view of organizations and a way to change them (Bostrom & Heinen, 1977). STS concerns the social system that is comprised of contributions of people (i.e., attitudes, skills, and values), the relationships among people and their roles in the organization, reward systems, and authority structures (Bostrom & Heinen, 1977). STS is also an intervention strategy in which technology implementations intervene within a work system to improve task accomplishment, productivity, and work quality of life, and to prompt supportive organizational structural changes. Innovative technologies may improve task efficiency and task effectiveness by automating or reengineering antiquated/manual processes, changing people's roles, and making organizational structures (Bostrom & Heinen, 1977). A graphical depiction of STS is displayed in Figure 1.

DESCRIBING NURSING REFORM USING AN STS FRAMEWORK

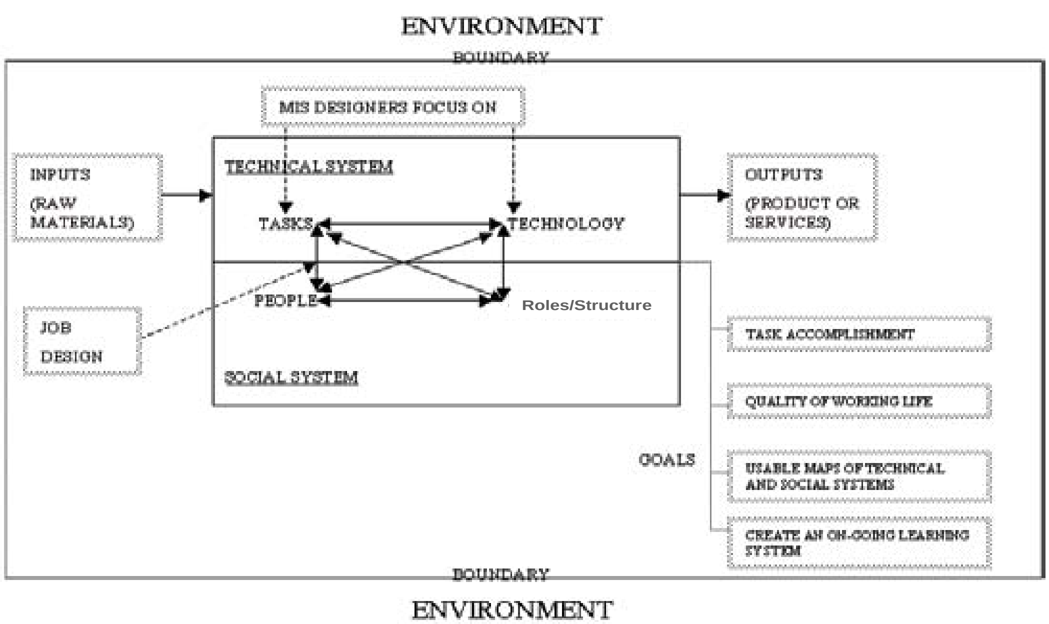
STS is used as a frame to describe elements addressed in the nursing reform initiative, such as tasks, technology, people involved, changes in roles, and structure in conjunction with their interplay, outputs, and goals.

Task

The tasks in this reform are indicative of the pervasive problems plaguing nursing and healthcare in general. There is a critical nursing shortage crisis in the United States alone in which more than 90,000 nursing position vacancies were reported in 2004, and nearly 400,000 are expected by 2020, which has grave impacts on quality of care (JCAHO, 2004). Similar statistics reported by the International Council of Nursing (ICN) also highlights the great supply and demand disparities. Much of this is attributed to the problems recruiting new nurses and retaining seasoned ones. Nursing is an aging workforce in which the following is reported:

- One in five registered nurses plan to leave the profession.
- 81% say morale is extremely low.
- 64% do not have enough time to spend with the patient.
- 60% note the manual paperwork burden to document information about patient care tasks is "a necessary evil."

Figure 1. STS (Bostrom & Heinen, 1977)



The last percentage indicates the manual paperwork burden, which is one problem that can be directly addressed via application of novel information systems (IS) and information technology (IT). Information-oriented patient care tasks for which nurses are primarily responsible entail the following:

- **Triage:** The process of taking vital statistics, documenting impending problems, and making initial assessments to categorize criticality of the emergent condition.
- **Charting:** The process of monitoring the patient and recording vital statistics, effectiveness of medical intervention, and overall patient wellness, which is an ongoing process across nurse shifts.
- **Throughput flow:** The process of managing when, where, and how patients are moved about in a patient care system across units within the hospital for labs, procedures, and so forth.
- **Medication administration:** The process of validating medication regimens with prescriptions, delivering the medication, and documenting the effectiveness.

Virtually 98,000 people die each year due to medical errors in hospitals (Institute of Medicine, 2000), and many of these are likely due to antiquated methods of information management and delivery during these fundamental patient care tasks. These errors can also be attributed to the inability of personnel relying on the information documented by nurses during these tasks to actually access it in a timely fashion. In essence, not having access to pertinent information when and where needed cripples the abilities of healthcare professionals such as nurses from validating medical information and diagnosing properly. So the primary task for reform becomes automating manual charting and equipping nurses, who are highly mobile in their work environment and move from patient to patient, with devices that enable easy and unobtrusive means of accessing and documenting needed information during patient care.

Technology

The reform in this industry recognizes that the paperwork burden is one where technology can be used as a facilitator of change or as part of the intervention strategy to promote change. Therefore, the goal is to promote productivity in which nurses are able to decrease errors associated with manual charting and reduce charting time via easy non-time-consuming data input and output capabilities. These improvements enable a nurse to spend more time with patients, which is a stated desire among nurses (Abraham, Watson, Boudreau & Goodhue, 2004). AMIA and ANIA encourage partnerships among vendors, academic researchers, and nurses in practice to discern technologies that are vehicles for promoting their workflow efficiencies. Table 1 provides an overview of these technology categories.

One aspect of technology that is specific to the healthcare industry and not akin to the average mobile business environment is the need to protect patients and caregivers from the transfer of infectious diseases or bacteria introduced by mobile devices. The typical mobile device is assigned to one nurse who carries it throughout his or her shift. Therefore, the nurse uses the same device/technologies across every medical intervention in which the likelihood of bacterial transfer is high. Thus, antimicrobial protective coatings or materials on healthcare mobile devices are of utmost importance in order to avoid transfer of bacteria from one patient environment to another, or from one nurse to another as the devices turn over during a shift change.

People

Nursing in general is a highly caring and nurturing profession (Patistea, 1999). Nurses have chosen their profession based on their individual desires to care for others and promote the sanctity of human life. Nurses, for example, who are satisfied in their jobs are characterized by high levels of affective empathy (i.e., the ability to be moved by other people's feelings) and service-mindedness (i.e., a strong tendency to let other people be central and dominant) (Sand, 2003). In addition, they display a high degree of sensitivity to nonverbal communication and a strong need for affirmation, support, and dominance (Sand, 2003). The traits prioritize patient care tasks for servicing nurses. For example if a patient is exhibiting physiological problems associated with anxiety or is in pain, the primary task becomes physical care of the patient. Additionally, since nurses do display a strong need for affirmation from their patients, peers, and superiors, the technologies need not interfere with the desire to

Table 1. Technology overview

Technology Category	Task Orientation	Purpose	Advantage
Bio-medical device integration 	Triage and Charting	Automatically capture patient vital statistics and other physiological metrics that otherwise would be taken manually such as blood pressure, oxygen level, etc through multiple point-of-care devices and provide data in a format that is easily integrated into the electronic medical record.	Decreases likelihood of human error or misreadings. Since the devices can be set to periodically take the measurements, they decrease the time required for scheduling to come back to the patient to take the measurements (i.e., promotes efficient use of personnel time).
Internal Communication 	Charting	Simplify staff assignments as for staff turnover intermittently during shift changes, provide internal communication that displays staff contact information, streamline patient bed turnover to notify housekeeping automatically.	Decrease administrative burden of assigning nurses to patients and provide access to nurses while on duty so that they can be more responsive.
Intra-hospital Patient Transport 	Throughput Flow	Provide a means to prioritize and schedule transport of patients with instructions and provides access to patient location information (i.e., the unit and time allocation for patients allotted transport time).	Eliminates the need for dedicated transport dispatch personnel, eliminates manual creation of transport schedules, enables on-time pick-ups to promote throughput flow efficiency.
Medication Administration 	Medication Administration	Provide access to patient medication regimen prescribed by the physician and validated by the pharmacist via a mobile medication workstation. Workstation is equipped with temperature controlled drawers, separated baskets to store medications in transport to the point of care and barcode scanners to scan medication labels and patient ID bands to automatically validate data with the patient medication information. Ensures that correct meds are being giving to the correct patient.	Decreases likelihood of errors in administering incorrect medications or dosages because of automatic validations and ability to have access to real-time information to be aware of medication changes. Saves time by eliminating the need to create meds list at the beginning of each meds pass that are not real-time . These static manually created lists lead to error if medications change unbeknownst to the administering nurse. Storage capacity minimizes the need for nurses to make multiple trips to the medication cabinet to obtain meds during the meds pass because the nurse can load virtually all meds needed in the medication workstation compartment at one time. Decreases the likelihood of spoilage or misplacement of medications because they are held in a temperature controlled compartments for each patients' mix of meds.

Table 1. continued

Technology Category	Task Orientation	Purpose	Advantage
Mobile Computing 	Triage and Charting	Provide access to medical information systems via untethered computers mounted on mobile workstations that nurses can maneuver with them as they move from patient to patient. Most likely a single workstation is provided to each nurse on shift who is servicing patients.	Allays problems associated with having to record information on a manual chart or rely on memory until the nurse can locate a computer to electronically document.
Wearable Technologies 	Triage and Charting	Less obtrusive technology geared for mobile workers via multimodal user interfaces for which the information system is operated via text, speech, touch, and gesture.	Keeps hands free to work with patients, enables easier maneuverability within workspace.

establish mutual trust with the patient and the need for nurses to exhibit confidence in use of the technology, especially in the presence of the patient.

The clinical nursing population can be divided into two demographics: A and B. Demographic A is an average age of 40, has work experience of 15 or more years, lacks professional computer training that is a systemic problem recognized by servicing IS personnel and nursing managers (Bass, 2002), and has low computer self-efficacy (Abraham et al., 2004). Demographic B is characterized by an average age of 25, has less than seven years experience, was trained under a "new" regimen that introduced him or her to PC-based documentation, and exhibits medium to high computer self-efficacy (Abraham et al., 2004). Both demographics use traditional PCs for other tasks, such as monitoring vital statistics or maintaining an apparatus for intravenous drug administration. However, information systems for electronic charting or mobile devices that provide access to these information systems are revered initially as foreign to this population (Abraham, forthcoming). The majority of nurses in Demographic A do not type effectively but regard narrative oriented data entry as problematic (Abraham et al., forthcoming). Additionally, the personality traits of nurses influence how they accept and use technology (Abraham et al., 2004).

In essence, intended utilization for mobile technologies is for the nurse to use at the point of care and, most likely, in the presence of the patient. Therefore, the technology should not impede nurses from being able to maintain eye contact nor interfere with the interaction with their patients. Additionally, healthcare workplaces are very tumultuous, hectic, and characterized by a great deal of uncertainty, which contributes to stressful work environments. Thus, the technologies need to be designed in a manner that are easy enough not to excite anxiety among the nurse user group that causes nurses to fumble with the technology, display a lack of confidence, or inhibit nurse/patient interaction (e.g., having to pay more attention to the computer because of ill-designed interfaces) (Abraham, forthcoming). Nurses feel that their lack of confidence concerning operating the technology is interpreted by patients as incompetence not only with the technology but with performing their required patient care tasks (Abraham et al., 2004). Not only does the technology need to support the way nurses work, but it also needs to support the way nurses think about servicing their patients. Also, adequate computer training, including how to most appropriately use the mobile technologies as vehicles to support the patient/nurse relationship, is of utmost importance.

Physical care of the patient will always overcome the need to document the intervention until the hands-on care has been performed. However, providing nurses with easy unobtrusive access to medical information when and where needed enables nurses to make better well-informed decisions.

Interplay Between Task, Technology, and People in Healthcare Environments

Mobile technologies make new dimensions salient that are driving novel interplay between the task, technology, and people in healthcare environments. For example, traits of the nurse concerning the need to attain affirmation or appear competent in front of the patient while operating the technology is novel since prior to mobile computing the act of operating the computer most likely was done away from the point of care (i.e., at the nurses' station). When computing using technologies that were tethered, nurses were less likely to exhibit as much anxiety about using the system in front of the patient (Abraham, forthcoming). The interplay among task, technology, and people in healthcare environments has become more pronounced because of changes in computing methods that enable access to information when and where needed via wireless technologies.

Nursing reform addresses initiatives in the development of technologies not only to better support the way nurses actually work, but also to develop information systems based on a unified nursing language known as the International Classification for Nursing Practice (ICNP). It is an arduous task to implement compositional terminology for the nursing practice since nurses affectionately note that each individual "nurses" differently (i.e., they label common patient care functions differently) (ICN, 2006). The goal of the ICNP is to provide a global infrastructure informing healthcare practice and policy to improve patient care via codifying and retaining tacit, experiential knowledge to inform the practice and promote easier cross-training, especially in light of the aging nurse workforce and the problems with recruitment and retention (ICN, 2006). In light of these globally recognized nursing shortages, persons with either formalized nursing training or interest in the field from foreign countries have been recruited and trained to fill many vacant positions (Bass, 2002). ICNP hopes to streamline the learning curve in order for these foreign nurses to become acclimated to the nursing profession.

Additionally, as people relocate, which is increasingly the case, their patient information should move or be automatically accessible despite the physical location of the patient (Council on Systemic Interoperability, 2006). However, the limiting factor is the lack of systemic interoperability within the United States and globally to make this idea a reality. ICNP focus is to ensure that at least care providers speak a common language, which is documented in the patient's medical record that patients transport when they relocate or acquire services from a multitude of different healthcare providers. Therefore, ICNP and systemic interoperability projects are addressing the interplay between fulfilling the task with suitable information systems and technologies to support the people who are both task doers and task recipients in this field in order to promote better quality of care—the ultimate goal.

Roles and Structure

These novel technologies and initiatives in improving the communication among nurses and about what they actually provide as value-added effort helps to better define and highlight the crucial role of nurses. By virtue of these technologies being placed in the hands of nurses, it is indicative of the technology being a facilitator of change to realize the role of the nurse as instrumental to the patient care process since they do perform the bulk of documentation for any medical intervention. Contributing to realization of the criticality of their role is the nurse's ability to recognize in an easier and more timely fashion the potential errors in the prescribed regimen, such as medication prescriptions that may have been prescribed erroneously or entered into the system mistakenly by a physician but validated by the pharmacist. In this sense, having access to IT and IS empowers nurses to at least bring to light problems they discern regarding the prescribed regimen for a patient. Typically, nurses that are assigned to in-hospital patients interface with their patients more frequently than any other medical personnel; they are very familiar with their patient's regimen and have the astuteness to recognize when there may be a potential error in the prescribed regimen. For example, the servicing nurse may discern allergic reactions to the prescribed medication or an ineffectiveness of the medication requiring a physician's order to be clarified or modified. Having access to information coupled with efficient means of communicating with other servicing medical personnel such as a patient's physician allows the nurse to discern the validity of the regimen or prescription in question. In essence, having access to information when and where needed and having the ability to communicate effectively because of the aforesaid novel technologies enables the nurse to appear more competent and thus gain more respect for his or her level of knowledge and critical role in the ability of the patient to be serviced properly.

As far as structural impacts, nurses contend that they have been somewhat neglected and overlooked as principal components in the care process, which contributes to poor morale and self-efficacy issues (Abraham et al., 2004; Bass, 2002). This role of the nurse as being critical in patient throughput needs to be adequately articulated to the population, management, and associated physicians (Abraham et al., 2004). With the dire status of the industry and the grave projections of the impact on patient care, more and more health-care organization administrators recognize the need to establish a vision of change for nurses, articulate how they fit into the care process, and explain why it is important for nurses to accept the technologies that enable efficiencies. Bringing physicians into the fold to internalize and articulate this message will also undoubtedly promote acceptance of the technology among the nursing population since they have a strong need for external affirmation. The vision needs to manifest into useful but nonobtrusive IT and IS training for nurses in order to improve computer self-efficacy and increase the likelihood that the technology will be used as intended to produce desired efficiencies. Nurses commented that the majority of the physicians they work with do not appreciate their services, which contribute to the nurses rejecting many technologies that management presents to them because they feel that the technologies are being thrust upon them in an effort to make the physicians' jobs less demanding and not for improving nursing work conditions (Abraham et al., 2004). The technology can be the main facilitator to empower nurses as the principal information managers in patient care. One area of future research is to explore more thoroughly how technology is facilitating a change in the authoritative structure between physicians and nurses. The hope is for physicians to see nurses as more competent and capable because of the ability to more readily address questions of them made possible with the use of IT and IS (Abraham et al., 2004).

FUTURE TRENDS

A future trend is the exploration of nursing decision support systems comparable to those developed for physicians, but with a focus on nursing-related patient care tasks that have elements of diagnoses. Another area for future research is the incorporation of project management skills and facilitating IS and IT into nursing curricula in order to aid nurse managers and clinical nurses with a means for balancing patient loads with fewer nurse resources.

CONCLUSION

The primary contribution of this chapter is to promote visibility of the needs of the nursing community regarding electronic information exchange, manipulation, and management that can be addressed in healthcare information systems research. Typically, IS research focus groups are geared toward physicians; however, nurses are responsible for the bulk of documentation for each medical intervention in each step of the patient care system. Physicians rely heavily on the information supplied by nurses concerning the historical documentation of charting patients' ailments, effectiveness of prescribed regimens, and anomalies in their condition (Abraham et al., 2004). Focus has been placed on using technology to streamline processes and automate as much as possible to avoid human documentation error. However, healthcare IS research has frequently underexplored nurses or not recognized them as the principal personnel who supply the information to the system, whether the system is manual or automated. IS researchers can help to uncover nuances in the nature of nursing and design IT and IS to better support the way nurses work in hopes of helping our society achieve its goal of improving the quality of patient care.

KEY TERMS

Charting: The process of monitoring the patient and recording vital statistics, effectiveness of medical intervention, and overall patient wellness, an ongoing process across nursing shifts.

Electronic Medical or Health Records: Electronic version of the manual chart that outlines historical medical information pertaining to one individual.

Medication Administration: The process of validating medication regimens with prescriptions, delivering the medication, and documenting the effectiveness.

Mobile or Wireless Computing: The use of mobile, untethered devices to access information stored in information systems or communicate via wireless networks.

Nursing: Encompasses autonomous and collaborative care of individuals of all ages, families, groups, and communities, sick or well and in all settings. Nursing includes the promotion of health, prevention of illness, and the care of ill, disabled, and dying people. Advocacy, promotion of a safe environment, research, participation in shaping health policies and patient and health systems management, and education are also key nursing roles.

Systemic Interoperability: Comprehensive network of privacy-protected systems of electronic personal health information developed around the healthcare consumer to facilitate wellness and the safe delivery of optimal healthcare.

Throughput Flow: The process of managing when, where, and how patients are moved about in the patient care system across units within the hospital for labs, procedures, and so forth.

Triage: The process of taking vital statistics, documenting impending problems, and making initial assessments to categorize criticality of the emergent condition.

Regularity Analysis of the Magnetoencephalogram Background Activity in Alzheimer's Disease Patients Using Auto Mutual Information

INTRODUCTION

Alzheimer's disease (AD) is the most common form of dementia (Bird, 2001), a group of conditions that gradually destroys brain cells and leads to progressive decline in mental function. This irreversible brain disorder is characterized by neuronal loss and the appearance of neuritic plaques containing amyloid-β-peptide and neurofibrillary tangles (Cummings, Pike, Shankle, & Cotman, 1996). Approximately 50–60% of patients with dementia over 65 years are clinically related to AD and the number of patients is expected to increase continuously (Lahiri, Farlow, Greig, & Sambamurti, 2002). A differential diagnosis with other types of dementia and with major depression is used. It can include Mini-Mental Statues Examination (MMSE) (Folstein, Folstein, & McHugh, 1975), magnetic resonance imaging, computerized axial tomography, positron emission tomography, and verbal tests. Nevertheless, a definite diagnosis of AD is only possible by necropsy. In order to complete the diagnosis, nonlinear analysis of the brain recordings might be used.

Magnetoencephalograpy (MEG) is a noninvasive technique that allows recording the magnetic fields produced by brain activity. SQUID (Superconducting QUantum Interference Device) sensors immersed in liquid helium at 4.2 K are used to detect the extremely weak brain magnetic signals. MEG provides an excellent temporal resolution, orders of magnitude better than in other methods for measuring cerebral activity, as magnetic resonance imaging, single-photon-emission computed tomography and positron-emission tomography (Hämäläinen, Hari, Ilmoniemi, Knuutila, & Lounasmaa, 1993). A good spatial resolution is also provided, although this depends on the source configuration (Hari & Forss, 1999). Moreover, this technique is independent of any reference point. In addition, magnetic fields are not distorted by the resistive properties of the skull (Hämäläinen et al., 1993). Nevertheless, the recordings are very sensitive to external artifacts. Thus, the signals must be acquired in a magnetically shielded room.

In this preliminary study, we examined the MEG background activity in patients with probable AD, and in age-matched control subjects using auto mutual information (AMI). Our purpose is to test the hypothesis that an abnormal type of nonlinear dynamics is associated with AD.

BACKGROUND

In the last years, brain activity of AD patients has been analyzed with several nonlinear methods. The most widely used are the correlation dimension (D_2) and the first Lyapunov exponent (L_1). D_2 is a measure of the system dimensional complexity (Grassberger & Procaccia, 1893a, 1893b) while L_1 is a dynamic complexity measure that describes the divergence of trajectories starting at nearby initial states (Jeong, 2004). Jeong, Kim, and Han (1998) showed that AD patients' EEGs exhibit significantly lower D_2 and L_1 than the EEGs of control subjects in many channels. Van Cappellen van Walsum, Pijnenburg, Berendse, van Dijk, Know, Scheltens, and Stam (2003) used MEG data and computed the D_2 in different frequency bands. In the broad band 0.5–40 Hz, the mean D_2 was lower in AD patients compared with control subjects. Nevertheless, there are several drawbacks in using these nonlinear methods. Reliable estimations of D_2 and L_1 require a large quantity of data (Eckmann & Ruelle, 1992), and stationary and noise-free time series (Grassberger & Procaccia, 1983a). These assumptions cannot be achieved for physiological data. Moreover, the computational cost is high, especially for great amount of data.

Therefore, other nonlinear methods which avoid these disadvantages are necessary to study the MEG background activity. Lempel-Ziv complexity measures the complexity of finite sequences, and is related to the number of distinct substrings and the rate of their occurrence along the sequence (Lempel & Ziv, 1976). Recent studies have applied this nonlinear method to EEG (Abásolo, Hornero, Gómez, García, & López, 2006b) and MEG signals (Gómez, Hornero, Abásolo, Fernández, & López, 2006) of AD patients and elderly control subjects, finding significant differences between both groups in certain regions of the brain. Other methods measure the irregularity of a signal, as the approximate entropy and the sample entropy. With both methods, an increased regularity was found in the EEG of AD patients (Abásolo, Hornero, Espino, Álvarez, & Poza, 2006a; Abásolo, Hornero, Espino, Poza, Sánchez, & de la Rosa, 2005). Finally, the interdependencies between MEG signals in six frequency bands were studied with synchronization likelihood (Stam, Jones, Manshanden, van Cappellen van Walsum, Montez, Verbunt, de Munck, van Dijk, Berendse, & Scheltens, 2006).

In this study, another nonlinear method, the auto mutual information (AMI), has been used to analyze the MEG signals. Mutual information (MI) has been used to study different types of diseases and brain states. It has been shown that MI might be useful to predict the response to anesthesia (Huang, Yu, Ju, & Cheng, 2003). Xu, Liu, Liu, and Yang (1997) computed the complexity of cross-mutual information (CMI) functions among eight EEG channels for four different functional states: awake with opened and closed eyes, light sleep, and deep sleep. Na, Jin, Kim, and Ham (2002) estimated the decreased rate of AMI and the CMI values from the EEG of ten schizophrenic patients and ten normal controls. Both nonlinear methods were also applied to study the EEG activity in AD (Jeong, Gore, & Peterson, 2001a). They found that AMI profiles decreased more slowly with time delay throughout the brain in AD patients than in control subjects. The CMI analyses showed a significantly decreased transmission of information between pairs of AD patients' electrodes.

MATERIALS AND METHODS

Subjects and MEG Recording

MEG signals were recorded with a 148-channel whole head magnetometer (MAGNES 2500 WH, 4D Neuroimaging) in a magnetically shielded room. The subjects lay on a patient bed, in a relaxed state, and with their eyes closed. Five minutes of recording were acquired at a sampling frequency of 678.17 Hz. Then, these recordings were down-sampled to 169.549 Hz. Artifact-free epochs of 20 seconds (3392 data points) were selected and filtered with a band-pass filter (0.5-40 Hz).

The MEG data were acquired from 30 subjects. 15 patients (three men and 12 women) fulfilling the criteria of probable AD (age = 71.13 ± 8.52 years, mean ± standard deviation SD) participated in the present study. All of them were recruited from the Asociación de Familiares de Enfermos de Alzheimer (AFAL). The patients were diagnosed according to the criteria of the National Institute of Neurological and Communicative Disorders and Stroke and the AD and Related Disorders Association (NINCDS-ADRDA) (McKhann, Drachman, & Folstein, 1984). Functional assessment staging procedure (FAST) was used for assessment of functional ability and MMSE for measuring the cognitive status of the subjects. The MMSE and FAST scores were 18.07 ± 4.18 and 4.00 ± 0.38 (mean ± SD), respectively. None of the patients used any kind of medication that could have an influence on the MEG.

MEGs were also obtained from 15 age-matched control subjects (seven men and eight women, age = 70.73 ± 8.29 years, MMSE = 29.13 ± 0.99, FAST = 1.67 ± 0.49, mean ± SD). Sex, age, MMSE, and FAST scores of all subjects are shown in Table 1. The local ethics committee approved the study. All control subjects and all caregivers of the demented patients gave their informed consent for the participation in the current research.

Auto Mutual Information

Mutual information (MI) provides a measure of both the linear and nonlinear statistical dependencies between two time series (Jeong et al., 2001a). It can be defined

Table 1. Sociodemographic data of AD patients and control subjects

Id.	Age	Sex	MMSE	FAST	Id.	Age	Sex	MMSE	FAST
Alz-1	71	Female	15	4	Con-1	84	Male	29	2
Alz-2	83	Male	10	5	Con-2	61	Female	29	2
Alz-3	56	Female	14	4	Con-3	70	Female	30	2
Alz-4	64	Female	15	4	Con-4	64	Female	30	1
Alz-5	59	Female	20	4	Con-5	60	Male	30	1
Alz-6	60	Male	16	4	Con-6	63	Female	30	1
Alz-7	72	Female	15	4	Con-7	73	Male	29	1
Alz-8	71	Female	15	4	Con-8	69	Female	29	1
Alz-9	75	Female	22	4	Con-9	56	Female	27	2
Alz-10	82	Female	21	4	Con-10	79	Male	29	2
Alz-11	72	Female	17	4	Con-11	79	Male	30	2
Alz-12	80	Male	24	4	Con-12	75	Female	29	2
Alz-13	77	Female	21	4	Con-13	74	Male	30	2
Alz-14	73	Female	23	4	Con-14	78	Male	27	2
Alz-15	72	Female	24	3	Con-15	76	Female	29	2
Mean ± SD	71.13 ± 8.52	–	18.07 ± 4.18	4.00 ± 0.38	Mean ± SD	70.73 ± 8.29	–	29.13 ± 0.99	1.67 ± 0.49

as the amount of information gained about one signal from the measurement of another (Xu et al., 1997). Furthermore, MI between two time series is zero when those series are completely independent, while MI has a maximum value if both series are equal.

We can compute the time-delayed mutual information between X and Y as follows (Jeong et al., 2001a):

$$I_{XY_\tau} = \sum_{x(t),y(t+\tau)} P_{XY_\tau}\left[x(t), y(t+\tau)\right] \cdot \log_2\left\{\frac{P_{XY_\tau}\left[x(t), y(t+\tau)\right]}{P_X\left[x(t)\right]\cdot P_{Y_\tau}\left[y(t+\tau)\right]}\right\} \quad (1)$$

where $P_X\left[x(t)\right]$ and $P_{Y_\tau}\left[y(t+\tau)\right]$ are the normalized histograms of the distribution of values observed for $x(t)$ and $y(t+\tau)$, while $P_{XY_\tau}\left[x(t), y(t+\tau)\right]$ is the joint probability density for the measurements of $x(t)$ and $y(t+\tau)$. This is the CMI and quantifies the information transmitted from one signal to another (Jeong et al., 2001a). Applied to MEG signals, the CMI measures the quantity of information transmitted between certain areas of the brain.

To calculate the AMI, the MI between $x(t)$ and $x(t+\tau)$, Equation 1 can be rewritten as:

$$I_{XX_\tau} = \sum_{x(t),x(t+\tau)} P_{XX_\tau}\left[x(t), x(t+\tau)\right] \cdot \log_2\left\{\frac{P_{XX_\tau}\left[x(t), x(t+\tau)\right]}{P_X\left[x(t)\right]\cdot P_{X_\tau}\left[x(t+\tau)\right]}\right\} \quad (2)$$

The AMI quantifies the mean predictability of $x(t+\tau)$ from $x(t)$ (Jeong et al., 2001a). To calculate AMI from experimental data is necessary to estimate the probability distributions of X and X_τ and the joint probability density P_{XX_τ}. These probabilities can be estimated constructing the histograms of the time series. For a given epoch length, the use of larger sampling bins produces more accurate estimates of the average probability, but the estimate of the joint probability distribution is too flat, underestimating the AMI. On the other hand, the use of smaller bins is better to indicate changes in the joint probability over short distances, but it produces fluctuation because the sample size is small, overestimating the AMI (Jeong et al., 2001a). In previous studies, 64 bins has been used to construct the histograms because this value provides stable estimations (Jeong et al., 2001a; Min, Jin, Kang, Lee, Kang, Lee, & Sakamoto, 2003; Na et al., 2002). In our research work, we have estimated the joint probability density using histograms of eight, 16, 32, and 64 bins.

We evaluated the AMI of all channels over a time delay from 0 to 0.5 seconds. In order to normalize the AMI profiles, they have been divided by the AMI value at $\tau = 0$. Hence, AMI values at a zero time delay are always one. The slope of the AMI profile was estimated by a line that fits the data in a least-squares sense. This slope was calculated from $\tau = 0$ to the first minimum value of the profile. Palus (1993) suggested that the decline rate of the AMI was positively correlated with the entropy. As entropy measures quantify the regularity (Costa, Goldberger, & Peng, 2002; Pincus, Gladstone, & Ehrenkranz, 1991), this decrease rate can be used to estimate the regularity of a signal.

Finally, a statistical analysis was carried out separately for each channel. Student's *t*-test was used to evaluate the statistical differences between the slopes of the AMI for AD patients and control subjects.

RESULTS

AMI was estimated for the 148 MEG channels, with a maximum time delay of 0.5 seconds, and eight, 16, 32, and 64 bins for the construction of the histograms. Figure 1 illustrates the normalized AMI profiles for the control subjects and the AD patients at squid A1. This figure shows that the AMI values decrease quickly for low τ values, and then become stable when the values of the time delay τ increase. As can be noticed, the AMI profile of the AD group declines more slowly than the profile of the control group. This behavior is the same for all channels, indicating that AD patients' MEGs are more regular than control subjects' recordings. Our results suggest that there are differences between the nonlinear dynamics of AD patients and control subjects' MEGs.

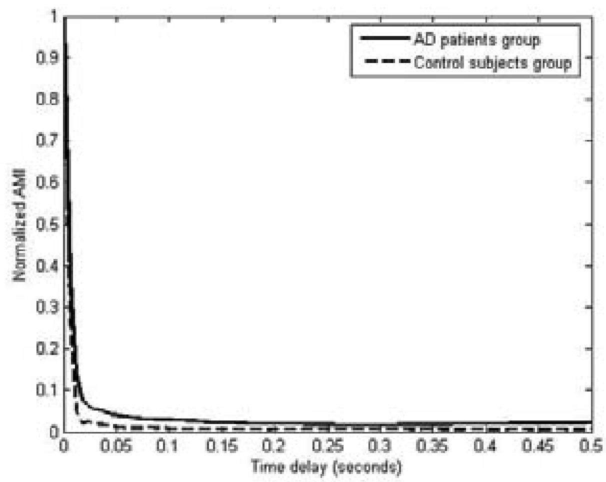
Moreover, these differences are statistically significant ($p < 0.01$, Student's *t*-test) in 133 channels for histograms of eight bins, in 132 channels for 16 bins, in 130 for 32 bins, and in 127 channels if the histograms are constructed with 64 bins. Figure 2 illustrates a squid diagram with the results of the Student's *t*-test using eight bins for the construction of the histograms. Although previous articles suggested the use of 64 bins to construct the histograms (Jeong et al., 2001a; Min et al., 2003; Na et al., 2002), our study shows that with a lower number of bins, the results get better.

DISCUSSION

This study presents the AMI as a method to analyze the MEG background activity in 15 patients with probable AD, and in 15 control subjects. AMI estimates the degree to which $x(t+\tau)$ can be predicted from $x(t)$. Moreover, the rate of decrease of the AMI with increasing τ is a measure of the MEGs regularity. For our pilot study, we used values of $\tau_{max} = 0.5$ seconds, and eight, 16, 32, and 64 bins to construct the histograms.

Traditional nonlinear techniques, as L_1 or D_2, have been widely applied to study the brain background activity (Jeong et al., 1998; van Cappellen van Walsum

Figure 1. Normalized AMI curves of the 15 control subjects and the 15 patients with probable AD at channel A1 (64 bins)



et al., 2003). Nevertheless, for a suitable estimation of these measures, stationary and noise-free signals, and a large number of data points, are needed (Eckmann & Ruelle, 1992; Grassberger & Procaccia, 1983a). These assumptions cannot be achieved for physiological data, as EEG and MEG. On the other hand, AMI does not require a large number of data points to be reliably estimated, and can be applied to nonstationary time series (Jeong et al., 2001a). Thus, this measure is much better suited for MEG complexity analysis than traditional nonlinear techniques.

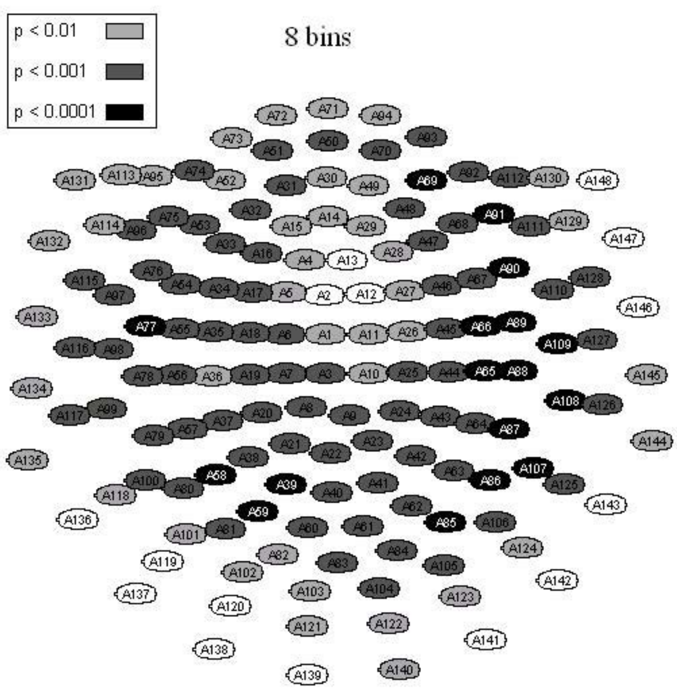
We found that the absolute values of the average AMI decrease rate are lower in AD patients in all channels. The differences were statistically significant ($p < 0.01$) in 133, 132, 130, and 127 channels for histograms of eight, 16, 32, and 64 bins, respectively. Because AD patients' group and control subjects' group were carefully matched for age, the significantly reduced AMI decline rate may well represent the cognitive dysfunction in AD.

Our results agree with previous studies of the EEG/MEG background activity in AD patients (Abásolo et al., 2005; Abásolo et al., 2006a; Jeong et al., 2001a). These studies suggested a loss of irregularity of the brain activity in the patients with probable AD. Jeong et al. (2001a) found that AMI profiles decrease with time delay slower in AD patients' EEGs than in control subjects' ones. Other study showed that sample entropy values were significantly lower in the EEG of AD patients at parietal and occipital regions (Abásolo et al., 2006a). With another nonlinear method, approximate entropy, significant differences were found at P3 and P4 EEG electrodes (Abásolo et al., 2005). The implications of this decreased irregularity in AD patients are not clear. It might arise from neuronal death, deficiency of neurotransmitters like acetylcholine, and/or loss of connectivity of local neuronal networks (Jeong, 2004).

FUTURE TRENDS

We found that an abnormal type of nonlinear dynamics is associated with AD. However, changes in EEG/MEG activity also appear in other pathological states as schizophrenia (Na et al., 2002), vascular dementia (Jeong, Chae, Kim, & Han, 2001b) and epilepsy (Jing & Takigawa, 2001). Therefore, we need a larger database, including recordings of these pathological states to confirm the performance of our method.

Figure 2. Squid diagrams with the results of the Student's t-test using eight bins for the construction of the histograms



The results of our study show that there are important statistical significant differences between controls and AD patients detectable using the methodology presented in our article. Nevertheless, our results do not show if AMI can detect a gradation of the disease process. Therefore, future studies are necessary to analyse MEGs from patients with different stages of AD and with mild cognitive impairment.

CONCLUSION

Our results show that irregularity, measured via AMI, is lower in AD patients' MEGs than in control subjects' ones. Moreover, the differences were statistically significant for most channels ($p < 0.01$, Student's *t*-test). This study suggests that cognitive dysfunction in AD is associated with an increased regularity in the MEG recordings.

In addition to this, we have shown that the AMI decrease rate could be a good method to differentiate between AD patients and elderly control subjects. Nevertheless, this is a preliminary study and a larger database is needed to confirm our results.

KEY TERMS

Alzheimer's Disease (AD): Progressive, degenerative, and irreversible brain disorder characterized by the appearance of neuritic plaques and neurofibrillary tangles.

Auto Mutual Information (AMI): Mutual information between a signal and its time-delayed version.

Electroencephalogram (EEG): Neurophysiologic recording of the brain electrical activity by electrodes placed on the scalp.

Magnetoencephalogram (MEG): Neurophysiologic recording of the magnetic fields produced by brain activity using extremely sensitive devices called SQUIDs.

Mutual Information (MI): Amount of information gained about one signal from the measurement of another.

Nonlinear Analysis: Broad, interdisciplinary field characterized by a mixture of analysis, topology, and geometry.

Signal Processing: Extraction of information from complex signals, generally by conversion of the signals into digital form followed by analysis using different algorithms.

A Rehabilitative Eye Tracking-Based Brain-Computer Interface for the Completely Locked-In Patient

INTRODUCTION

Despite contemporary advancements in healthcare, conventional methods of treatment have more than once proved ineffective in curing certain classes of neurological disorders, especially those where the central nervous system has been subjected to severe irreversible damage. Such disorders include, but are not limited to, cerebral palsy, cerebral aneurysm, traumatic brain injury, stroke, apraxia, and aphasia. In certain severe cases, more than one disorder might affect the same patient, making him or her completely locked-in—that is, cognitively intact, but unable to move or communicate (Kennedy & Adams, 2003).

A completely locked-in patient usually suffers from symptoms that include complete inability of controlling any voluntary muscles in the body, apart from those needed for eye movements and blinking. Nonetheless, the patient is capable of reasoning, thinking, as well as preserving all signs of consciousness. Moreover, normal sleep and wake cycles persist throughout the locked-in state. In addition, as is the case of most paralyzed people, a locked-in patient has the tendency to develop muscle atrophy and spasticity. Figure 1 illustrates a sketch of a locked-in patient.

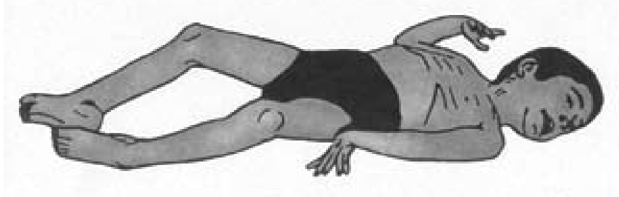
There are vast regions around the world where the completely locked-in patient is doomed to social rejection—in particular, when conventional rehabilitation methods fail to lessen the severity of the patient's handicap. For example, in the absence of motor control, it is practically impossible to use sign language or common input devices to interface with a computer system in order to communicate through spelling or expression-building software (Betke, Gips, & Fleming, 2002).

This article describes the design and development of a low-cost eye tracking-based brain-computer interface system for the rehabilitation of the completely locked-in patient having an intact ocular motor control to serve as an alternative means of communication (Abu-Faraj, Mashaalany, Bou Sleiman, Heneine, & Katergi, 2006). The developed system has been designed according to the following criteria: low cost, low processing power, simplicity of operation, little training requirements, minimal disturbance to the patient, and ease of customization to any mother tongue.

BACKGROUND

Brain-computer interface (BCI) methods for the rehabilitation of patients with neural disorders, similar to those previously listed, have been widely published. BCI systems are primarily classified according to the input technique utilized. Commonly reported techniques include electromyography (EMG) (Nagata, Yamada, & Magatani, 2004), electroencephalography (EEG) (Pfurtscheller, Müller-Putz, Pfurtscheller, & Rupp, 2005), electrooculography (EOG) (Barea, Boquete,

Figure 1. A sketch of a locked-in child



Mazo, & López, 2002), eye tracking (Amarnag, Kumaran, & Gowdy, 2003; Betke, Gips, & Fleming, 2002; Böhme & Barth, 2005; Cui, Ma, Wang, Tan, & Sun, 2004; Lee & Galiana, 2005; Li, Winfield, & Parkhurst, 2005; Yu & Eizenman, 2004), and other custom-designed input devices (Chen, 2001; Chen, Tang, Chang, Wong, Shih, & Kuo, 1999). The decision about which input technique to be used depends on the specific case being studied (Kennedy & Adams, 2003).

The EMG-based BCI requires that the patient be able to control at least one to three distinct muscles in order to be functionally effective, while the head-mounted tilt sensor method (Chen, 2001) can be used only if the patient has the voluntary ability of rotating his or her head. Accordingly, these two methods are precluded from consideration, since a locked-in patient does not possess any perceptible movements or EMG activity. Consequently, BCI methods employing eye tracking, EEG, or EOG remain possible for applications involving a locked-in patient (Kennedy & Adams, 2003). Nevertheless, EEG systems are expensive, sophisticated, cumbersome, and necessitate extensive training, while EOG methods suffer from inaccuracies at the extreme position of the pupil—particularly, small angle displacements (less than 2˚) are difficult to record, whereas large eye movements (greater than 30˚) do not produce bioelectric amplitudes that are strictly proportional to eye position (Clark, 1998). Hence, eye tracking systems would be more adequate for such applications, and are easier to setup.

THE EYE TRACKING BCI SYSTEM

The core of this work was to implement a fully functional rehabilitative system, while maintaining the development cost to a bare minimum. For this reason, the design specifications and requirements of the hardware were not only reduced, but also compensated for by the software program.

Hardware Description

A Genius® (KYE Systems Corp., Chung, Taipei Hsien, Taiwan, R.O.C.) Web cam was utilized and found suitable in terms of resolution, light sensitivity, and acceptable cost. The external packaging of the camera was redesigned, thereby substantially reducing its weight and volume, in order for it to be mounted on the patient's head. This alteration produced a headset consisting of a simple mechanical framework that separates the camera lens from the patient's eye by about five centimeters. The Web cam was connected to a notebook computer via a regular USB 2.0 port. The computer used in the development and testing of this system was a Toshiba Satellite™ M70-122 (Toshiba America, Inc., New York, NY, USA) notebook with a 1.73 GHz Centrino™ (Intel, Santa Clara, CA, USA) processor, 512 MB of RAM, and a 15 in. widescreen. Figure 2 shows a normal child instrumented with the eye tracking system.

Figure 2. A normal child instrumented with the eye tracking system

Software Description

A Matlab® (The MathWorks, Inc., Natick, MA, USA) program was developed to analyze the Web cam images of the contour of the eye in real-time. This program was implemented under Matlab® version 6.5, release 13, and consists of a series of image processing routines that are designed to locate the position of the center of the pupil. The point of gaze is localized as a pair of rectangular coordinates (x and y). The pseudocode lines presented in Figure 3 describe the algorithm that was exclusively developed to be used in this application. This algorithm proved to be efficient in terms of accuracy and processing speed. Furthermore, it was capable of processing around four frames-per-second on the previously designated computer system, a frame rate that is adequate for this specific application.

Upon acquiring the image of the eye (A), the program first converts it to an eight-bit grayscale intensity image, and then sweeps a black search window (w x h) over the entire surface of the frame (W x H). At each position (i, j) of the window, the program computes the error between the window and the corresponding area of the frame. The area that produces the lowest error is hence considered to be the darkest region of the image. Subsequently, this area is the approximated position of the pupil, which is marked at the center of the search window. This process is illustrated in Figure 4. Prior to running this pupil-allocating algorithm, the program cancels the effect of any white spot caused by reflection of light on the eye by eliminating high-intensity pixels. At the end of this algorithm, the coordinates of the pupil are passed to the next stage of processing, where interpretation of the data takes place.

The next stage of the software system is a graphical user interface (GUI) implemented under the JAVA™ platform (Sun Microsystems, Inc., Santa Clara, CA, USA). This GUI consists of various searchable pages, each of which contains a (2 x 3) grid of large buttons showing a collection of pictograms. Pictograms are simple, understandable images that represent basic human daily needs. As the locked-in patient focuses on a particular pictogram, the program determines the point of gaze and measures the duration that the patient spends looking at that pictogram. Three seconds were considered ample to ascertain the patient's intention. However, this duration can be adjusted by the computer operator.

Upon the confirmation of the patient's selection of a pictogram, the program obtains the corresponding wave file from the computer hard disk and plays it back to the patient's attendant through the built-in standard wave output device. The wave files can be recorded independently of the system, and in any desired language. To ensure that no erroneous executions are made, all buttons are initially *disabled,* except for a particular

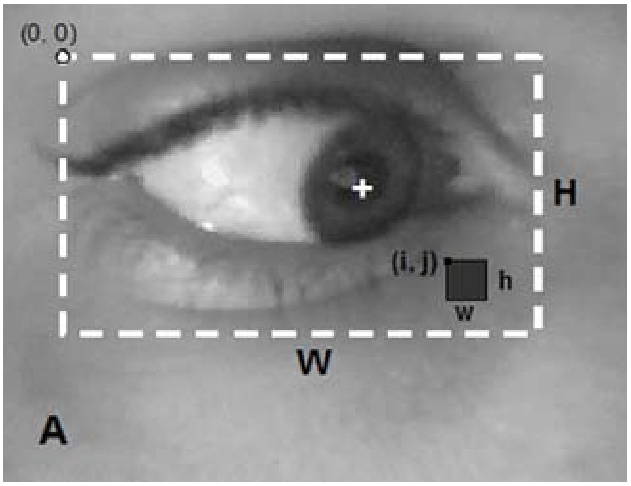
```
proc locate (A: array [1..H][1..W] of double)
    for i ← 1 to (H – h) do
        for j ← 1 to (W – w) do
            for m ← i to (i + h) do
                for n ← 1 to (j + w) do
                    error ← error + A [m, n];
            if (error <= minError)
                minError ← error;
                x ← (i + h/2);
                y ← (j + h/2) ;
            error ← 0;
    return x, y;
```

Figure 4. A visual illustration of the mechanism used by the algorithm to determine the approximated pupil position; A = image of the eye; H = height of the image; W = width of the image; h = height of the search window; w = width of the search window



button, located at the lower right corner of the screen. This button is used to activate the grid and to allow the switching of the buttons between the *enabled* and *disabled* states. The patient can thus choose to enable the buttons, and then commands the system to execute his or her desired choice. Upon the execution of the function, all buttons are automatically disabled, thus recovering the initial state of the program.

It is worth noting that the system currently consists of 24 pictograms stored in an expandable database. These pictograms are further classified into the following categories:

i. **Basic Needs:** *I Am Thirsty, I Am Hungry, I Want To Go To The Toilet, I Want To Take A Shower, I Want To Sleep, I Want To Change My Clothes, I Want To Go Out, I Want To Go Home*.
ii. **Common Sentences:** *Hello!, How Are You?, I Am Fine, I Want To Watch TV, Thank You, Mom!, Dad!, I Want To Listen To Music*.
iii. **Irritation Expressions:** *I Am Feeling Cold*, *I Am Feeling Hot*, *I Have A Headache*, *I Am Feeling Pain, It Is Too Loud, Turn Off The Light, Turn On The Light, I Don't Like The Food*.

Figure 5 shows a sample of the GUI that is used by the patient.

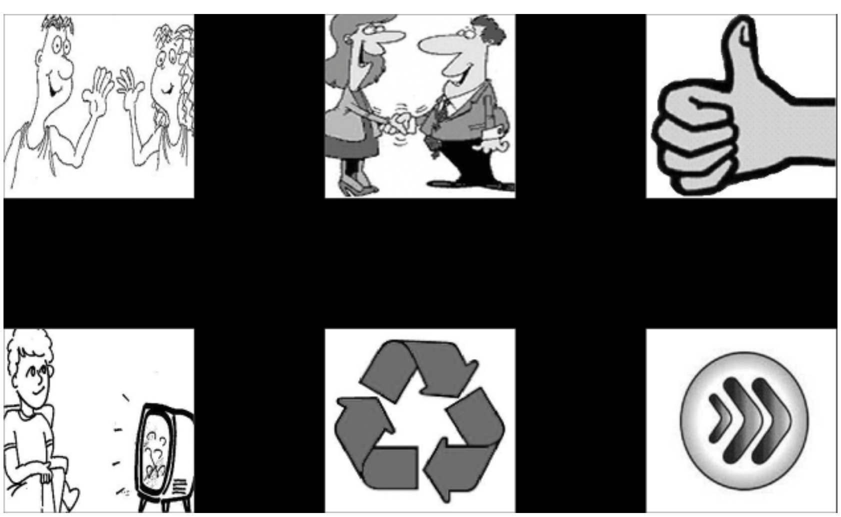
Calibration Process

A calibration procedure, upon which the point of gaze will be determined, must be executed by the patient prior to putting the system into operation. The algorithm sequentially displays a red disc, contrasted by a black background, through six predefined positions. The locked-in patient is instructed to remain focused on that disc. The center of the disc corresponds to the geometric center of the pictogram that will be displayed at that specific location. The disc is 120 pixels in diameter, and remains in a predetermined position for five seconds before moving to the next location. Eight samples are acquired at each location. The mean coordinates of the point of gaze for each disc location are subsequently determined, and will be referenced for a particular pictogram. The outcome of this procedure is a numerical grid of six rectangular coordinates representing the six different calibration points on the screen that correlate with the six pictograms per GUI. Figure 6 shows an example of the samples taken during the calibration process.

System Validation

In order to determine the overall accuracy and precision of the system, it was tested on 10 healthy adult volunteers (seven males and three females) ranging in age from 21 to 51 years (mean ± S.D. = 27.0 ± 9.5 years). Test subjects were free from any musculoskeletal or neurological disorders, had intact ocular motor

Figure 5. A sample GUI encapsulating six pictograms



control, and proper conjugate eye movement. Four of these subjects have myopia.

The validation protocol consisted of performing a series of three trials per subject in a well-illuminated environment. Test subjects were asked to execute a sequence of pre-instructed tasks, designed to test all six button positions in various combinations. Each task consisted of activating a certain pictogram by gazing at it for three seconds. The time allocated to activate a pictogram was set for 15 seconds. Beyond that time limit, the subject was considered to have failed to activate the desired pictogram and a *"miss"* was recorded for that task. The percentage of *"hits"* vs. *"misses"* was computed at the end of each trial. The values acquired from each subject during the three trials were then averaged, in order to obtain the overall system accuracy. The percentages of *"hits"* vs. *"misses"* obtained from the three trials of each subject were also used to calculate the overall system repeatability or precision.

Results

Validation results revealed a system accuracy of 96.11 ± 5.58%, and system repeatability of 94.44 ± 2.51%. These values represent the ensemble mean ± S.D. Figure 7 shows intersubject test results in terms of the rate of the *"hits"* to that of the "*misses*." Interestingly, all four myopic-test subjects exhibited reduced performance. This observation suggests that poor eye-sightedness may affect system performance, and thus requires further investigation.

Discussion

In the process of developing this system, critical questions were raised and, hence, highlighted some challenging constraints that were progressively solved:

1. The choice to use a head-mounted camera was based on three key disadvantages of remotely fixed cameras. First, remotely-placed cameras should have high resolution in order to get a sharp image of the pupil. This requirement would result in increased processing resources, and hence, would worsen system complexity. Second, to obtain the position of the pupil with a remotely placed camera, three-dimensional coordinates are required; while the position of head-mounted camera relative to the eye is always constant, thereby reducing the number of spatial rectangular coordinates to two. Last, once the image of the eye falls outside the field of view of the remote camera, re-tracking the pupil would be difficult.
2. A semicircular headrest, mounted at the back of the wheelchair, was used to reduce the effect of uncontrolled head movements relative to the screen. The headrest was ergonomically designed to avoid any discomfort to the patient and, in turn, decrease the degrees-of-freedom in head motion.
3. Images captured by the camera during an eye blink result in correlation values that do not exceed a certain preset threshold, since areas of dark pixel concentration (i.e., the pupil) are no longer present. Such images are irrelevant for the calculation of the pupil position, and are therefore discarded by the system.
4. The system disables all buttons, during and following the execution of a certain function, to prevent the patient from unintentionally activating another function. Erroneous executions are avoided by adding a confirmation step, whereby the patient is requested to assert the execution of the desired command. If within 15 seconds no confirmation is received, the system aborts the execution, returns to the home page, and disables all buttons.
5. Locked-in patients are, in some cases, expected to show signs of limb spasticity. In such situations, it has been recommended by consulted rehabilitative practitioners that the arms and legs be constrained to the wheelchair in an extended, comfortable position.

Finally, it is important to mention that the system must be further tested with a population of completely locked-in patients before it can be put into clinical use.

FUTURE TRENDS

The system can be considered as a threshold of future developments. It can be modified to be implemented on an automated wheelchair where the patient would control the movement of the wheelchair by simply gazing at directional buttons on the screen. Besides, expression-building add-ins can be developed to allow the completely locked-in patient to express his or her thoughts and personality. Furthermore, the GUI could be customized to personal needs, and the database modified to include recorded statements that fit the gender, age group, and language of the particular patient. Lastly, the system can be improved by being developed as a stand-alone application.

CONCLUSION

Brain-computer interfaces are imperative in the rehabilitation of individuals with neuromuscular disorders. They hold the promise to restore independence and mobility to the completely locked-in patient. The rehabilitative system developed in this study offers the locked-in patient, of any social class, the ability of a simple yet effective communication. The advantages of this system over existing systems are low cost, low processing power, ease of operation, little training requirements, minimal disturbance to the patient, and ease of customization to any mother tongue.

ACKNOWLEDGMENT

This work was supported in part by funds from the Research Council of the American University of Science and Technology (AUST, Beirut, Lebanon).

The authors thank the team at SESOBEL (Ain el Rihani, Kesrouan, Lebanon) for their assistance; Dr. Sami Sheeshia in the Department of Computer and

Communications Engineering at AUST for his technical support, and Mrs. Henriette Skaff in the Department of Languages and Translation at AUST for editing this article.

KEY TERMS

Aphasia: A deficit in language function caused by damage to the Broca's area, Wernicke's area, or to their interconnection.

Apraxia: The inability to control voluntary movement.

Brain-Computer Interface: Software or hardware (or a combination of both) systems that allow a person to send commands to a computer program via nonordinary input devices.

Cerebral Aneurysm: A permanent abnormal blood-filled dilation of a blood vessel occurring at a flaw or weak point in the wall of an artery that supplies blood to the brain.

Cerebral Palsy: A static encephalopathy representing a group of nonprogressive neuromuscular conditions caused by injury to the immature central nervous system during its early stages of development: fetal, perinatal, and infantile.

Completely Locked-In Patient: An individual who has lost all types of motor control and communication ability with the environment, while still maintaining a certain level of cognitive functions.

Expression-Building Software: A computer program used to build small sentences by selecting one letter (or word) at a time.

Eye Tracking: The process of measuring or recording the movements of the eye.

Rehabilitation Engineering: Application of science and technology to ameliorate the handicaps of individuals with disabilities.

Stroke: It usually occurs when the blood supply to a certain part of the brain is suddenly interrupted, or when a blood vessel in the brain bursts, spilling blood into the spaces surrounding brain cells. Accordingly, brain cells die when they no longer receive oxygen and nutrients from the blood.

Traumatic Brain Injury: It occurs when a sudden trauma causes damage to the brain.

Relationship Between Performance Error and Human Information Processing

Mitsuhiko Karashima
Tokai University, Japan

INTRODUCTION

Human information processing (HIP) performance using the working memory can be assessed by two types of indicators when an HIP task is carried out. One is error occurrence, and the other is HIP time taken when the HIP task is carried out using the working memory. Errors are classified into the error caused by the task requirement exceeding some human limitation, or the error caused by carelessness, even though all human limitations still allow enough capacity to do the task (Reason, 1990). The former is regarded as an error that is caused by the lack of the HIP ability in order to do the required information processing. The latter is regarded as an error that is caused by the temporary reduction of some HIP ability such as attention. Even though there are many kinds of factors of error generation, from the view point of HIP, error can be considered to be caused by the relationship between the required quantity or quality of the information processing and the HIP ability. The characteristics of HIP can be considered to influence error generation directly. In this chapter the characteristics of HIP related to the error are illustrated with the results of the experiments (Karashima, Okamura & Saito, 1994; Karashima & Saito, 2001).

BACKGROUND

In regard to error occurrence, the difference of the error ratio (calculated by the ratio of the number of error occurrences divided by the number of trials) in the HIP tasks has been explained by the degree of the efficiency of the information processing and storage with the interference in the working memory (Carpenter, Just, Keller, Eddy & Thulborv, 1999; Daneman & Carpenter, 1980, 1983; Just & Carpenter, 1992). Interference in the working memory means that the working memory is a system responsible for processing and storing information, and the processing and storage compete with the limited-capacity workspace in the working memory (Baddeley & Hitch, 1974; Carpenter et al., 1999; Case, Kurland & Goldberg, 1982; Danemen & Carpenter, 1980, 1983; Miyake, Just & Carpenter, 1994). These suggest that the error ratio increases when the storage information increases, and that the ways of the increase are different between the information processing in the HIP tasks.

On the other hand, the error ratio in the HIP task is rarely 0%. The HIP task is performed correctly in some cases but in some others performed incorrectly, even though all the conditions and the protocol for each subject are fixed. This means that there might be the variation of the performance under the same task. In a typical case, the subjects try to memorize and recall 7±2chunk, which is reported as the upper limit by Miller (1956) (Broadbent, 1975). But it is difficult to explain the variation by the influence of the working memory resource. The variation has not been studied enough to explain these characteristics of the error occurrence.

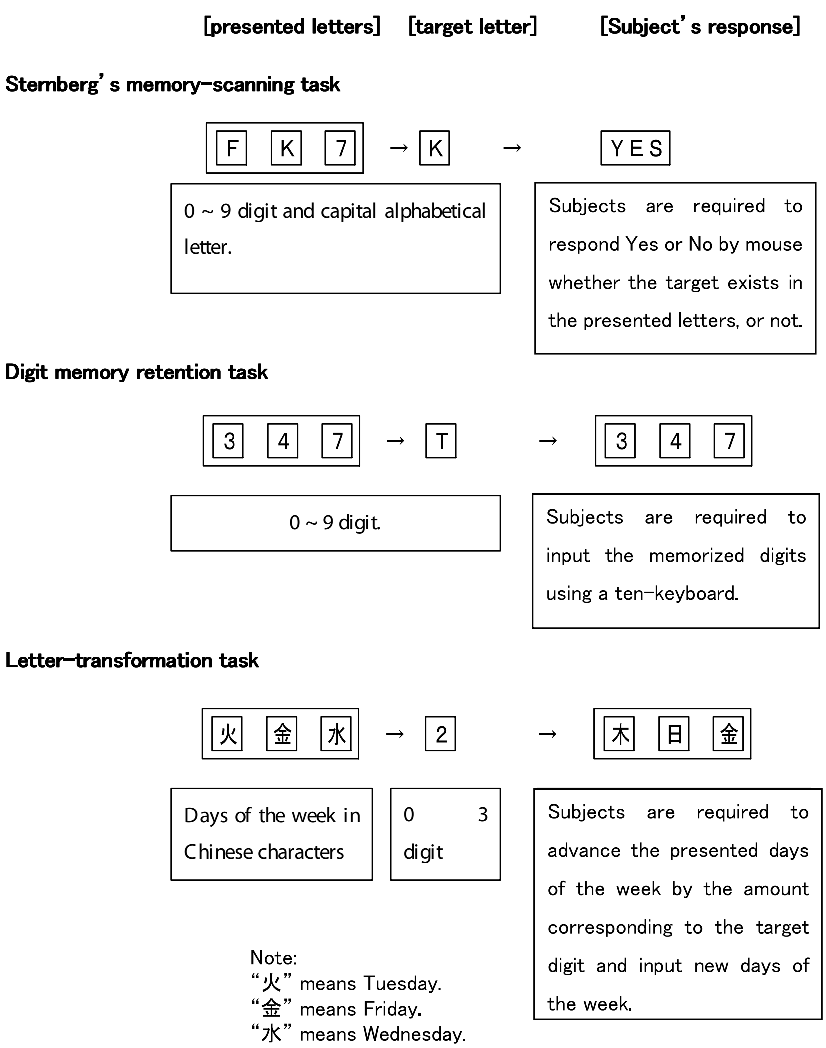
MAIN FOCUS OF THE CHAPTER

The Transformation of the Human Information Processing Ability by the Content of Human Information Processing

Generally, error occurs when the HIP ability is not enough to do the required information processing. This ability is sometimes transformed by the content of the required information processing or the environments. As the illustration of these characteristics of HIP, it is known that the HIP ability to deal with the presented information quantity is influenced by the constraints of the working memory, the interference of the working memory caused by the constraints, and the trade-off caused by the interference between information processing and storage. The constraints mean that the working memory resource has the capacity; the interference means that the information processing and storage compete with the capacity. The trade-off means that the capacity of information storage in the working memory decreases when the difficulty of information processing in the working memory increases, while the information processing in the working memory becomes more delayed when the quantity of information storage in the working memory increases. Because of the trade-off, concretely, the information processing ability to deal with the presented information quantity decreases as the difficulty of information processing in the working memory increases.

Karashima, et al. (1994) examined the relationship between the presented information quantity and the error ratio in three difficulties' tasks: Sternberg's memory-scanning task (Sternberg, 1966), digit memory retention task, and letter-transformation task. Figure 1 shows the details of three tasks. The Sternberg task is easiest, and the letter-transformation task is most difficult in three tasks. His experimental results reveal that the information processing ability to deal with the presented information quantity decreases as the difficulty of HIP increases. As Figure 2 shows, for example, in the case of six presented letters, the error ratio of letter-transformation task is more than 50%, although the error ratios of the other tasks are less than 10%.

Figure 1. Three experimental tasks



R

The Fluctuation of Human Performance by the Fluctuation of the Human Information Processing Ability

Generally, error doesn't occur when the HIP ability is enough to do the required information processing. However, the careless or dull condition causes error such as slip in this situation. This kind of error is interpreted by the lack of concentration. On the other hand, from the viewpoint of HIP, this error can be interpreted by the phenomena that the HIP ability decreases temporarily to less than the sufficiency ability to do the required information processing. This temporary decrease of the HIP ability can be interpreted by the fluctuation of the HIP ability itself.

Karashima and Saito (2001) examined the time series of the error occurrences in the HIP task. Figure 3 shows the experimental task and the required protocol of the subjects. The spectral slope of the time series of the error occurrences was similar to the spectral slope of 1/f fluctuation, which was between -0.5 and -1.5 (Voss & Clarke, 1978) and frequently appeared in the spectral densities of the time series in some phenomena (Johnson, 1925; Mandelbrot & Wallis, 1969; Musha & Higuchi, 1977), some classical music (Voss & Clarke, 1978), and some human functions such as heartbeat period (Kobayashi & Musha, 1982), alpha wave in

Figure 2. Mean error ratio in three tasks (M±SD, n=13)

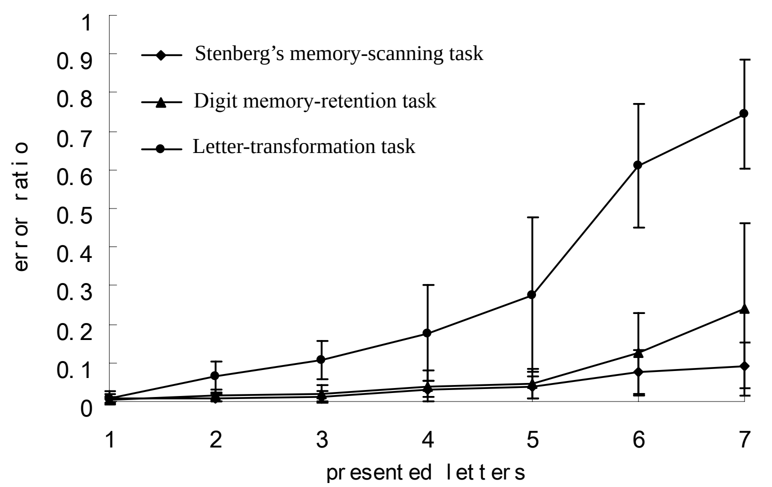


Figure 3. The experimental task

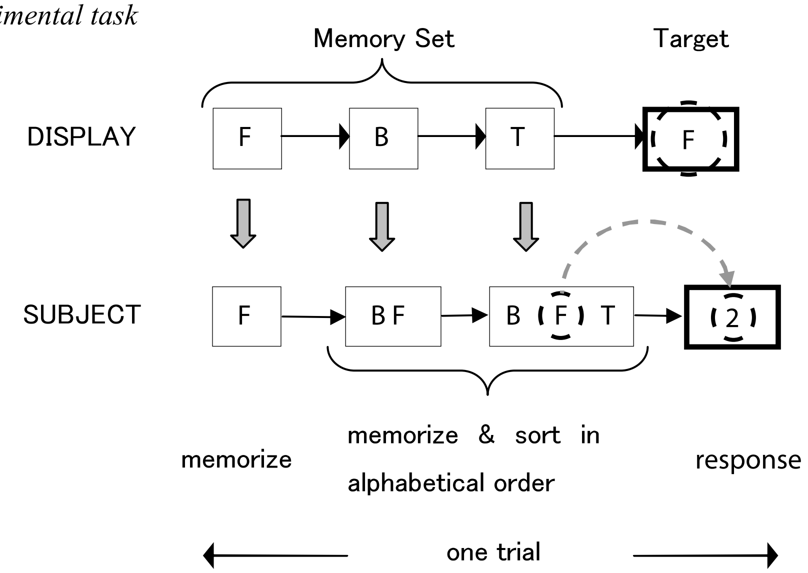


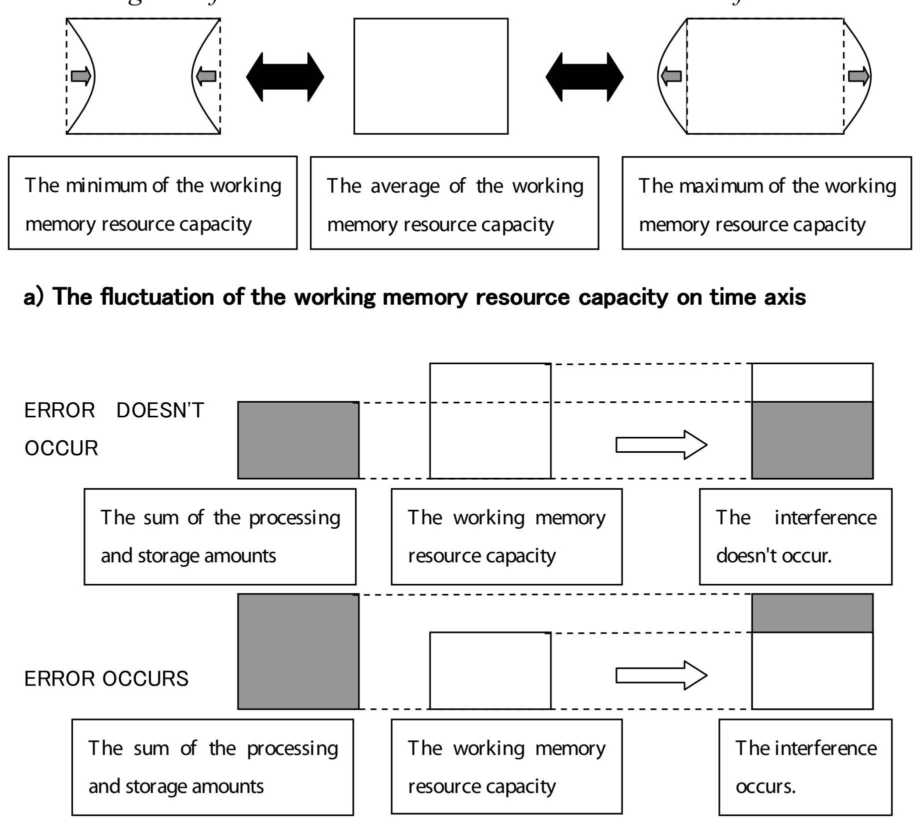
the brain (Suzuki, Ofaka, Kosugi, Ikebe, Matsuoka & Takakura, 1980), human cognitive functions (Gilden, Thornton & Mallon, 1995; Musha, Katsurai & Teramachi, 1985), and so on. It reveals that the time series of the error occurrences has some particular fluctuation in the same information processing task and the stable experimental conditions. It suggests that the HIP ability might have the fluctuation. The fluctuation of the HIP ability can be the main reason why errors sometimes occur when the HIP ability is enough to do the required information processing.

FUTURE TRENDS

The variation of the error ratio in the HIP tasks could be explained by the concept of the working memory resource capacity in the conventional working memory models proposed by Baddeley (1986) or Just & Carpenter (1992). However, it is difficult to explain the variation of the error occurrence where the protocol is fixed by the precedent concept, because the variation of the error occurrence implies the contradictive facts that the interference in the working memory occurs in some cases, while in some others, the interference doesn't occur and that the degree of the efficiency changes even though the sum of the processing and storage amounts is fixed under the same task. In addition, the characteristic fluctuation in the time series of the error occurrence also cannot be explained by the precedent concept.

It might be possible that these contradictions are due to the constant working memory resource capacity in the conventional working memory models. Karashima & Saito (2001) proposed the new theoretical hypothesis on the working memory resource capacity, which could explain the variation of the error occurrence without any contradiction in terms of the interference in the

Figure 4. FLOWM and diagram of the case in which error doesn't occur and of the case in which error occurs



a) The fluctuation of the working memory resource capacity on time axis

b) The relation among the sum of the processing and storage amounts, the working memory resource capacity, and the interference of the processing and storage in the working memory

working memory. This new hypothesis was named FLOWM (FLuctuation Of Working Memory resource capacity). FLOWM adds the concept of a fluctuation on time axis to the concept of the working memory resource capacity in the conventional working memory models, as shown in Figure 4. It is defined by FLOWM that the working memory resource capacity varies with some fluctuation on time axis. It is also defined by FLOWM that the interference occurs when the working memory resource capacity is smaller than the sum of the processing and storage amounts in the working memory and the interference doesn't occur when the capacity is larger, and that the interference causes the error occurrence. The variation of the error occurrence can be explained by applying FLOWM. In some cases, the error occurs because the working memory resource capacity is smaller than the sum of the processing and storage amounts, and the interference occurs. In some others, the error doesn't occur because the capacity is larger than the sum of the amounts, and the interference doesn't occur even though the protocol and the sum of the amounts are fixed. Figure 5 shows the explanation of the variation of the error occurrence where the error ratio is 50%. FLOWM can explain the variation of the error ratio in the same way as the precedent concept in the conventional model.

By applying FLOWM, the time series of the error occurrence can be regarded as the time series of the cases in which the sum of the processing and storage amounts becomes larger than the fluctuating capacity of the working memory resource when the task is carried out, thereby leading to the possibility that the characteristic fluctuation in the time series of the error occurrence is produced by the fluctuation of the working memory resource capacity.

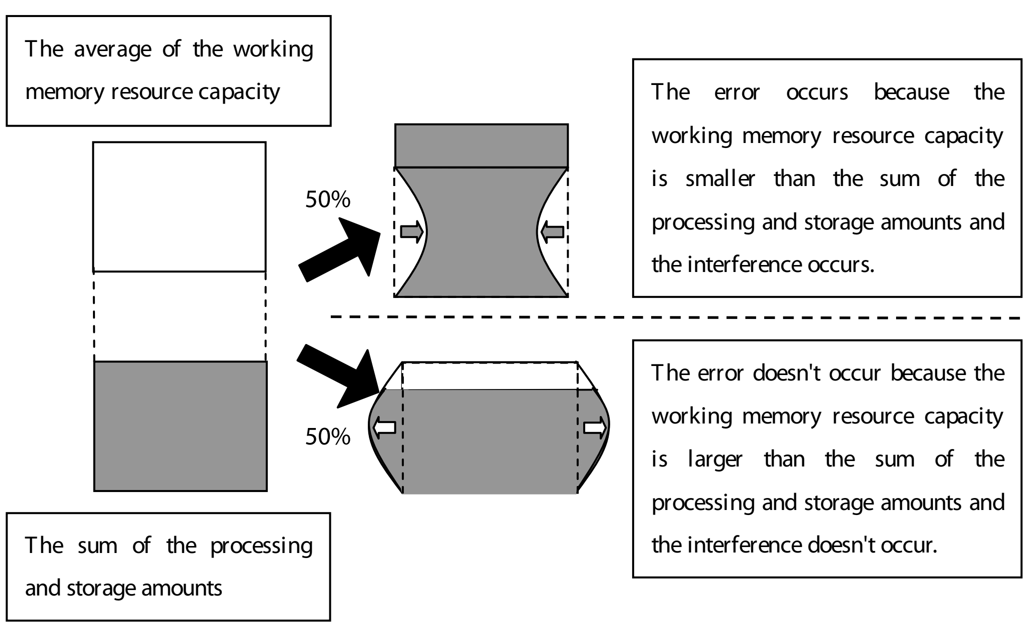
Karashima & Saito (2001) proposed the new theoretical hypothesis, FLOWM, on the working memory resource capacity, which could explain the variation of the error occurrence without any contradiction in terms of the interference in the working memory. In his paper, however, the validity of FLOWM was not directly confirmed because any physiological indicators of the human brain activities were not measured. Only the performances were measured. Further studies are left for confirming the validity of FLOWM from the neurophysiological standpoint.

CONCLUSION

In this chapter, the characteristics of HIP related to the error were illustrated:

1. The information processing ability to deal with the presented information quantity decreases as the difficulty of HIP in the task increases, because of

Figure 5. Explanation of the variation of error occurrence where the error ratio is 50% by applying FLOWM



the trade-off caused by the interference between information processing and storage in the working memory.

2. Errors sometimes occur when the HIP ability is enough to do the required information processing because the HIP ability might have the fluctuation.

FLOWM, the new theoretical hypothesis on the working memory resource capacity that could explain the characteristics without any contradiction in terms of the interference in the working memory, was introduced.

KEY TERMS

1/f Fluctuation: 1/f fluctuation is also called 1/f noise or pink noise. The power spectral density of this noise is proportional to the reciprocal of the frequency. It occurs in many fields. It is reported that people tend to feel comfortable to some time series that has 1/f fluctuation. The origin of its name is from being intermediate between white noise, $1/f^0$ noise, and red noise, $1/f^2$ noise.

Error Ratio: Error ratio is generally calculated by the ratio of the number of error occurrences divided by the number of trials in HIP task. Error ratio is measured as one of the indices of the performance, mental workload, and fatigue in the task.

FLOWM (*FLuctuation of Working Memory Resource Capacity*): FLOWM was proposed for explaining the performance such as the variations of the error occurrence and the HIP time, which could not be explained without contradiction by the conventional models such as Baddeley's model due to the constant working memory resource capacity. FLOWM is the new hypothesis that adds the concept of a fluctuation on time axis to the concept of the working memory resource capacity in the conventional working memory models.

Working Memory: Working memory is the theoretical framework in cognitive psychology that describes the processes for processing and storing information. Baddeley & Hitch (1974) made the model of working memory. It consists of one main system, "central executive," and two slave systems, "phonological loop" and "visuospatical sketch pad."

Working Memory Resource Capacity: Working memory consists of one main system and two slave systems. Every system has workspace for information processing and storage, and each workspace has the limited capacity. When the amount of information processing and storage in each system nears full capacity, the interference between information processing and storage occurs easily and the interference makes the performance of the information processing decrease or causes the loss of stored.

Relationship Management Competence and Organizational Performance

Murako Saito
Waseda University, Japan

INTRODUCTION

The competence of organizational management is required to cope with the complexity of technology and the diversity of social demands for maintaining good interpersonal relationships through the support of advanced technology. The competencies, such as self-management and interpersonal relationship management, play a crucial role in improving individual and organizational performance. Experiences of interpersonal relationships at work are multifaceted with value consciousness, mood states at work, and members' work attitudes, as well as technical knowledge and skills that are constituted of explicit cognitive information. Organizational climate or culture is focused on recent studies to improve human performance by avoiding erroneous actions, accidental occurrences, or withdrawal attitudes such as absenteeism and turnover intention. The participants to organization are expected to act as actors and some of them as leaders to help develop themselves and coworkers, building bonds to collaborate with team members, for improving organizational performance, and for providing a high quality of service. This article is focused on the effect of mood states at work on workers' perceived health and perceived performance, and on the effect of the competence of interpersonal relationship management on organizational performances.

BACKGROUND

Emotional competences represented by recognition of self and others' competences, emotional regulation of self and relationship management competence, and also mood states at work are important modulators in improving quality of care (QoC). We have tried to categorize care into four types by using two axes: one is the axis of care, lower or higher; the other is the axis of group level, individual or social, such as egoistic type (lower level of care, individual), bureaucratic type (lower level of care, social), specialist type (higher level of care, individual), and dynamic collaboration type (higher level of care, social). Our studies in healthcare sectors suggest that dynamic and collaboration types of care categorized by two axes play an important role in improving quality of team care and also organizational performances.

In order to identify the important role of dynamic and collaboration type of care, some evaluation indicators such as mood states at work, perceived health state, and emotional intelligence competence were applied in our studies. Our studies suggested that job consciousness, emotional states at work, and occupational health states gave critical effects on individual and organizational performance. The profile of mood states (POMS) developed by McNair, Lorr, and Droppleman (1971) was applied in investigations as to the measurement of mood states. The POMS consisted of six T-values: tension and anxiety (T-A), depression- dejection (D-D), anger-hostility (A-H), vigor (V), fatigue (F), and confusion (C). Perceived health status was measured by applying the Todai Health Index (THI) developed by Suzuki, Aoki, and Yanai, (1976) and Suzuki and Roberts (1991). Perceived health status was depicted as a radar chart constituted of 12 scale values, vague complaints (SUSY), respiratory (RESP), eye and skin (EYSK), mouth and anal (MOUT), digestive (DIGE), irritabilities (IMPU), lie scale (LISC), mental instability (MENT), depressiveness (DEPR), aggressiveness (AGGR), nervousness (NERV), and life irregularity (LIFE). In addition, with the pattern of health structure, health level was also diagnosed by using DF values (discriminant function values) for psychosomatics, neurotics, and schizophrenics, as shown in Figure 2. The larger the DF value, the greater the probability of disease. The competence of interpersonal relationship management was measured by applying Emotional Intelligence Competence (EIC), which was a learned ability and was classified into self-awareness, social awareness, self-management, and relationship management (Boyatzis, Goleman & Rhee, 2000; Cherniss

& Goleman, 2001; Goleman, Boyatzis & McKee, 2002).

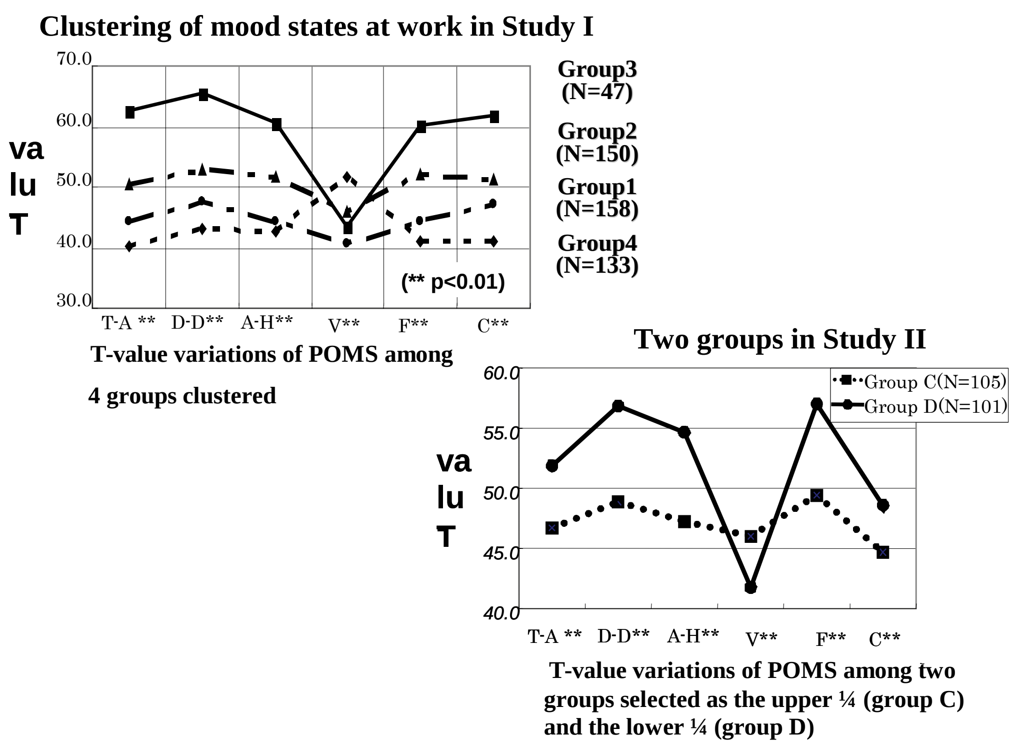
Performance reliability was measured by nine items of work environmental conditions called common performance conditions (CPCs), asking, How do you cognize the adequacy of (1) organization, (2) working conditions, (3) adequacy of Man-Machine Interface and operational support, (4) availability of procedures/plans, (5) number of simultaneous goals, (6) available time, (7) time of day/circadian rhythm, (8) adequacy of training and preparation, (9) and crew collaboration quality, which are developed by Hollanagel (1993, 1998). Subjects are requested to select one of four answers: very efficient, efficient, inefficient, and deficient. Erroneous human behaviors are predicted by measuring performance reliability both in improved reliability and reduced reliability.

MAIN FOCUS OF THE ARTICLE

The focus of this article is placed on the relation of mood states at work with workers' health conditions and with perceived performance, and also placed on the relationship of interpersonal relationship management competence with organizational performances of communication accuracy, team coherence, and performance reliability. As shown in Figure 1, subjects were classified into four groups in Study I, as shown in the upper left figure, and two groups in Study II, as shown in the lower right figure. An asymmetrical pattern of mood states at work measured by the POMS was observed between Group 3 and Group 4 in Study I.

Scores of interpersonal relationship managements were obtained by the questionnaire inventory of the EIC. The framework of the EIC consisted of four conceptual domains: self-awareness, social awareness, self-management, and relational management. Poor interpersonal relationship management in individual and collective levels (i.e., inappropriate recognition and regulation management) often causes the decrement of both task performance and contextual performance. The results shown in Figures 4 and 5 are on the comparison of organizational performances among the degrees of the EIC, communication accuracy in Figure 4, team member resources in Figure 5, and also the results in the section of performance reliability. Interpersonal relational management, mood-states at work measured

Figure 1. Clustering of mood states at work



in industrial fields, and healthcare sectors play crucial roles as moderators or mediators in changing health structure and health level as well as job performances (Murakami, Inoue, & Saito, 2007; Saito, Ikeda, & Seki, 2000; Saito, Inoue, & Seki, 2002, 2003; Saito, Murakami, & Karashima, 2007).

Classification of Mood States at Work

Asymmetrical patterns of mood states at work measured by the POMS were observed between Group 3 and Group 4 in Study I, and apparently low T-value in comparison with other five T-values in Group D in Study II were observed by clustering sample subjects of industrial workers as shown in Figure 1. T-values of vigor (V) among six T-values (T-A, D-D, A-H, V, F, and C) appeared as a characteristically lower value in Group 3 and Group D.

Health Structure and Level by Mood States at Work

Perceived health status was depicted as a radar chart constituted of 12 scales: vague complaints (SUSY), respiratory (RESP), eye and skin (EYSK), mouth and anal (MOUT), digestive (DIGE), irritabilities (IMPU), lie scale (LISC), mental instability (MENT), depressiveness (DEPR), aggressiveness (AGGR), nervousness (NERV), and life irregularity (LIFE), as shown in Figure 2. In Group 3 in Study I and Group D in Study II, characteristically deviated patterns of health structure appeared in comparison with other groups. The least deviation in the standard health pattern of Japanese workers was seen in Group 4, of which T-value of Vigor was the highest among four groups; DF values for diagnosing psychosomatics, neurotics, and schizophrenics were the lowest among four groups; and Group 3 was the highest probability of psychosomatics, neurotics, and schizophrenics. The larger the DF value, the greater the probability of disease. In Study II, health structure of Group D was significantly deviated, especially in the scales of DEPR and MENT; and DF values in psychosomatics and neurotics were significantly higher than those of Group C. Mood states at work play decisive roles in improving perceived health.

Perceived Performance by Mood States at Work

Mood states at work also have an effect on perceived performance. Perceived performance (actuality/potentiality) in Group3 appeared the lowest among the four groups, while perceived performance in Group 4 was the highest, as shown in Figure 3.

Figure 3. Perceived performance among four groups

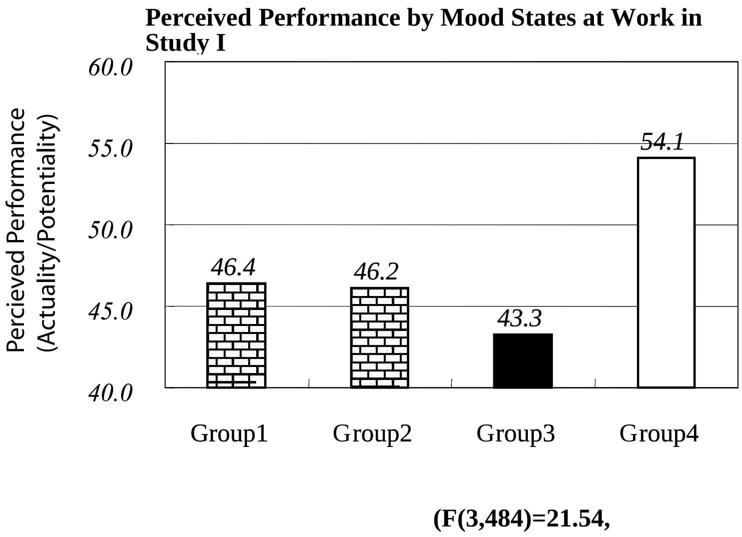

Figure 4. Comparison of communication accuracy between the higher and lower groups of interpersonal relationship management (N=124)

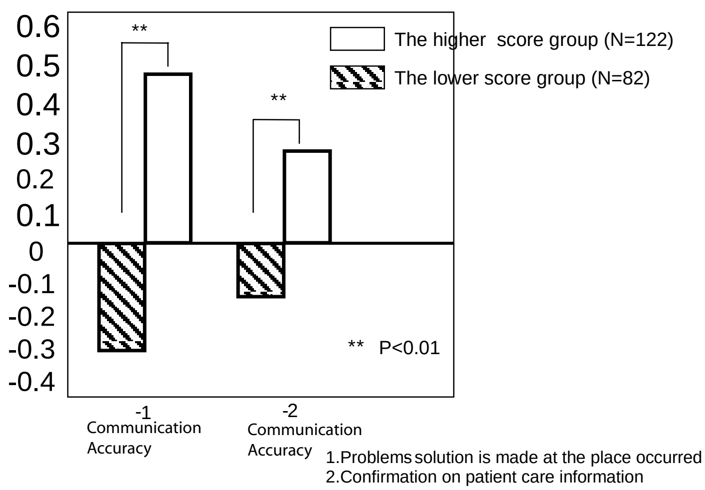


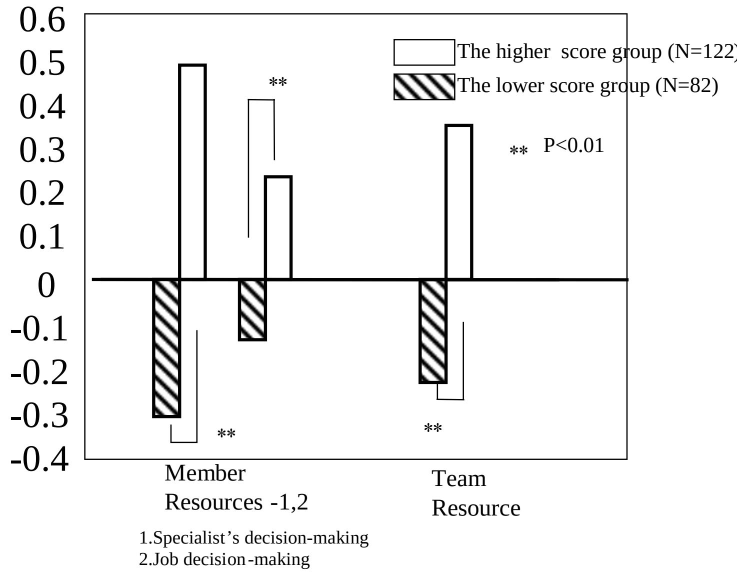
Communication Accuracy and the EIC

Recognition in social awareness and interpersonal relationship management gave strong effects on the performances, such as accuracy of communication, development of team and member resources, and performance reliability (Murakami, 2005; Saito et al., 2003, 2007). As shown in Figure 4, communication accuracy-1, which means the questions and problems are solved at the place occurred, and communication accuracy-2, which is confirmation of information on patient care and management procedures concerned, are significantly different between the higher and lower score groups in the EIC. This result suggests that the higher level of the EIC enhances accuracy of communication.

Team Member Resources and the EIC

Member resources-1 means decision-making as a specialist on the basis of established disciplinary knowledge, while member resources-2 denotes decision-making as practitioners; they were significantly different between the higher and the lower groups of

Figure 5. Comparison of member resources and team resources between the higher and lower groups of interpersonal relationship management



the EIC, as shown in Figure 5. Team resource representing effectiveness of teamwork, enhancing self-efficacy, also are significantly different between the two groups, as also shown in Figure 5. This result suggests that the EIC plays a significant role in enhancing team member resources.

Performance Reliability and the EIC

Performance reliability is measured by the CPCs and evaluated by two scales of improved reliability and reduced reliability. The higher score group of the EIC was significantly higher in improved reliability, while the lower score group of the EIC was significantly higher in reduced reliability. Our study results suggest that emotional intelligence competence plays a significant role in improving performance reliability, which is one of the important indicators of predicting human error (Saito, Murakami, & Karashima, 2007).

Relational management competence has a significant effect on performance reliability of care-providers through communication accuracy among team members and other professional staff. The results suggested that the difference of care performance in healthcare sectors and of work performance in industry could be explained by measuring interpersonal relationship management competence, as shown in Figure 4 and Figure 5. Intangible human assets embedded in the organization, such as interpersonal relationship management competence, play a great role in improving care performance reliability and other organizational performances.

LIMITATIONS AND FUTURE TRENDS

Empirical evidence in this article is limited in subject number, investigation area, and also in the method of measuring and analyzing. Continuing surveys in the future are required to testify to the relation of organizational performance with interpersonal relationship management by the use of contextual factors of organizational environment in addition to communication accuracy, team reciprocity, and performance reliability as shown in this article. It is of importance in redesigning organization to predict organizational performance in terms of a service provider's competence on interpersonal relationship management and its perceived health status. The enhancement of work ability and management competence of employees necessitates prompt and appropriate adapting to the changing technological and organizational environments, and improving the QOC, especially dynamic collaboration type of care, which promises to gain intangible human assets.

CONCLUSION

1. Mood states at work, emotional intelligence competences that were used to evaluate interpersonal relationship management, have a significant effect on organizational performances, such as perceived performance, communication accuracy, team member resources, and performance reliability both in improved and reduced reliability. These results suggest that emotional and mood regulation competences play a crucial role in improving performance both on individual and collective levels.
2. Studies shown in this article are limited in evaluating organizational performance and also in collecting the subjects in various working situations. Further studies were left for generalization of the results shown in this article.

KEY TERMS

Dynamic Collaboration Type of Care: Assessment of the quality of care has been inquired, but we thought that classification of care is required before assessment. We made a classification by using two axes: the axis of care, higher or lower; and the axis of care-provider, individual or group/social. We found four types of care: egoistic, bureaucratic, specialist, and dynamic collaborate. Our study results suggest that dynamic collaborate type of care plays an important role in improving quality of team care. This type of care leverages organizational performance.

Perceived Health: The measurement of the pattern of perceived health was made by using 12 scales of vague complaints (SUSY), respiratory (RESP), eye and skin (EYSK), mouth and anal (MOUT), digestive (DIGE), irritabilities (IMPU), lie scale (LISC), mental instability (MENT), depressiveness (DEPR), aggressiveness (AGGR), nervousness (NERV), life irregularity (LIFE), and a health level also made by using DF (discriminate function) values for psychosomatics and neurotics, which were developed by Suzuki, et al. (1976).

Perceived Performance: Perceived performance used in this article was measured by the use of methodology developed by Beer (1979) and applied by many other researchers such as Flood (1993), Espejo, Schumann, Schwaninger & Bilello (1996), Schwaninger (2000), and their co-workers. Perceived performance = Actuality/Potentiality, whereas actuality means actual work dealing with daily working time; potentiality is the best possible work when all the constraints in work environment are removed and you think it is your potential resource.

Performance Reliability: Developed by Hollnagel (1998) in predicting human error during work, measured by using nine common performance conditions (CPCs) with a four-point scale: very efficient, efficient, inefficient, and deficient. Improved reliability and reduced reliability are also measurable by using CPCs.

Team Resources: Team resources were measured by applying the TMX (Team Member Exchange Quality) developed by Seers (1989). Team resource was evaluated in this article to define mutual support, group cohesiveness, trust, responsibility for team goals, and team reciprocity, as defined by the developer.

The Relevance of Computer-Aided-Diagnosis Systems in Microscopy Applications to Medicine and Biology

Paolo Soda
Università Campus Bio-Medico di Roma, Italy

Giulio Iannello
Università Campus Bio-Medico di Roma, Italy

INTRODUCTION

Microscopy is a branch of medical sciences strictly related to image analysis and interpretation. Various sectors of medicine make use of micrographs[1] for different purposes. Moreover, since different biological substrates can be used, micrographs are usually divided into cytological and tissue images.

Humans are limited in their ability to distinguish similar objects, and to diagnose diseases during image interpretation because of noise and of their nonsystematic search patterns. In addition, the vast amount of image data generated by imaging devices makes the detection of potential diseases a burdensome task and may cause oversight errors. Developments in computer vision and artificial intelligence in medical imaging have shown that computer-based systems can be employed in different fields of medicine and biology, especially in those based on digital images (e.g., radiography, mammography, and echography, to name a few).

In microscopy, many qualitative or semiquantitative features have to be analyzed, demanding for qualified personnel that are not always available. Moreover, in several microscope applications the lack of quantitative information limits their reproducibility. For these reasons, in the last years the main research efforts on micrographs have been directed toward automated image processing and analysis, particularly in the field of both image segmentation and classification. The former aims at subdividing an image into its constituent regions or objects, whereas the latter works toward the recognition of image parts or objects detected by the segmentation process.

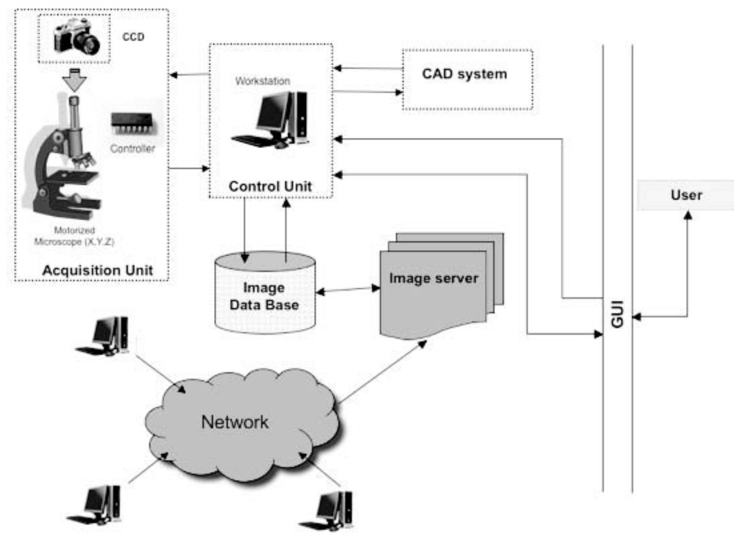
In this respect, many results have been achieved in a wide range of microscopy applications, such as the analysis of blood smears, chromosomes, tumour cells, brain, bone marrow, skin lesions, or autoantibodies analysis. These results can be attained, since the strategies in microscopy analysis have been expanded by ongoing automation of sample preparation, field selection, focusing, and imaging. Consequently, scientists and physicians are nowadays able to collect large sets of high-quality microscope images.

Figure 1 shows a typical architecture of a computer-based system devised to analyze the micrographs. The user controls and interacts with the system through a Graphical User Interface (GUI), which is located at a workstation. The workstation controls a full-motorized microscope, whose parameters, such as focusing, movement stage, objective, illumination, and magnification can be flexibly set. Moreover, the microscope is equipped with a digital camera to acquire one or more images of the sample under examination. The digital images are transferred to the workstation, and then they are automatically post-processed, stored, and shared on the Web.

Such architecture should act as a computer-aided diagnosis (CAD) system. It is well-known that such systems play an important role since they not only support the specialist in the image analysis task, but they also provide a set of useful functionalities that help in speeding up the routine part of the work.

In this article, we discuss the use of computer-based systems in microscopy, focusing on cytological images. We initially present recent results on image segmentation, and then we argue that it makes sense moving from a structural approach to a semantic interpretation of micrographs. In this respect, we focus on the relevance of using CAD tools to overcome the current limitations of microscopy, investigating several peculiar objectives of such systems. A short review of the literature demonstrates that the development of a

Figure 1. Typical architecture of a computer-aided diagnosis (CAD) system



flexible CAD applicable to various working scenarios is a future trend in microscopy healthcare systems. To support our position, we briefly describe a tool that analyzes and classifies fluorescence images.

BACKGROUND

The main contributions that healthcare information systems have given to microscope applications are basically related to the following two areas:

- **Image segmentation** (i.e., partitioning the image into regions as well as locating objects, e.g., cells)
- **Image classification** (i.e., recognizing the patterns or the objects of an image)

The classification systems may use data computed by image segmentation, thus integrating information that could be provided to the specialist to help him/her in the decision-making process.

Classically, image segmentation is defined as the partitioning of an image into not overlapping, constituent regions that are homogeneous with respect to some characteristic, such as intensity or texture. In the case of cytological micrographs, image segmentation is related to cells detection, which has to satisfy the following four main requirements:

- One micrograph has to be evaluated in a very short time to enable high throughput in screening many slides.
- Results must be reproducible to guarantee a reasonable statistical interpretation of the data.
- Robustness is needed, since cells vary in shape, density, and fluorescence properties.
- Microscope images may be taken at different magnifications so that the detection system has to be easily adaptable to cells' size changes.

Many cells segmentation methods have employed image-processing techniques dealing with domain-specific problems. Nattkemper, Ritter, and Schubert (2001) and Theis, Kohl, Kuhn, Stockmeier, and Lang (2004) use an adaptive neural classifier mapping each image point *m* to a fluorescent micrograph to a confidence value *C(m)* in [0;1], indicating how probable a cell lies in this image patch or not. This function is then used as a local filter on the whole image, providing a probability distribution with local maxima at cell positions. Analysis of maxima by thresholding reveals the number and position of the cells. Perner, Perner, and Muller (2002) and Chen, Zhou, and Wong (2006) localize fluorescent cells applying global thresholding by the Otsu's algorithm (Otsu, 1979). The algorithm well locates the cells with their cytoplasmic structure, but not the nuclear envelope itself. To overcome such limitations, Perner et al. (2002) use morphological filters, whereas Chen et al. (2006) apply watershed techniques. In both papers, overlapping cells are eliminated by a simple heuristic based on compactness evaluation. Fang, Hsu, and Lee (2003) uses local adaptive thresholding and watershed algorithm to separate the clumped cell clusters into individual objects. However, due to histological noise in the images, several false identifications are obtained that are recognized by a second stage. In (Wählby, Sintorn, Erlandsson, Borgefors, & Bengtsson, 2004) a region-based segmentation has been applied to both cervical and prostate carcinoma images. Morphological filtering combination of both the original image and its gradient magnitude creates the seeds representing both object and background that are used as starting points for watershed segmentation of the gradient magnitude image. Finally, clusters of nuclei are separated on the basis of their shape.

It is worth noting that segmentation methods based on thresholding or morphological filtering do not take into consideration the object shape. Therefore, retrieved contours tend to have irregular notches and the automatic separation of nuclei is not facilitated. In this respect, Würflinger, Stockhausen, Meyer-Ebrecht, and Böcking (2004) proposes a segmentation algorithm based on active contours. They use cubic B-Splines as an object model, whose movement is driven both by external image forces, computed from image edges, and by internal forces that model stiffness features.

The performances of segmentation algorithms are usually computed by comparing the results achieved using traditional methods (i.e., the manual one) with those obtained by automatic tools. In this respect, in the literature are reported some works that use commercial systems to detect cells (Méhes, Lörch, & Ambros, 2000; Yamamura, Yamane, Hino, Ohta, Shibata, Tsuda, & Tatsumi, 2002). In these papers, the authors report good correlation between results attained both manually and automatically. Moreover, Méhes et al. (2000) show that the determination of tumour cell content in haematopoietic sample is only reliable when it is performed together with a computerized system. The systems presented in (Chen et al., 2006; Fang et al., 2003; Nattkemper et al., 2001; Theis et al., 2004; Wählby et al., 2004; Würflinger et al., 2004) correctly detect a high rate of cells (i.e., approximately up to the 90-95% of cells). In (Nattkemper et al., 2001; Nattkemper, Twellmann, Schubert, & Ritter, 2003) for images of good quality the segmentation algorithm achieves the accuracy of the medium skilled experts, whereas in images with increased noise the computer-based method is outperformed by some of the experts.

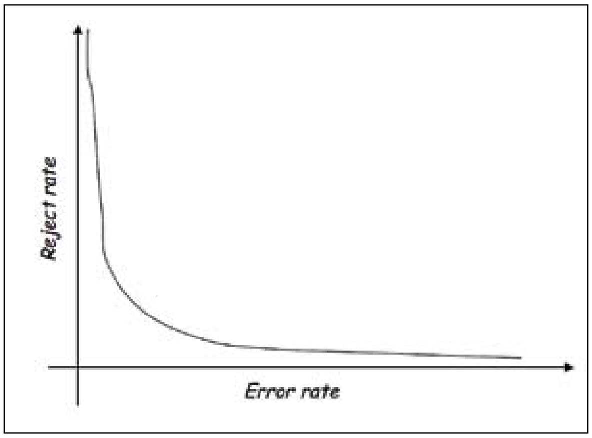
This brief literature review shows that using segmentation tools helps the specialists in the task of cells detection, providing more reliable data. Nevertheless, in several applications, physicians have to classify the images after the separation of biological objects from the background.

Up to now, during the inspection of micrographs, the physicians use only qualitative or semiquantitative information, thus limiting method reproducibility. In order to overcome these drawbacks, we deem that supporting more the specialist by moving from a structural approach to a semantic interpretation of micrographs is a promising trend. The final goal is the classification of the whole image as well as regions or objects detected by the segmentation.

To this aim, pattern recognition techniques are employed, such as those based on supervised or unsupervised approaches. Note that, in spite of several years of research and development in the field of pattern recognition, the general problem of recognizing complex patterns with arbitrary scale, orientation and location remain unsolved. Therefore these systems have to be tailored to the specific application domain as well as robust and efficient.

The ultimate performance measure of a general pattern recognition system is overall error rate (P_e). However, in many applications, such as the medical ones, the designers usually implement a *reject option* that aims at rejecting the highest possible percentage of samples that would otherwise be misclassified (i.e., misclassified without a reject option).[2] It is worth noting that, even when used adequately, this criterion introduces a side effect whereby some samples that otherwise would have been correctly classified are rejected. Invoking the reject option reduces the error rate; the larger the reject rate, the smaller the error rate. This relationship is represented as an error-reject trade-off curve that can be used to set the desired operating point of the classifier. It is monotonically nonincreasing, since rejecting more patterns either reduces the error rate or keeps it the same (Figure 2). As example, a good choice for the reject rate is based on the costs associated with reject and incorrect decisions (De Stefano, Sansone, & Vento, 2000; Golfarelli, Maio, & Maltoni, 1997).

Figure 2. Example of a theoretical error-reject trade-off curve



COMPUTER-AIDED DIAGNOSIS SYSTEMS IN MICROSCOPY

Achievements in computer vision and artificial intelligence have shown that CAD systems can be used in many field of medicine, especially in those based on digital images, such as microscopy. In general, a CAD tool provides useful data obtained by analyzing medical data by means of a computer, which can be used to support the human specialist in the diagnosis process (Cheng, Cai, Chen, Hu, & Lou, 2003; Sack, Knoechner, Warschkau, Pigla, Emmerich, & Kamprad, 2003; Takehiro, Kenichi, & Shinichi, 1992; Van Ginneken, Ter Haar Romeny, & Viergever, 2001).

Employing CAD systems, five major objectives can be pursued: (a) carrying out mass screening campaigns, (b) performing a preselection of the cases to be examined, enabling the physician to focus his/her attention only on relevant cases, (c) serving as a second reader, thus augmenting the physician capabilities and reducing errors, (d) aiding the physician while he/she carries out the diagnosis, (e) working as a tool for training and education of specialized medical personnel.

Each of those objectives has its peculiar requirements that are now further characterized and synthetically reported in Table 1.

In case (a), the CAD carries out mass screening campaigns, acting as a full-automated system that labels all input samples (i.e., as a zero-reject system), thus increasing the throughput. It is worth noting that the physician a priori knows such a rate, since the overall P_e can be experimentally evaluated.

In case (b), the physician will diagnose only cases rejected by the CAD, whereas the classified samples will not be presented to the human expert, who completely trusts in the system. Therefore, the recognition system approaches to a zero-error classifier whatever the reject rate (although in a real application it is almost impossible to not have misclassification). Indeed, with reference to a theoretical error-reject curve, the more the error approaches to zero, the greater is the reject rate (at limit 100%). Note that now the CAD approaches to a zero-error system and rejects doubtful samples. Therefore, with respect to case (a), fewer even though more accurate tests are completed.

In case (c), the CAD serves as a second reader, supplying an opinion to the physician. Now, the CAD acts as a zero-reject system, providing also a reliability measure of its decision.

In case (d), the recognition system aids the physician during the diagnosis, performing as a zero-reject system.

Finally, in case (e), the CAD acts differently on the basis of both training purpose and people skills.

It is worth noting that the recognition system can work between two extreme cases (i.e., the zero-error and the zero-reject). Therefore, the error-reject curve

Table 1. Description and requirement a CAD system for different working scenarios

Case	***Working scenario description***	***CAD requirement***
a	Mass screening campaigns	Zero-reject system
b	Samples pre-selection	Reject system
c	Second reader	Zero-reject system and reliability measure
d	Aiding expert in the diagnosis	Zero-reject system
e	Training and education of specialists	Depends on the purpose

can be used to flexibly set the system operating point between these extremes.

In the literature, several papers can be found employing computer-based tools that classify either the whole micrographs or single objects detected in them. They support the relevance of developing *intelligent* tools capable of performing semantic interpretation of micrographs. However, to our knowledge, analysis of the literature shows that CAD systems flexibly applicable to the previous different working scenarios cannot be easily found. In the following, we report some recent papers supporting such an observation.

Fang et al. (2003) integrate three classifiers (Naïve Bayes, decision-tree and association mining rule) using a majority voting strategy in order to distinguish between tumour and nontumour cells so as to improve the accuracy of the cells identification procedure (see section 2). The average P_e is 5.7%. To classify cancer cell nuclei in time-lapse microscopy, Chen et al. (2006) employs 6-Nearest-Neighbor (6-NN) classifier with a set of 7 statistical features. They apply heuristic rules on established biological knowledge of cell phases, thus correctly classifying the 98.4% of samples. Sack et al. (2003) and Perner et al. (2002) present some results on mining staining pattern of fluorescent cells in Indirect ImmunoFluorescence (IIF). Texture-based features are computed on 321 cells detected by the segmentation procedure reported in section 2. These 132 features are given to a decision tree induction program to find out the most relevant subset and to construct the classification knowledge. These systems exhibit an error rate of 25.6% (Perner et al., 2002) and 16.9% (Sack et al., 2003). The classification of cell types for the early detection of cancer has been presented in (Würflinger et al., 2004). The system distinguishes between mesothelial cells, lymphocytes, granulocytes and macrophages on the basis of eight features related to their size, form, and texture. The authors tested both Bayes classifier based on Gaussian mixture and kNN classifier. The latter performs better that the former, successfully recognizing the 87.5% of samples. Huang and Murphy (2004) presents a support vector machine system devised to classify fluorescence microscope images without segmenting them. Using a set of 26 statistical features, P_e is 5.2%. Boland (1998) demonstrates the feasibility of applying machine learning techniques to subcellular localization patterns in images of proteins and DNA obtained using fluorescence microscopy. They adopt both a backpropagation neural network and a classification tree induction. In both cases, the hit rate is 87%.

Finally, other classification system applied to microscopy can be found in Debeir, Decaestecker, Pasteels, Salmon, Kiss, and Van Ham (1999); Keller, Gader, Sohn, and Caidwell (2001); Lin, Xiao, and Micheli-Tzanakou (1998); Long, Cleveland, and Yao (2006); Milenovic, Stoiljkovic, and Stojanovic (1998); Seidenari, Pellacani, and Pepe (1998); and Weyn, van de Wouwer, Kumar-Singh, van Daele, Scheunders, van Marck, and Jacob (1999).

A deep analysis of these works shows that all of them can act only as zero-reject systems without providing a reliability measure of final classification. Therefore, with reference to Table 1, they are best suited to be applied in cases (a), (d), and (e).

In other fields of medical imaging, the introduction of a reject option allows varying the operating point of CAD (De Stefano et al., 2000; Golfarelli et al., 1997). Therefore, the range of application of CAD systems can be extended to cases (b) and (c). It is worth noting that the introduction of a reject option is usually related to the reliability measurement of each classification action since, in most cases, a sample is rejected when its reliability is smaller than a threshold (De Stefano et al., 2000).

Now, we would like to briefly discuss a recently proposed CAD tools applicable to a wide range of situations in the detection of antinuclear autoantibodies. Particularly, those CAD systems aim at classifying fluorescence intensity in IIF tests.

In this respect, both the systems proposed in Soda and Iannello (2006a) and Soda and Iannello (2006b) adopt a multiple expert system (MES) based on the classifier fusion paradigm, whereas in Soda, Iannello, and Vento (2006c) and Soda, Iannello, and Vento (2006d), the authors present two MES based on a classifier selection approach. The database used for evaluation is the same among these works and consists of 600 images; the results show that the system based on classifier selection performs better than the others.

CAD tools discussed in (Soda & Iannello, 2006a, 2006b) make use of features inspired to medical practice and show low P_e, up to 1%. Nevertheless, they use a reject option and do not cast a result in about 50% of cases. The adopted classification rule does not allow a flexible management of samples that are intrinsically hard to classify, justifying the high reject rate required to obtain low error rates. The CAD is suited to application in case (b), since it can reject or not input samples.

The MES proposed in (Soda et al., 2006c, 2006d) are made up of three specialized experts, each one devised to recognized one of the input classes. A combination module using two different rules, which provide both a fixed-reject and a zero-reject system, respectively, sets the CAD output. The first rule is based on the binary combination of the experts' outputs, whereas the second one adopts a zero-reject strategy based on reliability estimation of each classification act of the experts.

In the fixed-reject mode, the CAD exhibits an error rate of 1.33% and a reject rate of 11.33%; furthermore no samples are erroneously assigned to the negative class (0.00% of false negative). In the zero-reject mode, the hit rate is 94.33% (1.33% of false negative).

In order to understand when it is preferable to use one rule respect to the other, the authors introduce a global cost function that depends upon both the cost of a misclassification and the cost a rejection as well as the gain of a right classification.

Such a convenience analysis shows three different sets of operating points, which allow applying the CAD to all the working scenarios reported in Table 1 (Soda et al., 2006d).

FUTURE TRENDS

The field of micrograph processing involves a wide range of scientific disciplines and it is characterized by typical limitations. To overcome them, future trends in micrographs processing are directed toward both image segmentation and classification.

Hence, the current challenge is the development of CAD tools that can be flexibly set to the requirements of various working scenarios. We deem that such distinctive feature will allow using these systems in daily medical practice.

To pursue these goals it is desirable that problems across specific applications as well as terms for the evaluation of system performance will be proposed.

CONCLUSION

In this article, we discuss the use of healthcare information systems in cytological microscopy, since they have demonstrated the potential of overcoming the main limitations of microscopy. Indeed, in the last years, several results have been achieved in both image segmentation and classification, improving the medical practice.

The analysis of the literature shows that moving from a structural approach to a semantic interpretation of micrographs is beneficial. We investigated peculiar objectives of CAD tools, showing that the development of comprehensive systems that can be flexibly applied to various working scenarios is one of the current challenges in micrographs processing.

KEY TERMS

Computer-Aided Diagnosis (CAD) System: Computer-based system that analyzes medical data in order to support the human specialist in the diagnosis process.

Features: A set of attributes that represents a pattern.

Image Classification: Recognition the patterns or the objects of an image.

Image Segmentation: Partition of an image into not overlapping, constituent regions that are homogeneous with respect to some characteristic. Ideally, a segmentation method finds sets of points that correspond to distinct structures or regions of interest in the image.

Micrographs: Microscope images.

Multi-Expert System (MES): Aggregation of classification systems according to a combination approach, in order to improve the recognition performance.

Reject Option: Classification option that aims at rejecting the highest possible number of samples that would otherwise be misclassified (i.e., misclassified without a reject option). It is usually based on the estimation of the classification reliability.

ENDNOTES

1. In the following, microscope images are referred to as *micrographs*.
2. In the following, a classification system that makes a decision on all input samples will be referred to as *zero-reject*, as *reject system* otherwise.

Restructuring a Military Medical Department Research Center

W.F. Lawless

Hui-Lien Tung
Paine College, USA

INTRODUCTION

This case study is of a military medical department research center (MDRC) with access to advanced information systems (IS), yet struggling to determine the quality of its residents in training and their scholarly productivity (see the article on "Theory Driven Organizational Metrics" in this encyclopedia). Based on theory, this case study was guided by stories captured from MDRC in the collapse of four interdependent variables: planning, execution, resources, and time. Our primary goals for this case study were to: (1) Formulate recommendations to utilize the IS available to reduce the overall operational cost of MDRC; (2) increase the operational efficiency and growth of MDRC by enhancing its ability to attract new extramural funds; and (3) further explore the link between practice and theory. To the extent possible, all organizational names, references, and locations have been revised to fictitious ones.

Organizational Background[1]

The Medical Department Research Center (MDRC) is a regional military medical hospital located stateside in the USA. MDRC supports clinical and basic research for its staff and all hospital practitioners including family medicine, internal medicine, general and orthopaedic surgery, and dentistry (endodontics, peritonitis, oral maxillofacial, orthodontics, and nurse anaesthesiology). In addition to providing basic research support for the hospital, MDRC is responsible to teach the fundamentals of experimental research to the hospital's medical residents (residents working within a specialty, residents rotating among the hospital's different specialties, and interns in transition; in JWO, 2005, pp. 4), to provide continuing education for more experienced care providers, and to train dentists in research methods. One of the goals of the training provided by MDRC is to help the hospital's Graduate Medical Education (GME) candidates become certified by their respective American specialty boards. GME trainees are supervised by about 150 teaching staff members who are all board-certified in their respective specialties (JWO, 2005,p p. 4). MDRC's published goal is to provide the "best support possible for all research endeavours[…]by providing the facilities[…]and atmosphere of inquiry necessary to support and stimulate both basic and clinical medical investigations" (JWO, 2005, pp. 5).

The staffing level at MDRC is provided in Table 1. It is headed by a Chief and Assistant Chief, both military officers, with the staff separated into military (officers and enlisted) and civilian positions (full-time, part-time, and contractors) along functional lines (protocol coordination, veterinarians), and minimally by levels of education (Ph.D.).

Included among the responsibilities of MDRC are the certification and regulation of responsible practices in human and animal research. MDRC discharges its responsibility with mentors teaching residents about research, monthly Institutional Review Board (IRB) meetings for the approval of human clinical studies, and monthly meetings of the Institutional Animal and Care Use Committee (IACUC) for the approval of investigations with animals. Its IRB program has maintained "Federal Wide Assurance" certification that its training programs meet the strict federal guidelines approved by the National Institutes of Health (NIH). Its veterinary facility has maintained certification from the Association for Assessment of Laboratory Animal

Care (AALAC, a nonfederal advisory group) that its animal investigations also meet strict federal guidelines (viz., AALAC conducts peer reviews, but it has no direct regulatory role). AALAC approval indicates a superior program, and that the institution meets all the rules and regulations of the USDA, Public Health Service (PHS), and other regulatory agencies. IRB and IACUC meet monthly to review research proposed in Protocols submitted by official documents along with email copies (DWA, 2004; JWO, 2005). Based on these meetings some of the trainee Protocols are rejected or are required to be revised and resubmitted (INC, 2006, pp. 10).

The Annual Reports state that GME has about 75 physicians and dentists in training in 2004 and 2005 (DWA, 2004, pp. 4; JWO, 2005, pp. 4); however, the actual counts provided in these reports were 74 and 72.

In 2005, MDRC continued to expand its support for GME scholarly activities and its search for extramural funds (JWO, 2005, pp. 4). MDRC conducts three types of research at its facility: basic, clinical, and case studies (INC, 2006). MDRC assists resident trainees by providing research assistants to help them with designing, executing, and tracking their research protocols. However, the current IS is not used in this process, nor is the process automated at any point.

The discretionary funds provided for research average about $140,000 per year (INC, 2006). Extramural grants are an additional source of funds, currently averaging $3–400,000 per year. In 2005, MDRC received $800,000 in extramural funding for laboratory-based research (JWO, 2005, pp. 4).[8]

Some of the research supported by MDRC is performed voluntarily, but a larger fraction is required to be performed: "[…]supporting clinical and basic research for all [hospital] personnel [is] now a requirement for matriculation in many training programs" (DWA, 2004, pp. 4; JWO, 2005, pp. 4). And, "Student nurse anesthetists are required to complete a research project for publication" (DWA, 2004, pp. 4). However, the impact of making research a requirement on the scholarly activities of trainees is unknown.

CASE DESCRIPTION[11]

In 2006, a new director assumed command of MDRC (INC, 2006). Over the remaining two years of his administration, the Chief of MDRC wants to establish MOE's (Metrics of Effectiveness) to measure his organization's success and to craft a plan with MOEs to improve the performance of scholarly activities (i.e., plan, strategy, or Business Model, (BM)). Some resident trainees start their research rotation prepared with a line of investigation derived from their own interests, collaboration with peers, or previous mentors. But if they are not presently working in research or have a research interest, a mentor is assigned to them by MDRC staff. One problem with using MOEs is that much of the research proposed in the MDRC protocols has lasted or may last for a number of years before scholarly products are published, whereas other research protocols may last much less than one year, giving the less complex Protocols an advantage in the generation of scholarly products (see Table 4). As the complexity of a Protocol increases, the time necessary

to complete a program of research also increases. The Chief wants to increase the complexity of protocols, but remain able to measure the impact of complexity on scholarly productivity.

The Chief of MDRC wants to hire additional personnel, but justifications for additional personnel should be based on MOEs and not intuition. MDRC's overall status with all of its funding resources is also unknown. But without clear MOEs, the decision by the administrators has been that potentially 10–20% of new research is turned away. The Chief believes that better MOEs could justify more personnel to administer additional internal and extramural grants.

The Chief is required to give command briefings on productivity (INC, 2006). One administration goal is to make better presentations for Command briefings. In these presentations, the Chief would like to be able to compare his organization's performance with other MDRCs in his region and nationally. In Table 5, data are presented on the performance of MDRCs from other sites and regions across the nation. (per protocol, for the productivity based on the number of scholarly activities, number of personnel, facility space, and total funding).

CURRENT PROBLEMS

Productivity

Sometimes, the ratio of the number of protocols to publications can get as high as about 5:1. The Chief wants MOEs to better justify budget and staff at the beginning of the year, and to determine and track scholarly and funding trends during the year. He believes that scholarly activities have increased while funding has held more or less constant. However, one trade off possible is that the lack of focus among trainees precludes more protocols (INC, 2006, pp. 3–4,7). But he is hesitant to change his business model. If he pushes for increased complexity, it would likely result in even fewer manuscripts being published. Education is also a goal, but a MOE for education is problematic; however, the impact of scholarly products may help to indirectly determine the level of education and training of trainees. Scholarly productivity currently treats abstracts, manuscripts, and presentations equally. The picture presented in Table 5 could change dramatically once journal impacts are incorporated (e.g., see Garfield, 2006).

Technology Components

MDRC is located stateside at one of the American Department of Defense's (DoD) major military installations. Its primary mission is to ensure force readiness and mobilization in order to project power globally from its platform in the U.S. part of its responsibilities means that this military base serves as a major source of IT R&D for DoD. This also means that telemedicine and distance learning, directed by the base, have become a global military resource for all U.S. armed forces. The Chief implied that upon his request, the hospital's Division of Management Information will provide

limited support to implement the recommendations made in this study.

Organizational Concerns

As depicted in Table 5, there is wide variability in the time to complete a protocol. Protocols may take 3–10 weeks to complete, or 3–10 years (INC, 2006). In addition, there are no MOEs to distinguish their intrinsic value or performance (effectiveness and efficiency). The Chief and his Assistant would like to craft a MOE to determine performance based on data. For example, there are fewer protocols in 2006, but whether it makes a difference to their organization's performance or the research it supports are both unknown.

60% of MRDC's research support is derived from extramural grants (INC, 2006). But there are no guidelines to conduct a search for extramural funding or to measure its impact on MDRC's performance, increasing management uncertainty as a result.

Extramural finding appears not to be calibrated into mission plans or performance objectives (INC, 2006). Most of the funds MDRC relies on to perform research are provided in the military budget process, but it has remained relatively fixed. The Chief likens his Division to a research university in that it performs important research for the military and education for hospital GME trainees, but he believes that the process should be more focused.

Management Issues

MDRC is in a state of flux (INC, 2006). Overall, it is difficult to restructure (changing its Business Model), to distribute research funds equitably, or to determine what to do based on the popular literature (e.g., Allen, 2002). Since theory for organizations (Weick & Quinn, 1999) has failed, not surprisingly, data for restructuring outcomes is poor (Kohli & Hoadley, 2006). The end result is an ad hoc or shotgun approach of BPR. In early 2006, the two chief administrators began to consider how to improve the process. From Table 4, some protocols written 2–3 years ago have shown little progress. Presently, there are about 130 open protocols in 2006. But problems exist with MDRC's published data that raise questions about its reliability; for example, not all abstracts are in the FY05 data, meaning that the Annual Report understates performance. The Chief estimates that there are about 60 abstracts per year, but only about 10 were captured by his division in 2005 data (JWO, 2005). The database is currently unable to distinguish between abstracts and posters; further, the number of presentations made by trainees and staff are unknown, especially to outsider groups and organizations (INC, 2006). A correct accounting would help IRB as well as the military's public affairs to get their story out to advertise better. His division has been directed to increase the number of Abstracts published by hospital residents. But some manuscripts are written only after three years, due to complex protocols, plus he has about 25% fewer staff than last year. He is also unable to discriminate between case-study driven Protocols and laboratory bench studies. Protocols are generated by standard forms of 5–30 pages (but all information is either not collected or published; see a sample Protocol Data Sheets in DWA, 2004; JWO, 2005).

The Chief is uncertain about how the mentors external to MDRC are chosen (INC, 2006), their quality and their expertise; for example, one mentor can finish a given protocol in one month, while another takes about eight months to complete a similar protocol. Productivity of the hospital mentors is currently not measured.

Residents are assigned to MDRC for either six months full-time duty (INC, 2006), or one year at about 70% of their time; others are assigned to research duty for two weeks at MDRC before returning to two weeks of duty at the hospital, but the impact of these different assignments is currently not measured. The total number of residents at the hospital is unknown. All residents are placed on a Protocol, but their performance is a function of how rapidly they generate data in either the laboratory or with a case study.

Currently, MRDC is meeting all of the needs of hospital residents, but how well is unknown (INC, 2006). However, setbacks occur during a protocol that impede the execution of research in the short-term, and have unknown effects on the performance of research over the long-term. Some protocols have been rejected to minimize administrative costs and laboratory setbacks, requiring revisions by hand, but this process is not tracked. The internal seminars sponsored by other divisions are not tracked; however, mentors are supposed to review research before a presentation, even before an internal seminar is given. Each year, one internal seminar is sponsored and judged by MRDC, leading to awards given for the best research. Generally, it takes about one year to educate a resident on the research process.

Some residents are required to perform research at MDRC as part of their rotational duties, but a few residents actually want to participate in research projects (INC, 2006).[23] Most residents do case studies; only one resident in the last six years did laboratory research, whereas almost all dental residents perform laboratory bench studies. However, the research performed by the dental residents is usually setup with minor variations among their Protocols, even though dentists push for publications. The Chief's office supports dentists, but has little control over their Protocols.

In the Chief's opinion, attracting better quality residents will require an increase in the quality of publications and getting help from other Division Chiefs, plus having a stronger program (INC, 2006). Better graduates will attract other quality candidates, adding credibility to the BM.

Funding Concerns

Lots of clinical trials sponsored by industry occur on base, implying more research funds for the hospital and MDRC (INC, 2006). Industry grants are part of MDRC's Protocol data (he estimates about 50-60 of 130 of the ongoing Protocols), but MDRC is not tracking the manuscripts generated from these extramural grants. Industry grants often operate with 3–5 year clinic trials at multiple research centers by large research teams. Clinical trials tap into the local population, but data on local pathology is often unavailable and unknown; for example, the number of local diabetics is unknown (INC, 2006). Marketing to industry is good for the hospital. The MRDC Chief is a member of the local city's Research Alliance (including local state and other hospitals) working to attract industry to the area.[24] Seed money provided by the local Medial Association indicates an interest in determining the medical assets available in the area, the size of the local population, the scholarly output in the local area, and operational budgets. However, industry is not tracked in the database.

Equipment and Facility Concerns

Some equipment costs from $20,000–40,000 each requires maintenance contracts, yet sits in the laboratory unused, producing an inefficient use of funds and space (INC, 2006). Funds for medical and nonmedical technology replacement come from the Capital Expense Equipment Program fund (CEEP). The Chief has staff in additional offices at the hospital; the main facility for MRDC is located about one-half mile away from the hospital.

RECOMMENDATION

Throughout the case study, 30 recommendations using IT were reviewed and presented to MDRC management to improve its operational performance (for a full listing, see SSRN website). In general, these recommendations were designed to automate business processes, to reduce waste, and to minimize the loss of information pertinent to strategic decision-making. Every research protocol needs to be drafted, revised and resubmitted for approval then critiqued by the IRB/AALAC as necessary. Automating this process with an Electronic

Protocol System (e-PS) will save time and capture data that can help to identify and remove potential barriers to success (e.g., recently, speedup occurred subsequent to this review by making all submissions electronic, and making research starts not wait for post-IRB/AAUC command re-review). PMS will track due dates, research progress and project completion. The next step will be an automatic document management system (DMS). DMS will track document creation (manuscripts), revision, and submission status among organization internal reviewers and external publication reviewers. In addition, DMS will track author credit and journal impacts as well as providing a document storage-retrieval feature. The more important aspects of ePS and DMS will be the capability to compile data for administration functions (e.g., annual reports, organizational reports, audits), and for real-time online metrics.[25] The metrics will be designed to measure organizational by-in for each military department and support among MDRC members and trainees for the new IT process; how well the MDRC executes its plan as an organization; whether new resources are being brought into MDRC or being saved by MDRC; and how quickly MDRC is executing on average and responding to new opportunities.

SUMMARY

Fragmentation from a lack of focus among the members of an organization indicates a general reduction in motivation to serve the organization, and consequently the need to change a business model to refocus an organization's strategy. The present case study of MDRC indicated that fragmentation among its processes and researchers had reduced control over its future plans. On the one hand, fragmentation of an organization is associated with increased innovation at the individual level (e.g., Benz, 2006), but often at the expense of the organization. Successful organizations are entangled by Command Decision-Making (CDM) into centers of cooperation (Lawless, Bergman, & Feltovich, 2006a; Lawless, Bergman, Louca, & Kriegel, 2006b) to acquire new resources and reduce wasteful expenditures (Smith & Tushman, 2005), but that also tends to reduce innovation from their marginalization of new knowledge in making the organization; in this case, MDRC, more competitive in its marketplace for new grants, improved mentors, better trainee candidates, and new joint ventures with industry or other research facilities. But this reduced innovativeness can be countered by mindfully taking steps with IT to free MDRC from many labor-intensive activities by automating data collection and analytical processes in order to free resources to increase innovation. The overall goal of implementing the recommendations is to reduce the overall costs of MDRC, increase its operational efficiency, to increase its growth by enhancing its ability to attract new extramural fund, and to reduce wasted effort in order to improve organizational effectiveness as a means of saving scarce resources.

KEY TERMS

Agent-Based Model (ABM): Used to create complex models of organizations and systems; for example, with Monte Carlo methods, ABM's can be designed to reduce biases in Critical Path Method (CPM models and Program Evaluation Review Technique [PERT]) models.

Business Models (BM): A business model is a complex plan for business operations and strategy that, when it converges into a consensus, it maximizes productivity, but the stronger the consensus in support of the BM, the more that innovation is reduced. Alternatively, divergence increases opportunities for innovation, but by reducing productivity. This paradox is reduced by creating ambidextrous organizations that can operate in a state of tension between both increasing productivity and innovativeness (Smith & Tushman, 2005).

Command Decision Making (CDM): Top-down decision-making, especially the autocratic decision-making practiced in industry, business, and the military, but also by dictators. CDM reduces innovativeness but increases productivity. Further, CDM often employs consensus rules in its decision-making processes, because CR is open to exploitation (Kruglanski et al., 2006).

Consensus-Seeking Rules (CR): By reducing evidentiary barriers to discussion, consensus-seeking rules often lead to the least common worldview amongst risk perceivers, making it unlikely to reach a practical decision other than to instantiate past organizational practices, but consequently, reducing innovativeness. Further, consensus rules require considerable time to listen to each risk perception.

Majority Rules (MR): Majority rules often lead to faster decisions, more practical decisions, and, counterintuitively, stronger consensuses. The problem with majority rules is that they introduce conflict into decision-making. But if the conflict can be moderated or managed, the result is more learning among the participants compared to consensus rules.

Measurement Problem/Paradox: Assuming the existence of uncertainty in the four interdependent variables of planning-execution and resources-time, decreasing the uncertainty in either set raises the uncertainty in its correspondingly linked interdependent variable.

Methodological Individualism (MI): Game theory (Nowak & Sigmund, 2004) has attempted to substantiate the superiority of cooperation, based on the belief that cooperation leads to the highest social good, even if it is coerced (Hardin, 1968). However, the lack of substantiating evidence in support of the social worth of cooperation is reviewed in Lawless and Grayson (2004).

Metrics: The metrics for MDRC are being designed to convert the measurement problem into an organizational metric of performance.

RFID as the Critical Factor for Superior Healthcare Delivery

A. Dwivedi
University of Hull, UK

T. Butcher
University of Hull Logistics Institute (UHLI), UK

INTRODUCTION

Innovations in information and communication technologies (ICTs) have transformed the manner in which healthcare organizations function. Applications of concepts such as data warehousing and data mining have exponentially increased the amount of information that a healthcare organization has access to. Work flow and associated Internet technologies are being seen as instruments to cut administrative expenses. Specifically designed ICT implementations, such as work flow tools, are being used to automate the electronic paper flow in a managed care operation, thereby cutting administrative expenses (Dwivedi, Bali, & Naguib, 2005, p. 44; Latamore, 1999).

These recent innovations in the use of ICT applications in a healthcare context have altered the manner in which healthcare institutions exploit clinical and nonclinical data. The pendulum has shifted from the early 1980s, wherein the emphasis of ICT solutions for healthcare was on storage of data in an electronic medium, the prime objective of which was to allow exploitation of this data at a later point in time. As such, most of the early 1980s ICT applications in healthcare were built to provide support for retrospective information retrieval needs and, in some cases, to analyze the decisions undertaken. Clinical data that was traditionally used in a supportive capacity for historical purposes has today become an opportunity that allows healthcare stakeholders to tackle problems before they arise (Dwivedi et al., 2005).

However, simultaneously, a number of studies have noted that most information in healthcare is stored in silos, which do not interact efficiently with each other. Kennedy (1995, p. 85) has quoted Keever (a healthcare management executive) who notes that "Healthcare is the most disjointed industry … in terms of information exchange.... Every hospital, doctor, insurer and independent lab has its own set of information, and … no one does a very good job of sharing it."

This problem is being further acerbated by the fact that healthcare managers are being forced to examine costs associated with healthcare and are under increasing pressure to discover approaches that would help carry out activities better, faster, and cheaper (Davis & Klein, 2000; Dwivedi, Bali, James, & Naguib, 2001; Dwivedi et al., 2005; Latamore, 1999). Consequently, the expectations from modern IT applications in healthcare are for applications which support the transfer of information with context. This, in turn, has led to the emergence of clinical information systems that are led by mobile computing technologies (Dwivedi, Bali, & Naguib, 2007; Dwivedi, Wickramasinghe, Bali, Naguib, & Goldberg, 2007; Meletis, Dwivedi, Gritzalis, Bali, & Naguib, 2006).

BACKGROUND

The last decade has seen the rapid emergence and acceptance of healthcare information systems that support the concept of telemedicine and use technologies like Personal Digital Assistant (PDA), Radio Frequency IDentification (RFID) and other mobile computing technologies.

This trend has also been supported by a longitudinal survey (see Table 1) of over 200 U.S. healthcare organisations carried over a three year period, from 2000 to 2002 (Morrissey, 2000, 2001, 2002). As seen in Table 1, cClinical information systems in conjunction with mobile computing have become priority areas for healthcare institutions (see Table 1).

Modern day IT applications in healthcare, centred on mobile computing devices like PDA, RFID, and wireless local area network (WLAN) products, have already demonstrated their potential and financial vi-

Table 1. Adapted from Modern Healthcare's annual survey of information system trends in the healthcare industry (Dwivedi, Wickramasinghe et al., 2007; Meletis et al., 2006; Morrissey, 2000, 2001, 2002)

Year	2000	2001	2002
Number of healthcare organizations surveyed	224 healthcare organizations	212 healthcare organizations	255 healthcare organizations
Clinical Use of Web technology (Intranets)	60% - felt that could IT could facilitate data exchange among caregivers, that is, physician ordering of tests and access to test results	Low interest in maintaining a patient's personal health record accessible via the WWW and matching patients with clinical research. However there is renewed importance of addressing changes in this area due to regulatory obligations	Despite acknowledging that medication interaction and dosing alerts are possible within most IS - implementation has not commenced The few organizations who had made big investments in different HIS (EPR and pharmacy) are reporting substantial returns
General Uses of Web and Intranet technology	Limited use as shown by the following 15% - to share clinical guidelines 13% - to access multiple databases simultaneously 33% - as a bridge to other information systems 40% - for network wide communication of any kind	Some early success from linking "billing and insurance-query operations to payers via the Web" "Significant interest …in using the Web to improve data exchange with physicians and their office staff" About 50% indicated that they had no plans to try anything Web-related in the care-management area	33% - Using existing clinical and financial information sources to construct data repositories so as to that help spot trends and improve decision-making Further 22% are working to implement such practices whilst about 13% plan to start implementation of similar activities within a year

abilities in a healthcare context (Dwivedi, Bali et al., 2007; Dwivedi, Wichramasinghe et al., 2007; Meletis et al., 2006). Recent studies by Meletis et al. (2006) have noted that WLAN-based mobile computing allows healthcare workers to interact in real-time with the hospital's host computer system to enter, update, and access patient data and associated treatments from all clinical departments (Meletis et al., 2006).

A survey of WLAN healthcare installations found that 97% of customers indicated that "WLANs met or exceeded their expectation to provide…a competitive advantage" and that "if the productivity benefits are measured as a percentage return on the total investment … the return works out to be 48%" (McCormick, 1999, p.13). The use of PDAs by physicians has witnessed rapid acceptance in recent times. Today, about 40% of all physicians use PDAs (Serb, 2002). However, the majority of physicians are using PDAs to perform static functions. Most of them use PDAs to collect reference material with:

> *the most popular method being ePocrates - a drug reference application physicians can look up drugs by name or diagnoses, cross-reference similar medications or generic alternatives, and receive alerts on interactions…and which the Journal of the American Medical Association has described as indispensable.* (Serb, 2002, p. 44)

A few pioneering physicians have started to use PDAs in an interactive way, that is, to write prescriptions, to keep a record of all daily clinical patient interactions, and for bedside charting. This trend was confirmed by another study by Martin (2003), who noted that more then 50% of physicians working in developed countries and under the age of 35 used a PDA in 2003.

Similar findings were also reported in other studies. In a related survey, it was found that between 40-50% of all U.S. physicians (including junior doctors, i.e., residents) were either using a PDA or had the ability and the knowledge to use a PDA in healthcare settings (Miller, Hillman, & Given, 2004).

The above findings have been supported by a detailed study by Carroll and Christakis (2004) who noted that from a random study of 2130 physicians, about 35-40% of physicians were using a PDA and that the most common use (80%) of PDAs was for drug referencing. The recent advances in RFID technologies (RFID Journal, 2005) are further promoting the adoption of mobile computing technologies (e.g., PDA) among healthcare stakeholders who have to deal with patient information (i.e., medication, allergies, etc.) on the location of an incident (Dwivedi, Bali et al., 2007; Meletis et al., 2006).

EMERGENCE OF RFID AS THE CRITICAL FACTOR FOR SUPERIOR HEALTHCARE DELIVERY

The origins of Radio Frequency Identification (RFID) systems can be traced to the emergence and consequent large scale adoption of automatic identification procedures (Auto-ID) in purchasing and distribution logistics, and manufacturing companies. The original objective of automatic identification procedures was to provide detailed information about people, goods, and products during transit, so as to enable better tracking. Barcode labels, which today are omnipresent, were the first automatic identification procedures that triggered a revolution in identification systems. Recently, due to their low storage capacity and the fact that they cannot be reprogrammed, they have become less popular, despite being very cheap (Finkenzeller, 2003).

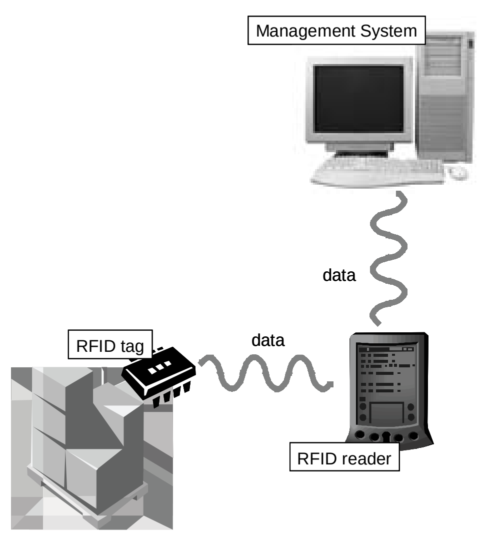
The rapid advances in computer hardware technology enabled the storage of data in a silicon chip. A disadvantage of this system was that smart cards, in order to be read, had to be placed in a smart card reader, which would in turn supply the smart card with power and a clock pulse, which was necessary for the smart card to function. However, the key drawbacks of smart cards as an automatic identification procedure are (a) smart card readers are expensive to maintain, (b) they tend malfunction, and (c) smart card readers kept in public places are prone to acts to vandalism (Finkenzeller, 2003).

These drawbacks in turn led to the evolution of automatic identification procedures wherein ideally the power required to operate the electronic data-carrying device was to be transferred from the reader using contact-less technology, and due to this connotation contact-less automatic identification procedures are called RFID systems (Finkenzeller, 2003).

An RFID as demonstrated in Figure 1 consists of three components: (1) a tag, (2) a reader, and (3) a computer network. The tag consists of a microchip that has some specific data that enables easy identification and an antenna, which is used to enable transmission of data. The second component of a RFID system is a reader and the reader uses radio waves to read the tag, and transmit data a computer system (i.e., the third component of a RFID system). The computer system enables the processing of information (Davis, 2004; Fanberg, 2004; Wilding & Delgado, 2004). This information system is illustrated in Figure 1.

RFID systems enable automatic identification and detail location of physical goods. Individual items or batches of goods carry an RFID transponder or "tag" that transmits a radio frequency signal. This signal can be remotely detected by an RFID "reader." When connected to a materials management system, the data downloaded from the reader is used to monitor and control the movement of those goods (Davis, 2004; Fanberg, 2004; Wilding & Delgado, 2004). In fact, it is the remote communication capability of RFID which differentiates it from existing traceability technologies. Previous automatic identification technologies such as printed batch cards and bar coding required individuals to read or scan the item/batch specific data at the location of the goods. Previous automatic identification

Figure 1. Radio Frequency Identification System (Davis, 2004; Fanberg, 2004; Wilding & Delgado, 2004)



technologies are also time consuming, laborious, and prone to inaccuracies, due to the scale and complexity of typical warehousing and distribution operations.

A number of studies (Anonymous, 2006a, 2006b, 2006c; Barlow, 2006; Carroll & Christakis, 2004; Davis, 2004; Fanberg, 2004; Hoppszallern, 2006; Pitts, 2005; Schuerenberg, 2005; Scott, 2006; Wicks, Visich, & Li, 2007; Williamson, 2006) have recommended the use of RFID in a healthcare context. In October 2005, the need to incorporate RFID in a healthcare context gained a big push when the Food and Drug Administration (FDA)—the U.S. based regulatory body—approved the use of RFID devices for medical purposes in humans, and listed RFID devices as a Class II medical device with special controls (Schuerenberg, 2005).

Some of the key advantages to be gained by the adoption of RFID in a healthcare context include: (1) tracking and combating counterfeit drugs (Fanberg, 2004; Pitts, 2005), (2) obtaining critical patient medical information, when the patient is clinically unable to provide the same (Schuerenberg, 2005), (3) preventing medication errors, (Anonymous, 2006b; Schuerenberg, 2005; Wicks et al., 2007), (4) tracking medical equipment (Anonymous, 2006c; Briggs & Martin, 2006; Scott, 2006), and (5) reducing surgical errors (Williamson, 2006).

RFID HEALTHCARE SUCCESS STORIES

St. Clair Hospital, a 331-bed hospital based in Pittsburgh, Pennsylvania, was keen to improve patient safety by employing IT to prevent errors in medication administration. In 2004, the hospital introduced a medication verification system that combined PDAs with scanning devices. The scanning devices would fit in the PC card slot on the PDAs. The nurses would use the PDAs to scan bar codes located on: (a) patient wristbands, (b) medications, and (c) their name/identification cards. When the system was introduced, nurses discovered that the entire process of scanning increased the time they had to spend on the process of medication administration (Schuerenberg, 2005).

Subsequent analyses revealed that a large part of the increase could be traced to the fact that the hospital's software required nurses to log in to the hospital system either by scanning the bar code on their ID badge or typing in a password on the PDA via a virtual keyboard. Furthermore, the use of bar codes meant that the nurses had to position the PDA near a patient's bar coded wristband to scan it and as their and/or patients wristbands became worn out, it would take the nurses several attempts before they could get a good scan on older bar coded wristbands (Schuerenberg, 2005).

To resolve this problem, the hospital administrators replaced the bar coded wristbands, patient wristbands, and clinical identification badges with RFID tags and the scanning devices that would fit into the PC card slot on the PDAs with a RFID tag. The introduction of RFID tags significantly reduced the time spent by the nurses on medication administration whilst also ensuring that medication errors were reduced. In addition, as RFID devices can exchange information without the need for direct device to device contact, as is the case for bar coded wristbands, the patient would not have to disturbed during the process, which was a regular occurrence when the bar coded wrist band was attached to the patient's arm (Schuerenberg, 2005).

Another use of RFID devices in healthcare has been to track clinical devices. In the U.S., as per Joint Commission on Accreditation of Healthcare Organization requirements, hospitals are responsible for ensuring that all their devices are regularly maintained or upgraded (as the case may be). Hospital staff have often complained that they have trouble tracking down medical devices (e.g., ventilators, intravenous pumps, etc.), some of which are regarded as life-saving-medical devices. The problem also has an administrative perspective as they have to tracked in-time for maintenance purposes as per the Joint Commission on Accreditation of Healthcare Organization requirements (Scott, 2006).

The paediatric critical care unit at the Vanderbilt Children's Hospital in Nashville, Tennessee, was concerned about the fact that, when required, a large part of their medical equipment could not be located, and often a search for medical equipment would result in location of their equipment in other parts of the hospital facility. When medical equipment could not be found, rental expenses for replacement equipment would cost the between $3,000 and $6,000 a month (Davis, 2004).

Vanderbilt Children's Hospital commissioned American Biomedical Group Inc. (ABGI), an Oklahoma City-based technology management company to implement a RFID solution with a deadline of 6 months for implementation to tackle their problem at a cost of $500,000. During the project, ABGI discovered that less than 50% of the paediatric critical care unit medical equipment were available at any given time, and adoption of RFID managed to alleviate their problems of equipment tracking (Davis, 2004).

Christiana Hospital, based in Newark, New Jersey, was concerned about the staff time lost and the distress caused in the time taken to locate patients who were based in the hospitals emergency rooms. A study in November 2004 found that "multiple phone calls and walking tours had to be carried out" in the hospitals emergency department to locate about 20% of their admitted patients. The hospital was able to resolve this problem by adopting a RFID system and within a 12 month period the hospital noticed dramatic improvements along a number of measurable targets (Briggs & Martin, 2006).

Mercy and Unity Hospital, a U.S.-based hospital was concerned about the effectiveness of their security mechanisms for tracking patient suffering from Alzheimer's Disease. In a pilot scheme, they used RFID tags which were embedded on patient wristbands to track patients suffering from Alzheimer's Disease, so as to prevent them from leaving the hospital unit. During the 4-month test period, adoption of RFID equipped wristbands helped reduce the number of patient watches by about 60% and saved about $30, 000 in costs (Davis, 2004).

The U.S.-based Joint Commission on Accreditation of Healthcare Organizations (JCAHO) has noted that it receives about five to eight new voluntary reports of surgical errors each month and further suspects that more cases of surgical errors are not being reported. The JCAHO further revealed that 76% of voluntary reports of surgical errors involved surgery on the wrong body part or site (Williamson, 2006).

In September 2005, Richard Choie, a physician at Washington School of Medicine, St. Louis, Missouri, adapted RFID technology to prevent surgical errors, and has termed the system as CheckSite. The objective of this system is to enforce surgical site marking that in turn will prevent surgical errors. The system has been implemented at Barnes Jewish Hospital in St. Louis in the U.S. and consequent to its adoption, "there have been no wrong site surgeries and no near misses" (Williamson, 2006).

The CheckSite system requires the physician to mark the surgical site on the patients body—this is done in consultation with the patient or the patient's representative. After the site is marked, the physician will place a special sticker on the patient's wristband, which has a RFID chip which will be deactivated by the sticker. If this process is not done before the surgery, the wristband will emit visual or auditory signals, and will page the concerned hospital personnel, thereby preventing surgical errors. This system is also financially quite cheap, as it costs only $2.50 per patient, apart from some installation expenditure (Williamson, 2006).

A more expensive and robust application of RFID technology to prevent surgical errors is the SurgiChip. It is the world's first RFID product approved for marking an anatomical surgical location. The SurgiChip system initially embeds surgical related patient information on an RFID smart label and on a chip that travels with the patient into surgery to help prevent errors. The information is also placed in the patient's file. Before the operation, the information on the chip is confirmed with the patient's chart and ID wristband (Williamson, 2006)

In February of 2004, the FDA, a U.S. based regulatory body had issued an guideline to pharmacy manufacturers that required them to provide a "pedigree" for each of their products. The origins of the term pedigree came from the art world wherein pedigrees are accepted as proof of authentication (Fanberg, 2004).

GlaxoSmithKline (GSK), in 2006, commenced an innovative RFID project to provide a pedigree for Trizivir (an HIV medicine) so as to enhance patient safety. GSK have started to put RFID tags on all bottles of Trizivir distributed in the U.S. These tags when scanned at a close range verify that the medication contained in the bottle is Trizivir. This mechanism was considered necessary as the U.S.-based National Association of Boards of Pharmacy had listed Trizivir as one of 32 drugs most susceptible to counterfeiting and diversion medication. Currently this project has cost GSK several million dollars and it has allowed GSK to track the genuineness (i.e., pedigree) of the medication as it moves through the distribution chain unto the at the point of dispensation to the consumer (Anonymous, 2006a)

The cost of implementing an RFID system in healthcare ranges from about $20,000 to $1 million—the variance dependent upon the size of the area where RFID technology is to be deployed and the application (e.g., patient tracking, equipment tracking etc) for which it is required. A typical return on investment on a RFID in healthcare system typically is less than a year, and in exceptional cases, the annual ROI can be up to 450% a year (Davis, 2004).

FUTURE OF RFID

Recent estimates on adoption of RFID systems in healthcare organizations indicate that RFID adoption in healthcare is on the verge of a dramatic rise beginning 2007. This estimate is partly based on a survey of more than 300 respondents. The results from the survey indicated that about 75% of respondents noted that adoption of RFID would lead to significant improvement in to patient safety and this was regarded to be the prime mover behind the projected rise of RFID adoption in healthcare (Anonymous, 2006b). The contention that RFID adoption in healthcare is on the verge of a dramatic rise is also supported by another study which has noted that, despite the fact that currently only 4% of U.S. hospitals use RFID to track moveable equipment, a recent study in 2005 by Hospitals & Health Networks Most Wired Survey indicated that over the next 2 to 3 years almost all hospitals will be adopting RFID based solutions to track medical equipment (Scott, 2006).

In 2006, the FDA commented that it is disappointed with the slow progress shown by drug manufacturers in adopting RFID solutions to enable better tracking of drugs so as to prevent counterfeiting. Since then, the FDA has released a draft compliance policy guide for public comment which makes a statement of origin of prescription drugs, that is, their "pedigree," compulsory (Anonymous, 2006b).

Another key obstacle in the uptake of RFID adoption in healthcare is lack of clear industry or government guidance on standards for adoption of RFID technology in Healthcare and about 60% of respondents indicated that they will delay their decisions on RFID adoption until clear guidelines or industry practices emerged. (Anonymous, 2006b).

CONCLUSION

On December 22, 2005, John Halamka, M.D., and CIO at Boston's CareGroup Healthcare System was the first person in the world to have an RFID chip embedded on his shoulder for medical use. The chip, whose size is about the size of a grain, was implanted in a painless 15 minute medical procedure under local anaesthesia, and it was inserted in a two-inch area on the arm between the elbow and shoulder. The chip inserted was manufactured by Applied Digital and is known as VeriChip. It contained a 16-digit identification number. The RFID chip can be read via a Pocket Reader (one has to wave the RFID reader over the patient to have access to all of the patient's medical information available on Boston's CareGroup Healthcare System (Schuerenberg, 2005). The drawback is that if John Halamka is being treated in any other then Boston's CareGroup Healthcare System, the physicians would not have access to John Halamka's medical data.

We believe that in the near future, the John Halamka experience will become the norm. This is based on the success stories of RFID in healthcare and of RFID in other sectors, which clearly demonstrate that there is a clear advantage of using RFID, in both clinical and nonclinical settings. Whilst the use of RFID is not compulsory, unlike legislation for bar coding, RFID has clear advantages (e.g., scan multiple items at the same time, remote scanning, scanned items do not have to be in sight at the time of scanning, etc.) over the traditional bar code as an automatic ID procedure. However, more work is required: (a) to improve the interface and interconnection abilities of RFID with mobile computing devices like handheld PDAs or tablet computers, and (b) to enhance the ability of RFID devices to work seamlessly with mobile computing devices in accessing EPRs.

KEY TERMS

Bar Codes: A barcode can be defined as data that is recorded in a form that is machine-readable, and can be used by machine barcode readers, and are typically used to implement Auto ID Data Capture systems.

FDA: Food and Drug Administration is a governmental agency within the United States Department of Health and Human Services. It consists of eight offices: (1) Center for Biologics Evaluation and Research (CBER), (2) Center for Devices and Radiological Health (CDRH), (3) Center for Drug Evaluation and Research (CDER), (4) Center for Food Safety and Applied Nutrition (CFSAN), (5) Center for Veterinary Medicine (CVM), (6) National Center for Toxicological Research (NCTR), (7) Office of the Commissioner (OC), and (8) Office of Regulatory Affairs (ORA).

Radio Frequency Identification: Radio-frequency identification (RFID) is an automatic identification method which uses devices called RFID tags. An RFID system consists of three components: (1) a tag, (2) a reader, and (3) a computer network. The RFID tag consists of a microchip that has some specific data that enables easy identification and an antenna, which is used to enable transmission of data. The second component of a RFID system is a reader and the reader uses radio waves to read the tag, and transmit data a computer system (i.e., the third component of a RFID system).

RFID Tagging of Pharmaceuticals

David C. Wyld
Southeastern Louisiana University, USA

INTRODUCTION

Pharmaceuticals play a more prominent role in American health care than in any other nation. The North American market today comprises 47% of the global prescription drug market, which now exceeds half a trillion dollars, with Americans spending approximately $251.8 billion annually on pharmaceuticals. This is up significantly from a decade earlier, when American consumption represented approximately one-third of the world market (IMS Health, 2006a). America's insatiable demand for prescription drugs has led to serious cracks in the drug supply chain of the world's leading pharmaceutical market.

This chapter examines the size and scope of the problem of counterfeit pharmaceuticals, both globally and in the United States. It looks at the impact this crisis is having both on public health and the pharmaceutical industry. Today, leaders in both the pharmaceutical industry and government are looking to more stringent regulations and radio frequency identification (RFID) tagging of pharmaceuticals as a way to head off the problems associated with an increasingly leaky drug supply chain. This chapter outlines the steps being taken in the United States to help secure this vital supply chain. Finally, an analysis is given of the impact the shift to electronic pedigrees of pharmaceuticals will have both on the pharmaceutical and RFID market spaces.

BACKGROUND

The World Health Organization (WHO) estimates that as much as 10% of the global pharmaceutical market—a half-trillion-dollar marketplace—is counterfeit. In some countries, the WHO estimates that 25% or more of the entire drug supply is counterfeit. The New York City-based Center for Medicines in the Public Interest recently predicted that by 2010, counterfeit drug sales will reach $75 billion worldwide, almost doubling from the estimated counterfeit sales in 2005. The Federal Bureau of Investigation (FBI) estimates that the financial impact of counterfeit drugs on U.S. companies is $30 billion a year (Brooks, 2006; Eban, 2006).

Today, the toll of counterfeit drugs is mounting worldwide. Consider these recent news headlines from around the globe:

- In Hamilton, Ontario, Canada, Abadir Nasr, a registered pharmacist, was arrested by the Royal Canadian Mounted Police. Mr. Nasr, who was working at a retail drug store, dispensed counterfeit doses of Norvasc® to heart patients—pills filled with only talc. The local coroner investigated five patient deaths—all caused by a heart attack or stroke—that may have been brought about by the substitution of the counterfeit drug (Pitts, 2005).
- Within the last year, counterfeit versions of three popular drugs—Lipitor® for cholesterol, Cialis® for erectile dysfunction, and Reductil® for obesity—have surfaced in England. One British expert, Graham Satchwell, has estimated that 100,000 counterfeit drug imports are dispensed by the U.K.'s National Health Service annually (Eban, 2006).
- In China, a counterfeit drug smuggling ring was recently broken up that involved almost a half-million fake pills, including Lipitor® and all three major erectile dysfunction drugs (Cialis®, Levitra®, and Viagra®). Eleven Chinese nationals were arrested in the scheme, along with one U.S. citizen. The American had only recently been released from a New York State penitentiary for his involvement with counterfeit drugs in his home country, and he was drawn to the lucrative China market upon his release from jail due to the considerable money involved.
- Lipitor® is a cholesterol-reducing medication taken by more than 600,000 Americans, making it the most widely prescribed drug in the country. The U.S. Food and Drug Administration (FDA) announced on August 31, 2005, that it had busted a Lipitor® counterfeiting and smuggling ring that

was trafficking almost $50 million worth of the drug (Gottlieb, 2005).

There is already evidence that counterfeit drugs are worsening public health in general around the globe. For instance, in many Southeast Asian countries, more than half of the drugs sold do not have the correct formulation or levels of the active ingredient (National Drug Intelligence Center, 2005). This is especially telling in the case of malaria. Deaths from the dreaded disease are on the rise, despite the introduction of the latest and most effective antimalarial drug, Artemisinin®. Because of the poor quality of Artemisinin—both legitimate and illegitimate outlets—drug resistance to antimalarials is rapidly increasing. In fact, it has been estimated that more than 100,000 people die annually directly as a result of counterfeit antimalarial medications in the region (Stevens, 2006). Likewise, new drug-resistant forms of the HIV virus that causes AIDS have been largely attributed to the use of counterfeit medications for HIV-positive individuals (Gaul & Flaherty, 2003). In the United States, customs agents recently seized a large quantity of Tamiflu®, which is highly sought after today due to fears of avian flu. Epidemiologists fear that fake Tamiflu® could actually exacerbate any HN51 outbreak, as the counterfeit treatment could actually help the virus mutate into new drug-resistant strains (Stevens, 2006).

Scott Gottlieb, M.D. (2005), the FDA's Deputy Commissioner for Medical and Scientific Affairs, recently outlined the negative health outcomes that may occur directly from the use of counterfeit pharmaceuticals. These include actual cases where the fake drugs have contained ingredients that were:

- Inactive
- Incorrect
- Improperly dosed
- Subpotent
- Superpotent
- Expired
- Contaminated

Gottlieb (2005) summarized, "The result is risks to patients' health, either risk to their safety directly if the products are dangerous or risks from people suffering from complications from the many diseases that prescription drugs can treat today—but that the counterfeit versions cannot."

Why is there such unfortunate growth in counterfeit pharmaceuticals? The answer is multifaceted and complex, but the causal forces can be captured in the following:

- Profitability of the activity
- Relative ease of the activity
- Demand for drug products
- Cost of prescription drugs
- Web of country-specific regulations
- Vast cost disparities among countries on products
- Ease of transporting pharmaceuticals (which are generally shipped in cases, not pallets)
- Practice of relabeling, repackaging, and reimporting controlled substances
- Low prospect of being caught once the counterfeit pharmaceuticals are integrated into the drug supply (Pitts, 2005).

Indeed, according to the U.S. Department of Justice, the lure of counterfeit pharmaceuticals is so enticing that both organized crime and rogue entrepreneurs around the world are increasingly turning to the production and trade of fake, legal pharmaceuticals over narcotics and other illegal drugs (Gaul & Flaherty, 2003). The global pharmaceutical industry's counterfeiting problem is only exacerbated by the nature of its supply chain. In fact, the industry has been characterized in a recent *CIO Magazine* article as having "one of the world's most complex and opaque supply chains," producing "a web of legitimate, quasi-legitimate and illegitimate trade" (Patton, 2006, n.p.). With that, the sourcing of counterfeit drugs is now global, as fake pharmaceuticals have come from not only China and India but also from Central and South American as well as African and European countries (Stevens, 2006).

The United States has long thought of itself as being immune from the type of counterfeit drug problems found "over there" in areas of the world such as Southeast Asia and Africa (Pitts, 2005). This is because in the United States, 90% of all prescription drugs pass through the systems of just three drug wholesalers on their way to retail and hospital pharmacies. These are:

- AmerisourceBergen
- Cardinal Health
- McKesson (Navas, 2005)

As Gaul and Flaherty (2003) described the situation, pharmaceutical executives, retail pharmacies, and government regulators have relied upon these consolidated intermediaries as providing a "straightforward chain" that is the "gold standard" for control over the drug supply.

According to the FDA, the number of actual prosecuted cases of counterfeit pharmaceuticals has risen dramatically in the past decade. As can be seen in Figure 1, while there was a slight decline last year, which has been attributed to the increased focus of law enforcement authorities on the problem of counterfeit drugs, the number of cases this decade is far above historical levels (Brooks, 2006). In fact, the FDA's investigations of counterfeit medicines have increased by *almost tenfold* since 2000. Even the FDA's most conservative estimate—that approximately 1% of our nation's drug supply is counterfeit—amounts to some 35 million prescriptions a year. While this is far below the global rate of 10% estimated by the WHO, it is still an astonishing figure (Eban, 2006).

What drugs are being counterfeited? In the United States, the National Association of Boards of Pharmacy (NABP) coordinates the National Specified List of Susceptible Products for use by those in the pharmaceutical industry and law enforcement. The NABP specifies that for a drug to be included on its counterfeit watch list, it must meet one or more of the following criteria:

- Drug is prescribed for serious or life-threatening conditions
- Injectable drug or immune globulin has a single source
- Product has already been adulterated, counterfeited, diverted, or stolen
- Price is high
- Pedigree has been faked or not provided (Top 32 drugs most susceptible to counterfeiting, 2006).

With the latest addition of Viagra®, the NABP's (2004) list (see Table 1) has now reached 32 medications. As can be seen, these susceptible prescription medications include everything from cancer and hypertension drugs, drugs for those fighting HIV, and the "usual suspects" of erectile dysfunction medications. According to the most recent market statistics, Americans take more than 100 million prescriptions of these 32 drugs combined, which represent nearly $30 billion in annual sales, or more than 10% of pharmacy revenues. In fact, four of the top 10 prescribed medications (see Table 2) are among the medications listed on the NABP's counterfeit watch list. Sales of

these four prescription drugs alone (Lipitor®, Zocor®, Epogen®, and Procrit®) reached $19 billion in 2005 (IMS Health, 2006b).

Yet, with the growing demand for prescription drugs, there is increasing concern among pharmaceutical and retail executives, along with government regulators and law enforcement authorities, over the rapid increase in the illicit prescription drug trade, with a significant rise in the theft and diversion of pharmaceuticals, particularly in the realm of narcotics. According to the most recent statistics available from the U.S. Department of Justice's National Drug Intelligence Center (NDIC) in its *National Drug Threat Assessment 2005*, there has been a 16% increase in such activity involving narcotic drugs in the 2000-2003 time period. In the United States, the rates of abuse for prescription drugs, particularly in the areas of painkillers and amphetamines, have increased sharply since the early to mid-1990s (NDIC, 2005).

Most of the theft of controlled substances is internal, as employees of the pharmaceutical drug manufacturers and commercial distributors account for most of the diverted pharmaceuticals (NDIC, 2005). Likewise, according to the most recent National Retail Security Survey report, retailers attribute 48% of their pharmaceutical inventory loss to employee theft. The remainder of pharmaceutical theft comes from shoplifting, break-ins and armed robberies of pharmacies and clinics, and theft from individuals, most commonly from friends or relatives who possess legitimate prescriptions for the desired medications (Hollinger & Dabney, 2002).

All told, according to a confidential report from the Pharmaceutical Security Institute (PSI), a research organization funded by the pharmaceutical industry, the United States experienced 76 incidents of counterfeiting, diversion, and theft of pharmaceuticals in 2004. To put this number in perspective, according to PSI, this is the highest reported number in the world, ahead of even China and Colombia (Eban, 2005).

Counterfeit drugs cost pharmaceutical companies an estimated $46 billion annually (Patton, 2006). Considering the fact that pharmaceutical companies expend sometimes hundreds of millions of dollars to develop new drugs, this is a hit directly on their profits. According to the analysis of Professor David Taylor (2005) of the University of London School of Pharmacy, "The average selling price of a patented medicine is many times the cost of its basic ingredients. This is because "sunk" costs associated with research, manufacturing and marketing must be recouped within a narrow window of time" (n.p.). In fact, the marginal production cost of a new medicine will by definition be much closer to its ingredient cost and its eventual generic price. Just making one additional batch of a product will typically require very little extra spending. Thus, counterfeit drugs take away incremental revenue from the pharmaceutical companies, the vast majority of which would have gone straight to their bottom lines.

In actuality however, counterfeit drugs can have an even more dramatic impact. Bret Kinsella of ODIN Technologies stated, "In their most benign manifestation, counterfeit drugs are akin to placebos" (quoted in Wyld, 2006b, p. 44). Yet their very presence in the market weakens legitimate brands; when patients and doctors fail to see results from the use of what are unknowingly counterfeit products, they will be less likely to use or prescribe that brand of drug in the future. Thus, counterfeit drugs do not simply take away from a fixed pie of sales for a particular brand or even an entire product line, as over the long term, counterfeits can weaken or even kill a brand's and even a company's long-term image and prospects (Harrop, 2006).

RFID TAGGING OF PHARMACEUTICALS

There have been significant developments in regards to RFID tagging of prescription drugs. Leading players in the pharmaceutical marketspace have recently announced significant RFID labeling programs for three of the most sought after (both legally and illegally) drug products:

- Pfizer announced that by the end of the first quarter of 2006, all shipments of Viagra®, the lifestyle drug for erectile dysfunction, would carry RFID tags (Gohring, 2006). Likewise, the major drug wholesaler McKesson will use Viagra® as the subject of its own RFID trial (Patton, 2006).
- The privately held Purdue Pharma has greenlighted a significant pilot program to apply smart labels to all shipments of OxyContin®, a narcotic painkiller (Wyld, 2006a).
- GlaxoSmithKline (GSK) has begun tagging its all bottles of its Trizivir®, a drug for HIV infection (Trizivir bottles get ID tags, 2006).

For Pfizer, Purdue Pharma, and GSK, the decisions to move to RFID on these specific items were based on the popularity of these products, both in the mainstream and grey markets. All are among the leading counterfeited and diverted prescription drugs today. For GSK, the choice of Trizivir was due to the fact that it was found to be one of the 32 most counterfeited drugs. According to Peggy Staver, Pfizer's Director of Trade Product Integrity, the decision to implement RFID was an easy one for her firm, commenting, "It was an easy decision for us, as it's safe to say that Viagra has been our most counterfeited item" (Smith, 2006, n.p.). Likewise, Purdue Pharma is concentrating its RFID-tagging efforts on shipments of OxyContin®. According to Aaron Graham, Purdue Pharma's Vice President of Corporate Security, RFID gives his firm new visibility and control over the sensitive supply chain for OxyContin®, which he describes as a "a high-flyer outside of legitimate commerce" (Wyld, 2006a, n.p.)

There have been significant developments in the area of RFID labeling of pharmaceuticals, as Pfizer, Purdue Pharma, and GlaxoSmithKline have all announced major RFID tagging programs of their most counterfeited and diverted products in the early part of 2006 (Wyld, 2006b). Despite these recent announcements from industry leading firms, both the federal and state governments are initiating new regulatory efforts to tighten the pharmaceutical supply chain.

At the state level, attention has focused on assuring the pedigree of the drugs being given to patients. Several states, including Florida and California, are beginning to enact their own regulations over the pharmaceutical supply chain (Skrinar, 2005). Such laws call for an "e-pedigree," providing the ability to track all controlled substances from the manufacturer to the wholesaler's distribution center and ultimately to the pharmacy (Wyld, 2005). A number of states, including Arizona, Indiana, Oklahoma, and Texas, are instead focusing on requiring at least paper pedigree information, not on all prescription drugs but rather those medications that are acquired from outside of what is being called the "normal distribution channel" (Wasserman, 2005). As can be seen in Figure 2, this would generally focus on the third model of pharmaceutical distribution, where drugs come from outside the country or from atypical sources. Still, such pedigree requirements will not necessarily necessitate RFID, as most states' requirements can be met through the use of paper records and bar codes (ABI Research, 2006).

At the federal level, the FDA has been consistent in its position that better control over prescription drugs is one of today's most pressing public health and safety concerns. In a February 2004 policy statement, the FDA (2004a) advised that "use of mass serialization to uniquely identify all drug products intended for use in the United States is the single most powerful tool available to secure the U.S. drug supply" (n.p.). The FDA recommended that the pharmaceutical industry move to implement RFID tagging throughout the supply chain for controlled substances by 2007. While at present the FDA has not moved to mandate the usage of RFID at the individual item level, it has strongly encouraged all participants in the drug supply chain to cooperatively work to make this possible. To that end, in November 2004, the FDA (2004b), wanting to keep the agency's oversight function to a minimum, issued a directive that allowed pharmaceutical companies to implement RFID labeling and product tracking without having to first gain approval from the agency.

In the end, could RFID be made mandatory in the labeling of prescription drugs in the world's largest pharmaceutical consuming country—the United States? If some members of the U.S. Congress have their way, what has been advice and wishes from the federal agency overseeing the American pharmaceutical sector could become federal law. There are two bills before Congress that would lead to such an RFID mandate (Roberti, 2006).

FUTURE TRENDS

There are exciting opportunities for research in the use of RFID in the pharmaceutical market. Looking ahead, researchers in the areas of management, marketing, supply chain management, logistics and distribution, and operations management will have chances to conduct a variety of firm-specific investigations, including:

- Case studies on RFID implementations
- Analyses of best practices
- Operations/economic impact

There will also be interest in longitudinal studies, looking at the impact of the introduction of RFID technology on the protection of the drug supply from counterfeiting. Similar studies could compare the RFID penetration in the pharmaceutical market to other retail sectors.

Figure 2. Drug distribution models

CONCLUSION

Pharmaceuticals are indeed likely to be one of the first consumer-level applications of RFID tagging of products. With all the concern over counterfeiting drugs among both regulators and the pharmaceutical companies, one would expect to see only rosy forecasts for RFID in the pharmaceutical sector. However, two recent reports have taken starkly contrary positions on just how fast RFID-based labeling and control will spread in the pharmaceutical marketspace.

IDTechEx issued a report—RFID Forecasts, Players & Opportunities: 2006-2016—which was extremely bullish on the pharmaceutical RFID market. As shown in Table 3, IDTechEx predicts that the tag market alone will grow by more than 700% in the next year alone and grow almost exponentially over the next five years as more companies choose to—or are mandated to—tag pharmaceuticals at the item level in more areas of the global market. From the perspective of the report's author and IDTechEx's Chairman, Dr. Peter Harrop (2006), the rapid growth of RFID in the pharmaceutical sector can be explained by the "unusually broad range of benefits" item level tagging offers in this sector. He commented, "Frankly, no other form of RFID can claim such a full range of benefits, including saving lives, preventing sickness, reducing theft, fraud, counterfeiting and costs, providing more responsive customer service and recalls of higher integrity" (n.p.). Harrop (2006) predicts that "drug tagging has so many compelling drivers for all in the value chain as well as regulatory authorities, it may rise to be around 60% of all item level tagging in 2010" (n.p.).

On the bearish side, Oyster Bay, New York-based ABI Research warns of a slowdown in the move to RFID in this critical sector. According to ABI's 2006 report, titled "The RFID Healthcare and Pharmaceutical Markets," ABI Research (2006) warns that despite the success of Pfizer's and Purdue's highly publicized pilots, the pharmaceutical industry will only start tagging a total of about 10 pharmaceutical products by the end of this year. Sara Shah, ABI Research's industry analyst for RFID, goes so far as to observe that the earlier forecasts for the speedy implementation of RFID in the pharmaceutical sector may have been a case of "irrational exuberance" (ABI Research, 2006, n.p.).

Whichever trend line proves to be correct, the important point is that RFID does provide compelling benefits for the pharmaceutical sector in its ability to head off the explosion of counterfeiting going on today. By 2010, with or without government mandates, the pharmaceutical sector will, of necessity, move to RFID labeling of its products. If not, multibillion dollar investments in life-saving medicines could be evaporated overnight, and worse, the lives of billions of people may lie in the balance as our aging and growing populations

Table 3. Predictions for item-level tagging of pharmaceuticals over the next decade

Year	Regions Affected	Activity Level	Approximate Number of Tags (in Millions)
2006	• USA	• Some prescription drugs in the USA	35
2007	• USA • Europe	• Some prescription drugs in the USA	270
2008	• USA • Europe • East Asia	• Many prescription drugs in the USA	1083
2009	• USA • Europe • East Asia	• All prescription drugs in the USA • Many prescription drugs abroad	5250
2010	• USA • Europe • East Asia	• All prescription drugs in the U.S. • Many prescription drugs abroad • Possibly some OTC (over-the-counter) nonprescription medications	1600

Source: IDTechEx, RFID Forecasts, Players & Opportunities, 2006-2016 depend on the ingenuity—and genuineness—of the pharmaceuticals that keep us alive.

KEY TERMS

Active Tag: A type of RFID tag that has its own power supply (battery or external power), and, when interrogated by a reader, the tag emits its own signal. Typically, active tags have far greater read distances than passive tags, and they can be combined with sensors to provide information on the environment and condition of the item. They are also more expensive than passive tags and – due to the battery – have a limited life span.

Automatic Identification (Auto-ID): This is a broad term, encompassing technologies used to help machines identify objects. A host of technologies fall under the Automatic Identification umbrella, including bar codes, biometrics, smart cards, voice recognition and RFID.

Electronic Article Surveillance (EAS): Acknowledged by many as the first widespread use of RFID technology widely used today in the retail environment and in libraries, these systems use microwave or inductive technology "readers" to detect the presence or absence of EAS tags as a means of detecting and deterring theft. When an item is purchased (or borrowed from a library), the tag is turned off. However, when someone passes a gate area holding an item with an EAS tag that hasn't been turned off, an alarm sounds. These tags are inexpensive and do not contain any data.

Electronic Product Code: This is a unique number - stored in the chip on an RFID tag -that identifies an item in the supply chain, allowing for tracking of that item. EPC is the generally accepted acronym for "Electronic Product Code."

Frequency: The number of repetitions of a complete wave within one second. 1Hz equals one complete waveform in one second. 1KHz equals 1,000 waves in a second. RFID tags use low, high, ultra-high and microwave frequencies. Each frequency has advantages and disadvantages that make them more suitable for some applications than for others.

Harvesting: The way passive tags gather energy from an RFID reader's antenna to be able to respond to the reader.

Passive Tag: A type of RFID tag that does not have its own power supply. Instead, the tag draws power from the reader, which sends out electromagnetic waves that induce a current in the tag's antenna. Without an onboard power source, passive tags have a lesser read range than active tags. However, they cost less than active tags and have an unlimited life span.

Power Level: The amount of radio frequency (RF) energy radiated from a reader or an active tag. Higher power outputs enable longer read ranges. However, most governments regulate the power levels at which RFID readers can operate in order to avoid interference with other RF devices.

Radio Frequency Identification: An automatic identification technology that uses radio waves to identify objects. RFID is the generally accepted acronym for Radio Frequency Identification.

Read: The process of retrieving data stored on an RFID tag by sending electromagnetic waves to the tag and converting the radio waves the tag sends back into data.

Read Rate: The number of tags that can be read by an RFID reader in a given time period.

Read/Write: The ability of an RFID system to change the data that are stored in a tag. For example, as a product moves from the final packaging area to the warehouse, a read/write tag can be modified to reflect the new location so that now, when interrogated, it passes the new location as part of its updated data stream.

Reader (also called an interrogator): A device that communicates with RFID tags. The reader has one or more antennas, which emit radio waves and receive signals back from the tag. Readers may have a digital display to relay information to the operator and may transmit data on to an organization's computer network infrastructure. Readers can be either fixed or portable, and today, they are beginning to be integrated into other electronic devices such as PDAs (personal digital assistants) and cell phones, and even into objects such as pens.

Semi-Passive Tag (also called battery-assisted tags): This type of tag is similar to an active tag in that there is an onboard battery. The battery is used to run the microchip's circuitry and to boost the effective read range of the tag. Some semi-passive tags sleep until they are woken up by a signal from the reader, which conserves battery life, while some are programmed to broadcast at set intervals of time.

Sensor: A device that responds to a physical stimulus and produces an electronic signal reporting on that stimulus. Sensors can be tailored to report on a variety of environmental conditions, including temperature, movement, vibration, and shock.

Slap and Ship: A manufacturer placing RFID tags on cases and/or pallets at the last possible point before shipping from a supplier to a mandating retailer or other organization. With a slap and ship strategy, a manufacturer or distributor is simply trying to meet the requirements of another firm's RFID mandate rather than attempting to capture any data—and value—from the RFID tagging in their own system.

Smart Label: A generic term that refers to a printed label that typically contains printed information, a bar code identifier, and an RFID tag. The label is considered to be "smart" because of its ability to communicate with an RFID reader.

Robust Blood-Glucose Control of Type I Diabetes Patients Under Intensive Care Using Mathematica

INTRODUCTION

This article presents a robust control design method on frequency domain using *Mathematica* for regularization of glucose level in Type I diabetes persons under intensive care. The method originally proposed under *Mathematica* by Helton and Merino (1998) is now improved with a disturbance rejection constraint inequality, and is tested on the three-state minimal model. Nonlinear closed loop simulation in state-space, in case of standard meal disturbances, demonstrates the robustness of the resulted high-order linear controller. The obtained results are compared with H_∞ design implemented with Matlab, proving that the controller (for the considered model parameters) can operate properly, even in case of parameter values of the worst-case scenario.

The blood-glucose control is one of the most difficult control problems to be solved in biomedical engineering. The main reason is that patients are extremely diverse in their dynamics and, in addition, their characteristics are time-varying. The investigations of Hernjak and Doyle (2005) discourage the use of a low complexity control such as PID, if high level of performance is desired. To design an optimal, high-quality control, one needs a relevant model of the process, as well as a proper control technique. There are several studies in both areas (Parker, Doyle, & Peppas, 2001).

The mostly used model, and also the simplest one, proved to be the minimal model of Bergman, Philips, and Cobelli (1981), but its shortcoming is its big sensitivity to variance in the parameters. Henceforward, the plasma insulin concentration must be known as a function of time. Therefore, extensions of this minimal model have been proposed (e.g., de Gaetano and Arino (2000) analyzed the different models of glucose-insulin interactions in human body). Also, more general models have been used in the literature, like the model developed by Hovorka, Shojaee-Moradie, Carroll, Chassin, Gowrie, Jackson, Tudor, Umpleby, and Jones (2002), or the 21st order nonlinear model of Sorensen (1985).

However, probably the best way to approach the problem of blood-glucose control is to consider the system model and the applied control technique together (Makroglou, Li, & Kuang, 2006; Parker et al., 2001). As models of diabetic systems are imprecise by nature, some research works are concentrated on adaptive control techniques using online parameter estimation (e.g., Lin, Chase, Shaw, Doran, Hann, Robertson, Browne, Lotz, Wake, & Broughton, 2004), others like Ruiz-Velazquez, Femat, and Campos-Delgado (2004) or Parker, Doyle, Ward, and Peppas (2000) suggest robust control design.

This study focuses on robust control design, for regulating glucose level in Type I diabetes patients under intensive care. The investigations were done using the minimal patient model of Bergman et al. (1981). The method applied using *Mathematica* lays on a different approach by that under Matlab. The corresponding *Mathematica* program package OPTDesign was originally developed by Helton and Merino (1998). The technique of the computations and closed loop simulations, employing the *Mathematica* Application, Control System Professional Suite (CSPS), together with OPTDesign, has been already demonstrated by Palancz (2006).

Mathematica is a mathematical program capable to work step by step, like a mathematical reasoning machine. In this way, it offers a more didactic approach as Matlab, which is focused on solving the problems in a more technical way (Palancz, Benyo, & Kovacs, 2005).

Here the authors have slightly improved this technique by suggesting an effective disturbance rejection constraint inequality for the disturbance transfer function. In order to check the quality, especially the robustness, the controller is designed with the most favorable model parameter values, but tested with the values representing the worst-case scenario in terms of difficulty of the system dynamics for control purposes. Results are compared with those obtained by Hernjak and Doyle (2005).

MODEL EQUATIONS

The three-state minimal patient model of Bergman et al. (1981) consists of the following equations:

$$\begin{aligned}\dot{G}(t) &= -p_1 G(t) - (G(t)+G_B)X(t) + h(t)\\ \dot{X}(t) &= -p_2 X(t) + p_3 Y(t)\\ \dot{Y}(t) &= -p_4(Y(t)+Y_B) + i(t)/V_L\end{aligned} \quad (1)$$

where the three state variables (as well as outputs) are the plasma glucose deviation G(t) (mg/dL), remote compartment insulin utilization X(t) (1/min), and plasma insulin deviation Y(t) (mU/dL). The control variable is the exogenous insulin infusion rate, i(t) (mU/min), whereas the exogenous glucose infusion rate h(t) (mg/(dL min)) represents the disturbance.

Other variables represent parameters of system given by Equation 1. The physiological parameters are G_B (mg/dL) the basal glucose level, Y_B (mU/dL) basal insulin level, V_L (dL) the insulin distribution volume and p_1, p_2, p_3, p_4 as the model parameters. As numerical values, the authors worked with the numerical values determined by Furler, Kraegen, Smallwood, and Chisolm (1985): p_1 = 0.028 (1/min), p_2 = 0.025 (1/min), p_3 = 0.00013 (dL/(min^2 mU)), p_4 = 5/54 (1/min), G_B = 110 (mg/dL), Y_B = 1.5 (mU/dL), V_L = 120 (dL).

The steady-state values used for linearizing the system are: G0 = X0 = Y0 = 0, h0 = 0, and for i0:

$$i_0 = p_4 Y_B V_L = 16.667 \text{ (mU/min)} \quad (2)$$

Loading CSPS of *Mathematica* the linearized system around the vicinity of the steady-state can be calculated. The system proved to be stable, controllable, and observable.

CONCEPT OF THE ROBUST CONTROL DESIGN

Performance Requirements

Considering the complementary sensitivity function of a general closed loop system (Zhou, 1996):

$$T(s) = \frac{P(s)C(s)}{1+P(s)C(s)} \quad (3)$$

where P(s) represents the transfer function of the considered plant, and C(s) the transfer function of the controller. As a result, the robust control method on frequency domain implemented by OPTDesign briefly can be summarized, satisfying the following conditions (Helton & Merino, 1998):

1. T must satisfy disk inequality:

   $$|K(i\omega) - T(i\omega)| \le R(i\omega), \text{ for } \omega_a \le \omega \le \omega_b \quad (4)$$

   where K and R are fixed functions that embody the desired specifications of the system. K is called the center of the disk, and R is called the radius.
2. Defining the gain-phase margin as $m = \inf|1+PC|$, the constraint should be:

   $$|T(i\omega)-1| \le \frac{1}{m}, \text{ for all } \omega \quad (5)$$

3. The bandwidth of the complementary sensitivity function (T(iω)) should be below than 1/√2 or in other words below -3 dB (Zhou, 1996).
4. For the closed-loop roll-off, specifying a given n and α_r, as well as the roll-off frequency ω_r for which the $C(i\omega) \le \frac{\alpha_r}{|\omega|^n}$ inequality is held, then for large ω frequencies, it is true that $T(i\omega) \le |P(i\omega)C(i\omega)|$, or by other words:

$$|T(i\omega)| \leq \alpha_r \frac{|P(i\omega)|}{|\omega|^n}, \text{ for } |\omega| > \omega_r \quad (6)$$

In addition, the authors introduced a new condition for disturbance rejection requirement. Considering $P_d(s)$ the transfer function of the disturbance and having the sensitivity transfer function (1-T(s)), the inequality should be:

$$|1 - T(i\omega)| \leq \frac{c}{|P_d(i\omega)|} \quad (7)$$

where c is a constant less than 1.

These requirements all together can be summarized in the requirement envelope presented in Figure 1.

In order to ensure the control purposes, as well as the proper performance of the optimized process, the following performance requirements were chosen: $c = 0.95$; $\alpha_r = 8.7641*10^{-7}$; $n = 2$; $\omega_d = 2.65$; $\omega_b = 4$; $\omega_r = 6.5$; $\alpha_g = 2.5$; $\alpha_b = 0.9$. Results are shown in Figure 2.

Optimizing Performance Function

Assuming that T(s) has no right-half plane (RHP) poles (is internally stable), the designing problem can be formulated as it follows:

- Given a plant P(s), a set of performance requirements $\overline{P}$ and a set $\overline{I} = \{ T(s) \in RH^\infty \}$ of rational internally stable transfer functions the task is to determine optimal $T \in \overline{I}$ which satisfies $\overline{P}$.

Starting from Equation 4, the performance requirements can be expressed in form of disk inequalities, which can be written in the following way:

$$\frac{1}{R(i\omega)^2}(|K(i\omega) - T(i\omega)|)^2 \leq 1, \text{ for } \forall\omega \quad (8)$$

Now, for a given T, one can calculate the largest value of the left-hand side:

$$\gamma(T) = \sup_\omega \left(\frac{1}{R(i\omega)^2}(|K(i\omega) - T(i\omega)|)^2 \right) \quad (9)$$

If T is optimal (T^*), it means that $\gamma(T^*) \leq \gamma(T)$ for all $T \in \overline{I}$ and satisfying $\overline{P}$. By other words, this means:

$$\gamma^* = \inf_T \sup_\omega \left(\frac{1}{R(i\omega)^2}(|K(i\omega) - T(i\omega)|)^2 \right) \quad (10)$$

Figure 1. Requirement envelope for robust control design in frequency domain. Data from Helton and Merino (1998).

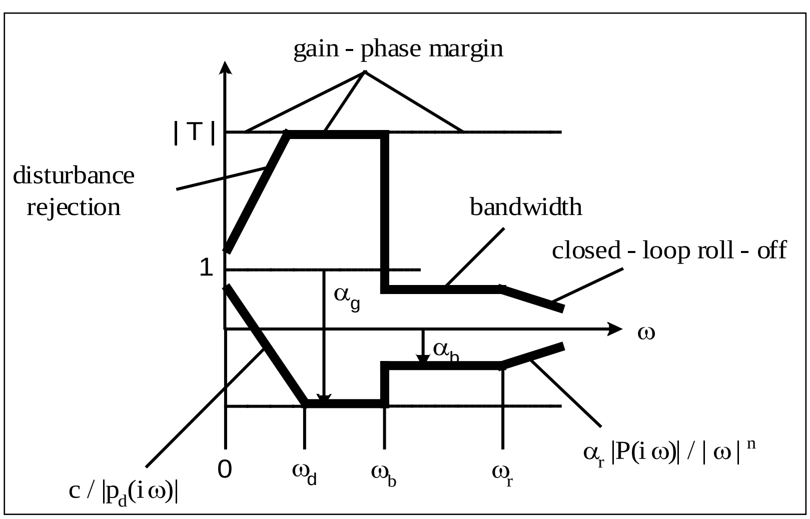

Figure 2. The actual original and smoothed requirements envelopes.

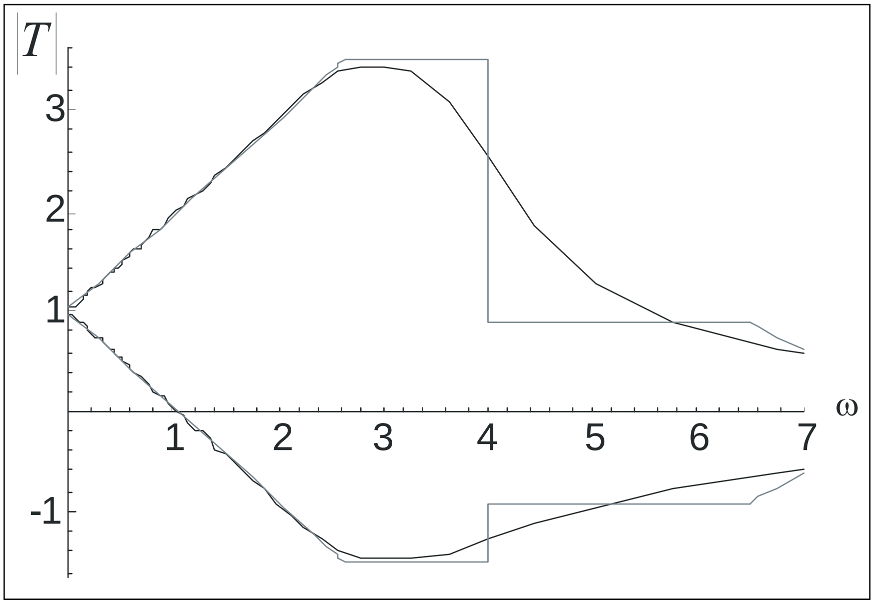

This γ^* value is basically the solution of the H_∞ suboptimal problem (Zhou, 1996) representing the worst-case performance of T^* (optimal worst-case performance of T). Its value should be in the [0,1] interval to guarantee robust performance (and also satisfying Equation 8). Furthermore, Helton and Merino (1998) demonstrated, there exist functions $A,\ B \in RH^\infty$ that:

$$T = A + BT^+, \text{ for some } T^+ \in RH^\infty \qquad (11)$$

or by other words, there exists a formula which gives all $T \in \bar{I}$ depending on RHP poles and zeros of the given plant P.

Running OPTDesign for the requirement envelope shown in Figure 2, the obtained result for γ^* was 0.3679. This value was also checked with the mu-toolbox of Matlab (working with a different approach of the H_∞ problem as *Mathematica* does), and a very similar result was obtained. Figure 3 presents the numerical values of the optimal T^* inside the considered constraining envelope. For internal stability parameterization the A and B functions were:

$$A(s) = \frac{1}{(s+2)^5},\quad B(s) = \frac{1}{(s+2)^5} \qquad (12)$$

With the calculated γ^*, the authors have checked the performance requirements similarly as in Palancz (2006), taking into account the specifications of Helton and Merino (1998). The resulted indicators diagnosing the optimality of the obtained solution are:

- Flat = 0.0032. It is a number between 0 and 1, measuring the "nonflatness" of the current guess. 0 represents the absolute optimal value.
- GrAlign = $1.9984 \cdot 10^{-15}$. It represents the gradient alignment, indicating how a certain winding number has the "appropriate value." Its true answer at optimality diagnostics is equal to 0.
- Ned = $4.35 \cdot 10^{-5}$. It is also a positive number, indicating when small that the numerical calculations contain little numerical error.

The numerical values of these optimal T^* will be approximated with a proper rational function. The minimal approximation error found a 20th order rational function. The local error of this approximation can be

Figure 3. The numerical values of the optimal T inside the considered constraining envelope.*

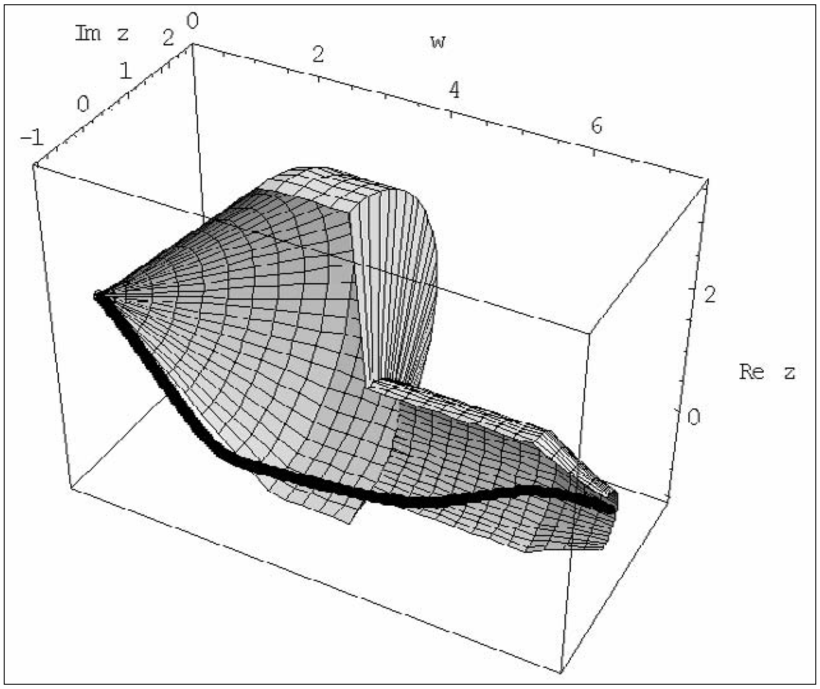

Figure 4. Local error of optimal rational T (in 10^{-4}).*

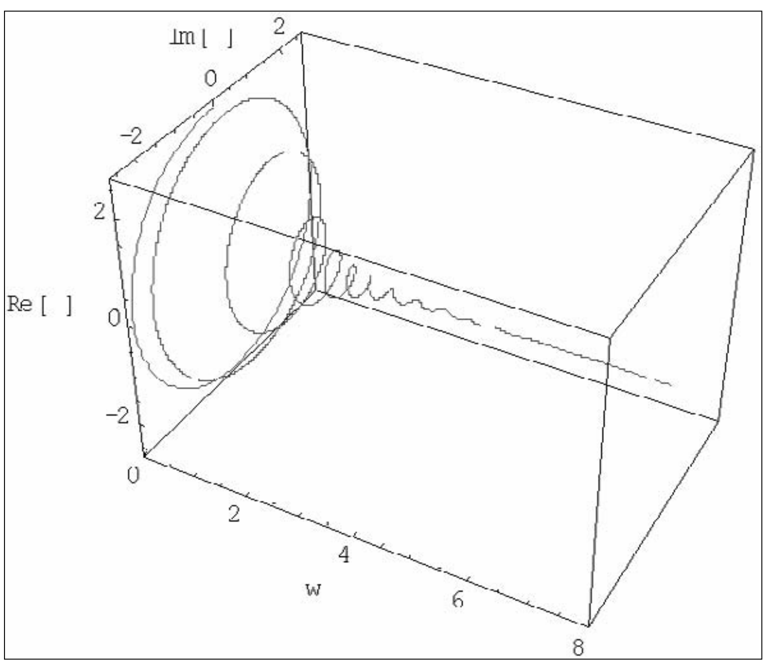

seen in Figure 4. Applying Equation 3, one can express the transfer function of the control part, C(s). In order to simulate the nonlinear closed-loop in time, domain C(s) should be converted in state-space form.

To reduce the size of the state-space form of the controller, the authors use the "MinimalRealization" technique built in CSPS. As a result, a sixth order model is obtained (see Box 1).

Nonlinear Closed Loop Model Simulation

Using the parameters given at the beginning of this article (see Equation 2), the performance of the control was tested by using a standard meal disturbance with about six hour duration. This was modeled by Lehman and Deutsch (1992) (see Figure 5).

Using the designed controller, Figure 6 and Figure 7 presents the controlled dynamics of the blood glucose and insulin infusion. These results are very similar to those published by Hernjak and Doyle (2005).

Testing Robustness of the Controller

The investigations of Hernjak and Doyle (2005) showed that considering the minimal model with $p_1 = 0$, the system is unable to regulate the glucose level on its own. Indeed, the eigenvalues of the linearized model in case p1 = 0 are {- 0.0925926, - 0.025, 0}. As a result, the open loop system is unstable, but controllable. The result of the simulation carried out with the same controller, but with nonlinear plant model having the

Box 1.

$$A=\begin{pmatrix} -5.488 & 0.189 & 0.0042 & -0.002 & -7.34\cdot10^{-6} & -1.27\cdot10^{-6} \\ -39.61 & -5.99 & -0.1335 & 0.066 & 2.29\cdot10^{-4} & 3.96\cdot10^{-5} \\ 81.03 & 12.05 & -1.754 & 0.876 & 0.003 & 5.23\cdot10^{-4} \\ 3823.16 & 568.03 & -83.024 & -5.837 & -0.02 & -0.003 \\ 50135.2 & 7448.91 & -1088.6 & -76.22 & -13.21 & -2.31 \\ -205374 & -30513.7 & 4459.35 & 312.25 & 54.54 & 5.26 \end{pmatrix}$$

$$B=\begin{pmatrix} -2.52\cdot10^{-5} & 1.87\cdot10^{-4} & 0.00038 & 0.018 & 0.237 & -0.97 \end{pmatrix}^T$$

$$C=\begin{pmatrix} -4.597\cdot10^{10} & 1.94\cdot10^{9} & 1.123\cdot10^{8} & -1.064\cdot10^{8} & 170668 & -33566 \end{pmatrix} \quad (13)$$

Figure 5. Considered exogenous glucose infusion (meal disturbance). Data taken from Lehman and Deutsch (1992).

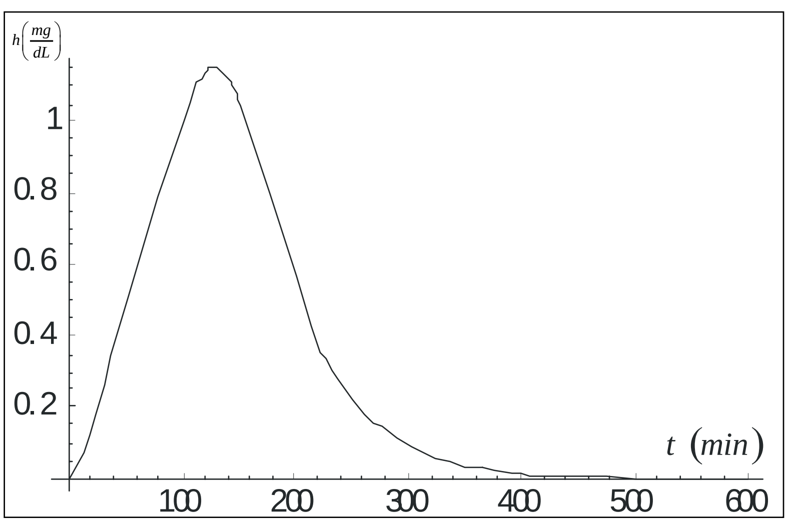

Figure 6. Controlled dynamics of blood glucose concentration, G(t)

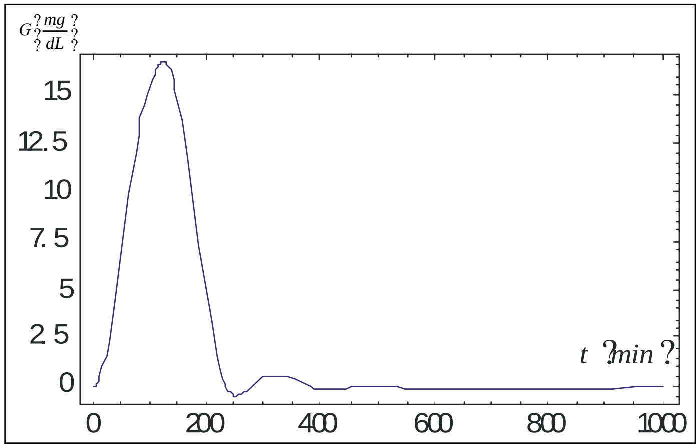

Figure 7. Controlled dynamics of insulin infusion rate, i(t).

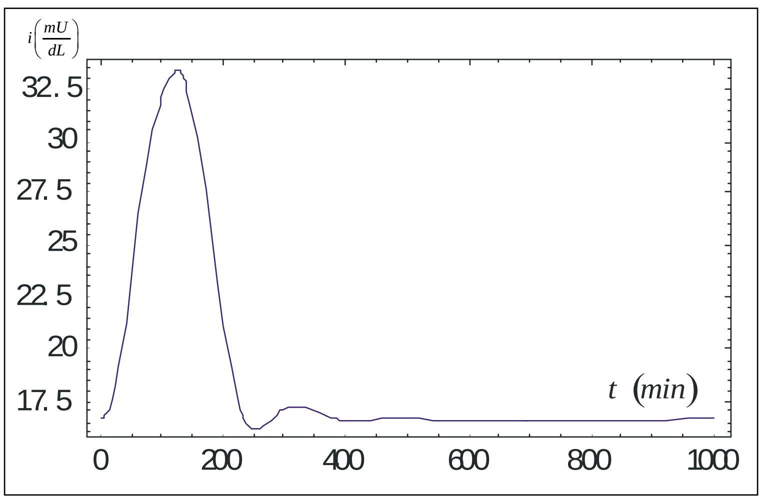

value of p1 = 0, shows that the compensator is able to control the system even in this case. However, the quality of the control is not as good as it was in case of p1 = 0.028. Results are illustrated by Figure 8 and Figure 9, and these are very similar to those obtained by Hernjak and Doyle (2005) with applying NMPC (Nonlinear Model Predictive Control) control method (in case of NMPC the best result was obtained, and the controller was originally designed for instable situation, p1 = 0).

FUTURE TRENDS

In the future, investigations of presented robust control method using *Mathematica* will be tested for the minimal Bergman model extended with the mixed meal model (Roy & Parker, 2006). The results will be supported by clinical measurements.

From another point of view, the robust method will be tested on the Type I diabetes model of Sorensen (1985). In this case, the aim is also to reduce the model keeping its characteristics, but in a reduced way, one is able to investigate it much easier.

Figure 8. The controlled dynamics of blood glucose, G(t) in case of unstable plant, p_1=0.

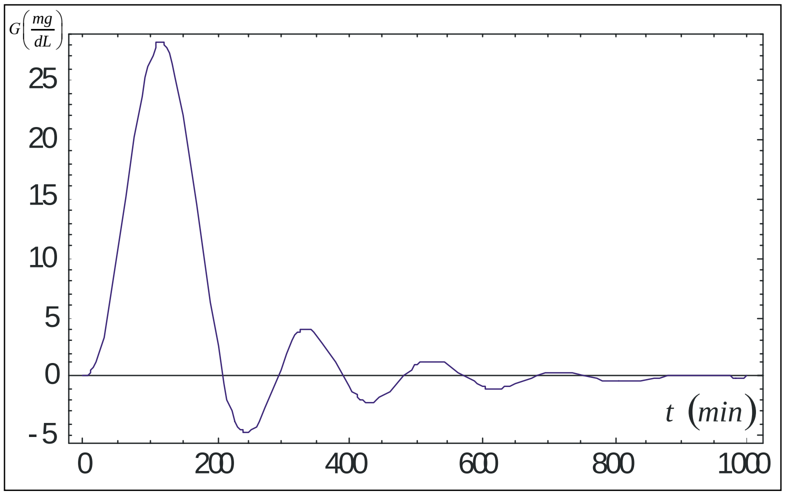

Figure 9. The controlled dynamics of insulin infusion rate, i(t) in case of p_1 = 0.

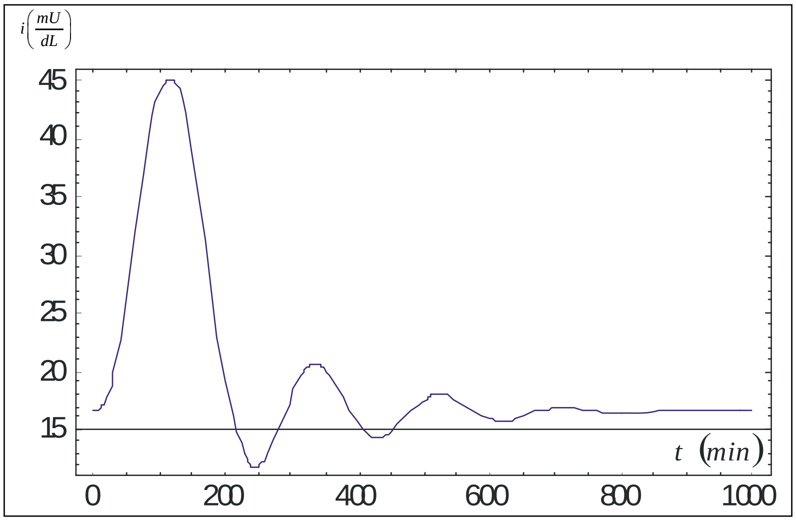

CONCLUSION

A practical method has been presented for designing a robust controller to regulate glucose-insulin system for Type I diabetic patients under intensive care. Employing *Mathematica* CSPS Application, together with the OPTDesign package developed by Helton and Merino (1998), one may define a linear, high-order compensator, in relatively easy way, which can be tested via nonlinear model simulation. Introducing a proper disk inequality constraint for disturbance rejection, this method is proved to be effective for providing acceptable control performance, even in a case when the model parameters have changed, and the system became unstable. After further verifications, this method could provide a useful help to control of blood glucose level, and in the optimization process of diabetic administration.

Furthermore, the proposed design procedure can be easily adapted to other problems too, where uncertainty plays an important role and robustness of the control is indispensable.

INTRODUCTION

Since the 1980's, questions have been asked the world over about the efficiency and contribution of nursing in the hospital treatment of patients and nursing performance within the framework of nonhospital health care.

The cause for these tendencies has many roots. For one, we can determine a push in professionalism through the increasing importance of nursing sciences on whole. The basic focus is on comparability, standardization (Johnson et al., 2005), and securing quality (ICN, 2003). Also, a significant part of nursing systems internationally are publicly financed and legally determined. This has the consequence that the political decision-makers, particularly in context with the financing and planning of nursing structures, have more of an interest in controlling the nursing systems and disposing of useable nursing data.

The different health systems have reacted to this cost pressure, not least because of the various political conceptions according to national criteria, even though it has been established that the basic tendencies of individual steps to reform are comparable in all health systems. Because of this, a diversification of the nursing professions corresponding to national demands was noticed on an international scale and the attempt was made to assign the nursing performance to the level of training. At the same time, the structural, hierarchical cooperation of the different nursing professions was regulated.

A professionally and politically specific intention concerns the availability of valid nursing data which serve just as much as a political decision basis for developing the need for nursing performance in the individual professional levels as they serve as essential support within the framework of information of individual nursing processes. Initiatives for reform and the forming of data structures in nursing came from the nursing branch, or rather nursing sciences themselves, as well as from the government decision-makers.

Along with other reform objectives in the area of professional training and distinctions of competence, the focus is on the definition of a list of nursing performances (nursing interventions) in context with nursing data. These performances have to be clearly defined and serve as a basic fundament for nursing documentation as well as for care planning on a national scale.

Nursing Minimum Data Set (NMDS) has been developed as a scientific term for this process, although the term is understood in different ways in different countries.

BACKGROUND

Nursing as an independent profession has a more far-reaching tradition in America than it does in Europe. In Europe, nursing as an autonomous profession and also therefore the science of nursing, only established itself in the last 20 years of the 20th Century. It is therefore not surprising that many foundations and discussion anchors of nursing science and practical nursing have their roots in Anglo-American areas such as the USA or Australia. This also applies to a large degree to the discussion about minimum nursing data which were defined by American nursing scientists at the end of the 1980s (Nonn, Mayer, & Evers, 2002). While in

America the issue of recording systems has a prominent position, the discussion about minimum nursing data in Europe is accompanied by establishing a "professional identity," which allows it to be followed through the constitution of junior and superordinate nursing job descriptions with corresponding training levels.

Nursing sciences and political decision-makers function as communicating vessels during the development of national NMDS, even though the motives for this development are completely different.

Being responsible, politicians concern themselves with constructing and configuring the nursing the system itself; the nursing scientists are actually more occupied with the systematology and basic knowledge from the nursing data.

The intrinsic problem relating to the development of NMDS arises from the differing motives and information expectance. This is because the government as legislator and designer of the nursing system has to fall back on data structures which enable data consolidation on varying metalevels and therefore enforce and secure structural and financial of nursing data systems. In respect thereof, the structural elements are an important part of governmental considerations.

The interest of the nursing sciences is concentrated on the availability of data structures which allow outcome studies and other nursing studies on a scientific level being simultaneously suitable for the support of the individual nursing processes (Lamb, Mowinski Jennings, Mitchell, & Lang, 2004). During the development of national NMDS, this implicit discrepancy can be observed time and again by means of various process descriptions. For example, the description of the objectives of the Swiss NMDS project were at first fairly extensive and included not just the demands of nursing science but also showed clear interdisciplinary traits (NURSING Data Model, 2001). Whilst implementing the project itself, these demands had to be largely reduced and adapted (NURSING Data Final Report, 2004). However, the focus of governmental needs of data availability in order to target the nursing system was expanded upon quite considerably or remained unchanged in the core areas.

This conflict of interests during the development of the NMDS is on the whole distinctly recognizable in all national projects. There are, however, less changes to the initial objectives where the government took the initiative from the start to develop an NMDS and made its objectives an essential part of the NMDS project, a case in point being Australia. Here the National Minimum Data Sets are created, coordinated by the Australian Institute of Health and Welfare (AIHW) (2006), which is also responsible for a broad reporting system in health affairs.

Regarding this, it can be discovered that governmental motivation and position on developing a nursing system followed by the establishment of a NMDS is of high importance for the final concrete embodiment of an NMDS.

THE INFLUENCE OF THE GOVERNMENT ON THE NURSING SYSTEM AND THE DEVELOPMENT OF NMDS

Politics Influencing Nursing Systems

In current literature about nursing research, a lot of room is taken up by the question about how far political intervention and system parameters influence the nursing concept and therefore nursing outcome.

In contrast to English-speaking and Scandinavian countries, where the question about political influence and actions on the nursing system is well established in nursing research, this approach in the European-German speaking area has only just begun. Particularly in connection with the effect of changed quality criteria of a nursing unit, current studies based on the longitudinal analysis method, attempt to produce evidence—limited by political parameters and the structural changes in nursing associated with them—that a changing effect in quality of nursing was achieved or rather is verifiable (Blegen, Goode, & Reed, 1998).

The influence of politics on the nursing system and nursing outcome is shown as being particularly extensive in these studies. According to this trend, individual sections, for example, the question of mortality, are examined in connection with political system design. The results of American nursing research tend to show that a direct connection exists between nursing outcome—in this case mortality—and politically specified structures (Czaplinski & Diers, 1998).

Within nursing research, Oddi and Cassidy (1990) chose a systematic approach regarding the interaction between politics and nursing. Their approach assumes the protection of human rights by American law. Based on the "rights of human subjects" and the

"Patient's Bill of Rights," the authors categorize the rights of the patients on a "professional, public, and private" sphere.

Whilst the majority of studies have portrayed nursing as a monocausal passive system which is at the mercy of politics, and have simply referred to the effects of political intervention, the authors have rather assumed interaction. This is even more remarkable as the protection of the patient and his data from the researcher and misuse within the context of clinical research takes an important position. Here it is the task of the government to protect the patient through standards. The authors arrive at the conclusion: "As professionals, nurses must be actively involved in the formation of public policy…" and introduce a applicable model—over and above the nursing research—within the setting of American structures.

Gorenberg, Alderman, and Cruise (1991) also take the same line. They write: "As health care providers, nurses have a professional responsibility to act on behalf of the public they serve by influencing health policy."

In a more recent study, Maas and Delany take a completely different approach (Mass & Delany, 2004). The authors critically view the significance of nursing outcome studies and relate upon the quality of the studies, preliminary irrespective how far the political system intervention takes place or not. As a parameter, based on the approaches of Fawcett and Russell (2001) ("grounded in the social contract between nursing and society"), the authors discuss and examine which data the system currently supplies or is in the position to supply to nurses.

First of all, the quality of communication and documentation in American health care facilities is discussed and examined. The result being that a standardized "nursing language" associated with the nursing process is not evident in a quality that system related outcome studies or data based scientific evaluation requires. The authors refer to a series of current field studies and come to the conclusion that sufficient terminology was indeed developed for individual case-related nursing, but that this terminology is insufficient for analyses on a metalevel.

There actually exist various IT-supported documentation systems in American health care facilities, the focus of these systems, however, is geared and adapted to in-house processes; in context with the missing nursing terminology, a sufficient basis for data exploration can not be assumed. Altogether the authors assess that actually the theoretical and operative conditions are not eligible for outcome studies in the USA due to the single case orientation of the nursing system.

Hence for political intervention there is not sufficient basic data for political intervention concerning the nursing system and therefore—if nursing wants to achieve goal-orientated and system-supported system adjustment—these shortcomings have to be rectified. "National and international policy implications are also compelling. As noted, nursing practice data are not currently included in large national datasets […] are often used for quality analyses that influence health policies in the United States and other countries" (Marin, Rodrigues, Delaney et al., 2000).

Nursing research outside of the USA and GB is also concerned with the question of data quality in connection with political and systemic interventions. In particular, terminology questions in connection with the definition and documentation of the nursing process are the object of European and German research. Hinz and Dörre (2002) introduce one approach.

A central point here is also the development of comprehensive and exact nursing terminology based on the nursing diagnoses definitions and classification of the North American Nursing Diagnosis Association (NANDA). The further development of nursing terminology through the International Council of Nurses (ICN) represents, according to the authors' opinion, a useful instrument, even though it could be shown that these classification system and terminology are not sufficiently implemented into nursing practice in German-speaking areas (Schaubmayr, 2004).

The authors also assume IT support as the instrument to create the requirements for comparability, and consequently, systematic intervention which are goal-orientated and able to be evaluated.

Another important question in association with the effect of political intervention on the nursing system and consequently on nursing outcome, is the concept of politics in a narrower sense and the kind of political intervention that occurs.

Maas and Delaney (2004) use a very wide term of political structures, and consider particular institutions and legislators, superior control structures and management functions, as well as financiers of the health system in the wider sense as politically active institutions. Even if they do not define the interactions or the interdependences of the different control mechanisms for the nursing system in particular and even more do not go into the different appearance of control, this concept of policy and intervention corresponds to the described wide approach of system interaction.

National Projects for the Development of NMDS

The development of NMDS in the individual states exhibits not only different priorities, but also different stages of development. Whilst there is still no national NMDS project in Austria, Australia, for example, is at a very mature stage on a national level. Therefore, in this article chosen projects will be briefly described.

Since 1987, Belgium has made it obligatory in its general hospitals to collect nursing data according to the Belgian Nursing Minimum Data Set (BeNMDS). This NMDS was developed between 1983 and 1986 together with two university research centres and the Belgian nurse professionals association. The BeNMDS comprises of a list of twenty three nursing action related items (nursing interventions) which, together with encoded institution and patient data, is collected quarterly on 15 consecutive days. With this approach, Belgium dispensed with a part of the nursing process data, but the collection of nursing relevant data can serve as a basis for the calculation of nursing input and demand. Due to this data collection policy, Belgium is assumed to be the only country that has long term nursing data at its disposal for analysis and report.

Based on the construct of the Belgian Minimum Data Set, similar concepts were also developed in other European countries. The difference to Belgium is that not all countries implemented a simultaneous legal obligation for the collection of data, or rather nationwide collection of data. The Dutch Minimum Data Set (NeNMDS) which was developed in the 1990s comprises nursing interventions, nursing diagnoses, and nursing outcome categories (Goossen, 2001).

Along with proprietary development of NMDS, the BeNMDS was repeatedly tested and adapted for national requirements (Turtiainen, Kinnunen, Sermeus, & Nyberg, 2002), whereby the validity of the individual nursing interventions from the BeNMDS under the requirements of local expansion of the list of variables according to national requirements was asserted several times (Turtiainen et al., 2002; Volrathongchai, Delaney, & Phuphaibul, 2003).

An enormously extensive approach in nursing data collection was decided by the Australian government. One of the main differences lies in the fact that the data collection and definition of the Australian National Minimum Data Set (AuNaMDS) was not solely restricted to the hospital branch, but was in fact extended for all community care providers. For each of the different areas of medical care in the widest sense, minimum data sets were defined and from their basis, nationwide health statistics are derived. The development of these minimum data sets occurred in the 1990s and the objective was the collection of data for the planning of nationwide care. For this reason, no uniform Nursing Minimum Data Set exist, rather respective minimum data sets for different branches of care, for example, the minimum data set for Home and Community Care (HACC).

In Switzerland, the implemented project for the development of Swiss nursing data started in 1998 and is being carried out in several scheduled stages. The planning phase and the test phase have, according to reports from the specially founded organisation NURSING data, already been completed (Berthou, Junger, & Kossaibati, 2005). The acquired Swiss minimum data set (CH-NMDS), also contains data of care providing institutions and information about the careers (nurses), along with nursing phenomenon and nursing interventions, which are in their logical and terminological structure aligned with the WHO-ICF classification. What can also be seen as a characteristic is the range of the CH-NMDS, which is not just designed for the hospital sector, but should also be valid in Swiss home care and for nursing performance in nursing homes (Stark & Hölzer, 2005).

The Interaction of Government, Nursing Sciences, and Nursing Institutions

The demand for structuring and structured collection of nursing data is from the outset supported by the idea of data material for nursing research on the one hand and for the planning of required care of the population with nursing care requirements on the other. Furthermore, the nursing documentation should shape the provision of nursing care more transparently and efficiently, and through this have an advantageous effect on the care of the patient or client. For all fields of nursing care there is one common vital condition, namely the comparability of collected nursing data which in turn has the condition of the development of a common "generally applicable" nursing language.

This fundamental idea is also the starting point for consequently brisk development of nursing terminologies, or rather terminological systems which were developed for nursing and whose integration is still not completed. These systems have led to efforts for more extensive regional and content expansion.

What all terminology systems have in common is that they attempt to break down nursing actions into operating levels on the one hand and provide uniform practicable formulations for the elements of a nursing action on the other.

Running along side this, classification systems were created which process the individual steps of the nursing process in uniformly formulated catalogues. For the various steps of the nursing process, the respective classifications were compiled which have been coordinated by the individual research groups for several years in order to achieve complete terminological coverage of the nursing process.

NANDA-Nursing Diagnoses (NANDA International, 2005), the Nursing Interventions Classification (NIC, 1996), the Nursing Outcomes Classification NOC (Johnson et al., 2005), and the International Classification for Nursing Practice (ICNP®) all have their origins in the American nursing sciences and professional initiatives. They all follow different approaches for systemizing nursing language and the classification of nursing actions.

In Australia, terminological agreements had already been made through the above mentioned state initiatives and they were published in the "National Data Dictionaries" of the AIHW (Australian Institute for Health and Welfare).

Irrespective of origin, it can be assumed that electronic support of collection and documentation plays and intrinsic role in all initiatives for data collection in nursing and for extensive nursing documentation. This is ostensibly rooted in the content and procedural range of nursing. The scheduled evaluation of nursing data for different groups, for example, nurses themselves, nursing management, nursing scientists, nursing needs-planners and structural planners implicates an electronic availability of the data. This is confirmed by the fact that all initiatives for nursing data collection to date were and are accompanied by more or less extensive IT projects.

The interaction of government, nursing science, and nursing institutions in particular when defining a NMDS and irrespective of the given motivation is shown in Figure 1.

The common denominator preliminarily lies in the question of structuring and defining the systems and terminologies which is considered to be the basic requirement for the digitalization of the nursing process. Only from this digitalized nursing process data can be made both available and analyzable. From now on, the precise implementation of these data structures depicts the formed NMDS.

According to Werely, Devine, Zorn, Ryan, and Westra (1991), the basic definition of minimum nursing data is: "a minimum set of items [or elements] of information with uniform definitions and categories, concerning a specific aspect or dimension of the health care system, which meets the essential needs of multiple data users." Multiple data users implicates different action partners who have an interest in the implementation of nursing documentation but whose objectives are different.

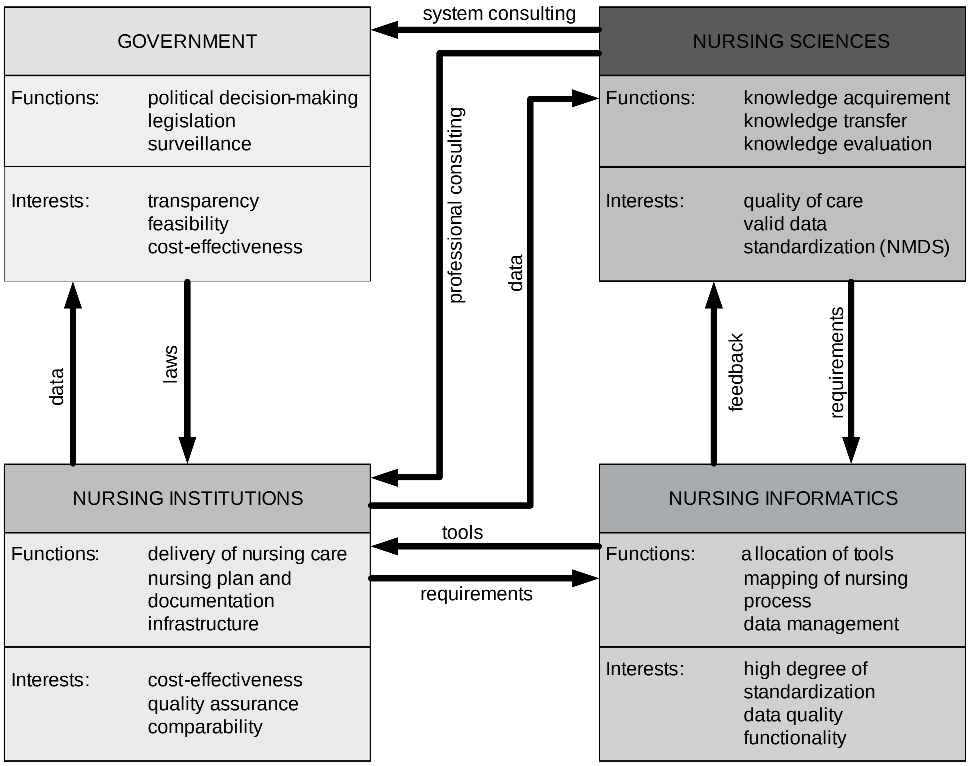
The government functions in association with the nursing system and nursing documentation can be summarized in the tasks of political decision-making, legislation for the nursing system and control function for the adherence of legal regulations within the framework of nursing people in need of care. These functions under the aspects of transparency, feasibility, and cost-effectiveness are converted into state parameters and initiatives for the achievement of these parameters.

Nursing sciences tend to acquire perception and transfer of knowledge under the aspects of nursing outcome quality and process standardization. Nursing sciences define the parameters and conditions of measuring nursing performance.

FUTURE TRENDS

The acquisition of knowledge, transfer of knowledge, and evaluation of nursing knowledge in the sense of an increase in quality within nursing as basic functions can be accredited to the nursing sciences as representatives of theoretical nursing. In this context, they have a great interest in the completeness, comparability and interoperability of the documented nursing data in order to fulfill their function. It can be assumed that the

Figure 1. Interaction between government, nursing sciences, nursing institutions and nursing informatics



question of terminological standardization as a basis for a uniform nursing language will be more strongly internationalized in the future. This means that national factors in this relation will move into the background in order to achieve international comparability of nursing. In return, this will have a direct effect on the development of NMDS which will be internationally useable and transparent and free of national stamping.

The institutions where nursing takes place are responsible for providing the necessary infrastructure and direct nursing process, that is, diagnoses, planning, implementation, documentation, and evaluation of the nursing provided. The delivery of nursing care is subject to the criteria of efficiency, quality, and individualization of nursing for the clients. The comparability of nursing is only secondary for evidence-based nursing here. But evidence-based nursing in particular will flow more strongly into all elements of the nursing process in the future, both on a national as well as international level. Here, more intensive integration of applied nursing with nursing science will be demanded in order to overcome the Theory-Practice-Gap as described in literature. An essential component for bridging this gap will be nursing informatic science.

The government as political constructor will have an increased interest in the international comparability of its nursing system when the objectives of transparency and political margin of national nursing systems are achieved and when it is in the position to establish an overall picture regarding efficiency, quality and cost of the national nursing system on the basis of the data obtained from NMDS.

CONCLUSION

Nursing sciences the world over are shaped by a trend of standardization. Here the focus is on the development of a uniform nursing terminology and a standardized definition of the nursing process. An essential basis for achieving this objective is the digitalization of the nursing process on the one hand and the development of Nursing Minimum Data Sets (NMDS) on the other. At the same time one can observe that health systems and therefore also the nursing systems are subject to increased cost pressure, which in turn leads the financiers and legislators to claim not only increased transparency of structures, but also to perform their mandate of configuring these systems on the basis of comparable and valid data from nursing care deliverers. Against this background, the state institutions also have a distinct interest in the development of NMDS. The motivation situation between the nursing sciences and practical nursing as well as that of the government is not consistent. Whilst the government needs consolidated data as a foundation of configuration of the nursing system, the emphasis of the nursing sciences and practical nursing is directed towards supporting the nursing process and the scientific acquisition of knowledge. On an international level, projects for the development of an NMDS were carried out in different countries, whereby the objectives of the individual projects more strongly support governmental or nursing motivation. The result, however, of all these projects is that, in the end, both objectives have to be fulfilled to a certain degree in order to be able to implement NMDS successfully. It can be assumed that this phase of considering national NMDS will continue in the next few years. This is because the advances in the respective countries are indeed different, but the question of developing an international NMDS will increase in importance in the medium-term. This is all the more so because the nursing sciences show clear international focus within the framework of standardization even today, and because international comparability of nursing systems is advantageous from a governmental point of view. Even if there is great governmental influence on the forming of the nursing system and, therefore, on the development of NMDS through its capacity as legislator and financier, it is nevertheless to be assumed that the interaction between government and nursing sciences or applied nursing resembles that of communicating vessels. This is because the nursing sciences deliver the necessary standardization and scientific penetration of the system which, in turn, represents the foundation for political decision-making within the framework of the formation of the nursing system.

KEY TERMS

Documentation System: An IT-Tool to register nursing action; nevertheless, this system can still be paper based.

Nursing Classification: Or nursing classification system. A catalogue structuring nursing action. The focus is on nursing diagnosis (NANDA), nursing intervention (NIC), or nursing outcome (NOC). All classification systems intend to be a basis for possible quantification and also comparability of nursing performance.

Nursing Documentation: Contains more than the registration of delivered nursing action. A complete nursing documentation also comprises the assessment, plan, and evaluation—altogether representing the nursing process.

Nursing Minimum Data Set (NMDS): Dependent on the regional scientific background, NMDS is used for the concept of a data structure or a list of nursing interventions being documented in a nursing documentation system.

Nursing Process: A concept of how nursing care should be provided from a nurses' point of view. The nursing process was internationally published by WHO in the 1980s and originally consisted of four steps (assess, plan, intervene, evaluate). Due to its importance, documentation was additionally introduced to the nursing process.

Nursing Terminology: A nomenclature which enables the comparability of nursing performances.

A Role-Based Agent-Oriented Approach to Medical Device Integration

Francesco De Mola
Università di Modena e Reggio Emilia, Italy

Giacomo Cabri
Università di Modena e Reggio Emilia, Italy

BACKGROUND

Monitoring heterogeneous medical devices is a key issue for efficient medical information management in high-quality health care delivery. Collecting vital signs and integrating data from various sources is very important in order to make precise diagnosis and provide effective emergency response. Current commercial rules and the scarce adoption of standard protocols are the first main obstacle to achieve a real integration.

We propose a work-in-progress, role-based, agent-oriented solution to overcome this obstacle: proper mobile agents are in charge of acquiring data from each kind of medical device (e.g., electrocardiograms, blood pressure, and oxygen saturation gauges), providing a uniform interface toward the business logic; in its turn, each medical device is provided by a vendor-specific role, embodying the capability to interface with the device by means of its own protocol. Thus, each time a new medical device requires the integration in a wider system, a generic mobile agent migrates to the device node; here, it assumes the role of the specific device manufacturer and starts delivering the acquired data hiding the heterogeneity of the device.

We will propose such a solution describing the implementation of a demonstrative prototype exploiting the RoleSystem infrastructure, which dynamically makes role capabilities available to the agents.

INTRODUCTION

Information technology can provide an interesting support to manage applications in health care scenarios. The tasks involved in health care exhibit wide heterogeneity and are often strictly related to one another. This demands the adoption of innovative and powerful paradigms, in particular to achieve device integration that is more dynamic and flexible than those usually adopted for traditional distributed systems.

Agents are software components that exhibit a high degree of autonomy (Jennings, 2001) and provide a useful paradigm to meet health care requirements in general (Nealon & Moreno); in the literature, we also find several approaches for medical applications (Lhotska & Stepankova, 2005; O'Donoghue & Herbert, 2006; Shnayder, Chen, Lorincz, Fulford-Jones & Welsh, 2005). This chapter aims to show a possible agent-oriented solution for the easy integration of medical devices facing heterogeneity by means of the concept of agent role (Cabri, De Mola, Quitadamo & Zambonelli, 2006). A first prototype, UbiMedic-RED (Role-Enabled Devices) has been developed on the basis of the proposed approach. In particular, the implemented system is based on the *UbiMedic framework* (De Mola, Cabri, Muratori, Quitadamo & Zambonelli, 2006), a context-aware middleware built on top of the multi-agent platform JADE (JADE, 2001). It provides several services of high and low (core services) levels to support medical and territorial emergencies in distributed contexts. The concept of role has been introduced in UbiMedic, thanks to the integration with *RoleSystem* (Cabri, Leonardi & Zambonelli, 2003b), an interaction infrastructure implementation allowing agents to dynamically assume roles and interact accordingly. Section Staring Points presents the starting points of our work: the UbiMedic framework and the Rolesystem infrastructure. The rest of the article proposes the UbiMedic-RED architecture based on the previously introduced systems, exploiting an application scenario.

STARTING POINTS

UbiMedic aims at building a distributed context-aware platform with mobile agents implementing helpful services for user applications in medical domain, focused on real-time monitoring and delivering vital signs and medical information. UbiMedic is an agent-based framework, designed to take into consideration the importance of portability even on small devices (e.g., PDAs or other limited user's terminals) (De Mola et al., 2006). The framework exploits the execution environment and the facilities provided by the JADE agent distributed platform. The latter is composed of several *Peripheral Containers*, representing different nodes with their own JVM, and a centralized *Main Container*, providing the basic facilities for the platform management. In particular, the *Directory Facilitator (DF)* provides a yellow page service useful for agent discovery and registration.

About monitoring and integrating physically distributed medical devices, the framework proposes a three-level decomposed approach related to three corresponding agents.

The main idea of each application accessing a medical device (e.g., an electrocardiograph or pulse oximeter sensor) is the definition of the following three kinds of agents (Figure 1): a *User Interface Agent* (UIA) in charge of managing user interactions by means of a more or less complex GUI providing all the suitable tools to end-user monitoring of the detected patient data; a *Physical Resource Interface Agent* (PRIA), which has to collect and make available the patient's vital signs measured by medical devices to requesters all over the platform; and a *Proxy Agent* (PA), an intermediate entity that includes the proper logic to process and filter the data collected by PRIA according to the specific medical device typology and to the particular goals of the application. The PA is also the logic unit where further intelligent and cooperative diagnostic capabilities can be included; for example, exploiting the agent social ability, the PA can compare the received data with medical traces coming from other devices or databases before returning to the UIA the processed diagnostic results.

Rolesystem is an interaction infrastructure (Cabri et al., 2003b) that implements the role interaction model of BRAIN (Cabri, Leonardi & Zambonelli, 2003a). It is completely written in Java and can be associated with the main agent platforms; in the following we consider JADE (2001) as the agent platform.

As shown in Figure 2, the Rolesystem infrastructure is divided into two parts: the upper one, which is independent of the agent platform; and the lower part, which is bound to the chosen agent platform. Our effort was in the direction of reducing the platform-dependent part.

In applications exploiting the Rolesystem infrastructure, agents can be seen by two points of view: they are both *subjects* of the role system and *agents* of the JADE platform. Accordingly, an agent is composed of two layers: the *Subject Layer*, representing the subject of the role system independent of the platform; and the *Wrapper Layer*, which is the JADE agent in charge of supporting the subject layer. For each context/environment, a specific agent called *Server Agent* is in charge of managing the roles and their interactions. It interacts with the wrapper layer of agents by exchanging ACL messages formatted in an appropriate way.

In the following sections, we will show how the UbiMedic framework has been combined with the RoleSystem infrastructure.

Figure 1. The three-level decomposition of UbiMedic for device monitoring

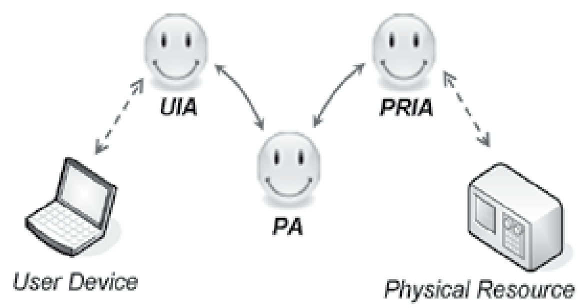

Figure 2. Domain separation in Rolesystem

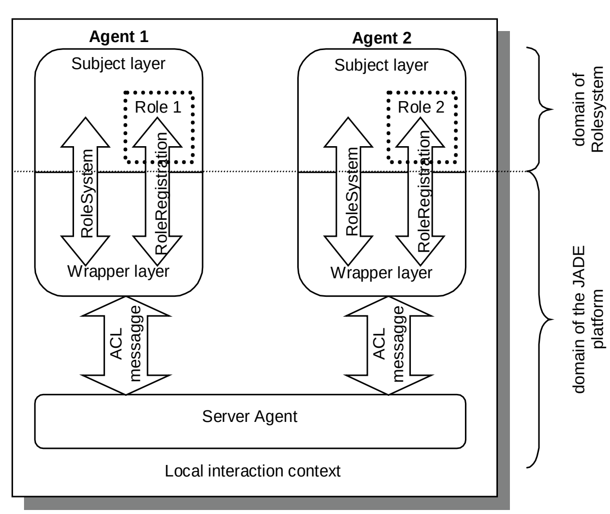


CASE-STUDY SCENARIO

A simple example is exploited in the following sections to show the use of UbiMedic-RED. Let us consider a typical integration issue in medical device monitoring contexts: the interconnection of two heterogeneous devices provided by two vendors, allowing the end users (i.e., doctors and specialists) to remotely display on their terminals the vital signs measured by both the devices. In this scenario, *DeviceA* (provided by *VendorA*) is able to measure a patient's electrocardiogram (ECG) and pulse oximetry, whereas *DeviceB* (provided by *VendorB)* deals only with ECG. *DeviceA* includes also a thermometer provided by a third vendor (*VendorC*). In the developed prototype, these devices have their own graphical user interfaces for on-site display and control, their private internal algorithms for data generation, and their personalized output protocols and data structures. In particular, *DeviceA* fills in a proper file with the tuples of the collected data (ECG and oximetry) for each sampling instant, whereas *DeviceB* exposes a method returning the current detected ECG value.

The end user can identify and display the information acquired by the desired devices, obtaining a uniform visualization for the same data typology. Then, the possible differences among the data original formats coming from different sources are transparent to the end user.

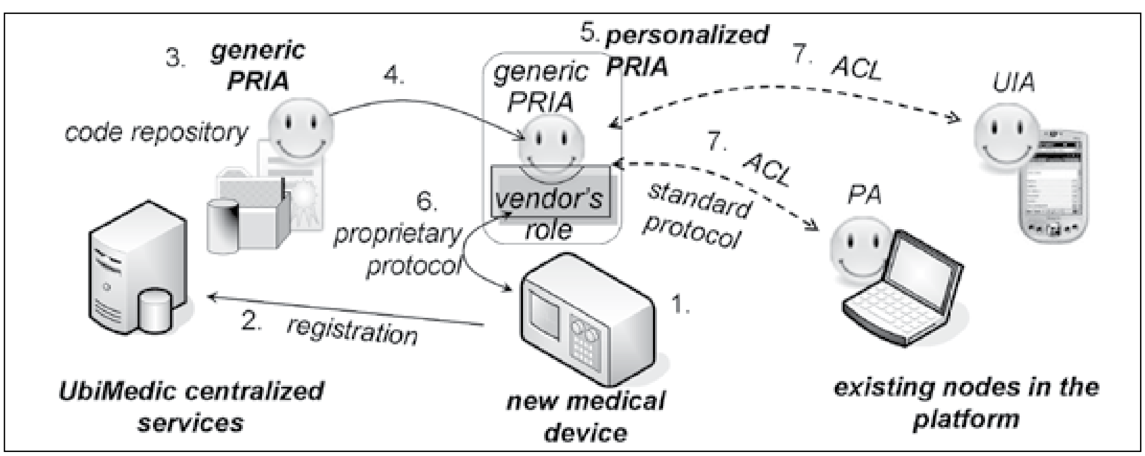
UbiMedic-RED ARCHITECTURE

UbiMedic-RED (Role-Enabled Devices) provides a role-based solution to *heterogeneous device integration* issues. The key point of the architecture is the encapsulation of specific medical device handling within software agents. This is reached through an interaction model based on the *role* concept. Among other advantages, roles can be exploited to achieve *separation of concerns* between the *business* logic and the *interaction* logic: the first is embodied in the agent, the latter in the role (Cabri et al., 2003b). When an agent assumes a role, it achieves the capabilities of a new behavior. Appropriate roles can be defined to support the interactions between agents and medical devices; the role can embed the specific logic to access the device information. In this sense, roles promote context-dependent interactions, where contexts are, in this case, the devices. The role implementer is in charge of designing the role adopting the UbiMedic standard interface for this kind of role. Internally, the code within the role will handle the interaction with the specific device, whereas the PRIA agent remains completely unaware of such inner details.

The adopted infrastructure in charge of providing role capabilities to the agent is the *BRAIN* framework (Cabri, Ferrari & Leonardi, 2004), and in particular, the RoleSystem infrastructure associated with the JADE agent platform.

Figure 3 clarifies the sequence of steps designed in UbiMedic-RED according to the role-based approach. A new medical device joining the platform must be

Figure 3. Interactions among the UbiMedic-RED components



equipped with a vendor-specific role (its implementation could be provided by the device's manufacturer), enclosing the know-how required to interact with the specific medical device (step 1 in Figure 3). First, the new device addresses a registration request to a centralized UbiMedic service to connect to the platform (2). The system reacts with the generation of a new generic PRIA in a centralized node, properly equipped with a code repository (3); then, the new PRIA moves back to the node of the requesting device (4), where it assumes the role of the specific device manufacturer, resulting in a complete personalized PRIA (5). The assumed role enables the device to interact with the other agents in the platform, although using its own procedures and proprietary protocols; the PRIA acquires data from the medical device via its proprietary protocol managed by the embodied role (6), and at the same time delivers the collected data to the target UIAs or PAs, interacting via standard ACL (7).

Such a role-based approach provides flexibility in device integration, since a brand new device can autonomously install itself in the system. In addition, the PRIA representing a multifunctional device (e.g., a device capable of performing electrocardiogram, blood pressure measurements, etc.) can assume different roles for each functionality.

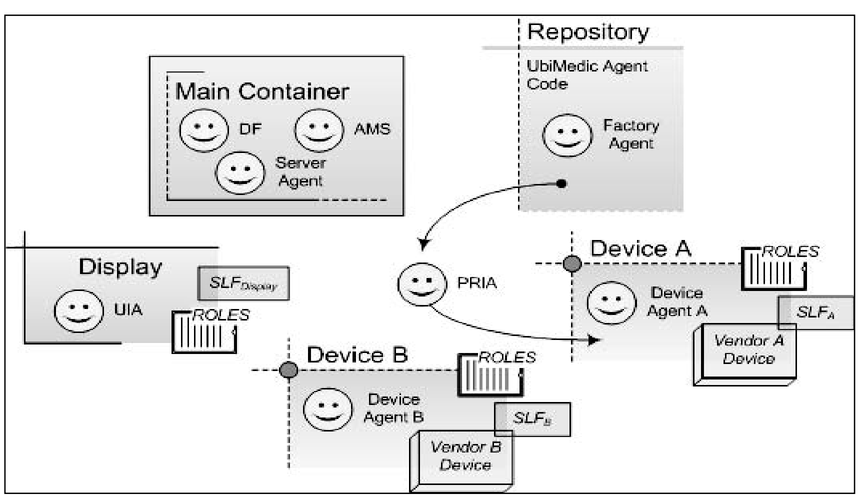
System Deployment

The nodes of the UbiMedic-RED platform are represented by common *JADE Containers*. The core of the system is the *Main Container*, including some UbiMedic centralized facilities and the RoleSystem *Server Agent* (besides to the standard JADE administration services) (Figure 4). Another *Container* called *Repository* implements the code repository in Figure 3; it is equipped with the code of the agents (PRIA) that can be dynamically created in the platform. A proper agent, the *Factory Agent*, is responsible for the generation on demand of such agents. The presence of such a centralized repository facilitates the system upgrade, avoiding multiple code updates in several locations and allowing a better management of the possible code releases.

The medical devices are represented in the agent platform by other peripheral containers. For each of them, a *Device Agent* is the first contact entity in the startup node configuration and the handshake phase to join the platform. This node also includes the abilities of acquiring data from the real device and the role packages related to the available medical functionalities. A PRIA can be considered the effective representative of the physical resource in the agent world only after these three steps: the agreement for a PRIA generation, the migration of the agent to the device node, and the assumption by the agent of the vendor-specific role. The PRIA works as a middleware stub to connect the device to the agent platform; its role behaves as a nonintrusive external wrapper of the device.

On the other side, some peripheral containers are built in the user devices with a proper UIA in charge to guide the medical practitioner in displaying the output of the various devices. The UIA must assume suitable

Figure 4. System deployment



roles to interact with the chosen data source. For this reason, all the peripheral containers provide a particular module, the *Subject Layer Factory (SLF)*, in charge to dynamically instantiate the proper roles for UIAs and PRIAs, according to the typology of the medical device chosen by the user, for the former, and to the vendor-based functionalities enforced by the medical device for the latter.

CONCLUSION

In this chapter, we presented UbiMedic-RED, a combined approach based on *agents* and *roles* to support the integration of heterogeneous medical devices.

Several advantages can be identified in the adoption of the proposed architecture. First, *separation of concerns* is achieved between the algorithmic and the interaction issues in developing agent-based applications; in fact, interaction issues with the physical devices are clearly separated from algorithmic issues, concerning processing activities to filter and transcode data in a common format for the whole platform. Then, since each device is equipped with an appropriate role, UbiMedic-RED can *integrate unknown kinds of medical devices*, allowing a sort of plug-and-play installation. In fact, the code related to the proprietary device protocols is completely embodied within the role. Another useful point is also the *reusability of solutions and experiences* allowed by the described agent and role-based model (e.g., the same code of an ECG PRIA can be used for electrocardiographs of various manufacturers). Besides, the presented solution results are suitable for a wide range of applications, not only medical device integration, such as m-commerce, warehouse management, robotics, and in general collaborative applications.

We are currently exploiting simulators of the medical devices, since role-enabled devices should be provided by the vendors along with appropriate (copyrighted) code. So the first step toward future works will concern the development of this code in collaboration with vendors and/or the exploitation of prototype devices whose specifications will be available for our purposes. Then, managing actual devices, we will be able to concretely evaluate the proposed integration approach. In connection with this, we point out that a performance analysis and discussion will be needed in order to evaluate the real applicability of the proposed solution. In fact, the health scenario requires not only appropriate abstractions and tools, but also quick responses, effectiveness, and robustness for the supporting infrastructures in order to save patients' lives.

KEY TERMS

Agent: A computational unit able to solve a problem and execute in open and dynamic contexts, thanks to the properties of reactivity, autonomy, proactivity, and sociality. The agents can run in a special agent platform such as JADE.

Device Integration: The connection of various devices in order to allow them to communicate, interact, and interoperate. The main issue to face to achieve integration is the heterogeneity of communication protocols and data formats

E-Health: The management of health-related issues by means of information and communication technology, exploited to improve quality and efficiency of health care services and facilitate caregivers in their work.

JADE: The most known and used agent platform. The framework, implemented in Java, provides many facilities to support the management of agent life-cycle and to develop distributed multi-agent systems.

Medical Device: A device able to detect and measure some kind of patient vital signs. The electronic devices usually provide outputs in their own format, based on the proprietary protocols and technical details implemented by the vendor, resulting in wide data heterogeneity and hard interoperability issues.

Role: A set of capabilities and expected behaviors related to the agent that plays such a role. The agent playing a role gets new functionalities and abilities to interact with the roles of the other agents.

Role-Enabled Device: A device equipped with a special role, which encloses its own communication details and is able to interact with the other agents of the platform by means of a standard interface. The role, possibly provided by the device manufacturer, acts like a sort of middleware stub to connect the device to the agent platform.

.

Security-Aware Service Specification for Healthcare Information Systems

Khaled M. Khan
Qatar University, Qatar

INTRODUCTION

With the rapid advancement of Web-based technologies, healthcare information systems are becoming increasingly heterogeneous in terms of their architecture, composition, and runtime characteristics. A healthcare system can be composed of several stand-alone service components, such as Web services available from various distributed sources for runtime execution. We use the terms *Web services* and *service* interchangeably in this chapter to refer to the same concept. A healthcare application system can be composed of multiple autonomous geographically dispersed software services. A healthcare software service is autonomous as it has its own executable code and uses its own data or files. The composition of a healthcare system can be dynamic or static, depending on how services are connected to each other to provide the services. Some of the services are downloaded directly from the Internet and executed dynamically with the application system. The use of independent services in the healthcare information system is appealing because it supports reusability of code and far efficient utilization of network resources, and it might be cost efficient.

Despite the benefits and usefulness of service computing, the characteristics of third-party services also present tremendous challenges for healthcare information security. As services are reused in far greater scale, there is a need for ensuring the security properties of third-party services to the composite healthcare system. Security is a systemwide property referring to the entire system composed of several services. Security architecture alone at the individual service level cannot protect a system unless the conformity of the security properties is checked with the enclosing application system in terms of required and ensured security properties. This issue of conformity of security properties between the individual service and the enclosing healthcare system has far-reaching implications because failure of this would seriously undermine the privacy of the patients and the reliability of the healthcare providers. Let us give a brief scenario (Han & Khan, 2006) in order to magnify the seriousness of the issue.

Consider a Web service that can generate various test data such as X-ray data, MRI images, CT scan images of the patients, and so forth. Another Web service uses these data as input and generates diagnosis reports to other Web services, which could ultimately produce prescriptions and prognoses of the patients' problems. Finally, the prescriptions are sent to another Web services that supplies medicines to the patients. In this scenario, we can see that the confidentiality and integrity issues of patient data are critical. Similarly, the authenticity of the service provider is an important issue, because the generated output of one service determines the outcome of the treatment produced by another service. Note that all these services are completely independent in terms of their development, their formation, and, most importantly, their security provisions. Different Web services have different security requirements as well as assurances during run-time processing of various sensitive patient data. The fundamental question is how service computing can cater various security requirements of different healthcare services in a composed federated e-healthcare system.

To address this question, this chapter proposes a framework of composing security properties for services used in healthcare information systems. It proposes a generic architecture of our proposed security-aware services and discusses the related issues. In contrast to most of the current initiatives that focus on incorporating existing security techniques into service computing, we see a great need and potential to develop a new framework for security-aware service composition in healthcare systems. The main objective of this chapter is to define a process that would enable us to compose various security properties of a federated healthcare information system that is assembled from various independent third-party software services.

BACKGROUND

The current practice of using software services in healthcare systems does not have any compositional process for properly evaluating the conformity of security properties between third-party services. This could dangerously lead to compromise to the enterprisewide security requirements of the healthcare systems, such as the confidentiality of patient data and the reliability of the services. Consequently, this risky practice of compositing systems of third-party services without due attention to the conformity of security properties could result in the degradation of system security. This practice virtually forces healthcare systems integrators to take undue risks by composing a system in order to achieve global services. Generally speaking, most systems integrators have neither the time nor the resources to examine the security properties of candidate software services. The required security functions that a healthcare system requires may not comply with the provided security profiles of a service.

A thorough examination of related literature reveals that very few research works in this area have been reported. Most research initiatives focus on how to make the individual services secure or how to make the enterprise systems more secure. In our opinion, these cannot solve the problem of "mutual" security conformity among various services

Web services paradigm is based on the Simple Object Access protocol (SOAP), the Web Services Description language (WSDL), and the Universal Description Discovery and Integration (UDDI). The Extensible Markup Language (XML) is the basic mechanism behind all of these technologies. Attempts have been made to extend WSDL to encode quality of services (QoS) properties (Curbera, Khalaf, Mukhi, Tai & Weerawarana, 2003) such as security, performance, and reliability. The aim was not to compose QoS properties along with the service composition, but rather to describe the QoS properties of Web services. None of the standards for XML-based definition language, such as Business Process Execution Language for Web Services (BPEL4WS) (Andrews et al., 2003), XML Process Definition Language (XPDL) (Kappel et al., 1995), Web Services Security Languages or WS-Security (Seely 2002), and Business Process Modeling Language (BPML) (BPMI, 2003), addresses the issue of the composition of security services to engineer the security properties of the composed Web services. WS-Security addresses Web service security by using existing security standards and specifications.

OUR FRAMEWORK

A healthcare software service may provide several functionalities; each may have quite different types of security properties from the others. For a software integrator, it is hard to predict what security properties a functionality supports unless they are well expressed with the interface of the functionality. Security properties are used for various reasons such as to authenticate a system, to authorize, and to ensure confidentiality and integrity. Examples of security properties can be passwords, private keys, secret keys, public keys, shared keys, and digital signatures. The protection of the service and its data and instructions is usually implemented with one or more security functions.

The security properties used to protect a functionality may have distinct security properties for a particular scenario. Security properties could also be grouped into two types based on their role in a functionality: security *precondition* and security *postcondition*. In order to verify whether the security precondition is met by the services user who wants to use the functionality, a reasoning engine is needed.

Based on these preliminaries, we can define the following types of *attributes* of a software service: (i) *the service has one or more functionality*; (ii) *a functionality may be protected with security functions*; (iii) *the security function is composed of security properties*; (iv) *the security properties can be classified as precondition or postcondition of the functionality*; and (v) *a reasoning engine is needed to verify the compliance of the security precondition and postcondition*.

Addressing the compositional security concerns discussed in the previous sections, we propose a framework for specifying these attributes at the architectural level of a service, as depicted in Figure 1.

The framework proposed in Figure 1 shows five distinct tasks. The task for identifying the functionalities of a service involves enlisting the associated functionalities of the service. For example, a *prepare diagnosis report service* may include functionalities such as *receiving pathological data*, *providing diagnosis report,* and so forth. In the next task, each of the identified functionalities is associated with its security properties. For example, *receiving pathological data*

Figure 1. A framework for specifying security attributes of the service

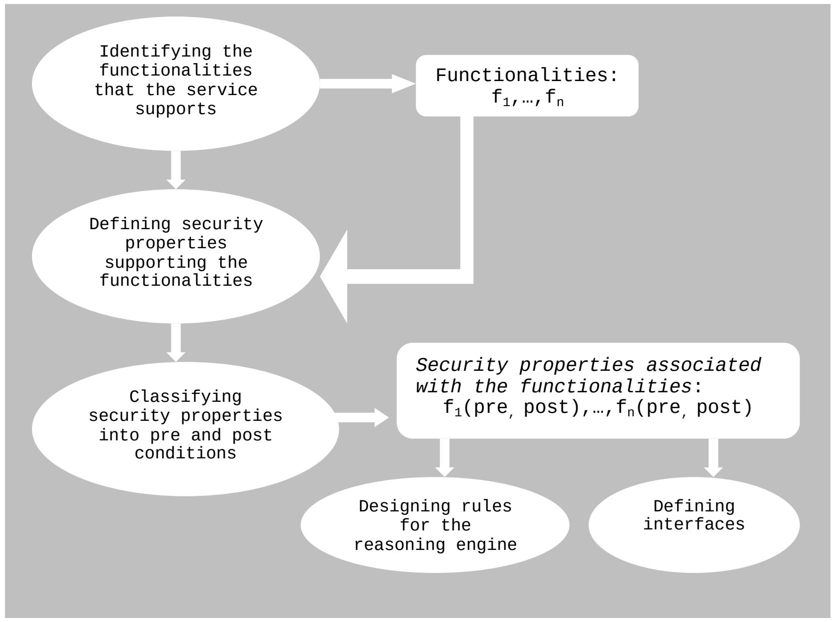

Figure 2. A healthcare service software with two functionalities

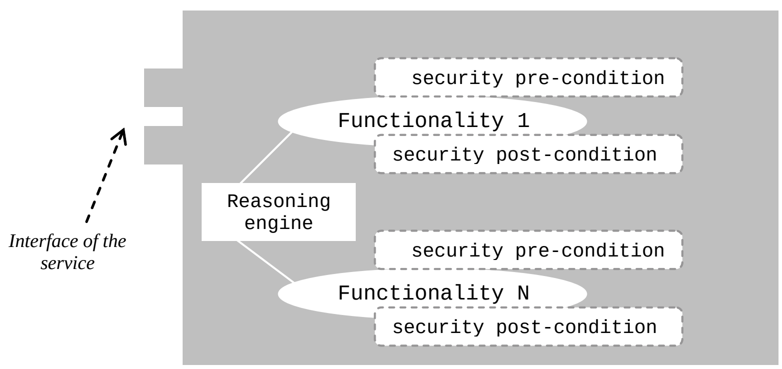

function may be supported with the encryption and digitally signed security functions. In task four, the employed security functions are classified into security precondition or postcondition of the function. For example, *providing diagnosis report* function may have encryption and digitally signed as its two security postconditions. The receiving pathological data function could have a security precondition such as encryption of the data. The specifying of security precondition and postcondition could be achieved by using the security characterization approach proposed in Khan and Han (2003). The designing rules for the reasoning engine function involves issues on how to check the conformity of the security precondition as well as postcondition. It could be a rule-based approach or any other approach. The final task defines the interfaces so that other applications or services may contact the service.

In our approach, the security properties are associated with the interface of the services in such a way that the other services or application systems could read the security properties along with the functionality of the service. The approach could also provide a mechanism so that the application could check the conformity between the application and services. The output of this framework could be a service with its functionalities mapped with the associated security precondition and postcondition, as shown in Figure 2.

The diagram depicts that a healthcare service provides two distinct functionalities to other services of applications. Each functionality has its own security precondition and postcondition. The service has one common interface to access the functionalities of the service. The employed security properties are mapped with the functionality that a service supports. In order to use any of these functionalities, other services or application systems must comply with the security precondition of the candidate functionality. In return, the functionality ensures the specified security postcondition.

CONCLUSION

The chapter has outlined the problems related to the issue of compositional security of healthcare software services at runtime. It has proposed a high-level framework to develop security-aware healthcare software services. A security-aware service has its functionality mapped with an associated security precondition as well as postcondition. In order to get the service of a functionality, other application systems or services are required to meet the security precondition of the functionality. In return, the healthcare service ensures security postcondition to the application systems. The chapter argues that different healthcare information systems may require from the services different types of security functions in order to protect the information. Our approach advocates a need-based, security-aware composition; that is, a healthcare application can only be composed with a service that could comply with its security requirements. Similarly, a service may also require certain security properties to be satisfied by the enclosing healthcare system in order to receive the service. We acknowledge that further investigations need to be done in order to build a complete framework. The framework also needs to be tested in a real-world situation.

KEY TERMS

Healthcare Service Functionality: A functionality provided by a service is a task offered by the service to its environment. A healthcare service may have one or more functionalities to offer. The client healthcare application system could use these functionalities at runtime.

Healthcare Services: A platform-independent, self-contained software with defined functionality that can provide healthcare related computing services. It provides a standard way to integrate mechanism with healthcare applications over the Web. A service can perform one or more functionalities for the complex healthcare application system.

Security-Aware Service: A service that has its own security requirements to be satisfied by the service user; in return, it guarantees certain security requirements. The approach also provides a mechanism to verify the compliance of the security requirements of the service as well as the service user.

Security Function: The implementation of a security policy as well as a security objective. It enforces the security policy and provides required capabilities. Security functions are defined to withstand certain security threats, vulnerabilities, and risks. A security function usually consists of one or more principals, resources, security properties, and security operations.

Security Postcondition: An ensured security property is a postcondition in a sense that it is the responsibility of the service or the application system to maintain the committed security assurances during the composition.

Security Precondition: An invariant in a sense that other entities must satisfy this before a composition takes place. It is a precondition the service user must ensure to the service provider that the required security properties are met and their validity is ensured before a service can be obtained.

Security Property: An implementation element used in a security function. A set of security properties can form a security function. A security property is an element at the lowest level of the implementation.

Security Reasoning Engine: Verifies the security compliance between a service and the service user. The reasoning engine could use rules that comprise a set of criteria that could be used to assess security properties between two services. A security reasoning engine tests whether a security function has the desired security properties.

Similarity Metrics for Medical Image Registration

Roger Tait
Nottingham Trent University, UK

Gerald Schaefer
Aston University, UK

INTRODUCTION

In general, image registration algorithms can be classified as either landmark or intensity-based. Landmark-based registration consists of four main stages:

- During the feature detection stage, distinguishing characteristics such as corners, edges, centres of gravity, and so forth are identified, either manually or automatically. This identification of landmarks is performed on both reference (fixed) and sensed (moving) images.
- The optimisation stage (Jenkinson & Smith, 2001) controls estimation of transform parameters that geometrically map landmarks between fixed and moving image.
- Upon selection of appropriate transform parameters, pixel values which are mapped into noninteger coordinates are interpolated in order to establish their value. This represents the image resampling stage (Grevera & Udupa, 1998).
- The feature matching stage is achieved through the use of a similarity metric in which a degree of closeness or accuracy of alignment between corresponding landmarks is calculated.

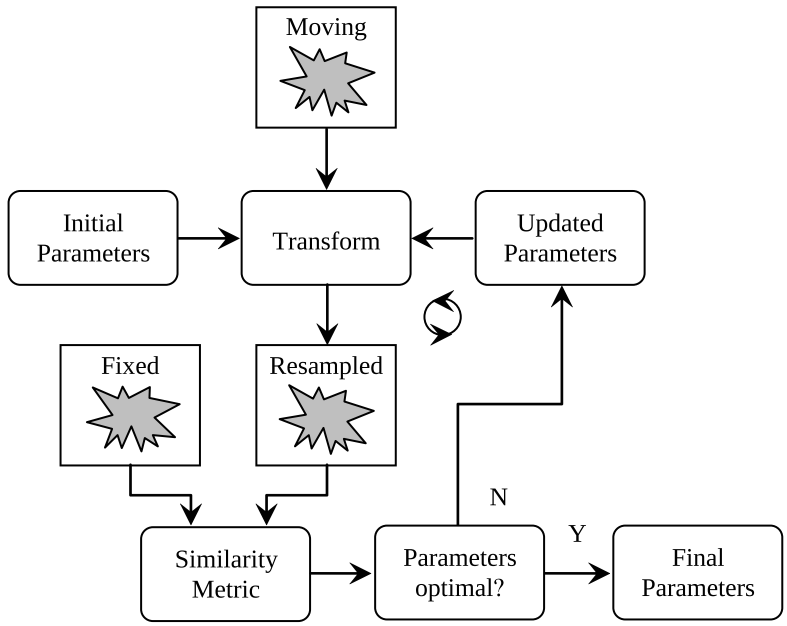
In intensity-based image registration methods, the feature detection stage is omitted. As a consequence, the transform optimisation and feature matching stages are performed using pixel intensities (or functions thereof) instead of landmarks. Intensity-based image registration algorithms comprise the following components:

- The spatial mapping of intensities throughout the alignment process is achieved with a transform component.
- An interpolation component is used to evaluate intensities at nondiscrete locations.
- The metric component calculates a measure of alignment accuracy.
- Optimisation of the similarity measure using a search space defined by transform parameters is achieved with an optimisation component.

The most important component of an image registration algorithm is the similarity metric used to determine when images are in accurate alignment (Penney, Weese, Little, Desmedt, Hill, & Hawkes, 1998). In Figure 1, the inputs to and output from a basic metric are illustrated. In general, a metric works by examining corresponding pixel values in both fixed and moving images and then formulating a measure of similarity based on the relationship between these intensities. The metric assumes that the relationship changes with variations in the spatial transformation used to map between images and a maximum similarity is achieved when the images are in close alignment (Brown, 1992).

Intensity equality which is high when pixels are similar is one such relationship employed as a similarity metric in single-modal registration where images are captured using the same sensor type. Total equality, however, is seldom reached due to noise and image acquisition inconsistencies. Additional robustness is therefore achieved by assessing the ratio of intensities and minimising the variance of such ratios. When images are acquired with different sensor types, as is typically the case in multimodal registration, an extension of the ratio method which maximises the weighted sum of variances can be employed. Alternatively, a relationship estimating the entropy of corresponding intensity pairs can be formulated where entropy, derived from information theory (Shannon, 1948), is the measure of the amount of information contained within a signal. Although many algorithms have been proposed, similarity calculation remains a complex task.

Figure 1. Flow diagram of similarity metric calculation



BACKGROUND

By comparing intensities, the metric component quantitatively measures how accurately fixed and moving images are aligned. The selection of a metric component is largely dependent on the type of registration problem to be solved (Roche, Malandain, Ayache, & Prima, 1999). For example, some metrics possess capture ranges that are well suited to images misaligned by a large transform. Other metrics, in contrast, are less computationally intensive but require initial transform parameters to be close to the optimum. During the alignment process, most metrics samples intensities over an entire image. Some metrics, however, employ a subset of samples drawn from the image. In both cases, similarity is calculated using intensities which fall within the boundary of the moving image. Intensity correlation has been used as a metric where a maximum similarity between fixed and moving images is searched for (Pratt, 1974). Using such an approach, high levels of alignment accuracy can be achieved by interpolating intensities before evaluating similarity. Such metrics are found predominantly in single-modal registration applications.

Although more difficult, the registration of images captured using different sensor types is commonplace in medical imaging applications. Viola (1995) suggests that for two images of differing modality, mutual information can be used as a measure of similarity where similarity is estimated using marginal and joint entropy based on probability distribution constructed using intensities from both fixed and moving images. As a consequence, mutual information can be described as the amount of information one image contains about another. Importantly, the ability to align multimodal images allows for the comparison of anatomical and functional data that can lead to a diagnosis which would be impossible to gain otherwise. For example, the evaluation of mutual information-based similarity metrics, used for the registration of brain scans, is presented by Holden et al. (2000).

SINGLE-MODAL REGISTRATION SIMILARITY METRICS

Intensity-based registration has been employed in the alignment of x-ray images and biomedical volume data (Russakoff, Rohlfing, & Maurer, 2003). In these applications, the cross-correlation of intensities can be used as a similarity metric. With such an approach, subpixel accuracy of alignment is achieved by interpolating intensities before similarity calculation. Traditionally, cross-correlation has been used to register translated images with only slight rotations and scalings. However, more sophisticated variants capable of handling complex geometric deformations are now commonplace. By employing phase correlation in the frequency, domain increased robustness to noise can be obtained (Castro & Morandi, 1987). Phase correlation involves the calculation of a cross-power spectrum for both fixed and moving images. The locations of peaks in both spectra are then identified and aligned.

The basic cross-correlation of intensities between fixed and moving images can be computed as:

$$CC(F,M)=\frac{\sum_{x=1}^{I}\sum_{y=1}^{J}F(x,y)M(x-u,y-v)}{\left[\sum_{x=1}^{I}\sum_{y=1}^{J}M^{2}(x-u,y-v)\right]^{\frac{1}{2}}} \quad (1)$$

where *F* and *M* are fixed and moving image intensity functions respectively. *I* and *J* are the number of pixel rows and columns. *x* and *y* are discrete pixel coordinates, while *u* and *v* represent the components of a transform. The measure of similarity produced by the metric forms a quantitative criterion which can be optimised in a search space spanned by the transform parameters. Importantly, the optimisation technique employed is used to produce derivatives of the similarity measure with respect to each transform parameter. The resulting derivatives are used to update the current transform and the process is repeated until an acceptable degree of alignment is achieved.

Although popular, correlation-based metrics are sensitive to the presence of outliers. These are artefacts which can appear in an image and cause biased registration. Using statistics, estimates of mean and covariance can be employed to increase robustness of the alignment process (Zhang & Rangarajan, 2004). Robustness is sought by weighting intensities in such a way as to reduce the effects of outliers and in some cases remove them completely. In particular, based on the computed distances of intensities from the mean, new intensities and a new mean are determined. Other common statistical approaches to increased robustness include weighted square error and nonquadratic error functions. An example of intensity-based registration that uses a robust correlation coefficient as a similarity metric was presented by Jeongtae and Fessler (2004). To evaluate the statistical properties of their approach, 2D-to-2D and 2D-to-3D registration of torso phantoms was performed. In each case, experimental results confirm an improvement in robustness to outliers. Unfortunately, correlation-based metrics are limited to the alignment of images from the same modality.

MULTIMODAL REGISTRATION SIMILARITY METRICS

In multimodal image registration applications, the data to be registered stem from two different capture devices, as opposed to single-modal tasks where images are retrieved using the same sensor type. According to Woods, Mazziotta, and Cherry (1993), the measure of alignment between images of differing modality can be based on the assumption that although different in value, regions of similar intensity in the fixed image will correspond to regions of similar intensity in the moving image. Furthermore, for pixels in corresponding regions, the ratio of their intensities should vary only slightly. Consequently, alignment can be achieved by minimising the average variance of this ratio. This can be realised through the construction of the joint probability distribution which represents a two-dimensional plot that contains combinations of intensities, taken from corresponding coordinates in both images (Hill, Hawkes, Harrison, & Ru, 1993). Hence, instead of identifying regions of similar intensity directly within the images, combinations thereof are analysed using the joint probability distribution.

Given fixed image *F*, moving image *M*, and transform *T*, the estimation of similarity using mutual information, as described by Mattes, Haynor, Vesselle, Lewellen, and Eubank (2001), is defined as:

$$S(F,M,T)=\sum_{l=1}^{MB}\sum_{k=1}^{FB}jpd(l,k)\log\frac{jpd(l,k)}{mmpd(l)\,fmpd(k)} \quad (2)$$

where *jpd* is a joint probability distribution extracted from both images using a set of samples and approximated as a histogram of intensities. Marginal probability distributions, *fmpd* and *mmpd*, are extracted from fixed and moving images respectively while *FB* and *MB* are the number of fixed and moving histogram bins. Each entry in the joint probability distribution denotes the number of times an intensity in the fixed image coincides with intensities in the moving image.

The marginal probability distributions, in contrast, are found by summing the number of times intensities appear in their respective images. In general, it is common for contributions to a probability distribution to be smoothed using a probability density function, for example, using Parzen windows. Once generated, both joint and marginal probability distributions are normalised and an estimation of similarity calculated. In this form, mutual information is a measure of the distance between the joint and marginal distribution of intensities. Mutual information is therefore a measure of dependence which is maximal when the two volumes are accurately aligned.

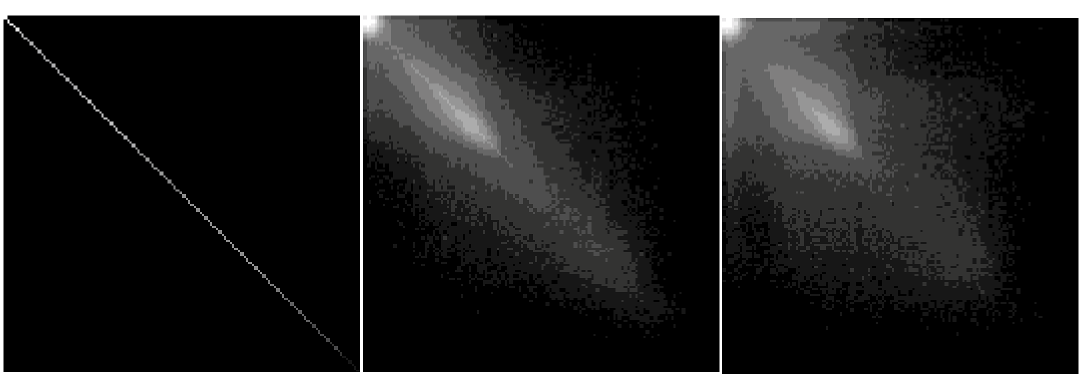
During the registration process, a variation in alignment between images causes changes in appearance of the joint probability distribution. When correctly aligned, corresponding structures in both images overlap causing a clustering of intensities combinations. Misalignment, in contrast, causes structures in the fixed image to overlap with different structures in the moving image which in turn results in the dispersal of intensity combinations within the joint probability distribution (Pluim, Maintz, & Viergever, 2003), as illustrated in Figure 2. Based on the changing regions within the joint probability distribution, measures of dispersion which guide the registration process have been proposed and successfully implemented (Maes, Collignon, Vandermeulen, Marchal, & Suetens, 1997). The concept of mutual information is a well recognised and accepted method of similarity calculation. The main advantage of employing mutual information is that the type of dependency between two variables does not have to be specified and as a result complex mappings can be modelled.

FUTURE TRENDS

To reduce the computational burden of similarity calculation, multiresolution schemes can be adopted. Subsampling at successive levels by means of interpolation is used to create a coarse-to-fine data structure (Thevenaz, Ruttimann, & Unser, 1998). Importantly, care needs to be taken to maintain geometric consistency at all resolution levels. Once subsampling is complete, similarity evaluation and transform parameter optimisation is performed. Crucially, optimisation proceeds through successive levels until the full resolution images are reached. As a consequence, the registration of large scale features is achieved first and only small corrections are required at progressively finer resolutions. Because the majority of iterations are performed at the coarsest level, where the fixed and moving images are small, a substantial saving in similarity evaluation burden is achieved.

The burden of similarity evaluation can also be alleviated using parallel processing (Tait & Schaefer, 2008). For example, a distributed blackboard architecture has been employed to provide an underlying worker/manager model in which image registration algorithms can be hosted (Tait, Schaefer, & Hopgood, 2006). Division of images into segments followed by allocation to multiple worker threads allow derivatives of the similarity measure with respect to each transform parameter to be estimated. The accumulation

Figure 2. Example joint probability distributions for cases where the moving image is obtained by rotating the fixed image by (from left to right) 0, 2, and 5 degrees. Intensity combinations disperse as the misalignment between images increases



and summation of local derivatives by the manager thread allows for the evaluation of similarity and the optimisation of transform parameters. Convergence of the optimisation process is then tested using the newly updated transform parameters. Depending on the success or failure of convergence testing, propagation of updated parameters and hence evaluation of a new transform occurs. Conveniently, the modular nature of the approach described permits different similarity calculation strategies to be employed without change to the underlying architecture.

CONCLUSION

In general, correlation-based metrics are best suited to images that do not contain high levels of prominent detail and where distinguishing information is contained within pixel intensities. These methods exploit directly the matching of image intensities without any structural analysis. However, as a consequence, they are sensitive to changes caused by noise and varying degrees of illumination. Traditionally, correlation has been used to register translated images. More sophisticated variants of the algorithm, however, which are capable of handling complex geometric deformations, are now commonplace. The main limitation of these metrics is that large translations and rotations are possible but render the algorithm obsolete due to the high computational burden associated with their evaluation. Although employed in alignment of images from the same modality, the development of mutual information as a similarity measure has successfully extended metrics to multimodal applications. As only few assumptions about the imaging process need to be made, mutual information-based similarity metrics can be generalised and applied to a wide variety of modalities. As similarity is calculated based on a subset of intensity samples, multimodal registration applications typically have reduced computational complexity.

KEY TERMS

Image Registration: The process whereby two images, differing by a spatial transformation, are brought into geometric alignment.

Multimodal Registration: In multimodal registration applications, the reference and sensed images are captured using difference sensor types.

Reference (Fixed) Image: The term given to an original image or template. In visual inspection applications, the reference image represents an image containing a sample with an acceptable level of quality.

Sensed (Moving) Image: The term given to the image to be mapped to the reference image. In visual inspection applications, the sensed image represents an image of a sample for which the level of quality is to be determined.

Similarity Metric: A measure used to quantitatively judge how well a transformed moving image fits a corresponding fixed image.

Single-Modal Registration: In single-modal registration applications, the reference and sensed images are captured using the same sensor type.

Spatial Transformation: The transformation used to change the spatial relationship between pixels by mapping locations between fixed and moving images.

Source Localization of Subtopographic Brain Maps for Event Related Potentials (ERP)

INTRODUCTION: DECOMPOSITION OF ERP DATA AND THE INVERSE PROBLEM

Event-related potentials (ERP) are transient brain responses to cognitive stimuli, and they consist of several stationary events whose temporal frequency content can be characterized in terms of oscillations or rhythms. Precise localization of electrical events in the brain, based on the ERP data recorded from the scalp, has been one of the main challenges of functional brain imaging. Several currentDensity estimation techniques for identifying the electrical sources generating the brain potentials are developed for the so-called neuroelectromagnetic inverse problem in the last three decades (Baillet, Mosher, & Leahy, 2001; Koles, 1998; Michela, Murraya, Lantza, Gonzaleza, Spinellib, & Grave de Peraltaa, 2004; Scherg & von Cramon, 1986). Generally, there are two main assumptions for the source models:

1. The number of sources are less than the number of measurements, which leads to the parametric methods that estimate the strength and position of the dipole sources by optimization methods (Mosher, Lewis, & Leahy, 1992).
2. The number of sources are more than the number of measurements that calls for the imaging methods searching for an optimum source distribution in a 3D brain image (Pascual-Marqui, Michel, & Lehmann, 1994). Since the number of source locations are much higher than the number of sensor measurements, the latter case is a severely underdetermined problem.

The uniqueness of the inverse solution for both cases can only be acheived by imposing additional constraints. Introducing a mathematical criterion such as the minimum norm, the maximum smoothness, or the minimum variance, or constraining the solution space is a common way to circumvent the uniqueness problem. Also, a well defined anatomical region where the orientation or position of the dipole is, a priori known can be used as an additional constraint. Other physiological constraints obtained from functional magnetic resonance imaging (fMRI), and Positron Emission Tomography (PET) studies may also be incorporated in the inverse solution methods. The sources underlying the ERP, which are rather distributed in the brain and nonstationary in time, also motivate the researchers to invent additional simplifications and analyses on the multichannel data before they apply source localizaton. Several studies aimed for isolating stationary frequency components in temporal windows, using time frequency analysis, and then applying source localization techniques to the scalp maps generated by these time frequency components. Source localization of epileptic discharges is performed after wavelet prefiltering to isolate the spiky waveforms from the background EEG (Ademoglu, Demiralp, Istefanopulos, Comu, & Baykan, 2004). Gonzalez Andino, Grave de Peralta Menendez, Lantz, Blank, Michel, and Landis (2001) proposed an eigen-based method to identify the location of each underlying source in the time-frequency plane that generates a certain topographic distribution. Unlike the previous time-frequency studies that use single channel data, Koenig, Marti-Lopez, and Valdes-Sosa (2001) perform time-frequency optimization on mutichannel data with the wavelet coefficients having minimum energy and maximum spatial smoothness distributions. A more general and unique space/frequency/time decomposition in terms of so-called atoms are proposed by Miwakaichi, Martinez-Montes, Valdes-Sosa, Nishiyama, Mizuhara, and Yamaguchia (2004), which overcomes the limitation of introducing artificial assumptions as indepence in

ICA or uncorrelatedness in PCA approaches (Zhukov, Weinstein, & Johnson, 2000).

BACKGROUND: SPATIAL DECOMPOSITION OF ERP MAPS

In all these studies, the problem of identifying the individul ERP components are treated by proposing a decomposition method that involves the time, frequency, channel, or their various combinations. Another common feature observed is that the concept of frequency is always associated with, and defined in, temporal domain. In Wang, Begleiter, and Porjesz (1998) the spatial ERP maps are enhanced by using first, a projection method that transforms the scalp poentials defined on a 3D surface to a 2D plane, and then applying a 2D multiresolution decomposition. This is the first approach that attempts to simplify the scalp topography by decomposing it into simpler maps using a spatial multiresolution.

A scalp topographic map for an ERP may be a superposition of several simpler subtopographic maps, each resulting from an individual electrical source located at a certain depth as a focal or extended activity. Furthermore, this source may have a temporal characteristics as an oscillation or a rhythm that extends in a certain time window, which has been a basis of assumption for the time-frequency analysis methods.

The subtopographic maps arising from sources located at certain depths with different extention of activities generally fall into different spatial frequency bands on the scalp. Therefore, a spatial frequency decomposition of a scalp potential distribution yields these subtopographic maps, whose source localizations will lead us to their electrical sources in the brain. It is essential to perform this spatial frequency decomposition on a realistic scalp surface without any distortion. To achieve this purpose, we propose a method that involves a realistic scalp model on which a 3D wavelet transform is performed, and the subtopographic maps obtained are source localized using inverse modeling.

FORWARD PROBLEM AND REALISTIC HEAD MODEL

Forward problem of EEG computes the electrical potentials on the scalp surface from the given source positions and strenghts in the brain. Boundary Element Method (BEM) is used with the Centre of Gravity (COG) approximation on a realistic head model (Hamalainen & Sarvas, 1989; Schlitt, Heller, Aaron, Best, & Ranken,1995). Realistic head model consists of brain, skull, and scalp surfaces. Surfaces of the brain, skull, and scalp are tesselated with 2000, 1200, and 1200 triangles respectively. If we have P different measurement sites in the conductor model, the forward problem can be formulated by the electrical potential $\mathbf{v}(\vec{s})$ at electrode location $\vec{s}$, due to a dipole at $\vec{r}$ with strength $\vec{m}$, as in Equation 1.

$$\mathbf{v}(\vec{s}) = \mathbf{H}(\vec{s},\vec{r})\,\mathbf{m}(\vec{r}) \quad (1)$$

Here, $\mathbf{v}(\vec{s})$ is $P \times 1$ electrical field vector, $\vec{m}$ is a 3×1 strength vector for a single current dipole source located at $\vec{r}$, and $\mathbf{H}(\vec{s},\vec{r})$ is a $P \times 3$ dimensional transfer function which depends on the dipole location $\vec{r}$, the measurement sites $\vec{s}$, and the geometrical and physical properties of the media.

BEM used for the forward problem is a numerical approximation technique which partitions the surface of a volume conductor into a triangular mesh. This technique has been used in dipole source localization of brain electromagnetic activity since the end of 80s. The human head is modeled as three homogeneous conductor layers: the outermost surface being the boundary for the scalp, the intermediate being for the skull, and the innermost being for the brain. The head model that we used in this study is developed using the average T1 weighted human brain MRI data provided by Montreal Neurology Institute (MNI). Statistical Parameter Mapping software 99 release (http://www.fil.ion.ucl.ac.uk/spm/), which is developed by Wellcome Institute is used for 3D segmentation of the brain, skull, and scalp. After segmentation, the surfaces are triangulated in order to generate the realistic head model. 30 channel electrode locations (Fp1, Fp2, F7, F3, Fz, F4, F8, FT7, FC3, FCz, FC4, FT8, T7, C3, Cz, C4, T8, TP7, CP3, CPz, CP4, TP8, P7, P3, Pz, P4, P8, O1, Oz, O2) are registered to the scalp surface by spline interpolation, using the T1 weighted MR data, the inion-nasion and pre-auricular coordinates, and the 10-20 Electrode Placement System. The surface of the scalp, which is represented with 16188 triangles, can be seen in Figure 1.

Figure 1. Realistic head model developed from T1 weighted human brain MRI data containing 16188 triangles and 7800 vertices

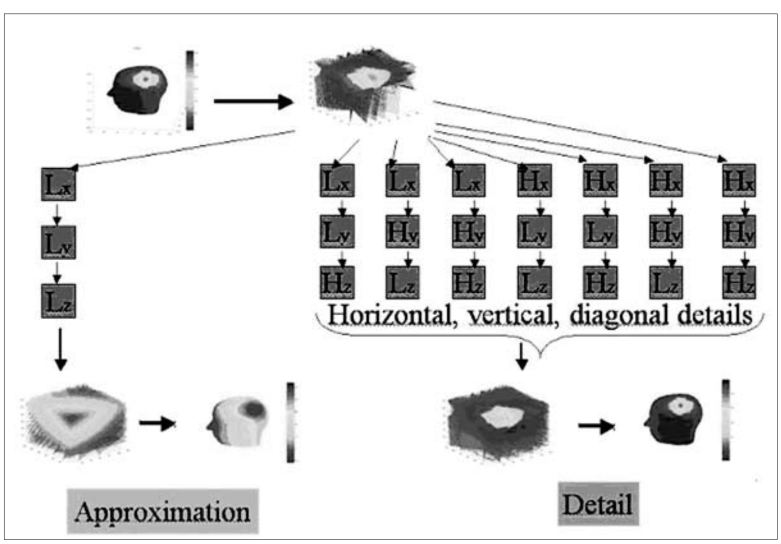
3D SPATIAL WAVELET DECOMPOSITION

Given a signal s of length N, the first step of Discrete Wavelet Transform (DWT) produces two sets of coefficients: approximation, and detail coefficients. These vectors are obtained by convolving the signal with the low-pass filter for approximation, and with the high-pass filter for detail, followed by dyadic decimation (downsampling) (Meyer, 1990). This decomposition splits data at level j into two components: the approximation at level j+1, and the detail at level j+1 (Daubechies, 1988; Grossman & Morlet, 1984; Mallat, 1989). For images, the algorithm is similar to the 1D case where the twoDimensional (2D) wavelets and scaling functions are obtained the by tensor product of respective 1D functions. 2D DWT leads to a decomposition at level j into four components: the approximation at level j+1, and the details in three orientations (horizontal, vertical, and diagonal). Similarly, to perform 3D wavelet decomposition, 1D DWT is applied on three directions on the 3D volume data, as seen in Figure 2. That leads to eight components from level j to j+1, one being the low pass filtered data, and seven others as the various combinations of low and high pass filtered data, in all three directions.

INVERSE PROBLEM

The inverse problem estimates the source positions, and their strength from multichannel ERP data. The MUSIC (Multiple Signal Classification) scanning algorithm is used for the inverse problem. MUSIC method is based on subdividing the brain tissue into a 3D grid, and computing the spatial power spectrum with an eigen-based approach for each voxel element. In order to do this, the transfer function $H(\vec{s}, \vec{r})$ in Equation 1 has to be computed numerically (Hamalainen & Sarvas,

Figure 2. 3D topography is converted to a 3D regular volumetric grid; by using 1D DWTs, at each stage, volumetric grid with raw data is decomposed into two sets called approximation and detail; finally, the original topograhies are regenerated from these volumetric maps



1989). In this study, the cortex of the brain is seleced as a solution space for MUSIC algorithm.

VALIDATION OF THE METHOD

In order to validate the method proposed, a simulated multichannel ERP data is generated by using COG approximation of the BEM. Two stationary radial point sources are assumed, one being superficial, while the other being deeper in the brain. Forward problem is solved for these point sources using BEM over the predefined head model given in Figure 1. The amplitude changes of the two point sources were sinusoidal with 128 data points, and they were temporally correlated. The inverse problem is solved using the total topographic activity. Although, temporally uncorrelated sources can be easily discriminated by the MUSIC algorithm, the source positions, in this case, are not clearly separated because of the temporal correlation of individual sources. MUSIC estimated the location of the superficial source from the total topography, which is a missing solution. Deeper source could not be localized by these inverse solutions. By the spatial wavelet decomposition prior to source localization, subtopographic maps, which originate from individual sources, can be identified, whose superimposition yields the original ERP topography. In our case, seven octave spatial wavelet decomposition is applied to the topography serie of total activity and the original topography serie is divided into two sets, as seen in Figure 3. One of the topographic map series denotes the approximation outputs, which is the low-pass filtered in all directions, and the other series shows the detail output, which is the remaining part of the original topography series. When these topographic map series are individually localized, it can be observed that the predefined sources can be easily discriminated, as shown in Figure 4. Superficial source is localized from the approximation output while the deeper source is estimated from the detail output. Although it could be decomposed into any number of subtopographies, the original simulated

Figure 3. Topography of superficial source, deeper source and total activity at the time instant of 32; fourth topography is the approximation and the fifth topography is the detail output

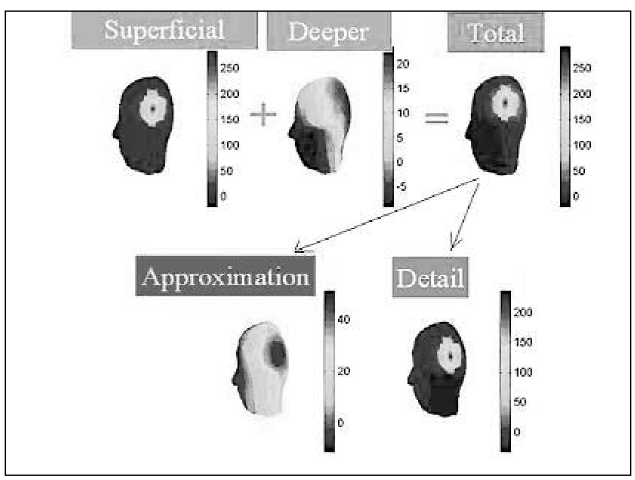


Figure 4. Inverse solutions of the total, approximated and detail topographies with MUSIC, respectively

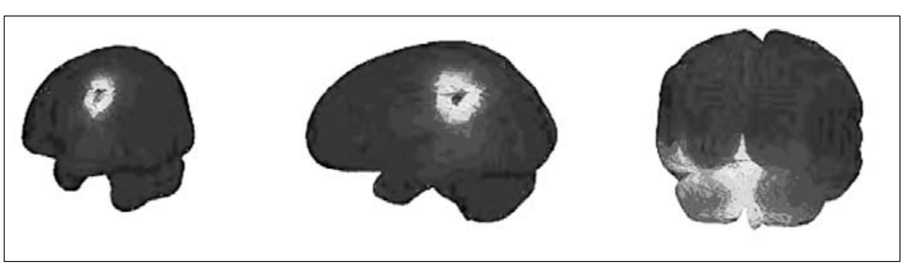

map is divided into two, each of which corresponds to one individual distinct source.

FUTURE TRENDS

Due to the large number of grid points, the spatial wavelet decomposition requires a high computational complexity and memory usage. More efficient algorithms will significantly decrease the computational cost and memory usage. The mutichannel data projected on the time-frequency and space domains will enhance the localization of nonstationary and distributed sources in the EEG/ERP, and help contribute to overcome the nonuniqueness inverse problem. Implications of these studies are that these individual nonstationary ERP sources when localized in space, time and/or frequency correlate with the distinct and/or interacting cognitive functions of the brain.

CONCLUSION

Spatial wavelet analysis of ERP at a given temporal location yields spatially stationary scalp maps at different spatial frequencies, determined by the depth and extension of individual ERP sources. Therefore, a spatial preprocessing of the ERP simplifies the complexity of the scalp map into several subtopographic maps produced by individual ERP sources prior to their source estimation. This helps us to enhance the accuracy and reliability of the source localization procedures.

KEY TERMS

Boundary Element Method (BEM): BEM is a numerical computational method of solving linear partial differential equations, which have been formulated as integral equations.

Event-Related Potential (ERP): ERP is any measured brain response that is directly the result of a thought or perception.

Forward Problem of EEG: The procedure that calculates the electrical potential over the scalp.

Inverse Problem of EEG: The procedure which estimates the activity of the brain from given electrical potential data.

Multiresolution Decomposition (MRA): MRA is the design method of most of the practically relevant discrete wavelet transforms (DWT), and the justification for the algorithm of the fast wavelet transform (FWT).

Spatial Frequency: The spatial frequency is a measure of how often the structure repeats per unit of distance.

Subtopography: Simple scalp topography originated from decomposition of main scalp map.

Spatial Heart Simulation and Adaptive Wave Propagation

INTRODUCTION

Sudden cardiac death, caused mostly by ventricular fibrillation, is responsible for at least five million deaths in the world each year. Despite decades of research, the mechanisms responsible for ventricular fibrillation are not well understood. As most computational studies are limited primarily to planar simulations, experiments so far have not elucidated the mechanisms responsible for spatial phenomenon (Janse, Wilms-Schopman, & Coronel, 1995) of ventricular fibrillation.

It would be important to understand how the onset of arrhythmias that cause fibrillation depends on details such as heart size (Winfree, 1994), geometry (Vetter & McCulloch, 1998; Panfilov, 1999), mechanical and electrical state, anisotropic fiber structure (Fenton & Karma, 1998), and inhomogeneities (Antzelevitch et al., 1999; Wolk, Cobbe, Hicks, & Kane, 1999). The main difficulty in development of a quantitatively accurate simulation of an entire three-dimensional human heart is that human heart muscle is a strongly excitable medium whose electrical dynamics involve rapidly varying, highly localized fronts (Cherry, Greenside, & Henriquez, 2000).

In ventricular tissue (which is the most important to study) the width of a depolarization front is usually less than half mm and a simulation that approximates the dynamics of such a front requires a spatial resolution of $\Delta x \leq 0.1$ mm. Forasmuch the muscle in an adult heart has a volume of 250 cm^3, and so a uniform spatial representation requires at least $2.5 \cdot 10^8$ nodes. Taking into account that each node's state is described with at least 50 floating number (with at least 4 byte resolution) the necessary storage space rises higher than 50GB (personal computers have no opportunity to handle such a huge amount of data in memory). It is known that the rapid depolarization of the cell membrane (this is the fastest event in heart functioning) blow over in few hundred microseconds. A reasonable resolution of this event requires a time step $\Delta t \leq 25$ microseconds. Since dangerous arrhythmias such as ventricular fibrillation may require several seconds to become established, the 10^{10} floating point numbers associated with the spatial representation would have to be evolved over 10^5 - 10^6 time steps. Such a huge uniform mesh calculation currently exceeds all existing computational resources (Cherry, Greenside, & Henriquez, 2003).

Previous efforts to improve the efficiency of simulations have followed several approaches. The most common way of simplification is based on a reduced mathematical model that can reproduce some of the behavior observed in more complex models but with only a few coupled fields. One widely used example is the two-variable FitzHugh–Nagumo model (FitzHugh, 1961), which describes behavior of a general excitable medium. This model can be modified to approximate various types of cardiac dynamics (Berenfeld & Pertsov, 1999). Another example is a three-variable model developed by Fenton and Karma (Fenton & Karma, 1998) that is designed to reproduce the restitution curves of more complex cardiac models. Albeit these and other simplified models can reproduce many known features of cardiac electrical propagation, some electronic (Fenton, 2000) and drug effects cannot be handled properly. Accordingly, efficient algorithms for more quantitatively-based models are still desirable.

The spatiotemporal structure of wave dynamics in excitable media suggests an automatically adjustable resolution in time and space. The basic idea of this improvement (Cherry et al., 2000, 2003) is deducted from experiments (Winfree et al., 1996; Witkowski et al., 1998) and simulation (Courtemanche, 1996), which recommends that the function of electrical membrane potential of a ventricular cell $f_V(t,x,y,z)$ in the fibrillating state consists of many spirals (for approximately two-dimensional tissue such as the right ventricle and atrium) or of many scroll waves (for thicker cardiac tissue such as the left ventricle). An interesting property of these spatiotemporal disordered states is that the dynamics is *sparse*: at any given moment, only a small volume fraction of the excitable medium is depolarized by the fronts, and away from them the dynamics are slowly varying in space and time. This idea permits the decrement of necessary computational effort and storage space (only the time dependent depolarization fronts have to be represented with high resolution instead of the whole tissue volume) for regular beats but the total front volume can greatly increase with a fibrillating state. By varying the spatiotemporal resolution to concentrate computational effort primarily along the areas with large spatial and temporal gradients, it is possible to reduce greatly the computational effort and memory required.

Most of previous studies (Rousseau & Kapral, 2000; Vigmond & Leon, 1999) implemented the adaptivity, locally and dynamically, by varying either the spatial or temporal resolution, but not both. However, these methods decreased the global processing volume significantly and they generally could not yield computational savings as significant as the time- and space-adaptive strategies. All of these adaptive approaches have the advantages that they are largely model- and method-independent.

The heart modeling method presented in this article is based on an algorithm developed by Berger and co-workers (Bell, Berger, Saltzman, & Welcome, 1998) and used successfully for three-dimensional simulations. Although the earlier presented methods involved dynamic time and space analysis, the a priori heart irregularities were neglected. The Purkinje fiber net has an unknown shape and highly varies from patient to patient. To handle this problem, we involved in our method the average heart tissue-topology that admits the appliance of probabilistic descriptions.

The rest of the article describes the applied human cell and tissue model, the time and spatial position dependent heart and torso model, the adaptively variable resolution wave-propagation method, and the parallel processing of these algorithms aided by graphic cards.

MATERIALS AND METHODS

Applied Human Cell and Tissue Model

We used the ten Tusscher heart cell model (ten Tusscher, Noble, Noble, & Panfilov, 2004) for ventricular and Nygren's model (Nygren, Fiset, Firek, Clark et al., 1998) for atrial cells, to investigate the accuracy and efficiency of the simulation algorithm. These models are based on recent experimental data on most of the major ionic currents, such as the fast sodium, L-type calcium, transient outward, rapid and slow delayed rectifier, and inward rectifier currents. With the inclusion of basic calcium dynamics, the contraction and restitution mechanism of the muscle cells can be investigated.

The model is able to reproduce human epicardial, endocardial, and M cell action potentials, to modify the internal state of the cells and to show that differences can be explained by differences in the transient outward and slow delayed rectifier currents. These properties allow the study of evolvement of reentrant arrhythmias. The conduction velocity restitution of this model is broader than in other models and agrees better with available data. We conclude that the applied model can reproduce a variety of electrophysiological behaviors and provides a basis for studies of reentrant arrhythmias in human heart tissue.

As presented in ten Tusscher et al. (2004), the cell membrane is modeled as a capacitor connected in parallel with variable resistances and batteries representing the different ionic currents and pumps. The electrophysiological behavior of a single cell can be described by equation (1):

$$\frac{dV}{dt} = -\frac{I_{ion} + I_{stim}}{C_{memb}} \tag{1}$$

where V is the voltage, t is time, I_{ion} is the sum of all trans-membrane ionic currents, I_{stim} is the externally applied stimulus current, and C_{memb} is the cell capacitance per unit surface area.

The ionic current's sum is given by the equation (2):

$$I_{ion} = I_{Na} + I_{K1} + I_{to} + I_{Kr} + I_{Ks} + I_{CaL} + \\ + I_{NaCa} + I_{NaK} + I_{pCa} + I_{pK} + I_{bCa} + I_{bK} \quad (2)$$

where I_{NaCa} is Na^+/Ca^{2+} exchanger current, I_{NaK} is Na^+/K^+ pump current, I_{pCa} and I_{pK} are plateau-, I_{bCa} and I_{bK} are background- Ca^{2+} and K^+ currents. The fast Na^+ current that is responsible for the fast depolarization of the cardiac cells is formulated by the equation (3):

$$I_{Na} = G_{Na} \cdot m^3 \cdot h \cdot j \cdot (V - E_{Na}) \quad (3)$$

where G_{Na} is the sodium conductance, *m* represents the activation gate, *h* the fast- and *j* the slow- inactivation gate. All detailed equations are described in Harrild and Henriquez (2000). These gates have mainly a voltage dependent behavior. The maximal value of the first derivative of the L-type calcium current I_{CaL}, transient outward current I_{to}, slow delayed rectifier current I_{Ks}, rapid delayed rectifier current I_{Kr} and inward rectifier K^+ current I_{K1} and all other described currents is lower with at least two magnitudes than for the fast Na^+ current I_{Na}.

A homogenous spatial cardiac tissue can be modeled in space as a continuous system with the following partial differential equation (4) (See Box 1) where ρ_x, ρ_y, ρ_z are the cellular resistivity and S_x, S_y, S_z are the surface-to-volume ratio in the *x*, *y* and *z* directions.

Computational modeling of the cardiac tissue is a useful tool for developing mechanistic insights into cardiac dynamics. The most important parts of human cardiac analysis are atria and ventricular tissue modeling.

Our study is based on Harrild's atria model (Harrild & Henriquez, 2000) that is the first membrane-based description of spatial conduction in a realistic human atrial geometry. This model includes both the left and right atria, including representations of the major atrial bundles and a right-sided endocardial network of pectinate muscle. The membrane's kinetics is governed by the Nygren et al. (1998) formulation for the human atrial cell. An advantage of this model is that it provides an easy perceptibility of atrial activation, particularly in regions that cannot be easily recorded in patients.

It has long been appreciated that cardiac ventricular fibers are arranged as counter-wound helices encircling the ventricular cavities, and that orientation of these fibers depends on transmural location (Streeter & Hanna, 1973). Fibers tend to lie in planes parallel to the epicardium, approaching a longitudinal orientation on the ventricular surfaces, and rotating toward the horizontal near the midwall. The direct anatomical reconstructions are labor-intensive and time-consuming tasks. In our study we applied Winslow's ventricular tissue model (Winslow, Scollan, Holmes et al., 2000).

Heart and Torso Model

There are many possible different heart structures (Quan & Evans, 1998). To describe various representative cases, we studied our breast MRI records (42 examples) and numerous CT images. These samples lead us to construct a morphological heart structure for simulation. The anatomical structure of the atria (Harrild & Henriquez, 2000) and ventricles (ten Tusscher, Bernus, Hren, & Panfilov, 2006; Vetter & McCulloch, 2001) was involved in geometrical model of the heart and torso, which was constructed using tetra meshes. The torso, lung, endo- and epicardial surfaces were divided into 23647, 38844, 78809, and 89723 subunits. Such a heart model could have a maximal spatial resolution of 0.025 mm that means more than ten billion individual compartments at highest decomposition. For a flexible simulation, we could choose the minimal time-slice between 0.01ms and 2ms over the whole ventricular excitation cycle.

The structure of the torso, its position in space, the relative position and distance of the compartments with respect to the electrodes, and the electrical behaviour of the torso's contents are necessary to be known (Ramon, Czapski, Haueisen et al., 1998). As the model has to take in consideration extremely numerous parameter values, the problem cannot be solved in a determin-

Box 1.

$$\frac{dV}{dt} = \frac{1}{C_{memb}} \cdot \left(-I_{ion} - I_{stim} + \frac{1}{\rho_x S_x} \cdot \frac{\partial^2 V}{\partial x^2} + \frac{1}{\rho_y S_y} \cdot \frac{\partial^2 V}{\partial y^2} + \frac{1}{\rho_z S_z} \cdot \frac{\partial^2 V}{\partial z^2} \right) \quad (4)$$

istic way (we have much more unknown values than known equations). That is why a stochastic method (genetic algorithm, adaptive neural networks, and fuzzy systems) should be applied to determine the values of the parameters.

Adaptively Varied Resolution and Parallel Implementation

The adaptive algorithm assumes that some user specified explicit relation has been chosen to approximate both time and space derivatives. For each subunit, the spatial and temporal resolution was determined using the calculated derivatives. The established coarse or fine level assures that internal simulated data can be interpolated with the desired precision from input information. As temporal units vary with the spatial resolution, more time steps are needed for finer patches, which lead to an asynchronous updating. Data on all resolution levels are synchronized only after one full time step on the coarsest grid level is completed. The efficiency of the method arises from its ability to refine or to coarsen the spatial and temporal representations of subunits automatically and locally. The approximation errors are estimated on each subunits to determinate the lowest necessary resolution to keep under a predefined tolerance value. This method is highly parallelizable. As subunit values are determined independently, these tasks can be effectuated on separate processors with reduced communication needs.

The hardware accelerated programmability of graphics processing units (GPUs) admits the development of programs called shaders. These programs, called vertex and fragment shaders, are loaded into the graphics card memory for replacing the fixed functionality. The fragment shaders can be used in our method to perform the single-instruction-multiple-data (SIMD) commands for each subunit. From architectural concepts result that the GPUs are most efficient in case of more than 1000 similar tasks.

Simulation Platforms

Experiments have been performed on four platforms with different configuration that are described in Table 1. Each computer has 1GB memory that admits a maximal resolution between 0.01 mm (normal beats) and 0.1 mm (ventricular fibrillation) for the most critic area (highly restricted size).

RESULTS

Table 2 informs us about simulation times using various configurations. All simulation tasks were performed with adaptive time and spatial resolution, and Table 2 show the finest ones among them. The simulated normal and pathological cases have one second duration. In all cases, the number of simultaneously performable tasks has an order of thousands. The conventional simulation (constant resolution) was performed only for 1 mm spatial and 0.2 ms temporal units, and was slower about 200 times in normal and 35 times in fibrillating case.

Section a of Figure 1 elucidates the relation between estimation error and spatial resolution. The obtained results are almost similar for normal and pathological cases.

In section b of Figure 1, we can observe the propagation of depolarization wave in an anisotropic ventricular tissue. The studied surface contain a rotated tissue, where the ratio of the conduction speed for an almost horizontal and vertical direction is considered 3.2.

Figure 2 presents a cell activation simulation that was effectuated and visualized after 200ms of the rises of sinoatrial node excitation. In the right part of

Table 1. Configuration of the simulation platforms involved in this study

Configuration	CPU	GPU	Memory
1st	Athlon 3000+	Nvidia 6600	1GB DDR
2nd	Core2 Duo 6400	Ati 1950 PRO	1GB DDR2
3rd	Core2 Duo 6400	2x Ati 1950 PRO	1GB DDR2
4th	Pentium D 805	Nvidia 7600GT	1GB DDR2

the image, the activation time of a cell is visualized. Each slice has 10mm distance from other, so totally a five centimeter wide ventricular tissue is visualized. Figure 3 presents a normal and pathological simulated 12 lead ECG signal.

DISCUSSION AND CONCLUSION

Table 1 present four configurations with shader model (SM) 3.0 ready GPUs. The third configuration is the most powerful due to the cross-fire connected ATI 1950 PROs. The type of CPU (Intel or AMD), the clock speed (1.86 - 2.66 GHz), the core number (solo or duo), and memory bandwidth (DDR or DDR2) did not play an important role because a powerful video card has a much higher floating-point calculation power (internally has 8-36 pixel shader units). In all cases, the size of memory was selected at 1GB that restricts the applicable maximal resolution.

From data of Table 2, we can observe the clear dominance of GPUs. Although the spatial and temporal resolution limit the necessary simulation time in all cases a massive parallelization could be performed.

Table 2. The simulation time of a one second duration event performed on involved platforms using two spatial and temporal resolutions. In simulation a normal beat, ectopic beat, and ventricular fibrillation state was included.

Conf. & resolution/ Pathological case	**Normal beat**	**Ectopic beat**	**Ventricular fibrillation**
1st – (1 mm, 0.2 ms)	11.3 sec	37.15 sec	4 min 2 sec
2nd – (1 mm, 0.2 ms)	1.32 sec	5.21 sec	33.11 sec
3rd – (1 mm, 0.2 ms)	0.7 sec	2.68 sec	17.13 sec
4th – (1 mm, 0.2 ms)	2.37 sec	9.03 sec	57.48 sec
1st – (0.1 mm, 0.05 ms)	1h 11 min	4h 22 min	1d 5h 11 min
2nd – (0.1 mm, 0.05 ms)	9 min 20 sec	37 min 10 sec	3h 53 min
3rd – (0.1 mm, 0.05 ms)	5 min 3 sec	19 min 17 sec	1h 59 min
4th – (0.1 mm, 0.05 ms)	15 min 40 sec	1h 6 min	6h 42 min

Figure 1. (a) The relation between the applied spatial resolution and resulting estimation error simulating a normal beat. (b) The simulated depolarization wave in anisotropic ventricular tissue is presented. From the pace origin the wave front propagation is plotted with 5ms resolution.

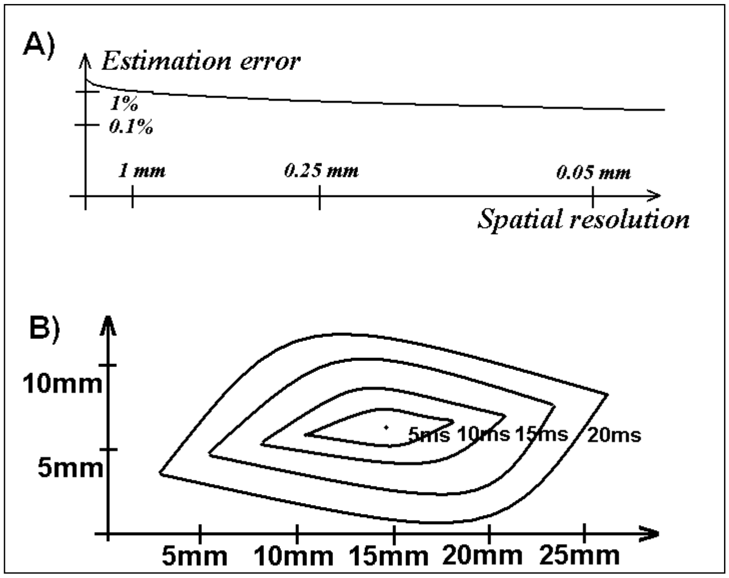

Figure 2. The simulated depolarization wave propagation in ventricles and atria in case of normal QRS beat

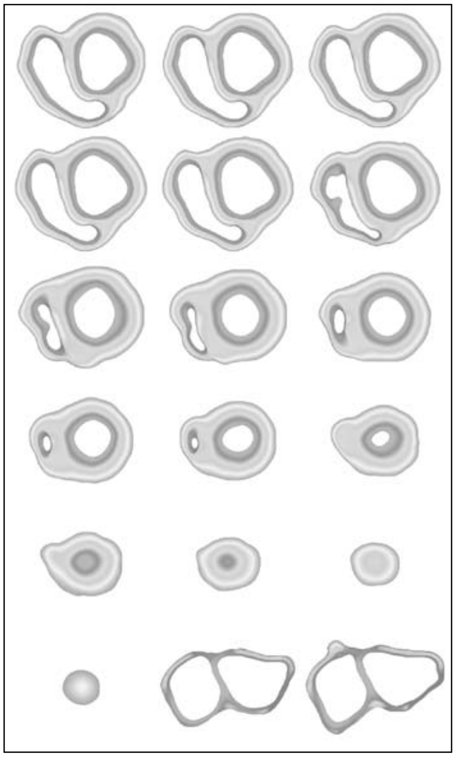

All shader programs were created using a low level programming environment. We could observe that in normal cases the active depolarization wave front has a much lower size than in case of ventricular beat of ventricular fibrillation. In a complex biological situation, as the wave front size grows the parallelization becomes harder. This assumption is reflected by the simulation times from Table 2. It is observable that a normal heart has at least 20 times lower front area than a fibrillating one. As a cardiac muscle (especially left ventricular) becomes less homogeny, the relative simulating speed decreases. Some basic characteristics of the heart such as size, maximal tissue volume, and left wall width significantly influence the maximal performance.

Section a of Figure 1 represent the estimation error in function of spatial resolution. The temporal resolution has almost similar effect but with lower impact. From measurements, we could deduct that estimation error is physiological state free. In normal and pathological cases, we measured almost the same error values.

In this article, we have discussed new features and new capabilities of a space-time adaptive heart-modeling algorithm. We have shown the algorithm's ability to simulate inhomogeneous and strongly anisotropic tissue regions.

This method can provide a variety of advances in addition to reductions in time and memory requirements. For example, the algorithm can allow a more complex ionic model and higher spatial resolution of a nonlinear tissue model. Similarly, it can allow the use of higher spatial and temporal resolution to reduce the angle dependence of propagation patterns in spatial domains with rotational anisotropy or to verify that a calculation is sufficiently resolved so that an increase in resolution does not affect the results (see section a of Figure 1).

We have presented a massively parallelized flexible and efficient heart simulation method that uses almost all features of a modern processing hardware. After that, we demonstrated that the processor of a modern graphics card can afford better performance than a modern CPU under certain conditions, in particular, allocating data in a regular and parallel manner. In these situations, the GPU should operate in a SIMD fashion to get the most performance hit. Experimental results show that the graphics card can be exploited in order to perform nonrendering tasks.

INTRODUCTION

The most important health problem affecting large groups of people is related to the malfunction of the heart, usually caused by heart attack, rhythm disturbances, and pathological degenerations. One of the main goals of health study is to predict these kinds of tragic events, and by identifying the patients situated in the most dangerous states, to make it possible to apply a preventing therapy.

Creating a heart model is important (Thaker & Ferrero, 1998) as the computer, while applying traditional signal processing algorithms recognizes lots of waves, but it does not really "understand" what is happening. To overcome this, the computer needs to know the origin and the evolvement process of the ECG signal (MacLeod & Brooks, 1998). During signal processing, if the traditional algorithm finds an unrecognizable waveform, the model-based approach is activated, which tries to estimate the causes of the encountered phenomenon (e.g., quick recognition of ventricular fibrillation) (Szilágyi, 1998).

The heart is a dynamic organ and places special demands on spatial techniques. To understand its physiology and pathophysiology, not only the electrical activity and spatial distribution of its structures is important, but also their movement during cardiac cycles. The measured ECG signal is influenced during repolarization by the mechanical movement of the heart.

The main goal of the inverse problem of ECG is to characterize and reconstruct cardiac electrical events from measurements. In contrast to the forward problem of electrocardiography, the inverse problem does not possess a mathematically unique solution and in order to improve stability, it needs to adopt regularization techniques.

Several approaches have been explored to handle the problem of multiple solutions by using equivalent cardiac generators (such as equivalent dipole and multipole), heart surface isochrones (Cuppen & Oosterom, 1984), or epicardial potential (Guanglin & Bin, 2001). The high sensitivity of solutions to the different disturbances forced the investigators to explore regularization techniques (Shahidi, Savard, & Nadeau, 1994). These methods allow a significant progress, but the different uncertainty elements of the processing hinder the potentially beneficial ECG inverse solutions from becoming a routine clinical tool at present.

Body surface potential mapping (BSPM) was developed to allow an almost complete data acquisition from the body surface (Mirvis, 1988). BSPM may have a great advantage over the standard 12-lead system in different situations due to deeper accessible information. Mirvis (1988) has shown some cases of BSPM recordings that clearly demonstrate the inadequacies of the standard ECG lead sets in a variety of pathologies. As we know more about the depolarization-repolarization mechanism, we can understand better the internal function of the heart.

Many interesting biomedical applications of artificial neural networks are in the area of data processing (Minami, Nakajima, & Yoyoshima, 1999). The best known neural solutions involve multilayer perceptrons, Kohonen self-organizing networks, fuzzy or neuro-fuzzy systems, genetic algorithms, and the combination of various solutions within a hybrid system (Lagerholm, Peterson, Braccini, Edenbrandt, & Sornmo, 2000). A typical heart modeling system applies many neural networks and chooses the best one, while discarding the rest. Most efficient approaches usually are based on the combination of many classifiers utilizing either different classifier network structures or different data preprocessing methods (Osowski & Hoai, 2001).

The support vector machine (SVM), pioneered by Vapnik (1998) assumed to solve the main drawbacks of conventional artificial neural networks (ANNs) such as:

- Modern biological problems are high-dimensional, and if the underlying mapping is not very smooth, the linear paradigm needs an exponentially increasing number of terms with an increasing dimensionality of the input space, which means an increase in the number of independent variables. This is known as "the curse of dimensionality."
- The real-life data generation laws may typically be far from the normal distribution and a model-builder must handle this difference in order to construct an effective learning algorithm.
- The maximum likelihood estimator (and consequently the sum-of-error-squares cost function) should be replaced by a new induction paradigm that is uniformly better, in order to model properly non-Gaussian distributions.

The SVM classifiers became quite popular due to their robustness and stability (Osowski, Hoai, & Markiewicz, 2004). An SVM used in a heart modeling system is rigorously based on statistical learning theory and simultaneously minimizes the training and test errors. Apart from that, they produce a unique globally optimal solution and hence are extensively used in diverse applications including medical diagnosis (Smola & Cholkopf, 1998).

This article presents an event recognition study performed with ECG signal analysis and 3D heart model using unified neural networks (UNN). The main purpose is to evaluate the strength and weakness of each method and to analyze the cooperation efficiency in malfunction diagnosis.

MATERIALS AND METHODS

Unified Neural Networks

If we focus on the two-class classification case and consider linear discriminant functions, the respective decision hypersurface in the *n*-dimensional feature space is a hyperplane that can be described as:

$$g(x) = w^T \cdot x + w_0 = 0 \qquad (1)$$

where $w = [w_1, ..., w_n]^T$ is known as the weight vector and w_0 as the threshold value. For a given vector x_d, if the function $g(x_d) = 0$ than x_d situates on the decision hyperplane. The distance z of a vector x from the decision hyperplane can be represented as: $z = \frac{|g(x)|}{|w|}$, where $|w| = \sqrt{\sum_{i=1}^{n} w_i^2}$.

In a classification problem, our purpose is the optimization of vector w in such a way, that the criteria function $J(w)$ is minimized. Let ω_1 and ω_2 be the two classes that we have to separate. We assume that this task can be performed using a linear relation. This means that there exists at least one such a w_{sol} hyperplane that fulfill the following relations:

$$w_{sol}{}^T \cdot x > 0 \text{ for } \forall x \in \omega_1$$
$$w_{sol}{}^T \cdot x < 0 \text{ for } \forall x \in \omega_2. \qquad (2)$$

If we design a classifier, where the desired output is $y_{des} = +1$ for $\forall x \in \omega_1$ and $y_{des} = -1$ for $\forall x \in \omega_2$, and try to modify weights in vector w in such a way that the criteria function $J(w) = (y_{des} - x^T \cdot w)^2$ is minimized, than we have constructed a root mean square error based separator method.

A very popular classifier algorithm is based on SVM-s. The main concept incorporates the search for the "most robust solution" vector w_{sol} that gives the maximum possible margin. The margin is represented by the minimal distance:

$$z = \frac{|g(x)|}{\|w\|}$$

This means the minimization of $\|w\|$.

Although these methods deliver good results in a certain noise-free environment, in biomedical simulation such sterile conditions never occur. The main reason of this problem is caused by measurement errors and the improper estimation of unmeasurable biological parameters.

The root mean square classifiers have the following drawbacks:

- Improper solution in case of asymmetric transfer functions
- Large estimation error of the criteria function in case of border-close high dispersion (uncertain) inputs
- In a noisy environment, the criteria function may possess multiple local minimal solutions that may cause low quality results
- The white noise is "unlearnable" so the function $J(w)$ will saturate at an uncontrollable error level.

The SVM produces a much better result in a hostile environment, but did not take into consideration the topology of the input vectors.

To overcome the above mentioned problems, we propose for classification a UNN. The main difference between unified neural network (UNN) and the described classifiers consists in the equation of criteria function:

$$J(w) = \lambda_d \cdot (y_{des} - x^T \cdot w)^2 + \lambda_{sm} \cdot \sum_{i=1}^{N} f_{sm}(x^T \cdot w) + \lambda_m \cdot f_m(z) \quad (3)$$

that is composed by a difference error, smoothness and margin part. Coefficients λ_d, λ_{sm}, λ_m are weighting the square error and the results of smoothing and margining functions represented by f_{sm} and f_m. The margin value is represented by $z = \frac{|g(x)|}{\|w\|}$.

Although this example illustrates a linear separation, the UNN may be applied in nonlinear environment.

Study Records

The first signal resource was a 192-electrode measurement (BSPM) database (sampled at 1000 Hz with 12-bit resolution) obtained from the Research Institute for Technical Physics and Materials Science (MTA-MFA) of Budapest. These registrations contain various malfunction cases as WPW syndrome, atrial and ventricular fibrillation, and flutter. In the second stage of the study, we used 12-lead ECG registrations from our database. These signals were sampled at 500-1000 Hz with 12-bit resolution.

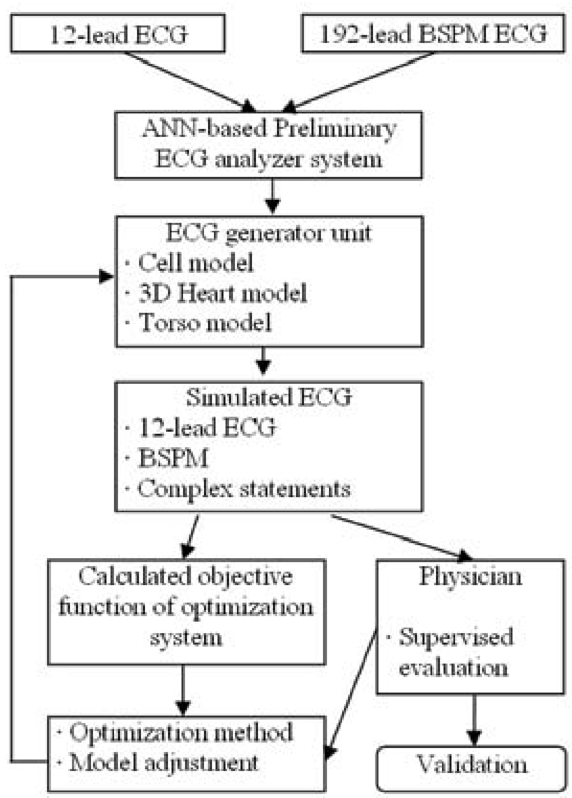
The Approach of ECG Inverse Problem

In contrast to methods that directly solve the matrix equation linking electrical sources with electrical potential fields to estimate ECG inverse solution, our approach indirectly obtains the result in terms of heart model parameters.

The preliminary ECG analyzer system (PAS) is based on detailed, a priori knowledge of human anatomy and physiology, developed using an ANN, tested and validated by physicians in clinical environment (see Figure 1).

In this study, the PAS was used to obtain initial information on the site of origin of cardiac activation. The output of the ANN provides the initial heart model parameters. Then the BSPMs or 12-lead ECGs

Figure 1. The schematic diagram of the heart analyzer and modeling method



were simulated by the ECG generator unit, and the objective functions that assess the similarity between the measured and simulated signals were determined. The heart model parameters are adjusted with the aid of optimization algorithms or in certain cases physicians. The simulation procedure is performed until the objective functions satisfy the given convergence criteria. Finally the parameters are validated.

ANN-Based Preliminary ECG Analyzer System

Application of a priori knowledge to reduce the searching space of heart model parameters is quite important. The PAS (see Figure 2) was developed to determine roughly the cardiac status and state, which was then used to initialize the model parameters and decrease the searching space for the optimization system.

In the present study, the PAS was developed based on a three-layer UNN as shown in Figure 2. This network is capable of mapping the nonlinear input-output relationship to a desired degree of accuracy. An adaptively weighted coefficient algorithm was used to train the ANN. The number of neurons in the input layer was set to 192, corresponding to the number of body surface electrodes used in the present simulation study. The hidden layer had 125 neurons that were determined heuristically. The output layer had 512 neurons, which corresponded to 32 ventricular myocardial segments of computer heart model: *MS-1* to *MS-32*. Sixteen cardiac cellular units were selected for each of 32 myocardial segments in the ventricles, and each of these 16 x 32 = 512 sites was then paced in the forward simulation using the computer heart-torso model, generating the dataset for training the ANN.

RESULTS

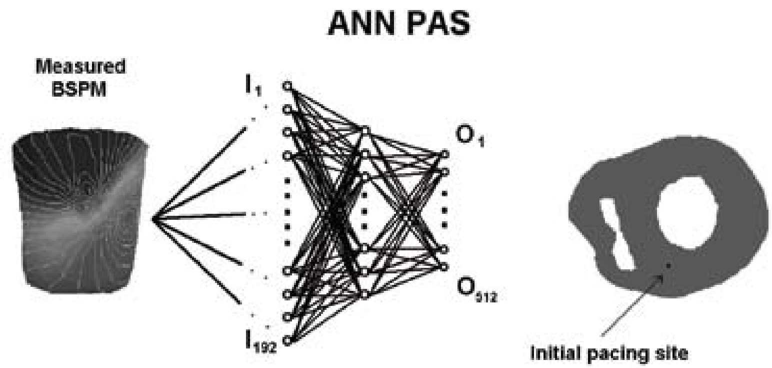
During the simulation, a parameter classification algorithm was applied to distinguish normal QRS complexes from abnormal ones, in order to determine the specific differences between the normal and abnormal parameter values. For normal cases, the detection ratio is practically 100%. The signals presented in Figure 3 were obtained via simulation using the initial parameter set for a normal and abnormal (bypass tract) situation.

Figure 4 presents the cell activation simulation that was effectuated and visualized after 200 ms of the rises of sinoatrial node excitation. In the right side of the image the activation time of each cell is showed. Neighbor slices are situated at 10 mm distance from each other, so totally a 5 centimeter wide ventricular tissue is visualized. Table 1 shows the efficiency of simulation for different cases. The evaluation of the simulated results was made by physicians. The performance was determined as the ratio of correct and total decisions.

DISCUSSION

Table 1 reveals that the 3D heart simulation (Szilágyi, Benyó, & Dávid Bey, 2003a, 2003b) succeeds in most cases, such as Wolff-Parkinson-White (WPW) syndrome, pre-excitations, and tissue activation model-

Figure 2. The ANN-based preliminary analyzer system used to estimate the pacing site from ECG



ling. Re-entry mechanisms and triggered event cases represent the weak points of the simulation model.

The application in practice of the model has several obstacles, which can be classified into the following groups:

- Effects of internal and external perturbations (such as environment, sympathetic and parasympathetic despondence).
- Lack of information on different elements of the model.
- Lack of technical background.

The Limitations of the Model

Several problems could be conceptualized, but the most important limitations are:

- The processes performed inside the cells are not well known, the behavior of the studied components cannot be determined with an acceptable precision.
- In critical cases, if a group of cells does not get the necessary food, it changes its behavior. A model created to simulate the normal behavior of the cell will not simulate it correctly in abnormal case.

Figure 3. The simulated ECG signal in normal and abnormal case (bypass tract)

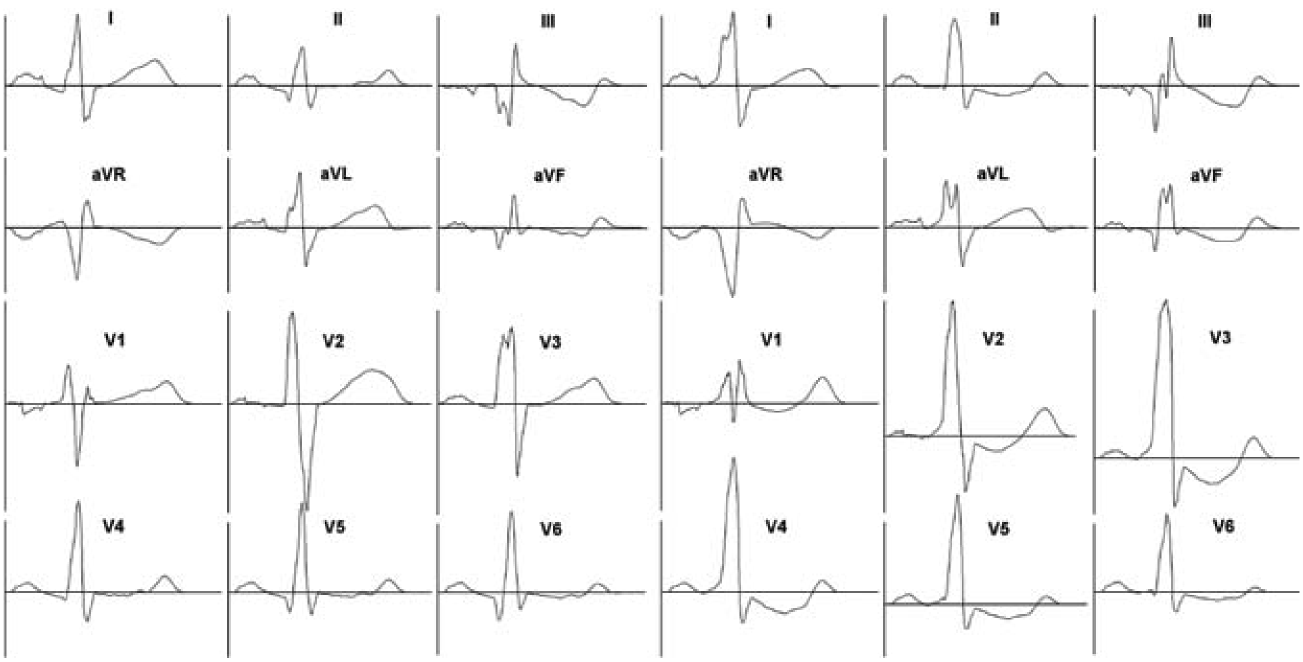


Figure 4. The simulated depolarization in normal and abnormal case (bypass tract)

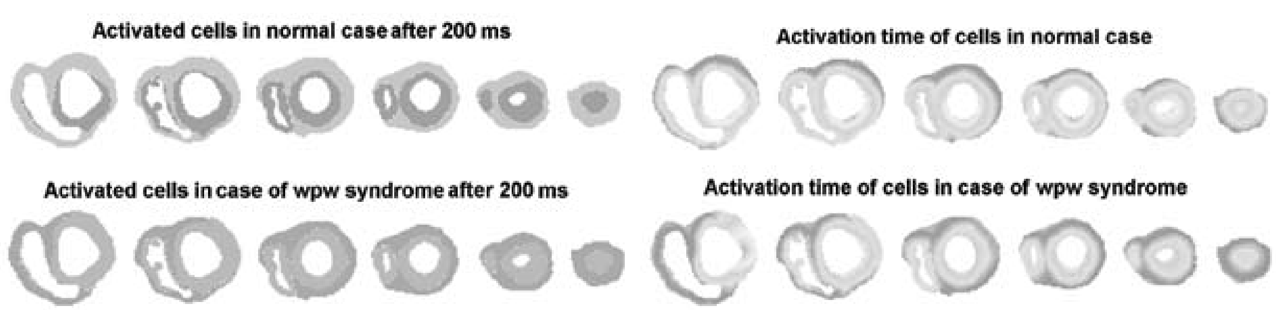

Table 1. Simulation performance in case of various pathological and normal situations

Pathological case	*Decision number*	*Failed decisions*	*Performance*
Normal	44	0	100.00%
Ectopic beat	21	0	100.00%
WPW syndrome	14	1	92.86%
Atrial flutter	22	1	95.45%
Atrial fibrillation	18	1	94.44%
Ventricular fibrillation	19	1	94.73%
Re-entry mechanisms	19	2	89.47%
Triggered activity	36	2	94.44%
Aberrant ventricular conduction	21	1	95.24%

- Because the structure of the heart differs from patient to patient, this structure is not known a priori and it has to be determined in real-time, based on the available information.
- Determining the torso's structure introduces the same problem. It is hard to determine the electrical conductivity and precise position of its elements.

Perturbation Phenomena

In case of human system identification, the most important disturbing phenomena are:

- It is known that respiration makes the heart change its shape and position. Although the motion of the heart can be tracked, it is not possible to determine from the ECG the amplitude of the motion.
- The continuous motion and displacement involves very hard problems. Because the motion has an effect on the behavior of all internal elements, the behavior of the heart will also be modified. The model has to follow the changes of the cell properties. For example: a resting man suddenly jumps out of the bed. The controlling mechanisms start their adjustment, the values of model parameters will change.
- Fever and respiration frequency can also cause alterations.
- External events (the patient senses something annoying or pleasant) change the dependence between the previously measured signals and the determined parameters. This is one of the causes why the perfect simulation of a human body is impossible.

Technical Background

At present, the performance of personal computers does not make possible the real-time determination of parameter values. The practical application is possible only in case of strongly parallel systems. The simplified model can be applied in real-time, but its efficiency is reduced because of the neglected parameters. The waveform of the simulated ECG in normal cases can be considered acceptable. The shape and duration of basic waves have realistic values. In case of abnormal cases the obtained waveform is not acceptable and more simulations are needed.

CONCLUSION

Regarding the fact that computerized ECG diagnostics refer to several medical and technical problems, at the moment it cannot be applied as a standalone system. The short-term solution is the application of fuzzy systems and systems based on multi-agents that, based on empirical information, make it possible to accomplish an adaptive advising system based on continuous transitions.

If a hybrid system (neuronal-fuzzy and model-based approach, simultaneously) is built, it may become possible to learn the model via the knowledge of the traditional advising system, which, after a suitable learning process, will be able to replace gradually the old system.

KEY TERMS

Body Surface Potential Map: A massively multichannel measurement of the ECG signal using several dozens or hundreds of electrodes that cover the whole torso

ECG Analysis: A collection of ECG signal processing methods aiming at the determination of medical parameters.

Heart Simulation: A simulation that focuses on the functional modeling of the heart.

Inverse Electrocardiography: A methodology that reconstructs the inner structure of the heart using multichannel ECG.

Search Space Reduction: A method for decreasing the problem complexity.

Support Vector Machine (SVM): A set of related supervised learning methods used for classification and regression.

Unified Neural Network: An advanced neural network whose criterion function includes the topology of the classified samples.

Wolff-Parkinson-White (WPW) Syndrome: A syndrome of pre-excitation of the ventricles of the heart due to an accessory pathway that causes an abnormal electrical communication from the atria to the ventricles.

Strategic Fit in the Healthcare IDS

Evelyn H. Thrasher
University of Massachusetts Dartmouth, USA

Terry A. Byrd
Auburn University, USA

INTRODUCTION

Interorganizational networks are defined as "clusters of organizations that make decisions jointly and integrate their efforts to produce a product or service" (Alter & Hage, 1993, p.2) and "advanced organizational structures perceived to improve efficiency, flexibility, and innovativeness and described as decoupled units developed because of rapid growth or knowledge and technology" (Schumaker, 2002). The healthcare integrated delivery system (IDS) is a distinct example of an interorganizational network. Defined as networks of healthcare organizations linked for the goals of clinical integration and an effective patient care continuum (Deluca & Enmark, 2002; Kilbridge, 1998; Young & McCarthy, 1999; Zucherman, Kaluzny, & Ricketts, 1995), IDSs may assume various organizational forms; namely, strategic alliances, contracted networks, or joint ventures, and may be comprised of multiple forms within a single network (Page, 2003). Also of interest is the distinction of the IDS as a lateral network of stakeholders, all directly serving the patient. This study uses the healthcare IDS to test a model of strategic fit and to examine differences in the nature and strength of the strategic fit to performance relationship across two distinct levels of IDS development.

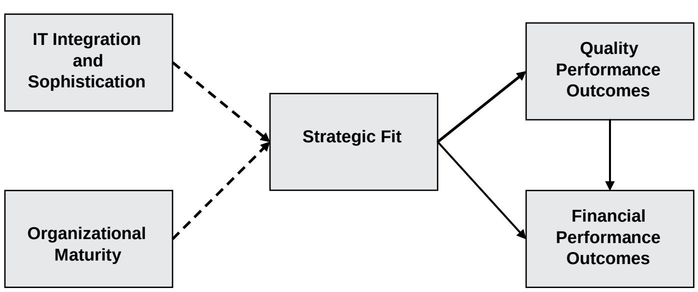
The conceptual model (Figure 1) is tested using data from HIMSS Analytics and the American Hospital Directory for 130 US IDSs. The IDSs are categorized into two levels of development, High Integration Aligned (HIA) and Low Integration Aligned (LIA), based on the alignment of IT integration/sophistication and organizational maturity. The relationship between strategic fit and IDS financial and quality performance is tested with comparisons made between the two groups.

BACKGROUND

Strategic Fit

Henderson and Venkatraman (1993), in the strategic alignment model, defined strategic fit as a process of adaptation in which organizational changes must be supported by complimentary IT resources and integration. Similarly, Chan and Huff (1993) defined strategic fit as "the fit between business strategy and IS strategy" (p. 345). We adapt these definitions to define strategic fit as the point of equilibrium at which the level of interorganizational network structure and maturity is properly aligned with a complementary level of IT integration and sophistication.

Figure 1. Conceptual model of strategic fit for the interorganizational network



Venkatraman (1994) developed the IT-Enabled Business Transformation Framework as an extension to the strategic alignment model, positing that IT is no longer simply an operational support resource, but rather a strategic tool with which to transform the firm's organizational structure and processes. He further proposed that IT's strategic role emerges more readily as firms establish strategic alliances and partnerships, as is the case with interorganizational networks. In advanced stages of organizational development, the need for and benefits from strategic fit should increase as interorganizational networks expand into more complex structures (Venkatraman, 1994). Yet little empirical evidence exists to support these suggestions. Much research around IT value and strategic fit has been conducted at the firm level (Bergeron, Raymond, & Rivard, 2001; Chan, Huff, Barclay, & Copeland, 1997), but research at the interorganizational network level is rare (Straub, Rai, & Klein, 2004).

Some researchers have examined the differences in firm performance between organizations at various levels of strategic fit. Zajac, Kraatz, and Bresser (2000) demonstrated significant positive links between strategic fit and ROA in savings and loan organizations that achieved advanced levels of strategic fit. These authors empirically supported the argument that organizations responding in a timely manner to needed strategy changes and achieving fit at this new level of development will realize greater benefits than those that do not.

Similarly, Bergeron, et al. (2001) found that small enterprises with a high level of strategic fit realized improved financial performance. These authors examined strategic fit through different lenses—profile deviation, moderation, matching, and other perspectives—to measure the performance impacts of fit. The results suggested that those organizations that pursue a highly strategic organizational and IT strategy tend to outperform organizations that fail to reach these higher levels. Thus, these past studies support the idea of a difference in the strategic fit to performance relationship, depending upon the achieved level of IT integration and organizational structure. More specifically, these studies suggest that performance improvements should be more apparent among highly integrated mature organizations that have achieved strategic fit.

Quality Outcomes

Quality outcomes are intangible, quality-related measures of organizational service and performance (Devaraj & Kohli, 2000; Li & Collier, 2000) and are of concern to IDSs due to the need for continual patient care quality improvement (Snyder & Paulson, 2002). Research suggests that patient-centered measures such as mortality rate, patient satisfaction, and average length of hospital stay (ALOS) are appropriate quality performance outcomes for the IDS (Devaraj & Kohli, 2000; Dowling, 1997; Smith & Swinehart, 2001); thus, ALOS is adopted for this study.

Initial formation and growth of IDSs led to reduced ALOS. For instance, Kim (2000) examined the impact of IDS formation on ALOS in the 1990s and found that ALOS was shorter for IDSs that had achieved a high degree of functional process integration across network participants. Those IDSs that had shortened ALOS had done so through the streamlining of patient care with expanded services and reductions in the time associated with administrative tasks. To the contrary, more recent studies indicate that ALOS reductions may have slowed or stalled (Page, 2003), suggesting that IDS formation alone is insufficient to ensure long-term quality improvements.

Regarding IT's role in healthcare performance improvements, Li and Collier (2000) investigated the impact of IT on performance through a survey of hospital administrators. The results indicated that IT had a significant positive impact on hospital quality and financial performance through IT's perceived ability to enhance accuracy, timeliness, and patient care effectiveness. Research suggests that increasing IT resource complexity and sophistication results in increasing pressure to pursue further business transformation for improved coordination and integration. Thus, as IDSs mature, IT's role seems to evolve from business process support to enabler of business transformation (Schumaker, 2002). Similarly, as IDSs expand, increasing differentiation of services often results, thereby forcing these networks to re-evaluate and improve both organizational and IT integration to maintain a streamlined patient care continuum (Schumaker, 2002).

Researchers suggest that strategic fit has a more significant impact on financial and quality performance among interorganizational networks with high IT integration and organizational maturity than among those with lower levels (Sabherwal & Chan, 2001; Smith & Swinehart, 2001). For instance, Sabherwal and Chan (2001) studied defenders, prospectors, and analyzers, and identified IT strategy profiles appropriate for various levels of organizational structure. These researchers found empirical support for a greater degree of performance improvement among more mature organizations with a focus on innovation and flexibility as opposed to immature organizations with an operational efficiency focus.

Extending the firm level findings and theories to the interorganizational network level, we propose the following hypothesis:

H1: The relationship between strategic fit and ALOS will be significantly more negative in HIA IDSs than in LIA IDSs.

Financial Outcomes

The current study uses operational cost as a measure of IDS financial performance to satisfy two conditions. First, by using cost measures, we can study both for-profit and not-for-profit IDSs, as both are concerned with reducing costs despite differences regarding profit-centered measures. Second, the healthcare industry is facing increasing pressure to reduce costs while continuing to improve patient care quality (Snyder & Paulson, 2002); thus, it is important to examine the impact of strategic fit on cost reduction. The formation of IDSs represents one attempt to control costs through the anticipated streamlining and improvement of the patient care continuum. Yet historical performance of IDSs has not supported this aim. Possibly due to the organizational complexity of newly formed healthcare networks, researchers suggest that organizational changes alone are insufficient to produce financial performance improvements for the IDS (Coddington & Moore, 2001).

In recent years, IDSs have begun to look closer at the benefits of IT integration in hopes of improving operational cost (Etchen & Boulton, 2000). Prior evidence suggests that IT may have a significant influence on the reduction of operational costs through improved efficiency and effectiveness (Barua, Kriebel, & Mukhopadhyay, 1995; Byrd, Thrasher, Lang, & Davidson, 2006; Coddington & Moore, 2001). For instance, a case study of 11 IDSs looked at steps taken to potentially reduce operational costs. In addition to the formation of the IDS and the streamlining of patient care within the IDS, all 11 stated that automation of clinical and administration processes through IT had resulted in significant operational cost reductions (Coddington & Moore, 2001).

Building upon these past results, Barua, et al. (1995) and Byrd, et al. (2006) also demonstrated support for the indirect cost benefits of IT associated with quality improvements. The premise behind these studies was that often the quality benefits of IT may be realized first and should, in turn, lead to financial performance improvements over time. Extending the firm-level evidence to the interorganizational network, we propose the following hypotheses:

H2: The relationship between strategic fit and operational cost will be significantly more negative in HIA IDSs than in LIA IDSs.

H3: The relationship between ALOS and operational cost will be significantly more positive in HIA IDSs than in LIA IDSs.

EMPIRICAL EVIDENCE OF IDS STRATEGIC FIT VALUE

Using 130 US IDSs, a strategic fit model was tested for the healthcare IDS. Profile matching (Chan et al., 1997) was used to categorize HIA IDSs and LIA IDSs, with 65 IDSs assigned to each group. Variables from the 2004 HIMSS Analytics Database were used to complete the categorization (Table 1).

Using standardized z scores and a six-point rating scale, each attribute was rated and averaged together to form an IT integration/sophistication rating and organizational maturity rating. Those scoring an overall rating of 4 or above were classified as HIA IDSs; those with an overall score of 3 or below were LIA IDSs. Table 2 presents descriptive statistics and ratings.

The measurement model was a second order model with IT integration/sophistication and organizational maturity as first-order factors forming strategic fit as a second-order factor. IT integration/sophistication and organizational maturity were measured reflectively using the factors in Table 1. The dependent variables, ALOS and operational cost, were measured using data from the 2004 American Hospital Directory.

Table 1. Variables for IDS classification

Construct	HIMSS Analytics Variables for the IDS
IT Integration and Sophistication	Number of enterprise applications in use Number of different types of enterprise applications (e.g., ERP, Clinical Decision Support, Case Mix Analysis) Number of available network nodes Number of personal computers in use Percentage of desktops with Internet access
Organizational Maturity	Number of facilities Number of different types of facilities (e.g., acute care, home healthcare, physician organization, insurer) Age (in years) of the IDS Number of hospital beds staffed Number of full-time employees Service population

Table 2. Descriptive statistics and IDS rating

Criteria	HIA IDS Rating N=65		LIA IDS Rating N=65	
	Mean	**SD**	**Mean**	**SD**
Enterprise Applications *(Mean=20.57, SD=23.26, Median=13)*	4.78	1.04	3.20	0.44
Types Enterprise Applications *(Mean=6.60, SD=0.70, Median=7)*	3.94	0.24	3.40	1.04
Available Network Nodes *(Mean=1744.35, SD=2460.84, Median=905)*	4.89	0.87	3.28	0.52
PCs in Use *(Mean=1272.42, SD=1809.48, Median=600)*	4.98	0.93	3.22	0.41
Percentage Personnel with Internet Access *(Mean=76.85%, SD=26%, Median=90%)*	3.75	0.66	3.35	0.89
Overall IT Integration and Sophistication	4.47	0.38	3.29	0.35
Facilities *(Mean=14.92, SD=17.24, Median=10)*	4.78	0.91	3.15	0.40
Diversity of Facilities/Services *(Mean=3.72, SD=1.02, Median=4)*	4.72	0.91	3.72	0.93
IDS Age *(Mean=56.79, SD=38.22, Median=52)*	2.94	1.04	3.66	1.05
Hospital Bed Capacity *(Mean=431.63, SD=490.38, Median=269)*	5.28	0.78	3.28	0.48
Full-Time Employees *(Mean=2256.95, SD=2903.53, Median=1300)*	5.22	0.80	3.26	0.44
Service Population *(Mean=1157848.28, SD=9172584.12, Median=270000)*	3.72	0.57	3.23	0.42
Overall Organizational Maturity	4.44	0.30	3.38	0.23
Overall Strategic Fit Rating	4.06	0.24	2.97	0.17

**Descriptives in italics*

Results

PLS was used for model analysis (Byrd et al., 2006; Sambamurthy & Chin, 1994), and T-tests were performed where needed to assess significance of differences. The results and measurement model are presented in Table 3 and Figure 2.

Discussion

Hypothesis 1 was supported, suggesting that HIA IDSs should see reduced ALOS, while ALOS may be increased in LIA IDSs. Researchers attribute increased efficiency, effectiveness, and knowledge sharing to high levels of IT integration and effective business processes. Perhaps these benefits contribute to improved ALOS in HIA IDSs. As researchers noted (Kim, 2000; Li & Collier, 2000), strategic fit with higher levels of IT and organizational integration may contribute to improvements in administrative processes and clinical care effectiveness, thereby resulting in shortened ALOS.

Hypothesis 2 was supported. Although positive for both groups, the strategic fit to operational cost relationship was significantly weaker for HIA IDSs, suggesting favorable progress is being made. History suggests that often the financial benefits of IT and strategic fit may not be readily apparent for a few years beyond the initial changes and investments. Thus, future research should consider including multiple years of operational cost data to better address the time lag issues of IT investments (Barua et al., 1995; Byrd et al., 2006).

Hypothesis 3 was not supported. HIA IDSs demonstrated a significant negative ALOS to cost relationship, while this relationship was insignificant and positive for LIA IDSs. One possible explanation is that as a patient's hospital stay is shortened, more frequent

Table 3. Hypotheses test results

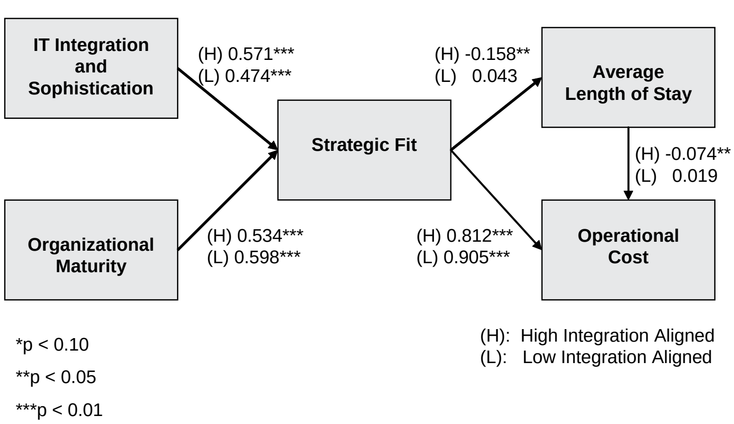
Figure 2. Strategic fit model



patient turnovers may result in increased operational costs. Another possibility relates to the proposed indirect IT effect on financial performance through direct quality improvements (Barua et al., 1995; Byrd et al., 2006; Currie & Guah, 2006). Because a negative direct relationship between strategic fit and operational cost was not supported, the time lag effect of IT may also help to explain the lack of support for a positive relationship between ALOS and operational cost. As noted previously, using multiple years of cost data in future research might provide better insight into the effects of IT investment and strategic fit on operational cost, both directly and indirectly, through quality performance improvements (Barua et al., 1995; Byrd et al., 2006).

FUTURE TRENDS

Unfavorable historical performance has made IDS administrators hesitant regarding additional investments in IT, and some have considered dissolving IDS arrangements (Parker, Charns & Young, 2001). This study has demonstrated that those IDSs that have achieved strategic fit with high levels of IT integration/sophistication and organizational maturity should see improved quality and financial performance. An emphasis on IDS performance research is warranted and needed to further define the impact of strategic fit on a variety of healthcare performance measures.

IDS formation and IT integration are relatively young concepts in healthcare; therefore, it is probable that those who have reached the level of HIA have done so only in recent years. Thus, the time lag effect of IT investment suggests that direct effects on operational cost may not yet be fully realized. Further investigation of the proposed model is needed with longitudinal data and in varying contexts to further refine the model, to examine a broad spectrum of interorganizational arrangements, and to build a body of knowledge around IT's value for the IDS.

CONCLUSION

This study used the healthcare IDS to empirically test a model of strategic fit across two levels of interorganizational network development. The results suggest that the benefits of strategic fit differ across distinct levels of interorganizational development, thus further illuminating the complexities associated with taking IT research to the interorganizational network level of analysis. Even within a single industry, tremendous variation of interorganizational network form, structure, goals, and management increases the difficulty of empirical studies of IT value for these networks. Nevertheless, this level of analysis brings with it the potential for a rich body of knowledge around the issues of complexity, interorganizational structure, variance of scope and strategy, and other similar phenomena. Thus, the current study lays the groundwork for a research agenda centered around the complexities and nuances of the interorganizational network, an area of focus lacking in the IT literature.

KEY TERMS

Average Length of Stay (ALOS): Number of days a patient must spend in the hospital, averaged across all lengths of patient stay for the hospital for one year.

Healthcare Integrated Delivery System: Network of healthcare organizations linked for the goals of clinical integration and an effective patient care continuum.

Interorganizational Network: A "cluster of organizations that makes decisions jointly and integrates their efforts to produce a product or service" (Alter & Hage, 1993, p.2).

Profile Matching: Profile matching assigns a score to both the IT integration/sophistication profile and the organizational maturity profile of the entity. If the two scores are equal or close within a very small predetermined range, the organization is deemed to have achieved strategic fit.

Strategic Fit: Point of equilibrium at which the level of interorganizational network structure and maturity is properly aligned with a complementary level of IT integration and sophistication.

Support Vector Machine Classification Applied on Weaning Trials Patients

INTRODUCTION

The most common reason for instituting mechanical ventilation is to decrease a patient's work of breathing. Many attempts have been made to increase the effectiveness on the evaluation of the respiratory pattern by means of respiratory signal analysis. This work suggests a method of studying the lying differences in respiratory pattern variability between patients on weaning trials. The core of the proposed method is the use of support vector machines to classify patients into two groups, taking into account 35 features of each one, previously extracted from the respiratory flow. 146 patients from mechanical ventilation were studied: Group S of 79 patients with Successful trials, and Group F of 67 patients that Failed on the attempt to maintain spontaneous breathing and had to be reconnected. Applying a feature selection procedure based on the use of the support vector machine with leave-one-out cross-validation, it was obtained 86.67% of well classified patients into the Group S and 73.34% into Group F, using only eight of the 35 features. Therefore, support vector machines can be an interesting classification method in the study of the respiratory pattern variability.

Support vector machine (SVM) is a binary classifier based on a supervised statistical learning through examples (Cristianini, 2000). SVM introduced by Vapnik (1998) and studied by others research (Burges, 1998; Veropoulos, Cristianini, & Campbell, 1999) is a new and powerful learning methodology that can deal mainly with nonlinear classification and regression. SVM are based on the use of decision hyperplanes which determine decision boundaries. A decision hyperplane is one that separates the set of objects having different class memberships. The algorithm is simple enough to be analyzed mathematically, since it can be shown that correspond to a linear method in a high-dimensional feature space, nonlinearly related to input space (Hearst, 1998).

One of the most challenging problems in intensive care is the process of discontinuing mechanical ventilation. Critical-care clinicians must carefully weight the benefits of rapid liberation for mechanical ventilation against the risks of premature trials of spontaneous breathing and extubation. The need for accurate prediction applies to all phases of weaning, beginning with reductions in mechanical support, as patients are increasingly able to support their own breathing, followed by trials of unassisted breathing, which often precede extubation, and ending with extubation (Meade, Guyatt, Cook, & Griffith, 2001). When mechanical ventilation is discontinued, up to 25 percent of patients have respiratory distress severe enough to require reinstitution of ventilation support (Tobin, 2001).

The respiratory pattern describes the mechanical function of the pulmonary system and can be characterized by the following time series: inspiratory time (T_I), expiratory time (T_E), breath duration (T_{Tot}), tidal volume (V_T), fractional inspiratory time (T_I/T_{Tot}), mean inspiratory flow (V_T/T_I), and frequency-tidal volume ratio (f/V_T).

The aim of the present work is the analysis of the respiratory pattern variability in patients during weaning trials by means of support vector machines, in order to find differences between patients that had been capable to maintain spontaneous breathing, and patients that failed in that purpose.

The following method employs techniques from the area of signal processing and incorporates the doctor's knowledge, in order to achieve a satisfactory level of reliability so as to act as a decision support system in respiratory treatments. This research is an effort to exploit the capabilities of SVM as a classification method to identify and analyze the respiratory pattern variability.

ANALYZED DATA

Respiratory flow was measured in 146 patients on weaning trials from mechanical ventilation (WEANDB data base). These patients were recorded in the Departments of Intensive Care Medicine at Santa Creu i Sant Pau Hospital and Getafe Hospital, according to a protocol approved by the local ethic committees. Using clinical criteria based on the T-tube test, the patients were classified into two groups: Group S, 79 patients with Successful trials after 30 minutes and Group F, 67 patients that Failed in the purpose to maintain spontaneous breathing, and had to be reconnected after 30 minutes of weaning trials.

Respiratory flow was obtained using a pneumotachograph connected to an endotraqueal tube. The pneumotach consists in a Datex – Ohmeda monitor with a Validyne Model MP45-1-871 Feature-Reluctance Transducer. The signal was recorded at a sampling frequency of 250 Hz during 30 minutes.

From each recorded signal, the aforementioned time series were obtained: inspiratory time (T_I), expiratory time (T_E), breath duration (T_{Tot}), tidal volume (V_T), fractional inspiratory time (T_I/T_{Tot}), mean inspiratory flow (V_T/T_I), and frequency-tidal volume ratio (f/V_T)

METHODOLOGY

Data Preprocessing

Each one of the seven-time series was processed by moving a Running Window (RW), with a width range of 15, the best width ($p < 0.001$), consisting of several consecutive breath cycles. Five statistics were calculated for each window: the mean ($\overline{x}$), standard deviation (S), kurtosis (K), skewness (Sk), and interquartile range (IQR) of the value. In this way, 35 new time series were obtained for each patient.

Next, the data of each patient were analyzed independently by applying a *k*-means clustering algorithm, which automatically determines the number of clusters. In this study, for all patients, there was a main cluster containing the most part of the patterns (i.e., data points) with a considerable internal cohesion (low intra-cluster variance), corresponding to more than 96%, for each group. The patients were distributed in 80% for training process, and 20% for test process.

Leave-One-Out Cross-Validation

Leave-one-out cross-validation is a suitable technique to give a rough estimate of the performance of learning algorithm (SVM), and can be used to value the accuracy of the classifier (Ambroise & McLachlan, 2002). This external cross-validation should be undertaken to correct the error committed by choosing randomly the training and testing set. In this cross-validation process, each sample is removed in turn and the classifier is built using the remaining samples. The class of the removed sample is then predicted using the classifier created each case. This process is repeated for each sample in the original training set with which the classification accuracy is estimated.

The 35 features were ranked through a forward selection procedure, and beginning with the most relevant feature, the cross-validation error was estimated in turn adding the next relevant feature each time.

The best result was obtained with the next eight features: $S(T_E)$, $\overline{x}\ (T_{Tot})$, $\overline{x}\ (T_I)$, $\overline{x}\ (T_E)$, $S(T_{Tot})$, $IQR(T_{Tot})$, $\overline{x}\ (f/V_T)$, $\overline{x}\ (T_I/T_{Tot})$. Only these most relevant features were used in the final classification process, based on support vector machines.

Histogram Equalization

In order to achieve a reduction of the overlap between successful and unsuccessful patients (Group S and Group F), the variances of the features might be similar. Unfortunately, these variances cannot always be expected to be similar, so to solve this problem, an equalization of the histograms of the previously selected features as a nonaffine normalization process is proposed in this article (Hilger & Ney, 2001).

Histogram equalization or cumulative distribution function equalization is a general nonparametric method to make the cumulative distribution function (CDF) of some given data match to a reference distribution (Balchandran & Mammone, 1998).

The principle of this method is to find a nonlinear transformation to reduce the mismatch of two signals.

This transformation maps the distribution of a signal back to the distribution of the reference signal, and it is defined by means of the cumulative distribution functions of the signals in process.

In the equalization process, the objective is to deal with more reliable data by performing cumulative distribution function estimation by intervals equally spaced out. Each interval $x\ E[q_i, q_{i+1})$ is represented by $(x_i, F(x_i))$, that corresponds to the average of data and the cumulative distribution function obtained into the interval.

$$F(x_i) = \frac{k}{M} \qquad x_i = \frac{\sum_l x_l}{k_i}$$

where $x_i = x \in [q_i, q_{i+1})$, k is the number of data in the interval, $[q_0, q_{i+1})$, k_i is the number of data in the interval $[q_i, q_{i+1})$, and M is the total number of data.

The $F(x_i)$ defines the boundaries of the intervals in the CDF that will be equalized. These boundaries $[q'_i, q'_{i+1})$, limit the interval of values that fulfils the following expression $F(q_i) \leq F(y) < F(q_{i+1})$. All values of y that are into the interval $[q'_i, q'_{i+1})$, will be transformed to their corresponding x_i value.

The statistical matching technique applied in the current work matches the cumulative distribution function obtained from one feature, and the cumulative distribution function obtained from another feature, both evaluated over the training data.

The designed equalization takes, as a reference, the feature whereby the minor classification error is obtained on the leave-one-out cross-validation process which is the $S(T_E)$ feature.

Support Vector Machines

It is a learning system based on statistical learning theory, which can be applied to classification and regression problems.

SVMs deliver performance in applications such as text categorization, hand-written word recognition, image classification, biosequence analysis, and much more.

This learning method can be treated as a pattern recognition problem in which the features are seen as input patterns to be labeled as Group S patients or Group F patients obtained from the weaning off mechanical ventilation.

Given a linearly separable set of training vectors belonging to two separate classes, the aim is to find an optimal hyperplane that splits input data in two classes: 1, and -1 (the target values that correspond to the Group S and Group F patients labels respectively), maximizing the distance of the hyperplane to the nearest data of each class.

The separating hyperplane for linearly separable data is defined by $x \cdot w_0 + b = 0$, where w_0 is the normal to the hyperplane obtained as a linear combination of a subset of the training data. Data are then classified by computing the sign of $x \cdot w_0 + b = 0$. However, data normally are not separable; in this case, a linear boundary is inappropriate, a nonlinear decision function is needed, therefore an extension to nonlinear boundaries is achieved by using a specific function called kernel function. The kernel function maps the data of the input space into a higher dimensional space (feature space) by choosing a nonlinear transformation a priori. The SVM constructs an optimal hyperplane in this higher dimensional space (feature space), creating a nonlinear boundary in the input space. The mentioned hyperplane for nonlinearly separable data is defined by:

$$f(x) = \sum_{i=1}^{N} \alpha_i t_i\ K(x, x_i) + b$$

The coefficients α_i and b are determined by solving a large scale quadratic programming problem for which efficient algorithms exist that guarantee global optimum finding.

Where t_i are targets, and $\sum_{i=1}^{N} \alpha_i t_i = 0$

The vectors x_i are the support vectors, a linear combination of the support vectors determine the optimal separating hyperplane, and correspond to the closest points of each class. N is the number of support vectors and $0 \leq \alpha_i \leq C$. C is penalty parameter, which allows some flexibility in separating the categories. It controls the trade off between allowing training errors and forcing rigid margins, and creates a soft margin that permits some misclassifications. Increasing the value of C increases the cost of misclassifying points, and forces the creation of a more accurate model that may not generalize well. The goal is to find the minimum value of C with which a minimum error classification is obtained.

Furthermore, kernel functions must satisfy some constraints in order to be applicable (Mercer's conditions) (Burges, 1998).

The kernel function used in this work is a radial basis function (RBF), expressed as:

$$K(x_i, x_j) = \exp\left[-\frac{1}{2}\left(\frac{\|x_i - x_j\|}{\sigma}\right)^2\right]$$

where σ is a characteristic parameter of this kernel. Typically a method of clustering is first employed to select a subset of centers. An attractive feature of the SVM is that this selection is implicit, with each support vectors contributing one local Gaussian function, centered at that data point.

The best value of the parameter σ is estimated by an internal 10-fold cross-validation applied only over the training set.

A support vector machine is a robust classification technique capable to classify very overlapped data without taking into account the type of the data (Crawford, Miller, Shenoy, & Rao, 2005; Furey, Cristianini, Duffy, Bednarski, Shummer, & Haussler, 2000; Georgoulas, Stylios, & Groumpous, 2006).

RESULTS

The data set was composed of 146 patients (79 patients of Group S, and 67 patients of Group F), of which the 80% (116 patients) formed the training set and the remaining 20% (30 patients) the testing set.

SVM classifier was learned from the training data. Using the whole set of features (35), the average of correct classification was 66.67%. Firstly, an internal M-fold cross-validation, shows that the best value of the parameter σ used in the kernel function is σ = 0,5. Secondly, an external leave-one-out cross-validation was applied to get the classification error obtained with each feature, with an SVM trained using one unique feature. This error estimation showed the contribution of each feature to the performance of the classifier, thus it was determined which of the features were the most important, and had to be taken into account in the final classification to get the best result.

The classification performance was exhaustively examined by means of a forward selection process, and the best result was obtained with the following features: $S(T_E)$, $\bar{x}(T_{Tot})$, $\bar{x}(T_I)$, $\bar{x}(T_E)$, $S(T_{Tot})$, $IQR(T_{Tot})$, $\bar{x}(f/V_T)$, $\bar{x}(T_I/T_{Tot})$.

Once the features were selected, the remaining noisy features are removed; the computational cost reduced, and so did the classification error.

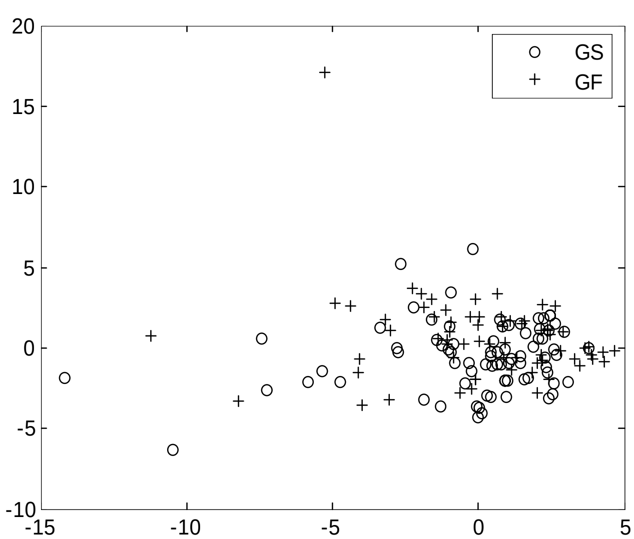
Histogram equalization technique was applied to the selected features with the aim of making their accumulation function be similar to the accumulation function of the reference feature that had given the best classification.

The classification percentage obtained after the process developed before is:

- Global percentage of well-classified patients: 80%
- Percentage of well classified Successful patient: 86.67%
- Percentage of well classified Unsuccessful patient: 73.34%
- The previous results, led to a sensitivity percentage of S=79%, specificity of E=82%, and value predictive positive of VPP=86%.

A grid-search was done to find the optimum penalty parameter *C*. As it was checked, the minimum *C*, which had given the best classification error accuracy, was

Figure 1. Successful (GS) and unsuccessful (GF) patients before the classification; orthogonal projections (Principal Component Analysis [PCA]) is used to represent hyperspace data on a plane before the classification



selected ($C = 15$), since the cost and the generalization error would be dropped.

Orthogonal projections (Principal Component Analysis [PCA]) were used as an attempt to visualize the hyperspace data variability on a plane before (Figure 1) and after the classification (Wang, Wu, & Liang, 2004).

Figure 2 and Figure 3 show the final classification of the training set and test set respectively.

CONCLUSION

Support vector machines is a robust classification technique capable to classify very overlapped data without taking into account the type of the data, leave one out cross-validation techniques allow searching the best subset of input features and histogram equalization maps the distribution of the selected features back to the distribution of the feature that gives the best classification result.

An innovative method based on support vector machines has been applied in order to analyze the respiratory pattern variability in patients during weaning trials, in order to find differences between patients capable of maintaining spontaneous breathing and patients that fail in that purpose.

The SVM trained with the whole set of 35 features achieved a well classification percentage of 66.67%. After the search of the most suitable features and the application of the histogram equalization method taking as reference the $S(T_E)$ feature, 80% was obtained using only eight of the 35 features. Although the groups are balanced, a greater facility of learning and generalization is observed on the part of the Group S with 86.67% of correctly classified percentage compared with Group S with 73.34%.

According to this classification, the following values of sensitivity S=79%, specificity E=82%, and value predictive positive VPP=86% were obtained.

These results permit to consider SVM analysis as a promising methodology to study the respiratory pattern variability in patients on weaning trials.

ACKNOWLEDGMENT

INTRODUCTION

In a typical *binary classification* problem, each pattern vector $\mathbf{x}_i \in \Re^d, i = 1,...,n$ belongs to one of two classes S^+ and S^-. A vector is given the label $y_i = 1$ or $y_i = -1$ if $\mathbf{x}_i \in S^+$ or $\mathbf{x}_i \in S^-$, respectively. The set of pattern vectors and their corresponding labels constitute the *training set*. The classification problem consists of determining which class new pattern vectors from the test set belong to. SVMs solve this problem by finding a hyperplane ($\mathbf{w}$, b) that separates the two classes in the training set from each other with the maximum margin.

The underlying optimization problem for the maximal margin classifier is only feasible if the two classes of pattern vectors are linearly separable. However, most of the real life classification problems are not linearly separable. Nevertheless, the maximal margin classifier encompasses the fundamental methods used in standard SVM classifiers. The solution to the optimization problem in the maximal margin classifier minimizes the bound on the generalization error (Vapnik, 1998). The basic premise of this method lies in the minimization of a convex optimization problem with linear inequality constraints, which can be solved efficiently by many alternative methods (Bennett & Campbell, 2000).

A hyperplane can be represented by $\langle \mathbf{w} \cdot \mathbf{x} \rangle + b = 0$ where $\mathbf{w}$ is the normal vector and b is the offset parameter. There is an inherent degree of freedom in specifying a hyperplane as $(\lambda \mathbf{w}, b\ \lambda)$. A *canonical hyperplane* is the one from which the closest pattern vector has a functional distance of 1, that is, $\min_{i=1,...,m} \left| \langle \mathbf{w} \cdot \mathbf{x}_i \rangle + b \right| = 1$.

Consider two pattern vectors $\mathbf{x}^+$ and $\mathbf{x}^-$ belonging to classes S^+ and S^-, respectively. Assuming these pattern vectors are the closest to a canonical hyperplane, such that $\langle \mathbf{w} \cdot \mathbf{x}^+ \rangle + b = 1$ and $\langle \mathbf{w} \cdot \mathbf{x}^- \rangle + b = -1$, it is easy to show that the margin between these pattern vectors and the hyperplane are both equal to $1/\|\mathbf{w}\|$. Maximizing this margin while satisfying the canonicality condition for the pattern vectors turns out to be the following optimization problem.

$$\min_{\mathbf{w},b} \frac{1}{2}\|\mathbf{w}\|^2 \tag{1a}$$

subject to

$$y_i \left(\langle \mathbf{w} \cdot \mathbf{x}_i \rangle + b \right) \geq 1 \quad \forall i = 1, \ldots, n \tag{1b}$$

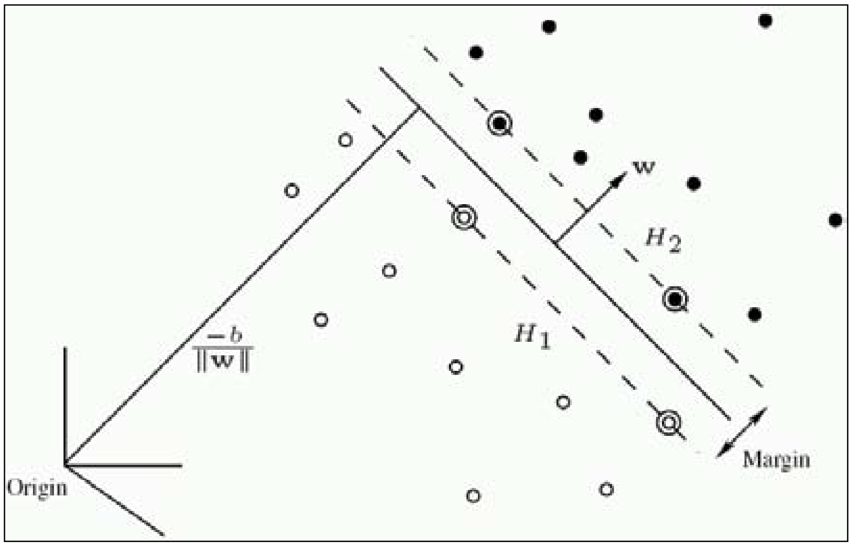
From the solution to (1), a new pattern vector $\mathbf{x}^*$ can be classified as positive if $\langle \mathbf{w} \cdot \mathbf{x}^* \rangle + b > 0$, and negative otherwise.

Most real life problems are composed of nonseparable data which is generally due to noise. In this case *slack variables* ξ_i are introduced for each pattern vector $\mathbf{x}_i$ in the training set. The slack variables allow misclassifications for each pattern vector with a penalty of $C/2$. In Figure 1-b, *soft margin classifier* is demonstrated that incurs penalty for misclassified pattern vectors. The maximum margin formulation can be augmented to soft margin formulation as follows:

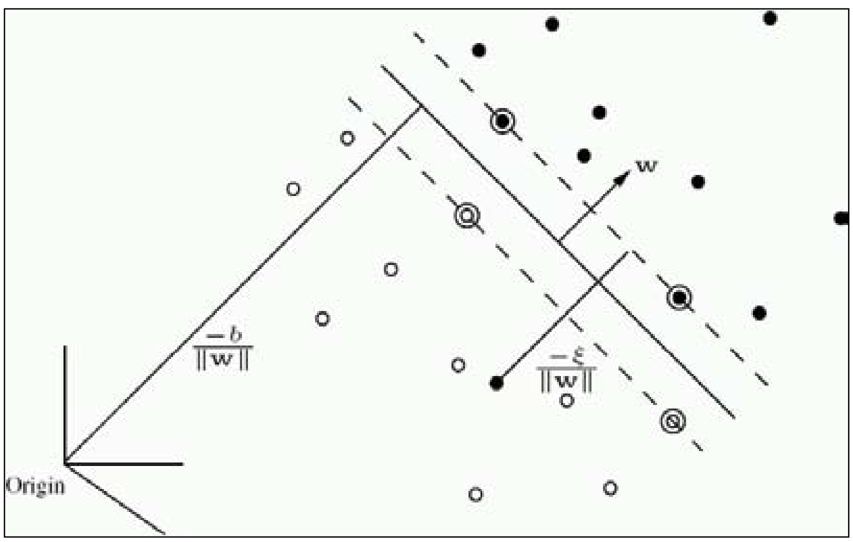
$$\min_{\mathbf{w},b} \frac{1}{2}\|\mathbf{w}\|^2 + \frac{C}{2}\sum_{i=1}^{n} \xi_i^2 \tag{2a}$$

subject to

Figure 1.



(a) Maximal margin classifier



(b) Soft margin classifier

$$y_i\left(\langle \mathbf{w}\cdot\mathbf{x}_i\rangle + b\right) \geq 1-\xi_i \quad \forall \mathrm{i}=1,\ldots,n \qquad \text{(2b)}$$

In (2), nonnegativity of the slack variables is implied since the solution cannot be optimal when $\xi_i < 0$ for any pattern vector.

The 2-norm of the slack variables is penalized in the objective of (2). An alternative formulation involves penalization of the 1-norm slack variables in the objective where nonnegativity of the slack variables is forced (Cristianini & Shawe-Taylor, 2000).

Dual formulations for both 1-norm and 2-norm SVMs can be obtained using the optimization theory. The significance of the dual formulations is that they do not involve inequality constraints, and they allow the *kernel trick* to be introduced for nonlinear classification. The standard method to obtain the dual formulation of the SVM problem consists of two parts. First the *Lagrangian function* of the primal problem is derived. This function provides a lower bound for the solution of the primal problem. Next, the Lagrangian function is differentiated with respect to the primal variables and stationarity is imposed. Equivalent expressions for each primal variable are substituted back in the Lagrangian function and added as constraints where appropriate. The dual problem is obtained by maximizing the resulting function with the new constraints. The dual problem is a concave maximization problem, which can also be solved efficiently. The Lagrangian function for the 2-norm SVM primal problem is given in Box 1.

Differentiating L with respect to the primal variables $\mathbf{w}$ and b, and assuming stationarity:

$$\frac{\partial L}{\partial \mathbf{w}} = \mathbf{w} - \sum_{i=1}^{n} y_i \alpha_i \mathbf{x}_i = 0$$

$$\frac{\partial L}{\partial b} = \sum_{i=1}^{n} y_i \alpha_i = 0$$

$$\frac{\partial L}{\partial \xi_i} = C\xi_i - \alpha_i = 0$$

Substituting the expressions back in the Lagrangian function, the following dual formulation is obtained which realizes the hyperplane $w^* = \sum_{i=1}^{n} y_i \alpha_i^* \mathbf{x}_i$ with geometric margin $\gamma = 1/\|\mathbf{w}^*\|$.

$$\max \sum_{i=1}^{n} \alpha_i - \frac{1}{2}\sum_{i=1}^{n}\sum_{j=1}^{n} y_i y_j \alpha_i \alpha_j \langle \mathbf{x}_i \cdot \mathbf{x}_j \rangle - \frac{1}{2C}\sum_{i=1}^{n} \alpha_i^2 \tag{3a}$$

subject to

$$\sum_{i=1}^{n} y_i \alpha_i = 0 \tag{3b}$$

$$\alpha_i \geq 0 \quad \forall i = 1, \cdots, n \tag{3c}$$

Note that from Karush-Kuhn-Tucker complementarity conditions, the constraints in the primal problem are binding for those with the corresponding dual variable $\alpha_i^* > 0$. Therefore b^* can be calculated using:

$$b^* = \sum_{i:\alpha_i^*>0} y_i - \langle \mathbf{w}^* \cdot \mathbf{x}_i \rangle. \tag{4}$$

The decision rule $\operatorname{sgn}(f(\mathbf{x}))$ is equivalent to the hyperplane $f(\mathbf{x}) = \sum_{i=1}^{n} y_i \alpha_i^* \langle \mathbf{x} \cdot \mathbf{x}_i \rangle + b^*$.

Kernels are introduced in classification to provide enhanced similarity measures between pattern vectors. They basically transform the so-called *input space*, χ, in which the original pattern vectors reside, to a usually higher dimensional dot-product space H called the *feature space*, via a map $\Phi : \chi \to H$, such that $\mathbf{K}(\mathbf{x}_i \cdot \mathbf{x}_j) = \langle \Phi(\mathbf{x}_i) \cdot \Phi(\mathbf{x}_j) \rangle$. The kernel $\mathbf{K}$ is required to be positive semidefinite in order to define a dot product space and create a feature map. A positive semidefinite kernel is defined as a function on $\chi \times \chi$ for a nonempty set χ, which for all $\mathbf{x}_1, \cdots, \mathbf{x}_n \in \chi$ gives rise to a positive semidefinite matrix $\mathbf{K}$ such that $\sum_{i,j} c_i c_j \mathbf{K}_{ij} \geq 0$ for all $c_i \in \Re$. In the literature it was shown that any algorithm that works on dot products can be kernelized through the *kernel trick* (Schölkopf & Smola, 2002). SVMs provide nonlinear classification by replacing the linear dot product $\langle \mathbf{x}_i \cdot \mathbf{x}_j \rangle$ in the dual formulation with an appropriate nonlinear kernel $\mathbf{K}$.

One of the most commonly used kernels both theoretically and practically is the *Gaussian kernel* which is represented as:

$$\mathbf{K}(\mathbf{x}_i, \mathbf{x}_j) = e^{-\frac{\|\mathbf{x}_i - \mathbf{x}_j\|^2}{\sigma}} \tag{5}$$

where σ is referred to as the bandwidth. The smaller bandwidths are better in classifying intricate patterns, but worse in generalization.

APPLICATIONS IN NEUROSCIENCE

Although the introduction of SVMs is relatively recent, this classification technique is gaining rapid acceptance as a robust neuroscience and medical research

Box 1.

$$L(\mathbf{w}, b, \xi, \alpha) = \frac{1}{2}\|\mathbf{w}\|^2 + \frac{C}{2}\sum_{i=1}^{n} \xi_i^2 - \sum_{i=1}^{n} \alpha_i \left[y_i \left(\langle \mathbf{w} \cdot \mathbf{x}_i \rangle + b \right) - 1 + \xi_i \right]$$

tool. SVMs have been shown to be highly effective at detecting complex pattern changes in neuroimaging data. Often patterns that are difficult, time-consuming, or perhaps impossible to detect by the trained physician's eye can be detected rapidly and accurately using SVMs. In this manner, SVMs can assist doctors with the challenging task of performing rapid diagnosis of neurological diseases and disorders. Expediting diagnosis means expediting proper treatment that may mitigate or even prevent permanent damage to the central nervous system.

Many of the medical SVM applications focus on image processing of magnetic resonance imaging (MRI) data to detect structural alterations in the brain over time. Magnetic resonance spectroscopy (MRS) data has also been analyzed with SVMs for a similar purpose. Single photon emission computed tomography (SPECT) data can be used to detect blood flow pattern changes over time. Often these neurophysiologic measurement modalities can be utilized in an SVM classifier to detect the presence of a disease or disorder.

Numerous neuroscience studies have utilized SVMs to classify neural states. fMRI is a useful imaging modality for neural state classification due to its ability to track changes in blood oxygenation level dependent signal, which is correlated with blood flow. In addition, the electroencephalogram (EEG) is a highly useful measure for SVM neural state classification due to its ability to quantify the electrical activity in the brain (e.g., voltage difference between a region of interest and a reference region on the scalp or in the brain) with exceptionally high temporal resolution.

The remainder of this article will provide an overview of the state-of-the-art SVM applications to various neuroimaging modalities for the purposes of medical diagnosis, understanding the physiology of cognition, and classification of neural states.

Magnetic Resonance Imaging

There are a number of studies which introduce different methods for image *segmentation*. Segmentation is the process of partitioning a digital image into different sections in order to change the representation of the image. This new representation may involve certain characteristics in the image such as curves, edges, color, intensity, or texture. Segmented images are usually used to determine brain abnormalities using image classification, and it is shown that SVMs perform very well. Lee, Schmidt, Murtha, Bistritz, Sander, and Greiner (2005) used SVMs and a new SVM based method developed earlier called *support vector random fields* for segmenting brain tumors from MR images. Rinaldi et al. (2006) classified brain inflammation in *multiple sclerosis* patients based on the peripheral immune abnormalities from MR images using nonlinear SVMs. They determined that brain inflammation in patients with multiple sclerosis is associated with changes in subsets of peripheral lymphocytes. Thus, SVM classification helped detect a potential biomarker candidate for the prognosis of patients in the early stages of multiple sclerosis. Quddus, Fieguth, and Basir (2005) combined SVMs and *boosting* (Schapire, 2001), another machine learning method, to perform segmentation (via nonlinear classification) on white matter lesions in the MRI scans. Their composite classification method was shown to be faster and just as reliable as manual selection. In another study by Martinez-Ramon, Koltchinskii, Heileman, and Posse (2006), a similar approach was used to create segments of the brain with respect to their functions. Later, these segments were aggregated using boosting, which is used for multiclass SVM classification of an fMRI group study with interleaved motor, visual, auditory, and cognitive task design.

Other Imagery Types

Other imaging modalities such as ultrasound and MRS are also used in medical classification problems. Kotropoulos and Pitas (2003) used SVMs for segmentation of ultrasonic images acquired near lesions in order to differentiate between lesions and background tissue. The radial basis function SVMs outperformed the process of thresholding of L2 mean filtered images for various lesions under numerous recording conditions. Darbellay et al. (2004) used SVM and other classification techniques to detect solid or gaseous *emboli* by transcranial doppler (TCD) ultrasound. Since the leading cause of cerebral infarction is due to the extracranial atherosclerosis, rapid assessment of the physical characteristics of solid objects in the blood flow is important. Darbellay et al. (2004) demonstrated that SVMs could distinguish between solid and gaseous embolisms from ultrasonic measures of the blood stream. A medical diagnostic device based on this technology may be able to prevent brain damage by providing the means to expedite the diagnosis and treatment of embolisms. Devos et al. (2005) devised a system that can automatically discriminate brain tumors based on data from MRI and *MRSI*, which is a function of MR imaging that produces a spectroscopic profile of the scanned brain region. In this study, MR spectra from MRSI was used for comparison with linear and nonlinear *Least squares SVM* (LS-SVM) (Suykens & Vandewalle, 1999). A similar study was carried out (Devos et al., 2004) based on only MR spectra with *short echo time H-MRS*, using the same set of classifiers. Lukas et al. (2004), on the contrary, used *long echo H-MRS* signals to classify brain tumors into four classes: *meningiomas*, *gliobastomas*, *astrocytomas grade II,* and *metastases*, with a number of classifiers including standard SVM, and LS-SVM. The study demonstrated that kernel-based SVMs were able to detect tumors without utilizing dimensionality reduction and still produce accuracy comparable to linear discriminant analysis.

Automated tumor detection algorithms are a sought-after tool for assisting physicians to make more accurate and rapid detection of tumors. Support vector machine classifiers have contributed significantly in this area. Menze, Lichy, Bachert, Kelm, Schlemmer, and Hamprecht (2006) utilized SVM classification of MRI images to serve as an automated diagnostic tool for the detection of recurrent brain tumors. They reported that SVM among other methods was able to rule out lipid and lactate signals as being too unreliable, and that choline and N-acetylaspartate are the main sources of information (most important features).

Rapid diagnosis of stroke in patients is desirable as punctual treatment can reduce the chance of permanent brain damage. One potential method for rapidly diagnosing stroke is to examine the contents of a potential stroke patient's blood for biomarkers indicative of a stroke. Prados, Kalousis, Sanchez, Allard, Carrette, and Hilario (2004) utilized SVMs to help identify 14 potential biomarkers which could be used to distinguish the chemical profile of a control subject's blood from the chemical profile of an ischemic or hemorrhagic stroke patient. Surface enhanced laser desorption/ionization *mass spectometry* is used with SVMs for feature selection to find a small subset of potential biomarkers for early stroke diagnosis. Glotsos, Spyridonos, Cavouras, Ravazoula, Dadioti, and Nikiforidis (2005) and Glotsos, Tohka, Ravazoula, Cavouras, and Nikiforidis (2005) used digitized images of *biopsies* of *astrocytomas* to detect brain tumors with an *unsupervised SVM clustering* method in conjunction with a decision-tree based multiple class classification in order to classify tumors. Using morphological brain data and high-dimensional shape transformations, SVMs are also shown by Lao, Shen, Zue, Karacali, Resnick, and Davatzikos (2004) to classify between male and female brain and age differentiation for old adults. Although brain images are the primary sources for detecting brain abnormalities, electrical brain signals can also be used (Lehmann et al., 2007). They compared a number of classification methods including SVMs for the detection Alzheimer's disease from the EEG recordings and discovered that the SVMs performance was superior to other methods.

Feature Selection

Though it may seem counterintuitive, classification of large volumes of neurophysiologic data is not always very informative. A small portion of the data is usually sufficient for classification and the remaining data hinders the performance of the classifiers. *Feature selection* algorithms are developed to isolate such features which significantly contribute to the classification of the data. For very high resolution brain images or multiple-channel brain recordings, feature selection plays a very important role in classification of neural data. Fan, Shen, Gur, Gur, and Davatzikos (2007) introduced a method for classification of *schizophrenia* patients and healthy controls from brain structures whose volumetric features are extracted from processed MR images. The best set of such features are determined using an SVM-based feature selection algorithm, which in return significantly improved the classification performance. Yoon et al. (2007) extracted principal components derived from cortical thickness to differentiate between healthy controls and schizophrenic patients using SVMs as a diagnostic tool. Yushkevich, Dubb, Xie, Gur, Gur, and Gee (2005) investigated the effect of abnormal development and brain structure in patients with schizophrenia with respect to the morphological characteristics and age related changes. They used deformed brain templates of a variety of subject images and used SVMs for classification and feature selection to classify between pathological cases from the healthy controls. A similar study was carried out by Liu et al. (2004) for automated schizophrenia and Alzheimer's disease detection. Fung and Stoeckel (2007) also used an SVM feature selection algorithm applied to *SPECT* perfusion imaging to detect Alzheimer's disease. They used a *1-norm* linear SVM classifier, which is known to give sparse solutions, which in turn is used for feature selection.

Diabetes mellitus (DM) is a common disease in the industrialized countries and it is a prominent risk factor for ischemic cerebrovascular accidents. Diabetes alone is responsible for 7% of deaths in stroke patients. Diabetes mellitus often results in brain micro-blood flow disorders that may cause cerebral infarction. However, assessing the function of cerebral microvessels is difficult, since they are located within the bony skull. Kalatzis, Pappas, Piliouras, and Cavouras (2003) performed a study where SVM was applied to distinguish between blood flow data in patients with diabetes vs. control subjects using *SPECT* images from cerebral abnormalities. Li, Yang, Ye, and Geng (2006) used SVMs with *floating search method* to find relevant features for assessing the degree of malignancy in brain glioma from MRI findings and clinical data prior to operations. Li, Liu, and Cheng (2006) further developed a novel algorithm that combines bagging of SVMs with embedded feature selection for the individual observations and compared the new algorithm using publicly available datasets.

Brain Computer Interface

Brain Computer Interface (BCI) is an extremely challenging research area which could revolutionize available treatment options for patients with paralysis. The main function of a brain computer interface is to detect brain activity patterns associated with the intention to execute some motor task which the paralyzed subject cannot physically perform. The BCI responds to the detected intentions by activating an attached prosthetic device which can enact the task for the subject.

BCI devices typically utilize neurophysiologic measures which can be acquired for extended durations and with high time resolution. Though fMRI can provide highly useful information about the temporal hemodynamic response to changes in brain activity, BCI research using electrographic signals has the significant advantage of relatively simple acquisition hardware and superior time resolution. The state of the art of electrographic acquisition systems give them potential for the creation of implantable BCI devices. One of the numerous challenges that stand in the way of enacting such a device is the ability to classify the brain activity patterns in real time while maintaining acceptable sensitivity and specificity. Of the many methods utilized for this task, SVMs have demonstrated a large degree of success.

The majority of the applications focus on prosthetics for patients suffering from conditions such as amyotrophic lateral sclerosis (ALS), brainstem stroke, and brain injury. Guigue, Rakotomamonjy, and Canu (2006) developed a new graph based method to classify nonstationary signals, each with a discriminant waveform with random time and location. The graph based representation was used to define an inner product between graphs to be used with SVMs, which increased the accuracy of the BCI system.

Many studies have utilized the P300 evoked potential as an SVM input for classifying text which is read by the user (Thulasidas, Guan, and Wu, 2006). The P300 evoked potential is an event-related electrical potential which appears approximately 300 ms after an infrequent event is perceived. A P300 spelling device could provide the means for communication for the disabled individuals who would otherwise be unable to communicate with the world. This technique is frequently used to assess the performance of BCI related methods. Kaper and Ritter (2004) and Kaper, Meinicke, Grossekathoefer, Lingner, and Ritter (2004) used SVMs on EEG recordings from the P300 speller BCI paradigm to reach high rates of data transfer and generalization. In these studies the subjects were given a 6 by 6 matrix with flashing symbols and were instructed to attend to only one symbol to count how many times it appears. The SVM classifier was used to detect this P300 component in the EEG, and was shown to perform with high accuracy. Guan, Chen, and Lin (2005) used a similar mental speller paradigm with a target and non-target symbols moving from right to left in a small window on a computer screen and detected significant differences in the EEG using SVMs.

Since BCI systems need to be computationally efficient, a robust feature selection algorithm is required for prediction of the EEG channels that may be involved in the cognitive task of interest. Lal et al. (2004) investigated the feature selection and EEG signal classification problems with the SVM-based *Recursive Feature Elimination* and *Zero-Norm Optimization* methods.

Although nonlinear methods can provide better results, linear methods may be preferred wherever possible. However, complex cases still require efficient methods in BCI which can handle nonlinear classification such as SVMs (Müller, Anderson, & Birch, 2003). Garrett, Peterson, Anderson, and Thaut (2003) also used SVMs to classify EEG signals from a well known

EEG data set (Keirn & Aunon, 1990), which involve five different mental tasks, and showed that linear and nonlinear methods may perform similarly. Liang, Saratchandran, Huang, and Sundararajan (2006) used the Extreme Learning Machine (ELM) algorithm to classify EEG signals from the same data set and showed that ELM has similar performance to SVMs.

Some BCI systems are developed using non-human subjects. Rats are the most common subjects for this kind of research. A BCI system adapted for rats was developed by Hu, Si, Olson, and He (2005), who showed that SVM classifiers and principal component analysis combined with a Bayesian classifier may perform equally well for classification. They also showed SVM classification of neuronal spike trains allow identification of individual neurons associated with the decision making process. Jakuczun, Kublik, Wójcik, and Wróbel (2005) applied SVMs to classify habituated states from aroused states using evoked potentials from a single barrel column of the rat's somatosensory cortex. Olson, Si, Hu, and He (2005) used spike trains from rats to predict left and right hand commands in a binary paddle pressing task performed by rats.

Optical measurement methods have also demonstrated success in SVM BCI systems. Sitaram et al. (2007) used near infrared spectroscopy to detect oxygenation in the left hand vs. right hand motor imagery of human subjects from a 20-channel NIRS system. They used SVMs and hidden markov models to assess the feasibility of NIRS to be used as BCI and concluded that NIRS can be a significant alternative to EEG in BCI.

A study by Acir and Güzeliş (2005) investigated the utility of SVMs for identifying EEG sleep spindles, an EEG pattern found in stage 2 of sleep. The study demonstrated that radial basis SVMs detected EEG sleep spindles with high accuracy. This application of SVMs may be useful in an automated sleep staging algorithm.

Epilepsy is the condition of recurrent seizures. Over the past few decades, the area of seizure detection and seizure prediction using quantitative EEG analysis has drawn great interest. Chaovalitwongse, Prokopyev, and Pardalos (2006) developed a seizure prediction algorithm using SVMs which was able to successfully classify between EEG patterns associated with an interictal (normal) brain state and EEG patterns associated with a preictal (seizure prone) state. Such an algorithm could be developed to become the basis for a bedside or implantable seizure control device.

Cognitive Prediction

Prediction of cognitive states plays an important role in enhancing our understanding of the physiologic mechanisms underlying brain functions. Brouwer and van Ee (2007) used SVMs on functional fMRI data to predict the visual perceptual states from the retinotopic visual cortex and motion-sensitive areas in the brain. Cox and Savoy (2003) investigated visual presentation of various categories of objects. They used SVMs to classify the images based on similarity from predetermined regions of voxels (volume elements) over a short period of time. This method was shown to produce similar results using much less data than traditional fMRI data analysis, which requires numerous hours of data across many subjects. Pessoa and Padmala (2007) also used fMRI images to predict perceptual states. SVMs are used to detect near-threshold fear detection, and concluded that multiple regions of the brain are involved and that behavioral choice is distributed across these regions to help manage the emotional stimuli and prepare the appropriate response. Shoker, Sanei, and Sumich (2005) introduced a hybrid algorithm which combines SVMs with blind source separation (BSS) and directed transfer functions (DTF), which are used to extract features from EEG recordings to distinguish between left and right finger movements. Seref, Cifarelli, Kundakcioglu, Pardalos, and Ding (2007) used intracranial local field potential recordings from macaque monkeys and developed a selective SVM-based classification method in conjunction with SVM-based feature selection methods to detect categorical cognitive differences in visual stimuli based on single-trials from a visuomotor task.

Other Modeling Techniques

Faugeras et al. (2004) studied brain anatomy and modeled brain function from MR images. SVMs combined with methods from information theory are used in clustering of voxels in the statistical modeling of the fMRI signals. LaConte, Strother, Cherkassky, Anderson, and Hu (2005) used SVMs in block design fMRI and compared them to canonical variance analysis (CVA). Mouro-Miranda, Reynaud, McGlone, Calvert, and Brammer (2006) investigated the performance of

SVMs with time compression on single and multiple subjects, and showed that the time compression of the fMRI data improves the classification performance. In a similar study, Mouro-Miranda, Friston, and Brammer (2007) introduced time series embedding into the classification framework. In this work spatial and temporal information was combined to classify different brain states in cognitive tasks in patients and healthy control subjects. In a study by Wang, Schultz, Constable, and Staib (2003), a nonlinear framework for fMRI data analysis is introduced, which uses spatial and temporal information to perform *support vector regression* in order to find the spatio-temporal autocorrelations in the fMRI data. Finally, Parra, Spence, Gerson, and Sajda (2005) present an array of methods as "recipes" for linear analysis of EEG signals, among which performance of SVMs is compared with logistic regression.

CONCLUSION

This review presents the numerous applications in neuroscience which have benefited from the efficient and robust classification ability of SVMs. As computer capabilities improve and novel implementations are developed, new SVM based methods will reveal more about the brain and its complex functions.

KEY TERMS

EEG: Electroencephalography is the measurement of the electrical activity of the brain from electrodes placed on the scalp or, in special cases, subdurally or in the cerebral cortex. The resulting traces are known as an electroencephalogram (EEG) and represent a summation of post-synaptic potentials from a large number of neurons.

fMRI: Functional magnetic resonance imaging is the use of MRI to measure the haemodynamic response related to neural activity in the brain or spinal cord of humans or other animals. It is one of the most recently developed forms of neuroimaging.

MRI: Magnetic resonance imaging, formerly referred to as magnetic resonance tomography (MRT), is a noninvasive method using nuclear magnetic resonance to render images of the inside of an object. It is primarily used in medical imaging to demonstrate pathological or other physiological alterations of living tissues. MRI also has uses outside of the medical field, such as detecting rock permeability to hydrocarbons and as a non-destructive testing method to characterize the quality of products such as produce and timber.

MRS: Magnetic resonance spectroscopy, also known as MRSI (MRS Imaging) and volume selective NMR spectroscopy, is a technique which combines the spatially-addressable nature of MRI with the spectroscopically-rich information obtainable from NMR. MR spectroscopy provides a wealth of chemical information on a region.

SPECT: Single photon emission computed tomography is a nuclear medicine tomographic imaging technique using gamma rays. It is very similar to conventional nuclear medicine planar imaging using a gamma camera. However, it is able to provide true 3D information. This information is typically presented as cross-sectional slices through the patient, but can be freely reformatted or manipulated as required.

SVM: Support vector machine is a set of related supervised learning methods used for classification and regression. SVMs belong to a family of generalized linear classifiers. They can also be considered a special case of Tikhonov regularization. A special property of SVMs is that they simultaneously minimize the empirical classification error and maximize the geometric margin; hence they are also known as maximum margin classifiers.

TCD: Transcranial doppler is a test that measures the velocity of blood flow through the brain's blood vessels. It is used to help in the diagnosis of emboli, stenosis, vasospasm from a subarachnoid hemorrhage (bleeding from a ruptured aneurysm), and other problems. It is often used in conjunction with other tests such as MRI, MRA, carotid duplex ultrasound, and CT scans.

Technology Adoption, Expectancy Value and Prediction Models

INTRODUCTION

During the last few decades, various theoretical developments have been carried out with a view to describing the characteristic and distinct behavioral process that lies under any adoption of technological services and products. These developments are based mainly on the Social Psychology approach.

There are three extensive theories within the field of Social Psychology whose ultimate purpose has been to define the internal psychological factors that explain human behavior: the expectancy-value theory, the cognitive dissonance theory, and the self-perception theory. While the expectancy-value theory has been widely used in the research of adoption and usage of information systems, the other two theories have been less recognized.

Of all expectancy-value theory models, we should draw our attention to the reasoned action model (Azjen & Fishbein, 1980), because it underlies many of the studies on usage of technology. The planned behavior model (Azjen, 1985, 1991) represents a reformulation of the reasoned action model, justified by the existence of conducts that, albeit in part, a person cannot voluntarily keep under control. A rough description of both models is presented in this chapter, inasmuch as they served as a basis for the construction of the technology acceptance model (Davis, 1989; Davis, Bagozzi & Warshaw, 1989), known as one of the main models for the technology readiness concept. The technology acceptance model seems to possess a similar or even better explicating power than its predecessors (Davis et al., 1989; Mathieson, 1991; Taylor & Todd, 1995a; Chau & Hu, 2002).

The TAM has also been successfully applied in the health care context in order to examine the suitability of the TAM in explaining physicians' decisions to accept telemedicine technology (Chau & Hu, 2002).

Recently, authors have attempted to apply current models of technology acceptance to the use of Internet technologies and e-commerce. In particular, several authors have selected the TAM in order to characterize individuals' perceptions and intentions toward the use of the Internet (Muthitacharoen & Palvia, 2002; Pavlou, 2003). Due to the technological characteristics of the Internet channel, the TAM should provide a good framework where the specific factors that influence the adoption and usage of e-health technologies can be integrated. Physicians are among the principal users of this technology and have profound influences on its success.

EXPECTANCY-VALUE MODELS

We now proceed with a brief examination of the main expectancy-value models that have served as a theoretical basis for models of use of technology prediction, so we can gain a much better insight of the latter.

The Reasoned Action Model

The reasoned action model (Azjen & Fishbein, 1980), whose ultimate aim is the prediction and understanding of human behavior determinants, argues that the latter is mostly under the subject's control and, as a consequence, can be forecast by observing the declaration individuals make of their intentions to carry out or not to carry out a particular type of conduct. Also, the behavioral intention directly depends on two factors: a personal one or an attitude toward behavior that represents the individual's either positive or negative evaluation of whether an action should or should not be done; and a social factor or subjective norm that is the personal awareness of social pressures that force us to take that course of action.

Attitudes can be explained by considering the information the individuals possess that shapes their beliefs in the consequences when a certain conduct becomes real. Attitudes do not depend solely on beliefs but also on the evaluation people make about each of those behavioral beliefs. Therefore, the drive of each belief (degree of certainty that upholds it) is boosted by the negative or positive intensity of the outcome of the conduct. The sum of all products results in an attitude.

Subjective norms can be indirectly assessed from two main components: first, the informative basis of individuals, which establishes normative beliefs, that is to say, beliefs about how other people or institutions (referees) judge how an individual should behave; second, the subject's motivation to observe the referees' directives. Like it happens with attitudes, each normative belief is boosted by the motivation to follow that opinion. The subjective norm is obtained from the sum of all these products.

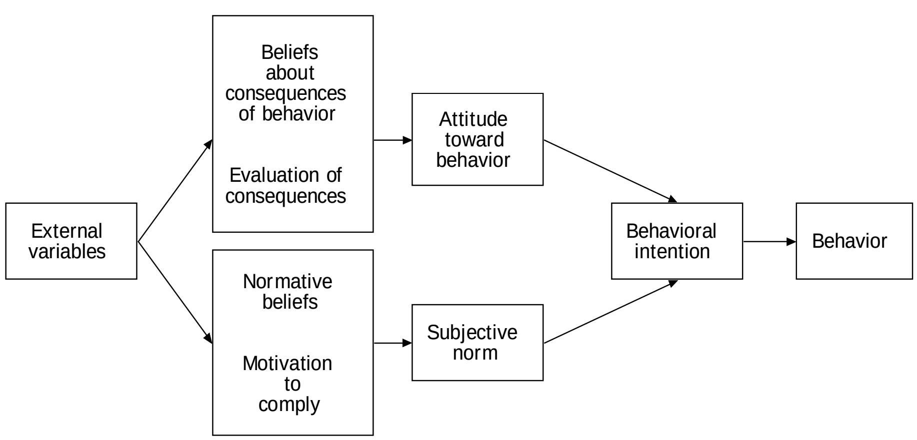
In this model, we can see a display of another series of external variables or stimulus conditions that affect relationships between intentions and behavior by means of their direct influence on beliefs in the consequences of conduct and in normative beliefs (see Figure 1).

Azjen and Madden (1986) introduced some nuances into the reasoned action model by pointing out that previous experience, attitudes, and subjective norm can influence one another; attitudes can influence behavior both indirectly through behavioral intention and also directly; subjective norm can only have an indirect effect on behavior; and previous experience can influence conduct indirectly as well as directly. The results of this investigation also show that the relation between intention and behavior is not as intense as it should be to make trustworthy predictions. Thus, "intentions only forecast behaviors not requiring either special abilities or skills, extraordinary opportunities, nor the other people's cooperation (Morales, Rebolloso & Moya, 1996, pp. 563–564).

The Planned Behavior Model

Azjen (1985, 1991) reformulated the aforementioned reasoned action model, thus originating the planned behavior model (see Figure 2). The difference between both models lies in the fact that the latter introduces the perceived behavioral control element to improve the behavioral intention forecast. The introduction of this intention-determining factor is justified by the existence of conducts, which at least in part cannot be kept under the voluntary control of the individuals. That is to say, irrespective of a likely favorable attitude toward a certain behavior and the strong pressure that individuals receive around them urging them to do it, their intention will

Figure 1. Reasoned action model



Source: Adapted from Ajzen and Fishbein (1980) also influence the subjective likeliness of achieving it or perceived behavioral control.

Perceived behavioral control depends on control beliefs, which decide whether individuals possess or do not possess the necessary skills or resources to carry out a certain conduct, and the suitable opportunities. Each control belief is boosted by the enhancing or inhibitory effect of the resource or opportunity dealt with. The final outcome after summing up all these products is the perceived behavioral control.

As the perceived behavioral control nears the control effectively exerted by individuals on their respective conducts, the relationship with the latter is direct.

PREDICTION MODELS OF USE OF TECHNOLOGY

The use of technology represents a generally accepted measure of the success of its widespread presence. Therefore, the aim of many investigations has been to determine which factors influence this kind of behavior.

In this section, we will look into the main theoretical models that aim to describe the characteristic behavioral process underlying the adoption of technological services and products. Through their analysis, we can detect the importance given to technology attitude as a key factor in predictions of use of technology.

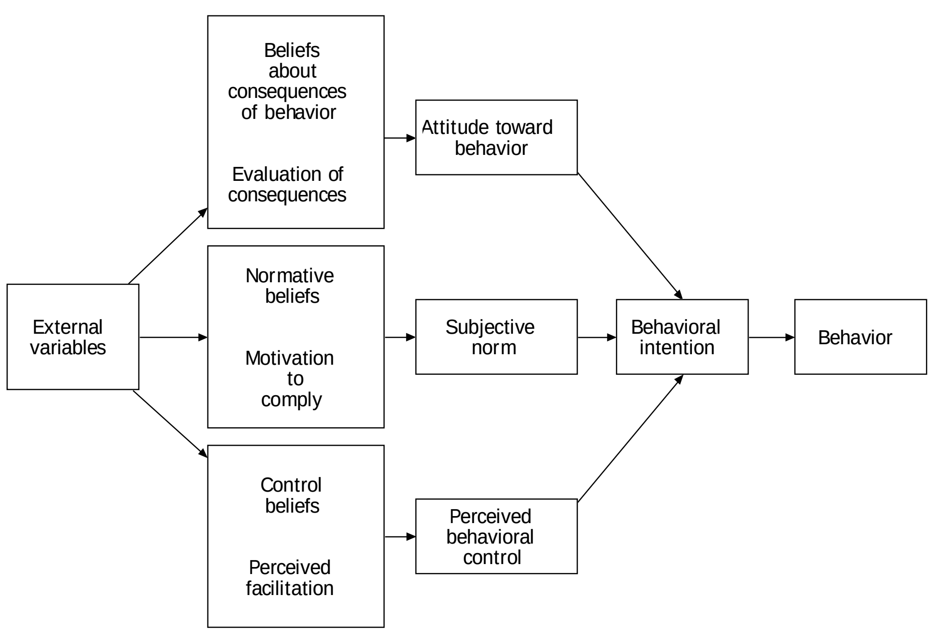
The review of the scientific literature has made clear that technology readiness is a multidimensional concept, although a consensus of opinion about the number and definition of these dimensions does not exist. In any case, such dimensions contain enhancing and inhibitory aspects of technology attitude.

With a view to completing the stage in which the domain of the studied concept is specified, after the exposition of each model, detailed aspects related to measure scales developed in various contexts and with different participants and technologies can be found. The examination of the various aspects of technology attitude (separately detected in the analyzed studies) will allow us to establish the suitability of its addition within the development of a measurement scale of the degree of technology readiness.

The Technology Acceptance Model

The technology acceptance model (Davis, 1989; Davis et al., 1989) is one of the most referred-to models for the explanation of adoption of information technologies. The acceptance of technology is firmly defined by

Figure 2. Planned behavior model



Source: Adapted from Ajzen (1985, 1991)

Gattiker (1984) as the psychological state of individuals with regard to their voluntary or desired use of a particular technology.

Based on the reasoned action model and the planned behavior model, the technology acceptance model put forward the idea that the behavior of adoption of a certain information system is determined by the intention of making use of it. In turn, such behavioral intention is determined by technology attitude, which is influenced by two factors: on the one hand, beliefs in perceived usefulness, and on the other hand, beliefs in the perceived ease of use of the analyzed technology. Perceived usefulness can be defined as the extent to which individuals think using the information system will improve their working productivity. The perceived ease of use can be defined as the extent to which an individual thinks the use of a system will not require any effort. Although component perceived usefulness has a direct effect on the behavioral intention, the perceived ease of use influences such intention only indirectly.

Furthermore, both types of factors are exposed to the influence of external variables. By operating on these variables, control can be exerted on the beliefs of the information system users, thus indirectly influencing the intentions of use and the effective utilization of technology. The described model is shown in Figure 3.

Technology Attitude Scales with a Theoretical Base on the Technology Acceptance Model

The technology acceptance model has been put into practice by making use of various types of technologies as a social object of interchange and considering various user profiles as a sample (see Table 1).

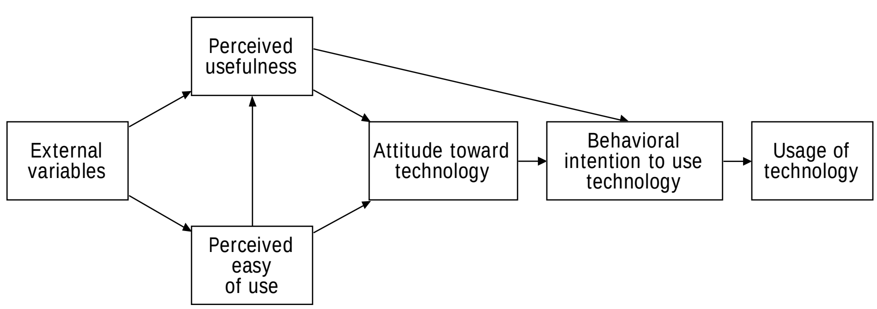
A review of various studies allowed us to note that among their authors there is a widespread inclination to remove the attitude component out of the model. They consider that behavioral intention is determined by two main components: on the one hand, beliefs in perceived usefulness, and on the other hand, beliefs in the perceived ease of use of the analyzed technology. In that way, the perceived usefulness component has a direct effect on the behavioral intention. The perceived ease of use influences such intention, indirectly and directly, through the perceived usefulness component.

Other authors, although considering attitude as a component of the model, identified no significant relation between attitude and behavioral intention.

The results obtained cannot lead us to erroneous conclusions about the dilemma of consideration or non-consideration of attitude as a key factor when predicting the use of technology. In the reviewed investigations, when attitude is taken into account as a component of the model, it is categorized as a one-dimensional concept. That is why simple scales have been applied to measure it, following the ones suggested by Ajzen and Fishbein (1980), introduced in the reasoned action model and planned behavior model. From our point of view, an attitude scale constructed like this lacks validity of content, insofar as it does not comprise all possible dimensions and contents of the analyzed concept.

The decision made by various authors to remove the attitude factor from the Technology Acceptance Model and, in its stead, to consider the direct effect of perceived usefulness and perceived ease of use factors on the behavioral intention, suggests to us that we should consider attitude as a multidimensional feature.

Figure 3. Technology acceptance model



Source: Adapted from Davis (1989) and Davis, Bagozzi and Warshaw (1989)

Therefore, attitude is not something global. It is made up of a combination of a series of variables or dimensions that determine attitude toward technology.

Once we established which dimensions constitute the domain of the attitude concept and made clear that it is a multidimensional one, the priority of the following step was to identify items in accordance with the conceptual dimensions as found. Next, we displayed in Table 2 the items included in the measurement subscale of perceived usefulness in the analyzed studies, whereas in Table 3 we placed the items of the measurement subscale of perceived ease of use.

As can be seen in the measurement of perceived usefulness, the use of the following items stands out:

- Using (information technology) increases my productivity.
- Using (information technology) increases my job performance.
- Using (information technology) enhances my effectiveness on the job.
- Overall, I find the (information technology) useful in my job.

With regard to the measurement of the perceived ease of use dimension, the items most frequently used are as follows:

- Learning to operate (information technology) is easy for me.
- I find it easy to get the (information technology) to do what I want to do.
- The (information technology) is rigid and inflexible to interact with.
- Overall, I find the (information technology) easy to use.

Limitations of the Investigations with a Theoretical Base on the Technology Acceptance Model

A review of the studies that used the technology acceptance model as a predictive model of the use of new technologies allowed us to identify some limitations of the research carried out. The most outstanding are the following:

- Starting with a selection of the sample to validate the model, we consider that the used samples comprise very specific population profiles. In

many of the reviewed investigations, a choice of student groups as a target population stands out, a quite common practice for economic reasons. This fact limits the power of generalization of their results to the population as a whole.

- As for the type of technologies that represent the social object of interchange in the examined studies, we notice how all of them center on the prediction of the use of specific technologies. The analysis of office automation computer programs or system development applications must be pointed out. The circumstance described reduces the generality of the model and questions its applicability to any situation regarding the use of technology.

- The investigations carried out propose the existence of two key factors to take into consideration when user attitude toward the use of a certain technology is assessed. However, there is a unanimous agreement among authors when they concur that it is necessary to include other components in the model so they can contribute to the explanation of the variance in the use of technology. This suggests that it would be convenient to thoroughly study the dimensionality within the technology attitude concept, redefining and improving some of the variables the various dimensions are made of, and also attempting to identify new ones.

KEY TERMS

Acceptance of Technology: Psychological state of individuals with regard to their voluntary or desired use of a particular technology**.**

Attitude: A state of mind or a feeling.

Ease of Use: Refers to the property of a product or thing that a user can operate without having to overcome a steep learning curve.

Expectancy-Value Behavior: Existence of conducts that, albeit in part, a person cannot voluntarily keep under control.

Perceived Behavioral Control: Refers to people's perceptions of their ability to perform a given behavior.

Technology Readiness: Refers to a combination of beliefs related to technology that collectively determine the inclination in a customer, employee, or executive to adopt new technologies in order to reach his or her objectives, both at work and during leisure time.

Usefulness: The quality of being suitable or adaptable to an end.

Telemedicine and Information Technology for Disaster Medical Scenarios

INTRODUCTION

Disasters constitute events which are catastrophic in nature. Such events critically threaten the health, safety, and lives of people and their environment (and even aspects of the global environment), and as a result, overwhelm the affected community's emergency response capacity. Globally, a major disaster occurs almost daily. Consequently, disaster events are virtually an everyday fact of life. Emergency medical services constitute one important aspect of disaster responses. Those populations affected by disasters require a complete range of health services and the appropriate mechanism of delivery. In this respect, increasingly, information technology is playing a greater role. Disaster medicine has become more than merely a mass-casualty, and affected health response; the affected population's needs are assessed, which range from medical requirements, to rapidly coordinating and providing casualty, routine, and preventive health services. These kinds of assessments are significantly more effective, given the appropriate deployment of current information technology.

There are three major time phases associated with disaster response (Patoli, 2005). In the Predisaster Phase, emphasis is placed on activities which address prevention and preparedness, which entail hazard and vulnerability assessments, human and material resource inventory, comprehensive planning, and exercises to test disaster and recovery plans, capabilities, and skills.

In the Disaster Relief Operations Phase (hours to weeks), assessment of damage and consequent recovery requirements, and the planning and implementation of emergency plans, have priority.

The Postdisaster Rehabilitation Phase may extend for months, or even years, as management, maintenance, and infrastructure, and various community activities are rehabilitated and restored.

Telemedicine can be integrated into all of the actives of medical disaster management. This article will explore the role of telemedicine in (medical) disaster management. The use of communications pathways—information technologies which include global positioning system (GPS) technologies, hypermedia, artificial intelligence, software and hardware for computer miniaturization, and advanced wireless sensor systems—in telemedicine will be discussed with respect to their advantages, disadvantages, and future potential.

WHAT IS TELEMEDICINE?

Scott (1996) indicates that telemedicine is "just a new label for applications of telecommunications and information technologies [applied to the area of medicine]." But more specifically, telemedicine can be defined as diagnosis, consultation, treatment, education, and the transfer of medical data (i.e., high resolution images, sounds, live video, and patient records) using interactive audiovisual and data communications (Jerant, Schlachta, Epperly, & Camp, 1998). What this means is that a physician located far from a reference center can consult his colleagues remotely in order to solve a difficult case, supplemented with continuing education course over the Internet, or by accessing medical information from digital libraries.

From Sunday and Pothier (2001), "telemedicine isn't a new medical specialty; it simply offers another way to deliver existing services to people who can benefit from them no matter where they are." Sunday and Pothier note that in the Telemedicine Report to U.S. Congress, 2001, telemedicine was defined as "the use of electronic communication and information technologies to provide or support clinical cases at a distance" (Sunday & Pothier, 2001). These same tools can also be used to facilitate exchanges between centers of medical expertise, at a national or international level (Geissbuhler, Ly, Lovis, & L'Haire, 2003).

In terms of its commonly understood sense, in which a doctorpatient interaction involves telecommunication, historically, this goes back at least to the use of ship-to-shore radio for giving medical advice to sea captains. A few years ago, the term "telemedicine" began to be supplanted by the term "telehealth," which was thought to be more "politically correct," but recently, this too has been overtaken by even more fashionable terms, such as "online health" and "ehealth." (Wootton, 2001)

Telemedicine in Medical Disaster Management

As noted in brief in the Introduction, Patoli tells us (Patoli, 2005) that telemedicine in medical disaster management is divided into three areas. We will now explore those areas in more detail:

- **Phase 1: Predisaster Preparedness.** The first consideration is planning and development, and technological needs. In this planning stage, Patoli (2005) indicates there are six categories of information that are crucial: management, clinical, surveillance and epidemiological, literature in terms of documentation and reports, diagnostic knowledge, personal, and community knowledge. The second consideration is the human factor. Patoli (2005) indicates that the human factor is broken into four interrelated areas: management and administration of the telemedicine system, medical expertise and other health and medical activities, patients and telemedicine users, and e-training. Four more major areas for Phase 1 follow: databases, artificial intelligence, expert systems and decision support systems, geographical information systems, and research projects (Patoli, 2005).
- **Phase 2: Disaster Relief Operations.** In this phase, responses are activated as immediately as possible after the disaster is detected. The main areas in this phase are: robot assisted medical reachback, patient tracking systems, critical state patient's telemonitoring through sensor devices, prehospital management through mobile technology, telediagnostics entailing both teleradiology and telepathology, clinical decision support systems, and finally, telesurgery and teleconsultation (Patoli, 2005).
- **Phase 3: Postdisaster Rehabilitation.** In this phase, many of the disaster victims live in camps and temporary shelters, suffering from depression and stress. The main areas in this phase are: telepsychiatric intervention, public health threats entailing early warning systems, disaster medicine, epidemiology, and telerehabilitation (Patoli, 2005).

APPLICATIONS OF TELEMEDICINE

To summarize from Tracy (2004):

Telehealth and telemedicine are becoming more and more engrained in the delivery of everyday healthcare, distance education and health care administration. Extensive numbers of patients in underserved areas are receiving services they may not have otherwise received without traveling great distances or overcoming other transportation barriers. Telemedicine services (from the youngest of patients to the frail elderly) range from primary care, to the highly specialized care found in leading academic medical centers. Telehealth systems can be found in hospitals, clinics, nursing homes, rehabilitation hospitals, homes, assisted living facilities, schools, prisons, or health departments. In fact, today you may find telehealth systems any place healthcare is provided. (Tracy, 2004)

TELEMEDICINE IN DISASTERS AND EMERGENCIES

Garshnek and Burkle (2000) very articulately sum up:

Emergency and Disaster events are the most important scenarios where telemedicine can best be utilized. Success or failure of a disaster response often is determined by timely access to communication and reliable information. The rapid progress and future course in telecommunications indicate that lack of communications no longer needs be the paralyzing factor in a disaster scenario. This is important especially for medical response where time is of essence to save lives.

What is most urgent in the events of medical disasters and emergencies is the need for smart deployment of systems and procedures that provide for the accurate assembly of personnel, equipment, and telecommunications resources. The recent hurricanes in USA alone, let alone recent tsunami and earthquake disasters, have acutely sharpened awareness in this respect. More specifically, in a recent statement from the USA Homeland Security (http://www.gtp-etc.com/docs/ECU%20Homeland%20Security.doc):

These [types of] experience have stimulated the Telemedicine Center to address the development of capabilities that include: (1) rapidly deployable and reconfigurable medical device and sensor toolkits; (2) on demand, geography-independent telecommunications resources; and (3) tools to improve field responders' capabilities in emergency or disaster situations.

Indeed, disaster telemedicine systems do not need to be special or sophisticated. We again reiterate that the challenge is to match the right systems with a appropriate disaster plan or scenario (Garshnek & Burkle, 1999). In almost all cases with natural disasters which are wide-ranging, the basic infrastructure of the region is dislocated and largely unusable. Therefore, without ground communications, special considerations need to be enacted.

In the past, providing telemedicine capabilities to local disaster areas has been expensive. To establish land line or satellite linkages, often bulky equipment needs to be deployed. Traditionally, only large governments and commercial enterprises have been able to acquire such systems and infrastructures. (Garshnek & Burkle, 1999)

Consequently, "satellites do play a significant role for mobility and land-line independence for telemedicine" (Garshnek & Burkle, 1999). Flexibility such as this is especially important. However, as indicated above, the advantages of satellites are often outweighed by their disadvantage in terms of initial costs and maintenance costs. The good news is that portable satellite terminals, now being evolved, will be less expensive in the very near future (Garshnek & Burkle, 1999).

Garshnek and Burkle (1999) succinctly note the following:

Real-time video teleconferencing of a sophisticated nature was not always required or useful in disaster [scenarios]. The time flexibility of store-and-forward teleconsultation has now been appreciated and if often necessary where real-time cases are not needed. Internet and multimedia e-mail are evolving. In complicated disaster scenarios, easy-to-use [and portable] Internet-based consultation systems might well be ideal.

TELEMEDICINE AND INTERNATIONAL DISASTER RESPONSE

Furthermore, Garshnek and Burkle (1999) note the following:

While many information management and telecommunications technologies are currently employed in disaster response, there are few reports of telemedicine being utilized in disaster settings. The Pan American Health Organization (PAHO) has provided satellite communication ground stations to support disaster response. The longest and most extensive use of telemedicine was the NASA-Russia Space Bridge employed during the Post-Disaster Rehabilitation Phase after the devastating Armenian Earthquake of l988.

In relation to the Space Bridge Project, which used satellite communications to provide medical consultation to several Armenian regional hospitals, Scott (1996) noted that:

in a separate link, consultation was also provided to the Russian town of Ufa, where a gas explosion during this same period of time caused a large number of casualties. Slow-scan black and white video was transmitted from Ufa to one of the Space Bridge sites in Armenia (Yerevan) which provided satellite uplink.

Consequently, Telemedicine was tested and deployed for the first time on a large scale in the Space Bridge Project, in such a way that the technology utilized was proven very effective.

TELEMEDICINE COMMUNICATIONS PATHWAYS

As indicated above, from Garshnek and Burkle (1999), a correct match needs to be effected between the medical disaster plan or scenario, and the communication and contingency system. In this respect, wireless transmissions, which utilize the entire frequency spectrum, are advantageous, especially when it is considered that disaster damage has little affect on wireless transmissions. However, when there is damage to repeater stations, satellites offer better long distance communications than other means. And portable satellites offer great advantages.

INFORMATION TECHNOLOGIES FOR TELEMEDICINE

There are a whole range of information technologies available for telemedicine. This article will focus upon GPS technologies, hypermedia, artificial intelligence (in particular artificial neural networks), software and hardware for computer miniaturization, and advanced wireless sensor networks.

GPS Technologies for Telemedicine

In relation to GPS technologies, Finnegan (School of Information Technology, Charles Darwin University) is currently working on extending GPS technology into everyday use of mobile computer technologies, particularly supporting project and other work in remote locations. The intent is to provide context specific information, time, and location, which would be significantly important for telemedicine. This development will be leveraged by the emerging practice of embedding GPS into (portable) wireless laptops (Finegan, 2006).

Hypermedia for Telemedicine

Another important information technology for telemedicine is Hypermedia Documentation. Hypermedia can briefly be described in terms of the presence of information types such as multimedia (text, image, video, and audio), and the mapping of semantic connectors or links within these various multimedia types. In a paper by Saleem and Kanwal, they state the following: "hypermedia documentation schemes can be efficiently used in telemedicine development and implementation, especially in the case of scarce resources with an additional advantage of economy as compared to primitive databases" (Saleem & Kanwal, 2006).

Artificial Intelligence for Telemedicine

Much has been written in the literature concerning the relation between artificial intelligence and telemedicine, but the literature is relatively silent on artificial neural networks. Artificial neural networks (ANNs) offer potentially great advantages, among other considerations, such as pattern recognition generally, forecasting, and optimisation, not to mention the provision for early warning disaster scenario detection.

As Kumar and Haynes (2004, pp. 7) note:

ANN systems can be used to assist actively in a number of problems faced in the operations research area and statistical like: Prediction/ estimation (curve fittings, forecasting etc); pattern recognition (classification, discrimination analysis and diagnosis); clustering (grouping without a prior knowledge of classes); optimization (the solution of linear and non linear mathematical programming model involving continuous and/or discrete variables). Pattern recognition related decision problems suit artificial neural networks more than to statistical techniques primarily because of the complex nature of problems, which are not well understood mathematically and involve subjectivity. In addition, such problems have qualitative and noise data. Even if the values of every input feature are not known, a trained neural network will produce a response.

Consequently, artificial neural networks are very robust—that is, their input data can vary and the ANN will still be able to process, or train upon the data, to make a "conclusion," or more precisely, an output. And in the view of the authors, they would be ideal in a medical disaster situation where precise inputs are not readily available.

One current disadvantage of an ANN, even with portable PCs, is the time it takes to collect data; but, with advances in online real-time collection techniques, the advantages and future potential of ANNs is very promising for telemedicine.

Telemedicine and Software and Hardware for Computer Miniaturization

Perhaps the most interesting example of computer miniaturisation, and one of the most recent for telemedicine, is the scalable software infrastructure for miniature medical devises, known as CodeBlue (CodeBlue, 2006). The design of CodeBlue provides for "routing, naming, discovery, and security for wireless sensors, PDAs, PCs, and other devices" (CodeBlue, 2006), for the treatment and monitoring of medical patients.

In terms of the hardware computer miniaturisation, CodeBlue utilises SHIMMER, which incorporates a TI MSP430 processor, a radio, a triaxial accelerator, and a rechargeable battery, all in miniature. The latest SHIMMER is three times the size of an Australian twenty-cent piece. Further,

Shimmer includes a MicroSD slot supporting up to 2 GBytes of flash memory. This allows SHIMMER to store significant amounts of data (2GB can store up to 80 days of continuous triaxial accelerometer datas sampled at 50Hz. Shimmer can also be configured with an optional Bluetooth radio. (CodeBlue, 2006)

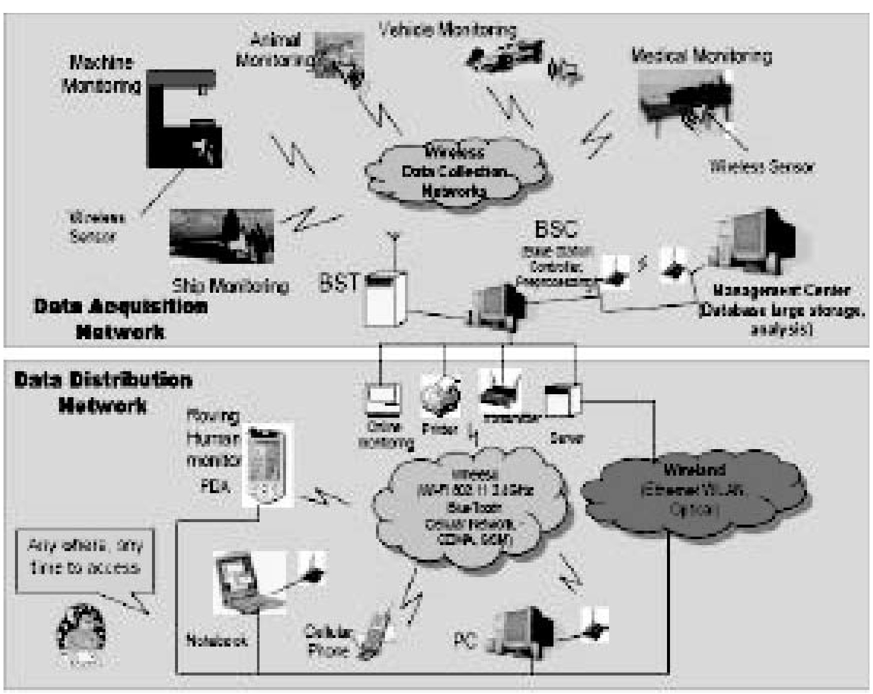
Advanced Wireless Sensor Systems for Telemedicine

In 1980, modern research commenced at DARPA in the Distributed Sensor Networks Program (DSN) (Bobbie, Deosthale, & Thain, 2006). Today, small and inexpensive MEMS technology sensors, wireless technology and low-power processors provide excellent support for telemedicine. A typical wireless sensor network can be seen in Figure 1 (Lewis, 2004).

For disaster medical scenarios, the advantages for wireless sensor networks are relative inexpensiveness, portability, and nonreliance on land-lines. However, a disadvantage can be where wireless repeater stations are damaged by the disaster, in which case satellites are preferred.

It is not the aim of this article to go into a detailed analysis of wireless sensor networks. More appropriate

Figure 1. A typical wireless sensor network (Lewis, 2004)



are a series of recent applications of wireless sensor networks for telemedicine. Bobbie et al. (2006) discuss four such applications:

1. **Blue Nurse:** This was developed by the University of Queensland; its design entails point-to-point communication to a single bluetooth module for the purpose of receiving ECG date on a PC. As mentioned by Bobbie et al. (2006), the reference is Daniel Marr, ECG Application Featuring Data transmission by Bluetooth Ph.D. thesis, University of Queensland, October, 2001.
2. **Proactive Health:** This is a system for the daily activities of the elderly entailing postage sized wireless radio frequency identification tags (RFID), where data is communicated back to a central system. Bobbie et al., (2006) indicate the reference as: http://www.cms.hhs.gov/hipaa.
3. **Blue Medica:** This entails a tablet PC viewing data from a hospital information system by a doctor, where a wrist band carrying the sensor was used to measure conditions, such as temperature. Bobbie et al. (2006) give the references as Kostelnik, R., and Lacko, P. Blue medica – wireless medical data access appliance. *Journal of Electrical Engineering, 52*(9–10), 311–315.
4. **NSF COPIRE:** Provides a system for cardiology evolution, where a sensor communicates data with a PC.

Stankovic et al. (2005) discuss wireless sensor networks in terms of their potentials and their challenges. They state that wireless sensor networks for the future must be able to address each of the following medical applications: integration within existing medical practices and technology, real-time, long-term, remote monitoring, miniature wearable (and durable) sensors, and assistance to the elderly and chronic patients (Stankovik et al., 2005). From our perspective in terms of medical disaster scenarios, clearly, victims of disasters, in a sense, fall into the category of the embodiment of "degrees of helplessness" (such as homelessness, depression, and acute stress) to the elderly and the chronic class of patients. They state that the Wireless Sensor Networks can easily display their use in terms of (1) sleep apnea (2) journaling support, particularly rheumatic diseases—but, for our purposes in medical disaster scenarios, the patient under journaling support records changes in bodily functions (pain, sleep, headache, irritability, and so on), (3) cardiac health, especially cardiac arrhythmia and cardiac stress.

The (USA) National Science Foundation (NSF) indicate that the future potential of sensors and sensor systems need to include effective responses to (1) toxic chemicals, explosives, and biological agents, (2) enhanced sensitivity and fewer false alarms, and (3) unattended functionality in complex environments (NSF, http://www.nsf.gov/news/special_reports/sensor/nsf_sensor.jsp). The NSF, to indicate a few they mention, suggest that genomic tools may be incorporated to aid in detecting ecological changes with the support of nano- and meso-scale complex miniature hardware structures; arrays of ultra low-power wireless nodes need to be incorporated into high bandwidth reconfigurable networks (refer to NSF Web site).

THE INTEGRATION OF INFORMATION TECHNOLOGY AND TELEMEDICINE

It is suggested that once a medical disaster management has been implemented in a country or a site that it become a learning event for that community. If it can happen once, it can happen again. Therefore, preparedness is the key. Preparedness entails learning and preparing for the future on a larger scale entails community involvement, hence the key becomes a community learning culture focused towards the possibility of another medical disaster. Haynes (Haynes, 2001, pp. 17) notes in this respect:

the learning culture must evolve [for itself], if it were to remain static or stagnate it would die as a culture. A learning culture is alive in the sense that it is intimately connected with the humans that draw strength from it and who, by having a deep sense of it, keep it alive.

The further key, then, is to instill in a community a sense of what it entails to be a learning culture; in this case, a learning culture directed towards medical and community disaster management and what information technologies to effectively implement, based on their continued use and development and to provide effective plans for these information technologies integration into the societies concerned.

A crucial point made by Saleem and Kanwal (2007) is that the development and evolution of telemedicine should be "need driven and not technology driven."

Clearly, many disadvantages can be enumerated in respect of telemedicine for underdeveloped countries, but with appropriate polices and the realization that telemedicine systems must be viewed by practitioners as useful to them, the advantages and an exciting future potential for telemedicine and information technology can be realized.

CONCLUSION

Disasters are virtually, globally, a daily occurrence. Telemedicine can be utilized in disasters only within the constraints of local and regional infrastructure capabilities. But three phases are common to all medical disaster events: predisaster; disaster relief operations; and postdisaster rehabilitation. We have considered what telemedicine is defined as, and perhaps the most succinct definition is the utilization of "electronic communication and information technologies to provide or support clinical cases at a distance" from the Telemedicine Report to U.S. Congress, 2001. We have explored issues associated with the role of telemedicine in disaster management in terms of the use of communications pathways—information technologies which have included GPS systems, hypermedia, artificial intelligence, software and hardware for computer miniaturization, and advanced wireless sensor systems. We have examined their respective advantages, disadvantages, and future potential. Perhaps the most promising of these information technologies are artificial neural networks and the development of advanced wireless sensor networks in conjunction with computer miniaturization.

Two principal recommendations from this article are: first, that if a disaster can happen in one place once, then it can happen in the same place again; therefore, preparedness needs to be paramount. This entails the evolvement of a learning culture focused upon what to do for future medical disaster events and what appropriate information technologies need to be implemented. These information technologies must be developed in terms of their continued use with the necessary provision for effective plans for their continued evolvement. Second, that telemedicine must be need-driven and not technology driven. It follows that community needs should be at the foundation of the development of information technologies, not only in relation to medical disaster management, but also for humanity as a species.

KEY TERMS

Artificial Neural Networks: Computer systems (hardware and software) that "learn" by training on inputs, largely with pattern recognition as their basis of operation.

Hypermedia: Information types such as multimedia (combination and integration of text, image, video, and audio).

Need-Driven Telemedicine: Information technology that is developed with the benefit of the community in mind, in relation to telemedicine.

Medical Disaster Management: A disaster plan for medical disasters consisting of three phases: predisaster, disaster relief operations, and postdisaster rehabilitation.

Telehealth: Synonymous with telemedicine.

Telemedicine: Electronic communication and information technologies to provide or support clinical cases at a distance.

A Theoretical Model of Observed Health Benefits of PACS Implementation

Lucy Firth

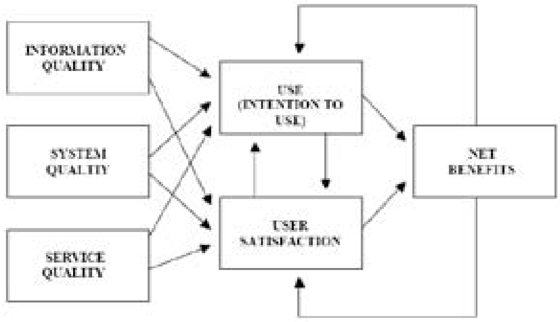
INTRODUCTION

Picture Archiving and Communication Systems (PACS) is an important e-health application, playing a significant operational role within hospitals in electronically transmitting image-based data. Various authors have attributed a range of benefits to PACS, including diagnostic accuracy (Scott et al., 1995; Slasky et al., 1990), interpretation time savings (Kato et al., 1995), workflow (Gale, Gale, Schwartz, Muse & Walker, 2000) and user satisfaction (Philling, 1999). While there is general consensus that PACS brings some or all of these benefits, there is little agreement as to the mechanism through which these benefits are generated.

The work of Delone and McLean (2003) provides a generalized model that attributes information systems success to benefits accruing from relationships between characteristics of the information system (e.g., information quality, system quality, service quality) and user intention to use and user satisfaction (see Figure 1).

Figure 1. Delone and McLean's (2003) model of IS success



This chapter provides empirical evidence that the Delone and McLean (2003) model with modifications explains the source of PACS benefits. Not only do we suggest a new model, but we also recommend that each specific information system context may require specific modification of Delone and McLean's (2003) model to explain the source of success.

BACKGROUND

This model and its earlier incarnation (Delone & McLean, 1992) have been applied to a range of IS contexts, including PACS (Cox & Dawe, 2002; Reiner et al., 2002). While this indicates that Delone and Mclean's (2003) model is robust when applied to PACS, it appears from the literature that other factors are causally related to the net benefits attributed to PACS. In particular, the literature suggests the following:

- The environment in which images are viewed and interpreted (Abdullah & Ng, 2001; Rostenberg, 2006; Reiner & Seigel, 2000) impacts the speed, accuracy, and comfort of interpretation. Rumreich and Johnson (2003) specifically argue that a purpose-designed reading environment improves radiologist satisfaction and efficiency.
- Training offered to users is also said to be important to the benefits from PACS (Protopapas et al., 1996; Watkins, Weatherburn & Bryan, 2000; Law & Zhou, 2003; Huang, 2003). Not only does training improve performance (Barney, 1991; Ulrich, 1991), but the way it is conducted also

increases user satisfaction (Bradford & Florian, 2003).

This suggests that while Delone and McLean's (2003) model may be valuably applied to PACS environments without modification, the inclusion of environmental and training issues may better explain the source of benefits and, thus, IS success.

IDENTIFYING AND EXPLAINING SOURCES OF PACS SUCCESS

The identification of the nature and source of benefits from PACS involved a single-stage case study of 18 PACS users, administrators, and managers at a large private hospital. The hospital has more than 60 departments and service centers, 500 beds, and nine operating theaters. The Medical Imaging Department is equipped with all imaging modalities and provides radiological services throughout the hospital. A mini-PACS was implemented in 1995 covering the intensive care, emergency, and imaging departments. In 2000, a decision was made to implement PACS hospitalwide, and in 2004, this was achieved.

This investigation asked the following: Are the two extra elements (image interpreting environment training) considered to be of importance at the hospital, and would their inclusion improve the relevance of Delone and McLean's 2003 model to the PACS environment? The investigation was part of a larger project that sought to evaluate the recent PACS implementation from three benefit perspectives: the impact on workflow; the impact on timeliness of image delivery and reporting; and the impact on patient throughput. The work presented here cuts across each of these perspectives, to focus on the aim of understanding the nature and source of benefits of PACS.

The investigation had both qualitative and quantitative components. Semistructured interviews around the topics of benefits (perceived or formally evaluated), system quality, service quality, training, viewing environment issues, and the attainment of hospital goals. Each interview was followed by a quantitative survey that was administered by the researcher. The survey addressed issues of self-efficacy and intention to use PACS, training, support, and level of user satisfaction. These questions were drawn from scales developed by Speier and Venkatesh (2002). The interview, survey, and documents were analyzed using open coding to divide the data into concepts and categories of concepts, and to assign properties to those categories (Miles & Huberman, 1994). Following this, axial coding was used to organize the categories and dimensions into groupings of ideas that are thematically related (Strauss, 1987). The quantitative survey data were analyzed descriptively only as the sample was too small for more sophisticated analyses.

The major findings and the modifications that they suggest for Delone and McLean's (2003) model follow:

- Adoption of PACS was universal with no interviewee indicating that he or she still used or preferred film-based images where there is a PACS digital browser-based alternative.
- Users universally reported not only that they were satisfied with PACS, but also that the more they used PACS, the more satisfied they became and the greater intention they had to use PACS' functionality. That is, use/intention to use and satisfaction with PACS are recursively promoted by the benefits that the users perceive. The model would be improved by arrows indicating a reverse loop from benefits to use and satisfaction (see Figure 2).
- DeLone and McLean's (2003) suggestion that where use (intention to use) and user satisfaction exist, net benefits will follow is confirmed. No modification of the model is needed.
- "Information quality" could be meaningfully relabeled "information and image quality" to reflect the multimedia nature of PACS presentation of data.
- For some respondents, information and image quality is directly related to benefits as well as indirectly via user perceptions and responses as Delone and McLean (2003) suggest. This direct benefit was not universally reported. Those that did not report this direct benefit commented that image quality was better, notwithstanding the trade-off between contrast and resolution, but that this benefit was entirely accounted for by the indirect effect through intention to use. Those that did report a direct effect included orthopedic surgeons who commented that because the size of the digital image is not necessarily related to

the object of interest, they experience direct disbenefits, as indicated by the following quote:

In orthopaedics surgery we focus on joint replacements, we like to be able to look at an X-ray and say we know how big that patient's knee is and how big his hips and that's where one of the biggest draw backs is with the computerized X-ray system. ... So there is an inefficiency in terms of planning for some operations and not able to easily put up plastic templates or plastic picture or a transparent picture of a joint replacement. Put that over an X-ray and say that's the correct size… Now if I put a ruler on this on computer that will measure anything between 29 and 32 ml and that leaves you with 2-3 ml.

This finding suggests that the model be modified to incorporate the possibility of a forward loop direct from information and image quality to benefits (see Figure 2).

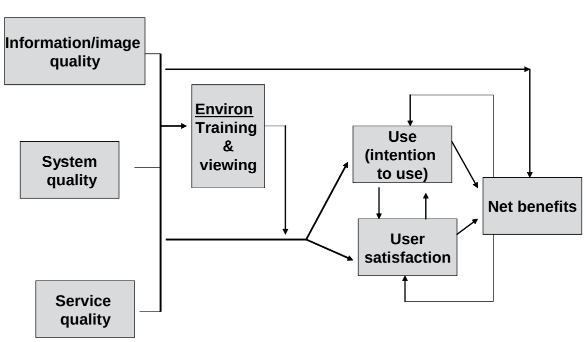
- While DeLone and Mclean (2003) found a direct relationship between the system characteristics and user perceptions and responses, our finding suggests that this relationship is both direct and indirect. The relationships are indirect to the extent that they are intermediated by two environmental factors that play an active role not normally attributed to environmental factors. The two environmental intermediators are training and the image viewing environment. In our findings, the training that impacted users' levels of satisfaction and intention to use was not training received by that user but by those in the environment upon whom that user relied in order to perform his or her own tasks. Our data show that user satisfaction and users' sense of their own productivity in using PACS were enhanced by the training that had been received by others. Interviewees reported that, where their colleagues had been inadequately trained, the effect on their own user satisfaction and on benefits in terms of productivity were strongly negative. The data also show that a lack of training of colleagues made it more difficult for users to gain the benefit of the information and image quality, and of the system quality. The data do not indicate that the user's ability to gain the benefit from service quality was impaired by environmental factors. While no interviewee reported intentions not to use the system because of the impact of the training and consequent competence (or lack thereof) of others, the impacts on user satisfaction and on benefits are captured in this quote by a surgeon:

There are a lot of people that don't know how to use it all, nursing staff etc. so we are operating a scrub or unable to register a computer screen. In the past you just say "can you put up that Xray," for the nursing staff who were not educated in using the system it's a big deal. It's very difficult for them, and it's very difficult to explain as well without touching anything.

This finding that training of colleagues plays on important role in intermediating between the characteristics of the system and the user satisfaction and benefits attributed to that system suggests that training of colleagues be introduced to the model as a possible mediator between system characteristics and user attributes (see Figure 2).

- If the benefits of image manipulation and contrast are to be enjoyed, the image interpreting environment has to be suitable in terms of lighting, screen size, and monitor quality. Moreover, the monitors need to be located appropriately, given the ward layout and workstation to ensure that images can be quickly and easily accessed. The fact that several clinicians might share one monitor was not considered to be a problem. This is partly because they have been accustomed to sharing light boards. The importance of the image interpreting

Figure 2. Model of PACS success



environment to both the user's intention to use and his or her satisfaction was especially apparent to those who were familiar with a previous mini-PACS implementation in only the emergency and intensive care wards. The mini-PACS had the viewing monitors isolated from the ward in the old reading room. While the number of walking steps from the current location of the monitors in the ward to the old viewing room location was as few as 10, the clinicians reported that it had been problematic. The implicit disruptions to workflow coupled with the poor viewing conditions not only led to inefficiencies, but also reduced the level of satisfaction and intention to use. This suggests that the model be modified to include the viewing environment as a possible mediator between system characteristics and user attributes (see Figure 2).

These findings suggest the model for information systems success in the PACS environment depicted in Figure 2. The model presents an extension to, rather than a departure from, Delone and McLean (2003). The model should be read as saying that as well as the expected relationships among the three characteristics of the system and the user response, there are intermediating environmental factors (i.e., training of others and viewing) playing an active role. Also, as well as the indirect relationship between the system characteristics and the net benefits, there are direct net benefits that are not mediated by intention to use and by user satisfaction.

FUTURE TRENDS

The need to evaluate health care information systems indicates a need for models that suit the health care environment specifically. Because of the differences in health contexts and conventional business contexts, this may mean customizing models validated in other contexts. This may be the case particularly in evaluating health care information systems used in not-for-profit, a service to underserved communities (including remote, impoverished, and elderly). The work presented here is evidence that it is possible to develop models that capture the uniqueness of health contexts while piggybacking on the work done for conventional business contexts. The growth of interest in informatics to provide relief in least developed nations (especially African) indicates a future trend toward model modification. Such modification is to be recommended if appropriate, relevant, and powerful evaluations are to be undertaken.

CONCLUSION

The first conclusion is that although Delone and McLean's (2003) model has the flexibility and robustness to apply to PACS contexts, its relevance may be enhanced by the inclusion of context-specific factors. In the case of explaining the source of benefits from PACS, two factors that should be included are training of others and the image interpreting environment.

Second, the inclusion of mediating conditions, both environmental, make Delone and McLean's (2003) model less primitive, while not destroying its simplicity. It would be valuable to have a quantitative measure of the strengths of the relationships as offered by a path analysis. The present study did not collect data suited to such an analysis, which is at once a limitation of this study and a proposed future direction.

The third conclusion is that training of colleagues plays a direct role in intermediating between system characteristics and use/intention to use. This direct role for environmental factors may be common to contexts in which knowledge workers rely on each other and on the information system in stressful conditions. The orthopedic theater is a particularly good example.

Fourth, we need to constantly be aware that the technology may matter. In this example, we see that the technology (PACS) is of central importance to the design of the viewing environment. Locating, lighting, and accessing new technologies in the same way that we did previous technologies may reduce the net benefits of the new technologies. In the extreme, it could make for net disbenefits.

Therefore, the model of PACS success, as developed in this project, shows how a theoretical approach can add real insight to practice. It provides an academic explanation of the practical question regarding the source of observed and measured benefits of PACS implementations.

KEY TERMS

Environmental Training: Represents activities that teach staff how to better perform their present jobs in order to cope with environmental changes, such as changes in lighting, monitors, and so forth.

Evaluation: The systematic acquisition and assessment of information using an overarching perspective to provide useful feedback about some sort of object/subject.

Hospital Strategy: An integrated set of actions with a focus on increasing the long-term prosperity and strength of hospitals relative to its environment and (strategic) goals.

Information Quality: Concerned with such issues as the relevance, timeliness, and accuracy of information generated by an information system (Seddon, 1997).

Information Systems: A system that comprises people, machines, and/or methods organized to collect, process, transmit, and disseminate data that represent information.

Not for Profit: The concept that the primary objective is to support some issue or matter of private interest or public concern for noncommercial purposes.

Service Quality: The degree of inconsistency between customers' normative expectations for the service and their perceptions of service performance (Parasuraman et al., 1985).

Strategy: A pattern of decision in a company that determines and reveals its objectives, purposes, or goals; produces the principal policies and plans for achieving those goals; and defines the range of business the company is to pursue, the kind of economic and human organization it is or intends to be, and the nature of the economic and noneconomic contribution it intends to make to its shareholders, employees, customers, and communities.

System Quality: Concerned with whether or not there are "bugs" in the system, the consistency of the user interface, ease of use, quality of documentation, and sometimes quality and maintainability of the program code (Seddon, 1997).

Viewing Environment: The characteristics of the workspace in which digital images are viewed.

Theory Driven Organizational Metrics

Hui-Lien Tung
Paine College, USA

INTRODUCTION

The inability to establish first principles has kept organizational theory from being successful. Moreover, due to snapshots in time and researcher biases, case studies are limited to hindsight, rather than serving as a proactive source of solutions to organizational problems. Yet case studies guided by theory have illuminated and tested the first principles that we have discovered. Unlike simple Newtonian mechanics, however, social-psychological mechanics among organizational members are hidden behind and within explanations and discourse, eluding a science of fundamental interactions. When an interaction stops for measurement (e.g., case studies), significant information from the collapse of organizational interdependence is lost. The path forward is to predict the uncertainty left from the collapse of interdependent variables: planning and execution; or resources and time. In this article, we develop a new organization theory; in a related article ("Restructering a Military Medical Department Research Center" in this encyclopedia), we apply the theory to a case study of a military medical research center (MDRC) with access to advanced information systems (IS), yet struggling to determine the quality of its residents in training, and their scholarly productivity.

BACKGROUND

Organizational theory has failed to produce predictable (Pfeffer & Fong, 2005) or replicable results (Weick & Quinn, 1999). Traditional organizational theory, generally based on (MI) (e.g., game theory; in Nowak & Sigmund, 2004), assumes that open information from individuals is stable and freely accessible (Baumeister, Campbell, Krueger, & Vohs, 2005), making an organization a rational aggregation of the contributions from its individual members. Yet defining rationality as "normative consistency," Shafir and LeBoeuf (2002) concluded that neither average humans nor experts make consistent choices, preferences, or justifications, undercutting the traditional model of rationality. Agent-based models (ABMs) based on MI with the same assumption about rational aggregation have had to discount the value of prediction as a consequence: "the value of a [computational] model is not prediction but insight" (Bankes, 2006). But to successfully operate an autonomous computational organization in the field (robot teams, human-robot teams, and networked and virtual organizations), a rational process using information systems (IS) and technology (IT) to formulate predictions is necessary to protect humans, the environment, and to ensure the execution of missions.

THEORY AND ORGANIZATIONAL METRICS

In contrast to methodogical individualism (MI), adopting the quantum uncertainty relations as first suggested by Bohr (1955) and Heisenberg (1958), has begun to successfully model interdependent uncertainties in human social interaction (Lawless, Castelao, & Abubucker, 2000) to predict decision-making among human organizations in the field (Lawless, Bergman, & Feltovich, 2005), and to study organizations in the laboratory (Lawless, Bergman, Louca, & Kriegel, 2006b). Subsequently, online metrics based on the "measurement paradox" have been proposed (Lawless & Grayson, 2004).

The paradox indicates that measuring an interaction or organization collapses the existence of its interdependent information into strictly classical information that cannot be aggregated to reconstruct the organization (Levine & Moreland, 1998), nor apparently even to reconcile differences between individual beliefs and actions—despite more than 30 years of research, no better than a weak link has been confirmed between selfesteem and actual performance at school or in the workplace (Baumeister et al., 2005). In addition, it has been known for some time that surveys or case study interviews fail to generate information that can validly predict individual and organizational change (Eagly & Chaiken, 1993). But surprisingly, the measurement paradox suggests that the collapse of interdependent information can be exploited to favor one of two interdependent states in the mathematical model of interdependence to produce predictable outcomes under certain rather extreme conditions, such as the difference between consensus (CR) versus majority rule (MR) decision processes in organizations (Lawless et al., 2005): It has been predicted and found that CR leads to less concrete decisions less welcomed by an organization's customers, but at lower resource expenditures that take longer to process; in contrast, MR leads to more practical decisions more welcomed by customers, but with more conflict and resources expended that quicken decisions.

The development of a complete theory of organizations, however, requires concepts beyond extreme situations to more general cases. Recognizing that two stories are always possible (Wendt, 2005), the measurement paradox arises because no better than one story at a time is ever collected during measurement. Further, the relationship between decision processes and organizations is itself complex, especially for CR. The purpose of CR is to convert the neutrals in a group into active individual participants (Bradbury, Branch, & Malone, 2003). However, the process in CR that suspends the criticism of beliefs no matter how bizarre lends itself to being hijacked: "The requirement for consensus in the European Council often holds policy-making hostage to national interests in areas which Council should decide by a qualified majority" (WP, 2001, pp. 29). Organizations are primarily hierarchical and governed by a single leader or command decision-making (CDM), making the link to CR more obvious under the control of multiple leaders (e.g., the leadership crisis at Unilever prior to 2005; the current management crisis at Europe's aerospace EADS group that includes Airbus). However, single leaders using intimidation or even violence can convert an organization or system into a quasi-CR process that stifles widespread criticism; for example, Germany's lack of response in 1934 from its citizens or institutions to the multiple murders during Hitler's "Night of the Long Knives" (Benz, 2006, pp. 54). But, counter-intuitively, instead of actively seeking consensus (CR), it has been found that the most robust consensuses are derived during competitive decision-making (i.e., MR), more learning occurs under competition (Dietz, Ostrom, & Stern, 2003), and the more competitive is a team, the greater the cooperation among its members (Lawless et al., 2000)[1].

In addition to laboratory studies, the paradox has been exploited by proposing the first mathematical set of interdependent metrics designed to measure the real-time performance for a system of military forecasters in the field (Lawless, Bergman, & Feltovich, 2006a). These metrics were revised and extended to analyze the reorganization of IT services provided by the Management Information Service Center (MISC) at a major university in Europe to test first principles that were then used to reverse model terrorist organizations (Lawless et al., 2006b). Mindful that a case study reflects a static snapshot in time which exposes the findings from a case study to confirmation bias (Eagly & Chaiken, 1993), the potential for biases were countered with a theoretical foundation directed at two sets of two interdependent variables (in Figure 1, planning and execution; resources and time). Based on these four interdependent variables, it was found that corruption at MISC and its university occurred by operating without a structured business model (BM). The lack of a focused BM for the university had led to a disorganized assemblage of faculty, staff, and students that discouraged innovation, promoted administrative malfeasance, and resource mismanagement, impeded student progress and faculty research, and significantly reduced opportunities for MISC and its university. The conclusion followed that a loose aggregation in the limit approaches a CR process, in that less information is processed by the organization than its members, consequently precluding organizational learning and change in response to environmental perturbations (Dietz et al., 2003). The results helped to specify a computational model of an organization with artificial agents that could be used as a test laboratory for organizations, and also used as online metrics for traditional and virtual organizations, based on applied IT algorithms.

In Figure 1, uncertainty in the social interaction is represented by an interdependence between strategy, plans, or knowledge uncertainty, ΔK (where K is a function of the social location where it was learned; from Latané, 1981), and uncertainty in the rate of change in knowledge or its execution as $\Delta v = \Delta\ (\Delta K/\Delta t)$; this agrees with Levine and Moreland (2004), that as consensus for a concrete plan increases (ΔK reduces), the ability to execute the plan increases (Δv increases). By extension, interdependence also exists in the uncertainty in the resources expended to gain knowledge, ΔR, and by uncertainty in the time it takes to enact knowledge, Δt (for proofs, see Lawless et al., 2006b). That these two sets of bi-stable factors are interdependent means that a simultaneous exact knowledge of the two factors in either set is precluded.

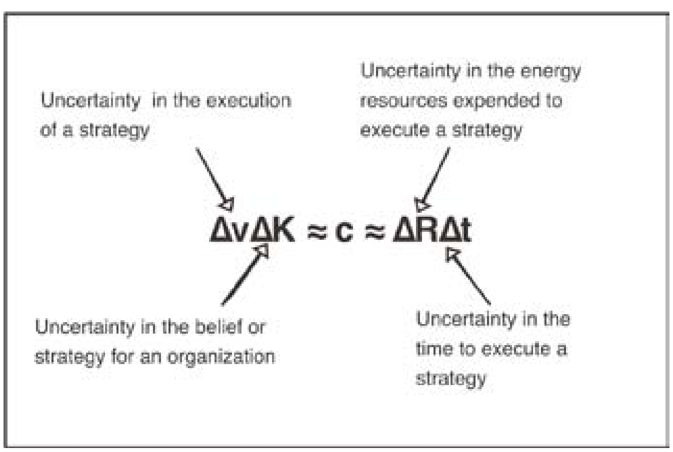
CASE STUDY: APPLICATION OF PRINCIPLES TO MDRC

In 2006, briefly, a new director assumed command of a military Medical Department Research Center (MDRC) at a regional military medical hospital. MDRC supports clinical and basic research for its staff and all hospital personnel, including family practitioners, internal medicine, general and orthopaedic surgery, and dentistry. In addition to providing basic research support for the hospital, MDRC is responsible to teach the fundamentals of experimental research to the hospital's medical residents[2], to provide continuing education for more experienced care providers, and to train dentists in research methods. One of the goals of the training by MDRC is to help the hospital's Graduate Medical Education (GME) candidates become certified by their respective American specialty boards, in what is becoming a matriculation requirement for many training programs.

The Chief, MDRC, wants to establish Metrics of Effectiveness (MOE) to measure his organization's success, and to craft a plan with MOEs to improve the performance of scholarly activities (i.e., Business Model (BM)). One problem with using MOE's is that much of the research proposed in the MDRC protocols has lasted or may last for a number of years before scholarly products can be published, whereas other research protocols may last under one year, giving the less complex Protocols an advantage in the generation of scholarly products. As the complexity of a Protocol increases, the time necessary to complete a program of research also increases. The Chief wants to increase the complexity of protocols, but remain able to measure the impact of complexity on scholarly productivity[3].

Fragmentation from a lack of focus indicates a general reduction in motivation to serve an organization, and consequently the need to change the business model to refocus the organization. The present case study of MDRC indicated that fragmentation among its processes, and researchers had reduced control over future plans. On the one hand, fragmentation of an organization is associated with increased innovation at the individual level (e.g., Benz, 2006), but often at the

Figure 1.Organizational uncertainty



expense of the organization. Successful organizations are entangled by command decision-making (CDM) into centers of cooperation (Lawless et al., 2006a; Lawless et al., 2000b) to acquire new resources and reduce wasteful expenditures, but that also tend to reduce innovation from their marginalization of new knowledge in making the organization, in this case MDRC, more competitive in its marketplace for new grants, improved mentors, better trainee candidates, and new joint ventures with industry or other research facilities. But this reduced innovativeness can be countered by mindfully taking steps with IT to free MDRC from many labor intensive activities by automating data collection and analytical processes in order to free resources to increase innovation. The overall goal of implementing the recommendations is to reduce the overall costs of MDRC, increase its operational efficiency, and to increase its growth by enhancing its ability to attract new extramural funds.

CASE STUDY: MEASUREMENT RESULTS

The results from data collection at MDRC invokes the measurement problem for the four interdependent factors in Figure 1.

Planning Uncertainty for the Organization's Business Model (BM, or ΔK)

In the MDRC Chief's opinion, attracting better quality residents will require an increase in the quality of publications, and in receiving help from other Division Chiefs, plus having a stronger program. Then better graduates will begin to attract other quality candidates, adding credibility to the BM.

The MDRC Chief observed that the support provided by his organization is satisfactory from all accounts, but that it should be better organized and more focused (INC, 2006). The revised BM should permit everyone to work under the same roof, gain more extramural funds, improve scholarly productivity, and keep education as the primary goal of MDRC. As part of an innovation plan, new resources or funds must be sought from State, Federal, and industrial sources. If successful, the plan should produce a qualitative shift among mentors and GME trainees under the new system; trainees will also learn new professional techniques that should help them to find better jobs afterwards.

The new BM must focus organizational resources to produce high quality research executed under a sense of competitive urgency. The goal should not be to seek complexity, but instead publishable research that helps to drive more and more competitive scholarly productivity, and the search for extramural funds. Complexity should be a byproduct of the plan.

Planning Execution (Δv)

The goal of executing the BM should be to increase the number of customers per period (new grant funds; new trainees; and new recognitions of quality).

The lack of focus at MDRC has primarily arisen from an internal lack of competition among its organization's members in the execution of its current BM. However, a lack of focus again suggests that an implicit CR exists to block the execution of a revised BM. Resistance to implementing a new BM can be anticipated, implying that barriers must be anticipated and overcome, as well as an average rise in activation that should be exploited to increase the rate of execution.

With support from his fellow Division Chiefs, colleagues, and staff, eventually the barriers that arise can be overcome among new mentors and new trainees around which time a new culture should be encouraged to become established and grow.

The MDRC and hospital staff should be educated to understand the need for regular professional training to improve research performance, especially the quality and the quantity of scholarly productivity; and the need for new information channels to distribute technical information about research opportunities. Numerous messages about the change should be given to trainees in seminars provided by MDRC, and designed to revise the culture to match the new BM.

Resource Uncertainty (ΔR)

The goal of the plan of action (BM) is to maximize the resources available to MDRC to execute its BM in the minimum of time. Such a BM, however, will likely reduce innovation, but practices instituted to seek innovation can offset this shortfall (e.g., including in the BM a strategy to continually seek new partners to obtain extramural grants, along with MOE's of grant progress).

One measure of progress is the level of teamwork across the organization (MDRC staff, mentors and trainees) to increase the competitiveness of MDRC's performance in completing its protocols as an indirect measure of the overall effort by its research teams; however, teamwork must not be simply commanded, but encouraged as a part of the competitive process and demonstrated to work.

As innovation increases from the gathering and expenditure of resources derived from the discovery of new resources (new trainees and new faculty become more attracted by new skills and the initiation of new industrial-state-federal projects), and a reduction of costs (less waste), planning complexity increases correspondingly as the ability to direct these freed funds to a random exploration of new projects for MDRC and the hospital with success determined by a reduced effort (practice effects; stochastic resonance) in discovering new sources of free energy.

Time Uncertainty (∆t)

The goal is to reduce the time to execute a BM, gain new resources, and discover new opportunities.

As the available resources are increasingly directed by MDRC to the completion of existing projects with the ultimate goal of freeing resources for new projects, the average time to complete and execute existing projects should decrease. At the same time, if and only if an innovation circuit has been established, the time to innovate should decrease correspondingly as new opportunities arise.

As new opportunities become available and exploited by MDRC, they will provide new opportunities to trainees, adding incentives that should further improve the quality of future trainee candidates.

FUTURE TRENDS

Should our initial exploitation of the measurement paradox for MDRC prove fruitful in the design of new organizational metrics, we expect to shift from the static metrics we have envisioned in this study to dynamic and online metrics that MDRC can deploy in real-time to tune and execute the strategic vision in its Business Model (BM). MDRC will do this with feedback derived by focusing its BM on its core missions, by optimally aligning its scarce resources to drive its vision forward, by reducing existing barriers to its strategy, and by seeking opportunities to exploit its strategy, as well as new opportunities to employ its organizational expertise.

We also expect to create a model of MDRC with artificial agents that could be used as a test laboratory to explore variations in its strategy, variations in its execution, different sources of new resources and barriers, and variations in the time it takes to execute its BM and to deploy its resources.

We have also recently begun conversations with other MDRC-like units in the military. We are exploring the possibility of an online metric for the entire system to reduce the costs of automating these metrics. It will consist of a system-wide automated electronic Protocol System (ePS), an automated Document Management System (DMS) for academic manuscripts, and an automated Metrics System (for a source of the value of an electronic Protocol-IRB System, see Hood, Gugerty, Levine, & Ho, 2005).

CONCLUSION

MDRC is located at one of the DoD's most advanced IS bases, yet its administrators have been using ad hoc processes to manage its protocols, educate its residents, improve patient care, and track manuscripts. Guided by theory, we hence exploited the measurement problem to construct a set of metrics to help MDRC restructure its operation and measure its performance. The resulting metrics represent a significant step forward in applied organizational theory.

KEY TERMS

Agent-Based Model (ABM): Used to create complex models of organizations and systems; for example, with Monte Carlo methods, ABM's can be designed to reduce biases in Critical Path Method (CPM models and Program Evaluation Review Technique (PERT)) models.

Business Models (BM): A business model is a complex plan for business operations and strategy, that when it converges into a consensus, it maximizes productivity, but the stronger the consensus in support of the BM, the more that innovation is reduced. Alternatively, divergence increases opportunities for innovation, but by reducing productivity. This paradox is reduced by creating ambidextrous organizations that can operate in a state of tension between both increasing productivity and innovativeness (Smith & Tushman, 2005).

Command Decision-Making (CDM): Top-down decision-making, especially the autocratic decision-making practiced in industry, business, and the military, but also by dictators. CDM reduces innovativeness but increases productivity. Further, CDM often employs consensus rules in its decision-making processes, because CR is open to exploitation (Kruglanski, Pierro, Mannetti, & De Grada, 2006).

Consensus-Seeking Rules (CR): By reducing evidentiary barriers to discussion, consensus-seeking rules often lead to the least common worldview amongst risk perceivers, making it unlikely to reach a practical decision, other than to instantiate past organizational practices, but consequently, reducing innovativeness. Further, consensus rules require considerable time to listen to each risk perception.

Majority Rules (MR): Majority rules often lead to faster decisions, more practical decisions, and, counterintuitively, stronger consensuses. The problem with majority rules is that they introduce conflict into decision-making. But if the conflict can be moderated or managed, the result is more learning among the participants compared to consensus rules.

Measurement Problem/Paradox: Assuming the existence of uncertainty in the four interdependent variables of planning-execution and resources-time, decreasing the uncertainty in either set raises the uncertainty in its correspondingly linked interdependent variable.

Methodological Individualism (MI): Game theory (Nowak & Sigmund, 2004) has attempted to substantiate the superiority of cooperation based on the belief that cooperation leads to the highest social good, even if it is coerced (Hardin, 1968). However, the lack of substantiating evidence in support of the social worth of cooperation is reviewed in Lawless and Grayson (2004).

Metrics: The metrics for MDRC are being designed to convert the measurement problem into an organizational metric of performance.

ENDNOTES

1 We speculate that the consensus produced by MR is more action oriented than the world view consensus produced by CR, and, therefore, qualitatively different.

Time-Frequency Analysis for EGM Rhythm Classification

Hamid Sheikhzadeh
ON Semiconductor, Canada

Robert L. Brennan
ON Semiconductor, Canada

INTRODUCTION

In this article, we study the problem of rhythm classification and event detection based on intracardiac electrogram (EGM) signals. At present, only a very limited scope of signal processing is possible in implantable cardioverter defibrillators (ICDs), due to the scarcity of available resources. As a result, relatively simple beat-by-beat time-domain analysis of the EGM signal(s) is employed for rhythm detection. Recently, researchers have attempted to exploit more sophisticated signal processing methods, such as wavelet transforms and template matching (Astrom, Olmos, & Sornmo, 2006; Brown, Christensen, & Gillberg, 2002; Koyrakh, Gillberg, & Wood, 1999). However, the new methods have rarely been employed in practical systems because of their computational and power demands.

Modern implantable cardiac rhythm management (CRM) systems such as ICDs face many challenges, some of which are summarized here:

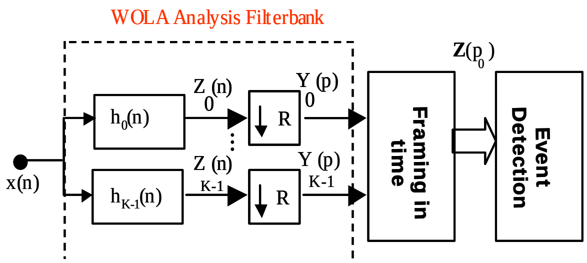
1. Quick and reliable detection of serious cardiac events is yet to be achieved by CRM devices. Errors in event detection occur, due to many reasons, such as quick morphology, rate, and polarity changes of the EGM signal, abnormally wide R-waves and P-waves, and external noise (Astrom et al., 2006).
2. Modern CRM devices are challenged by a considerable rate of inappropriate device therapy (IDT) (between 10 to 30%) (Rojo-Alvarez, 2002). Major causes of IDTs include: poor EGM signal quality, sinus tachycardia, supraventricular tachycardia (SVT), myopotential interference, external interference, and T-wave oversensing (Schaer, 2000). In addition to being painful for the patient, IDT's deplete valuable device battery power, and potentially place the patient at serious risk (Rojo-Alvarez, 2002; Schaer, 2000).
3. Rapid redetection of the EGM rhythm after device therapy (low-energy pacing or high-energy cardioversion) is problematic for CRM devices. This is particularly difficult when utilizing time-domain methods, due to their sensitivity to polarization of the EGM electrodes or baseline variations of the EGM signal following device therapy.
4. Modern CRM devices offer increasingly sophisticated multichamber detection and control, offering the physicians more potential therapies. In absence of powerful signal processing methods, however, the physicians are unable to fully exploit the multichannel information for effective programming of the device. The multichamber detection systems also require increased immunity to crosschannel interference.

In view of these challenges, we propose a multitiered detection method offering improved rhythm detection accuracy for CRM devices. This method, based on time-frequency analysis of the EGM signals, is targeted for implantable devices operating with extremely low-power budgets. It operates in real-time, and the processing delay is in the acceptable range for these applications. Although the method employs a specific filterbank implementation, it is not limited to this specific filterbank. Instead, the point is to prove that parallel processing of subband signals, resulting from a time-frequency analysis, offers more reliable detection in compromised situations.

BACKGROUND

Time-frequency analysis has already been exploited to extract features for electrocardiogram (ECG) rate and QRS detection (Kohler, 2002).

Figure 1. WOLA oversampled filterbank analysis for subband rhythm detection



Among various time-frequency analysis methods, oversampled filterbanks have been implemented by a Weighted Overlap-Add (WOLA) structure in ultra-low resource devices (Brennan & Schneider, 1998). We, therefore, propose a cardiac event detection based on the WOLA analysis of the EGM signals, and demonstrate its capabilities in various signal conditions. As the intention here is to describe the basis for the detection method, we limit our attention to single-electrode analysis; an extension to multiple-electrode analysis is straightforward.

After surveying the literature, the contribution by Afonso et al. (1999) on ECG beat detection in real-time is most relevant to our research. Afonso analyzes the ECG signal by a critically sampled polyphase filterbank to extract six features that are all based on the energy (or absolute value) of groups of subbands to obtain six time-frequency signals. Each of these signals is then passed through a peak detector that compares the signal moving average to a threshold that is determined based on an estimation of the background noise. Next, in a cascade of five stages (levels), peaks are further refined. This method was evaluated on a standard ECG database with satisfactory performance.

Afonso's method and similar methods proposed for ECG analysis are, unfortunately, not applicable to ultra-low power implantable CRM devices using EGM signals for the following reasons:

1. The sensed EGM signals and ECG signals differ in many aspects.
   a. ECG signals provide a composite signal after propagation of various electric waves to the body surface. In contrast, EGM signals provide direct access to individual heart chambers at the signal source.
   b. Relative timing of various EGM signals is crucial in discrimination of various cardiac events. For ECG signals however, such timing information is not available.
   c. Unlike ECG signals, sensed EGM signals are prone to cross-talk.
2. The ECG methods are too complex or unsuitable for real-time applications, are specifically designed for (and evaluated on) ECG signals, and do not provide the robust and reliable performance essential for EGM signal processing.

SUBBAND-BASED CARDIAC EVENT DETECTION

Overview

A time-domain digital EGM signal $x(n)$ is analyzed by an oversampled filterbank (depicted in Figure 1) with K subbands. For efficiency, a WOLA structure is adapted that can be implemented with ultra-low resources (Brennan & Schneider, 1998, 2003). The filterbank parameters are: $K=32$ subbands, analysis filters $h_k(n)$, $k= 0, 1, \ldots, K$-1, each of length of $L=256$, subband decimation of $R=4$, and oversampling factor of $OS=K/R=8$. These parameters were optimally selected for the EGM signal analysis through experimentation. As depicted in Figure 1, the subband signals are decimated with respect to the EGM signal. Figure 1 only depicts a schematic representation of the WOLA analysis. The actual WOLA implementation based on Brennan and Schneider (1998, 2003) is involved, and not described here. The WOLA time-frequency analysis stage produces K complex-valued subband signals $Y_k(p), k= 0, 1, \ldots, K-1$, where $Y_k(p)= Z_k(n.R)$, and k is the subband time-index. Due to Hermitian symmetry, half of the subbands are unique for real signals, because the other half are complex conjugates. For the next stage, subband signals are framed with blocks of M samples (in time) for further analysis. For a subband time-index of p_0, this generates a $K/2$-by-M matrix $\mathbf{Z}(p_0)$ including subband signals $Y_k(p), k= 0, 1, \ldots, K/2-1, p=p_0-M+1, (p_0-M+2),..,p_0$. The frame-length M and the frame-shift p_0 were selected to be three and two seconds, respectively. The frame-length should be long enough to cover more than one beat for slow beats (around 60 beats per minute (bpm)) for statistical analysis. At the same time, the frame should be as short as possible to track the dynamics of potentially quickly varying beats. The choice of frame-shift is rather arbitrary, and depends on how often a decision is needed. Notice that irrespective of the frame-length and frame-shift, the WOLA analysis is continuously applied to the input signal, yielding a new block of subband signals every R input samples.

The basic idea behind the proposed subband detection method is the concept of "subband synchrony" described now. Since the cardiac beat generates a sharp pulse, the magnitudes of subband signals ($|Y_k(p)|$) exhibit mainly coherent peaks at the time of cardiac depolarization. By properly exploiting this subband coherence (or "synchrony") in selected subbands, one can achieve robust peak detection. We propose a simple detection method based on binary operations to exploit the subband synchrony. Of course, various other methods might be designed based on the same principle.

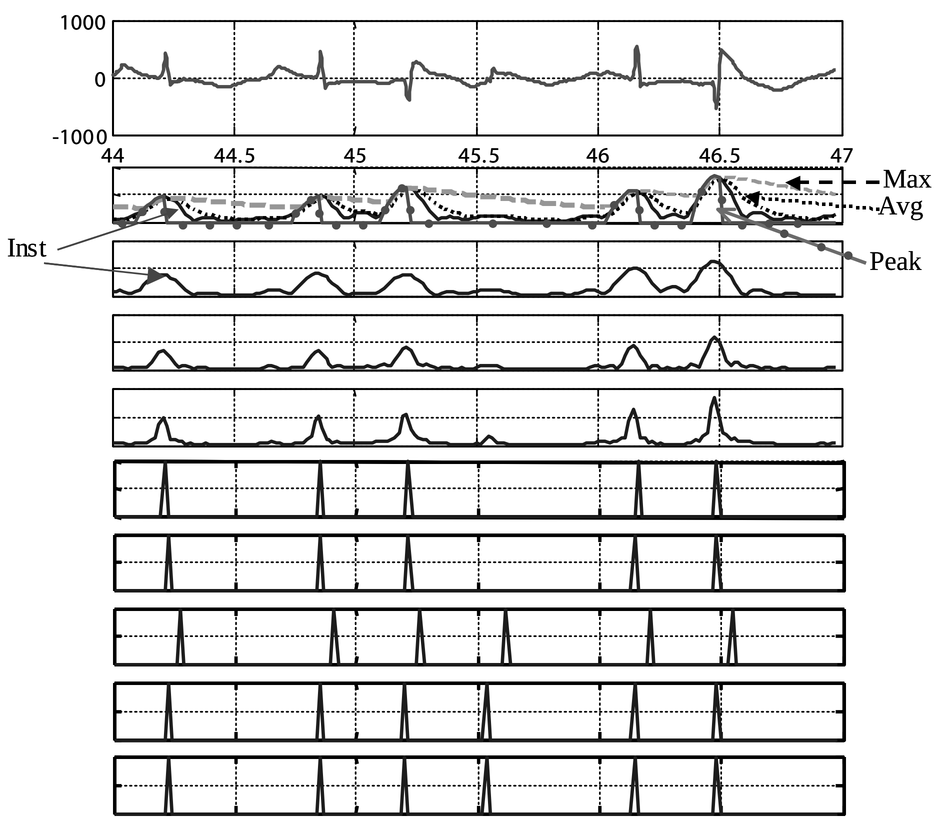
After the synchrony analysis, subband beats are combined to obtain a "final beat" sequence for every $\mathbf{Z}(p_0)$ matrix. Then the periodicity and the regularity of the final beat, together with the synchrony measure, are considered for event detection.

Subband Peak and Synchrony Detection

Each subband magnitude signal $|Y_k(p)|$ in signal matrix $\mathbf{Z}(p_0)$ is tracked in time to detect its peaks. In each subband, we tracked the maximum with a two-time-constant first-order recursive filter. For a subband magnitude signal $|Y_k(p)|$, two time-constants of $0.9<\alpha_{m1}<1$ and $0.1<\alpha_{m2}<0.5$ are employed to obtain the maximum signal $M_k(p)$ as follows:

$$\alpha=\alpha_{m1}$$
$$\text{If } |Y_k(p)| > M_k(p-1),\ \alpha=\alpha_{m2}$$
$$M_k(p) = M_k(p-1).\alpha + |Z_k(p)|.(1-\alpha)$$

Figure 2. From top to bottom, A segment of ventricular EGM signal, four WOLA subband energies (with average, maximum, and peak signals sown for the first subband), their corresponding binary pulses $B_k(p)$ (rows 6-9), and the final detected pulse (bottom row)



After each subband peak, the filter acts as a leaky integrator. Thus, the first filter coefficient (α_{m1}) is selected close to one to control the so-called "release-time" of the filter. The other smaller coefficient α_{m2} allows the filter to react quickly to the next peak.

A similar average tracking with a two-time-constant recursive filter is used to track the average signal ($A_k(p)$) with $0.7<\alpha_{a1}<1$ and $0.5<\alpha_{a2}<0.7$. A peak ($P_k(p)$) is detected by comparing the instantaneous value ($|Y_k(p)|$) to the average and maximum values, as described in the following pseudo-code:

$P_k(p)=0$
If $\{|Y_k(m)| > A_k(p\text{-}1)$ & $|Z_k(p)|> 0.5\ M_k(p\text{-}1)\}$ &
  $\{A_k(p\text{-}1)< 0.9\ M_k(p\text{-}1)\}$,
$P_k(p)= |Y_k(p)|$

In absence of EGM activity, $P_k(p)$ and $M_k(p)$ converge into each other. In this situation, the last term in the condition prevents peak detection. Currently, peak detection is limited to subbands 2-9, ignoring the first subband, as it is compromised through the capture of noise and baseline wander. Also high-frequency subbands ($k>9$) were ignored, due to low levels of synchrony in them. Figure 2 depicts a typical segment of ventricular EGM signal (top graph), and four WOLA subband instantaneous energies with maximum, average, and peak signals shown for one of the subbands.

To simplify further operations, we convert each subband peak signal $P_p(p)$ to a binary (0/1 for peak/no-peak) signal $B_k(p)$ after peak detection. Once a pattern of consecutive peaks followed by zeros (e.g., {1 1 1 0 0}) is found, the falling edge of the peak is registered as a valid peak. The rest of the peak signal is reset to zero. This avoids detecting short-term spurious peaks. All further operations are applied to the binary peak signals $B_k(m)$. Next, the degree of synchrony between various subband peaks is measured by simple AND operations of binary peak signals. Given a pair of signals $B_k(p)$ and $B_l(p)$, synchrony of the pair $S_{k,l}$ is measured as the ratio of coinciding peaks in the pair over the maximum number of peaks in the two signals.

The synchrony of all nonidentical pairs is evaluated, and the top three synchrony scores are kept as measures of the frame synchrony. Based on the top 3 scores, using fixed synchrony thresholds, the detection algorithm classifies the subband beats as perfectly synchronous (*Syn=4*), as borderline synchronous (*Syn=2*), or asynchronous (*Syn=0*).

The signals in each of the top three most synchronous binary pulse pairs are combined in pairs by the AND operation. Next, the results are used for robust detection of beat times. Applying a majority voting rule (two out of three) and using the AND results, the final beat times are detected. This proved to be very robust in noise, and especially when the signal quality was compromised in flutter and fibrillation. The result of beat detection is a final beat sequence per frame. Figure 2 (rows 6-9) depicts binary subband pulses for the EGM segment, together with the final detected beat (last row).

Periodicity and Regularity Analysis

The detected beat signal is further analyzed to find its period histogram, its mean period ($\bar{T}$), and the mode of the histogram (T_m). Also, the standard-deviation-to-mean ratio of the detected periods (σ/μ) is calculated. σ/μ values more than 40% indicate very irregular beats, values less than 20% show very regular beat patterns, and values in between indicate moderate regularity. Also, if unusual lack of EGM activity is detected within a frame, it indicates irregularity.

Cardiac Even Detection

Based on the synchrony score (*Syn*), periodicity ($\bar{T}$ T_m, σ/μ), and regularity of the final beat sequence, cardiac events are classified to be one of the following 8 events:

1. Stable Sinus Rhythm (SR)
2. Transitional SR (T-SR)
3. Stable Tachycardia (VT or AT)
4. Transitional Tachycardia (T-VT or T-AT)
5. Flutter (VFLUT or AFLUT)
6. Fibrillation (VFIB or AFIB)
7. Synchronous but Irregular rhythm (Syn-Irg)
8. Unclassified

Represented by VT, VFLUT, and VFIB are ventricular events of tachycardia, flutter, and fibrillation respectively. Similarly, AT, AFLUT, and AFIB represent the corresponding atrial events. A transitional event of T-SR is detected when the mean period is within the range for sinus rhythm, but the rhythm is irregular. A similar criterion is used in detection of T-VT or T-AT.

Event 7 is detected when there is perfect synchrony, but the periods are too irregular or insufficient in number to be considered for other classes. Finally, event 8 is reserved for unclassified rhythms.

The event detection algorithm uses three features of synchrony, rate, and regularity of periods. The algorithm operates by "setting traps" for various events. It first tries to identify fibrillation or flutter (classes {5,6}). In absence of the two, it searches for fast beats (classes {3,4,7}), and then sinus rhythms (classes {1,2,7}). If none of the traps are triggered, the beat remains unclassified (class 8). Details of the detection algorithm are presented in Sheikhzadeh, Brennan, and So (2006).

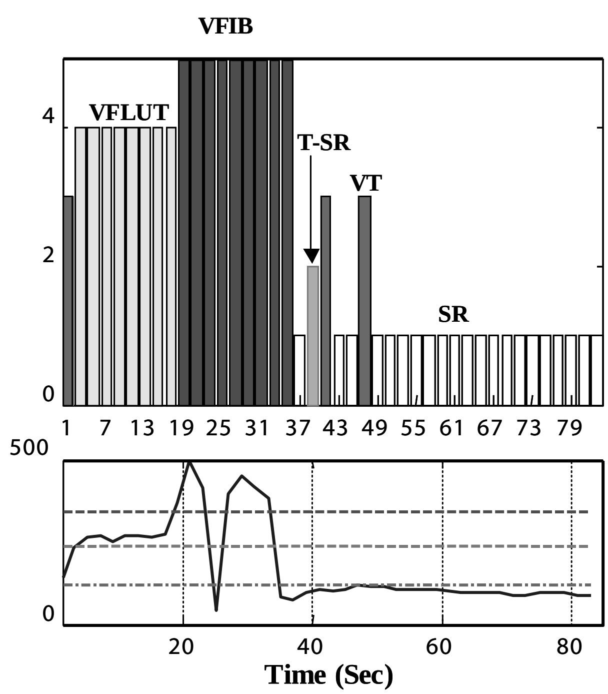
Performance Evaluation

All of the EGM data from Volume I of the Ann Arbor Electrogram Libraries (AAEL, 2006) were employed for system evaluation. Only the two bipolar EGM signals were utilized as they offer the best quality. The signals are recorded from Right Ventricular Apex and High Right Atrium, termed RVAb and HRAb in the AAEL documentation, respectively. The EGM signals were down-sampled from the original sampling frequency of *1000* Hz to *Fs=250* Hz, since our analysis and simulations revealed that it suffices. The detection system was optimized for a small (but diverse) set of input signals, and then tested with all available RVAb and HRAb EGM data, comparing the results to the AAEL annotation. The system parameters were tuned until there were no missed events, and the frame-by-frame classification was as accurate as possible for all types of rhythms. Figure 3 depicts a typical summary of the detection system output, including various detected events, and the beat-rate.

Detection in Noise

Practically, noise robustness is an important feature of an EGM processing system. To examine the effect of noise on system performance, noise was added to the EGM signal prior to detection. Employed noises included: 1-white noise, 2-lowpass, 3-bandpass, 4-highpass, and 5-tonal (60 Hz) noise. Noises 2-4 were filtered white noise with a 3-dB bandwidth of a quarter of full-band. Measurement of the signal-to-noise ratio

Figure 3. Algorithm performance for RVAb EGM signal (AAEL file: SET1, A177A26.SIG), top view: detected events in time, bottom view: detected rate in beats per minute (solid line) in time, and VFIB, VFLUT, and VT rate thresholds (dashed line, from top to bottom respectively)



(SNR) was based on tracking the short-term (four seconds) signal envelope (rather than power) of EGM and noise signals.

Event detection was performed at the noise levels reported in Table 1 for the whole EGM database, comparing the outputs to the ones for clean EGM signals. Events were clustered into two separate groups, {1-4} (SR/Tachy), and {5-6} (Fib/Flut). To further evaluate the performance, we compared the detection results in noise with the results in clean conditions, keeping in mind that it is especially vital to ensure that no event group is lost under noisy conditions. We measured the detection performance using frame counts of *TP, TN, FP,* and *FN* defined as:

1. *TP*, True Positive: Correct detection of {5-6}
2. *TP*, True Negative: Correctly not detecting {5,6}
3. *FP*, False Positive: Falsely detecting {5,6}
4. *FN*, False Negative: Falsely not detecting {5,6}

Then the Fib/Flut Positive Predictivity (+*P*) and Negative Predictivity (-*P*) were calculated as:

+P= TP/(TP+FP), -P= TN/(TN+FN).

The +*P* and –*P* measures for the five noise types are summarized in Table 1. As expected, white and lowpass noises have the most effect, and 60 Hz noise and high-pass noise have the least effect on performance. Overall, no block-event was missed or misrecognized with the five noise types in Table 1. The recognition errors in noise were sparse, and mostly confined to immediately before or after fibrillation or flutter events when the quality of EGM signal was already compromised.

Table 1. Positive and negative predictivities for noise types of 1-white, 2- lowpass, 3- bandpass, 4- highpass, and 5- 60 Hz at SNR levels of 15 dB for types 1-3 and 0 dB for 4-5

Noise Type	Positive Predictivity	Negative Predictivity
1	95.9	99.6
2	95.2	99.7
3	97.4	99.5
4	99.2	99.8
5	98.1	99.7

FUTURE TRENDS

Subband-based detection could be easily expanded to include morphology analysis and pattern-matching, based on subband features. This could outperform comparable time-domain methods, due to the superior and more robust representation of signal spectral features. Also, research is being conducted towards an ultra-low power implementation of the WOLA-based detection algorithm at power levels comparable to current ICDs (typically less than one μW). Initial results confirm the feasibility of this implementation. Subband-based detection methods may beneficially be combined with time-domain methods when time response is crucial (for example, in pacing).

CONCLUSION

As a result of subband decomposition and multitiered detection, subband-based EGM detection methods are superior to time-domain methods in terms of accuracy and robustness. Capturing synchrony of the subbands is key to the reliability and accuracy. The WOLA implementation, together with proposed simplified techniques, offers a feasible subband-based detection system for ultra-low resource platforms. Extensive testing of the proposed method with the AAEL database has shown excellent performance in terms of correct event detection and beat-rate measurement, even in fibrillation or flutter when the signal quality is compromised. Evaluation in noise and in the presence of far-field R-waves (not reported here) has also demonstrated significant robustness to noise and interference.

KEY TERMS

Atrial Fibrillation (AFIB): A common heart rhythm disorder caused by a problem in the conduction of electrical impulses in the upper chambers, or atria, of the heart, causing it to beat chaotically.

Atrial Flutter (AFLUT): A heart rhythm disorder in which the upper chambers of the heart (the atria) contract faster than the lower chambers (the ventricles) in an organized, predictable pattern.

Atrial Tachycardia (AT) and Ventricular Tachycardia (VT): Refer to tachycardia originating from the ventricular and atrial chambers, respectively.

Cardioversion: The conversion of one cardiac rhythm or electrical pattern to another, almost always from an abnormal to a normal one. This conversion can be pharmacologic or electrical.

Defibrillation: The use of a carefully controlled electric shock, administered either through a device on the exterior of the chest wall or directly to the exposed heart muscle.

Electrogram (EGM): Sensed electrical activity of the heart by an electrode implanted in the heart.

Implantable Cardiac Defibrillator (ICD): A device that is put within the body, and is designed to recognize certain types of abnormal heart rhythms (arrhythmias), and correct them through cardioversion and defibrillation.

Supraventricular Tachycardia (SVT): AFIB and other rapid heartbeats that arise in the atria, or in the juncture between the atria and the lower chambers (ventricles).

Tachycardia: A rapid heart rate, usually defined as greater than 100 beats per minute.

Ventricular Fibrillation (VFIB): In VFIB, the heartbeat is rapid and chaotic, which causes the lower heart chambers, or ventricles, to go into a spasm.

INTRODUCTION

Central venous pressure (CVP) is a measure of the mean pressure within the thoracic *vena cava*, which is the largest vein in the body and responsible for returning blood from the systemic circulation to the heart. CVP is a major determinant of the filling pressure and cardiac preload, and like any fluid pump, the heart depends on an adequate preload to function effectively. Low venous return translates into a lower preload and a drop in overall cardiac output, a relationship described by the Frank-Starling Mechanism.

CVP is an important physiological parameter, the correct measure of which is a clinically relevant diagnostic tool for heart failure patients. In addition to other vitals such as heart rate and mean arterial pressure, accurate measures of central venous pressure through simple diagnostic instrumentation would provide physicians with a clear picture of cardiac functionality, and allow for more targeted treatment. Recent literature has also shown that measuring CVP can be an important hemodynamic indicator for the early identification and treatment of more widespread conditions, such as sepsis (Rivers, Nguyen, Havstad, & Ressler, 2001). With over five million patients (American Heart Association, http://www.americanheart.org/presenter.jhtml) in the U.S. presenting with heart failure-like symptoms annually, a current challenge for physicians is to obtain a quick and accurate measure of a patient's central venous pressure in a manner that poses minimum discomfort.

A novel noninvasive method to estimate CVP is to use ultrasound imaging in conjunction with a surface pressure measurement. Ultrasound is first used to visualize the *internal jugular* (IJ) vein below the skin on a patient's neck, and a custom pressure transducer is then used to detect the surface pressure required to collapse the IJ. The collapsing pressure is correlated to the central venous pressure and reported back to the operator. This proposed measurement procedure is suitable for emergency situations or primary care settings where rapid diagnosis of a patient's CVP is required, and mitigates the need for further invasive and costly procedures.

BACKGROUND

Central Venous Pressure is dependent on the ratio of venous blood volume (V_v) to venous compliance (C_v), as described in (1):

$$CVP = \frac{V_V}{C_V} \quad (1)$$

From this relationship, it is clear that an increase in blood volume within the thoracic *vena cava* will lead to greater pressure exerted on the vessel walls, and that a vessel with low compliance will experience greater pressure from an increase in blood volume than a vessel with high compliance. A variety of physiological conditions may influence CVP, due to changes in blood volume and/or compliance, and a few are presented here:

- **Hypervolemia:** Condition where overall blood volume is too high. Hypervolemia can arise from high salt intake or a failure in the kidney's ability to excrete salt and water from the body. Excess fluids seep into body tissue leading to edema (swelling), which can cause headaches and respiratory difficulties. The increase in blood volume increases central venous pressure.

- **Hypovolemia:** Condition where overall blood volume is too low. A common cause of hypovolemia is blood loss due to trauma, which leads to weakness and, in extreme cases, organ failure. The drop in venous blood volume decreases central venous pressure.
- **Heart Failure:** Condition where the heart is no longer able to maintain adequate blood circulation. Some causes of heart failure including coronary artery disease, valvular disease, and myocardial infarction. Low cardiac output leads to a backup of blood in the venous compartment, and increases central venous pressure.
- **Sympathetic Activation:** General increase in the activity of the sympathetic nervous system. Sympathetic activation, characterized as the "fight or flight" response, leads to increased heart rate, inhibition of the digestive system, and increased vascular tone. The latter decreases venous compliance, and increases central venous pressure.

Due to the high compliance of the thoracic *vena cava* and its inconvenient physiological location, direct measurement of CVP using a sphygmomanometer has long been considered impractical. Physicians have instead relied on direct measurements of intraluminal venous pressure, or crude noninvasive techniques for estimating CVP. This section explores both the traditional and more novel diagnostic approaches for measuring CVP, as a prelude to our discussion of the proposed measurement procedure and device.

Traditional Methods of Measuring Central Venous Pressure

a. Lewis (1930) describes one of the oldest methods to estimate CVP using jugular vein distension. When hypervolemic or cardiac failure symptoms manifest as increased venous blood volume, the extra blood pools and increases the size of the patient's jugular veins. The jugular vein's proximity to the surface of the neck makes it possible for a clinician to visually identify the swelling of neck veins, but this technique is not a true measurement of CVP since it is quite subjective. For one, the jugular veins are not always visible, especially when obscured by layers of fat, and venous distension is only readily apparent in cases of extremely high CVP. Therefore, this technique is useful for rapid diagnosis of a major increase in CVP, but not suitable for an objective measurement, rendering it largely inadequate for continuous monitoring.

b. Another noninvasive measurement technique that attempts to quantify CVP readings involves treating the jugular veins as manometer tubes to the right atrium, implying that higher pressure leads to a greater column of blood in the jugular veins (Lipton, 2000). The selected zero-reference point is the angle of Louis, located at the junction of the *manubrium* and the *sternum* 5 cm above the right atrium, because venous pressure at this point changes very little with posture. The height of the blood column can be determined by visually identifying jugular vein pulsations, which are oscillations in pressure caused by the cardiac cycle, and visible where the vein transitions from the distended (filled with blood) to the collapsed (no blood) state. The hydrostatic pressure that corresponds to the height difference between the point of fluctuations and the angle of Louis is used as a measure of CVP. In practice, this quantitative approach is often impractical, because the venous pulsations are only visible when the top of the blood column is in an area of the neck where the jugular passes close to the skin surface. If not, the clinician must raise the patient slowly upward from a supine position until the pulsations become visible, a process that is both physically taxing and time-consuming. Furthermore, if CVP is too high, then the top of the blood column may lie above the mandible, even with the patient sitting upright, making the fluctuations invisible. As with the previous method, layers of fat may also hinder visualization of the venous pulsations on the neck.

c. Numerous studies have shown that noninvasive methods fare poorly in quantifying CVP, because subjective measurements are difficult to standardize. Factors such as posture are hard to control in heart failure patients that must be lifted upright to observe jugular pulsations, which leads to highly variable and inaccurate measurements when compared to invasive recordings (McGee, 1998). Therefore, situations necessitating accurate CVP readings for prompt and correct treatment rely on invasive catheter-based measurements as the standard-of-care. Central venous access is the process of placing a venous catheter inside a major vein, which allows clinicians to obtain pressure readings from directly within the vessel lumen. A common insertion method is intravenous cannulation, which requires a larger insertion point in the vein to fit the cannula, and may lead to complications from excessive bleeding (Mitchell & Clark, 1979). A modified approach that uses a smaller insertion point is the Seldinger technique, which threads a small guide wire to the appropriate location, and then pushes the catheter along the wire (Seldinger, 1953). Although routinely performed, central venous accesses are susceptible to a variety of complications, such as difficulty locating the vein after the initial incision, overinsertion of wires and cannula leading to accidental puncture of an artery or lungs (Mitchell & Clark, 1979), and neurological complications from nerve lesions (Defalque & Fletcher, 1988). Due to the difficulty inherent in these techniques and the risk of complications, central venous access procedures require skilled medical personnel in a hospital setting.

Alternative Methods of Measuring Central Venous Pressure

a. Bloch, Krieger, and Sackner (1991) describe a method where an inductive neck plethysmograph is used to detect and record the small changes in neck dimensions that correspond to venous and arterial pulsations. In certain positions, such as the head-down position, the venous pulsation dominates in strength, whereas in the recumbent position, a mixed venous-arterial pulsation is detected. The device relies on measuring the height with respect to the phlebostatic axis, at which the waveform level changes from a venous to a venous-arterial or arterial configuration. Measurement of this height is a measure of CVP in cm H_2O. Their study indicates that this noninvasive method is accurate, compared to invasive catheter measurement. However, the measurement procedure is time-consuming and requires specialized equipment, like the plethysmograph, which is not as common as an ultrasound device.

b. Lipton (2000) describes a method where an ultrasound machine is used to locate the jugular venous pulsations. An ultrasonic probe is applied to the *internal jugular vein* (IJ), which lies very close to the neck surface, and provides a straight path to the right atrium. The IJ is a prime location for viewing jugular pulsations, and it is easily located by referencing the *sternocleidomastoid* muscle. This method allows the clinician to more easily determine the location of these pulsations, especially in situations where they are not visible on the surface of the neck. The vertical distance between this location and the right atrium is used as a measure of CVP.

c. Baumann, Marquis, Stoupis, Willenberg, Takala, and Jakob (2005) describe a method where an ultrasonic probe is custom-fitted with a quartz pressure-transducer. The probe is pressed against the IJ, until the vessel first starts to collapse on the ultrasound display, and this pressure is recorded as the bearing pressure. The probe is then pressed until the IJ fully collapses, and the final pressure is recorded. The difference between collapsing pressure and bearing pressure is the pressure needed to directly collapse the vessel. This quantity is equal to the pressure within the vessel lumen if the vein is assumed to be an ideal vessel following the Law of Laplace. While the assumption is imperfect, it is still a useful approximation compared to existing noninvasive approaches. The study noted high inter-operator variability and low precision, which may be improved by better design of the force transducer and standardized training.

A NOVEL NONINVASIVE APPROACH

A novel noninvasive method to estimate central venous pressure using ultrasound-guided surface pressure measurement is discussed here. Specifically, the device works in conjunction with an ultrasound machine and probe that is used to visualize the *internal jugular* (IJ) vein below the surface of the skin on a patient's neck. Once the vein is located, the device detects the pressure on the skin required to collapse the IJ, and correlates this value to a central venous pressure reading reported to the operator. This quick and noninvasive measurement is suitable for emergency situations or primary care settings where rapid diagnosis of a patient's CVP is required, and prevents the need for further invasive and costly procedures. The measurement procedure is also simple enough to be performed by operators without extensive medical training.

Measurement Principle

The measurement principle assumes that the IJ vein can be modeled as an ideal vessel according to the Law of Laplace as described in (2) and shown in Figure 1:

$$T = \frac{P \times R}{M} \qquad (2)$$

where T is wall tension, P is transmural pressure (difference between internal and external pressure), R is vessel radius, and M is wall thickness. When transmural pressure is zero, the tension falls to zero, and the vessel collapses. Conversely, if the vessel is directly collapsed, it can be inferred that the external pressure required to collapse the IJ is equal to the CVP. A custom handheld probe is responsible for measuring this applied external pressure, and is used alongside an ultrasound probe capable of visualizing the IJ. The *internal jugular vein* is located underneath the *sternocleidomastoid* muscle, and anteriolateral to the *common carotid artery*. The IJ is targeted because it provides a direct pipeline to the heart, and because of its anatomical proximity to the skin surface, making it easier to see on an ultrasound (Lipton, 2000).

After locating the IJ on the ultrasound monitor, the operator applies pressure with the handheld probe until the IJ first begins to collapse, and records this as the *initial pressure* required to collapse the superficial tissue between the skin and the vein. Since the tissue surrounding the IJ is not homogenous, the pressure applied at the skin surface will not directly collapse the IJ, but will be affected by factors like skin compliance and the presence of layers of obstructive tissue between the skin and vein. This step helps factor out the effects of surrounding soft tissue and varying initial skin compliance on the pressure measurement. The operator then continues to apply pressure until the IJ is completely collapsed, and records this final *collapsing pressure*. The central venous pressure is estimated as the difference between the final collapsing pressure and the initial pressure, as described in (3). In this manner, one can dynamically account for the surrounding soft tissue without need for calibration on each use.

$$CVP = P_{collapse} - P_{initial} \qquad (3)$$

This device utilizes the same principle of operation described in Baumann et al. (2005), but differs in its integration of a highly sensitive pressure transducer

Figure 1. Model of ideal vessel described by wall tension T, internal pressure P_i, external pressure P_o, and vessel radius R (Klabunde, 2004)

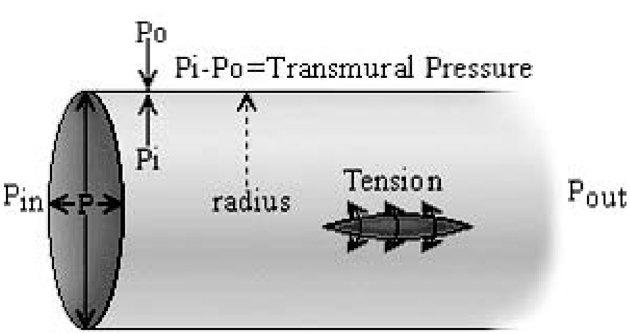

Figure 2. Left column shows progression of probe during each step of the measurement procedure; right column depicts actual ultrasound images visible to operator

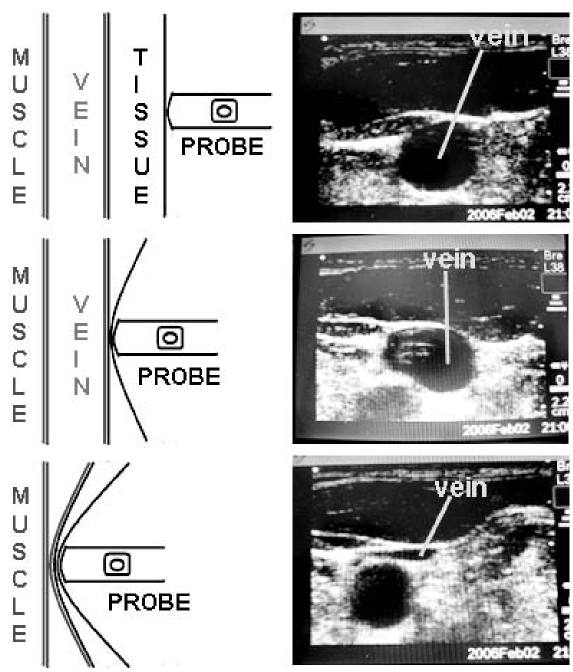


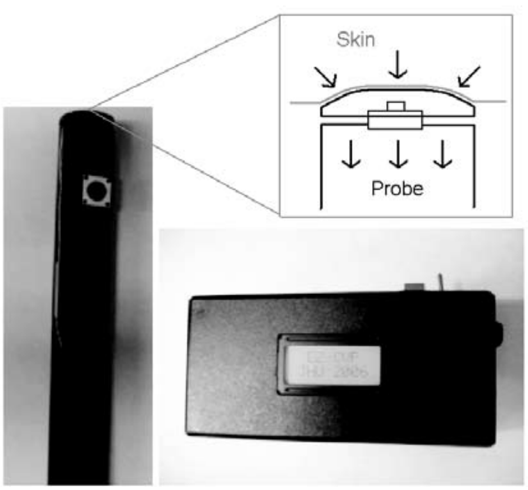
with a custom-designed probe that can be used in conjunction with any available ultrasound. Operation of the device is illustrated more clearly in Figure 2, with the probe and actual ultrasound images of the IJ during each stage of the measurement procedure.

Device Design

As shown in Figure 3, the device consists of a handheld probe with a pressure transducer and a control unit. The handheld probe is cylindrical in shape, and has a high-precision 5-lb load cell on the tip that detects the applied pressure and transmits this reading to the control unit. The probe also has a button along the longitudinal side of the probe body, which is used to initiate and end the CVP recordings. The probe tip (see inset of Figure 3) is designed to address how the collapsing force at the surface of the skin is transmitted to the IJ. Since the IJ is not exactly an ideal vessel, vessel compliance disperses the force somewhat. In order to minimize this, the probe tip is curved with a contact surface area of approximately 2 cm^2 that helps localize the applied force appropriately, and is an effective contact profile for compressing the IJ.

The control unit is battery-powered and consists of a microprocessor that analyzes the incoming load cell data, and an LCD that outputs the CVP readings.

Figure 3. Handheld probe (left) and control unit (right). Inset details design of custom probe tip, which takes distributed force from skin surface and channels it to the force transducer



The probe and control unit are meant to work in conjunction with an ultrasound machine and transducer for visualization of the *internal jugular vein*. The choice of ultrasound machine is up to the operator, since the described device is self-contained and does not require a particular ultrasound machine model. To aid in emergency diagnosis, a portable ultrasound is recommended; to aid in visualization accuracy, a high-frequency linear ultrasound transducer with low penetration depth is recommended.

FUTURE TRENDS

Ultrasound-guided therapies have gained significant momentum in the last decade, and are expected to continue to revolutionize health care technology. The U.S. ultrasound market is forecasted to grow at a compound annual growth rate (CAGR) of 5.9%, and reach over $1.89 billion by 2010 (Frost & Sullivan, 2004). This growth is driven primarily by the demand for portable units, as well as the increasing adoption of ultrasound technology among new end users such as cardiologists. Ultrasounds for cardiology, specifically, have a market with a CAGR of 7.6%, and will reach over $638 million by 2010—34% of the total market (Frost & Sullivan, 2004). And with manufacturers rapidly releasing smaller portable ultrasound machines that are easily transported and deployed in emergency settings, the future of medicine may see compact ultrasound machines replace stethoscopes as the diagnostic instruments of choice for physicians. The fast pace of research in ultrasound technology has brought faster and more accurate devices that are also equipped with features such as color flow Doppler mode, used commonly to detect blood flow velocity and direction in large vessels and cardiac chambers (Perry, Helmcke, Nanda, Byard, & Soto, 1987). Doppler ultrasound is one example of an imaging strategy that might support the proposed measurement procedure by providing operators with a less subjective means of determining complete collapse of the IJ during application of the probe. Considering the advances in ultrasound technology, our CVP measurement device fits well in this rapidly growing market, and may lead to widespread adoption of ultrasound devices by cardiologists and emergency room doctors, to primary care physicians and nurses.

The incorporation of a noninvasive measurement of central venous pressure into standard practice will enable clinical practitioners to use this vital parameter more often in their assessment of patient health. The benefits are clear in cases where patients present with heart problems and central venous access is a routine procedure. However, physicians have also begun using central venous pressure, along with other hemodynamic indicators, to help treat a wide variety of disorders. Hocking (2000) recommends that CVP should be measured in patients that are hypotensive, unresponsive to basic clinical management, or those requiring infusions of inotropes; Rivers (2001) used regular CVP measurements, among other indicators, as part of a goal-directed therapy to manage patients in septic shock; and Wang, Liang, Huang, and Yin (2006) report that patients who had their CVP lowered suffered less blood loss during liver resection. As CVP becomes an increasingly vital parameter for patient treatment, the advent of a reasonably accurate approach to noninvasively measure CVP can lead to significant improvements in standard of care in fields outside cardiology.

CONCLUSION

Clearly, there is a need for a system that provides a reliable noninvasive measure of a patient's central venous pressure. The real impact of the proposed measurement procedure and device will be felt in the 6,000 ICUs (NJHA, 2004) and 35,000 primary care facilities (HRSA, 2006) across the country, either as a necessary step in a life-saving procedure, or during measurement of key vitals during a standard exam. Critics who consider the price of an ultrasound too high for simply measuring CVP should also consider the numerous additional uses of ultrasound, including guidance in central venous access procedures (Denys, Uretsky, & Reddy, 1993; Troianos, Jobes, & Ellison, 1991) and visualization of organs such as the heart, liver, and kidneys. Another benefit of the proposed noninvasive approach is to mitigate the costs and risks associated with central venous access, a procedure that would be performed less often if a cheaper and safer alternative to measure CVP were available. The novelty of the technology may be a deterrent to its adoption by medical practitioners, but clinical studies of the technology and measurement procedure should be pursued to provide hard evidence of its utility. If the data is encouraging, industrial partners would be free to pursue product development and marketing in an open and highly profitable field. In conclusion, the direct ultrasound-guided noninvasive surface pressure measurement of CVP is a significant improvement over previous diagnostic techniques, and has the potential to make CVP measurements quicker, easier, and safer—thus more suitable for rapid diagnosis in emergency situations and primary care environments.

KEY TERMS

Cardiac Preload: Initial stretch of cardiac muscle before the systolic contraction phase; preload directly affects stroke volume and cardiac output through the Frank-Starling mechanism.

Cardiac Output: Total volume of blood ejected from left side of the heart into systemic circulation per minute.

Central Venous Pressure (CVP): Mean pressure inside the thoracic *vena cava*, near the right atrium of the heart; primary determinant of cardiac preload, and sensitive to changes in blood volume and venous compliance.

Compliance: Ratio of change in blood volume to change in intraluminal pressure; highly compliant vessels will respond to increased blood flow by distending, whereas low compliance vessels are more rigid, and will have increased pressure with more blood flow; compliance is regulated by the sympathetic nervous system, and affected by collagen build-up and short-term changes in vascular tone.

Frank-Starling Mechanism: Pioneering work of Otto Frank and Ernest Starling that provides a framework for relating cardiac muscle length, tension, and activation to parameters such as preload and cardiac output.

Heart Failure: Pathological condition whereby the heart has reduced cardiac output, leading to backup of blood volume in the venous system and increased central venous pressure; causes include coronary artery disease, valvular disease, and myocardial infarction.

Intravenous Cannulation: Insertion of a flexible tube or cannula into the venous compartment to allow for passage of a catheter; a procedure commonly performed when inserting a central intravenous line.

Plethysmograph: Instrument used to measure changes in volume of a vessel or organ.

Sphygmomanometer: An instrument for measuring arterial blood pressure, also known as a blood pressure cuff.

Ultrasound Imaging: Procedure by which high-frequency sound waves are reflected off internal tissues or organs to produce echoes, which are analyzed to form an image of body tissues, called a sonogram; ultrasound is commonly used in fetal monitoring, and more recently used in cardiology and radiology.

Using Object Oriented Technologies to Build Collaborative Applications in Healthcare and Medical Information Systems

INTRODUCTION

The adoption and diffusion of e-health and the application of IT in healthcare is increasing at a rapid rate. Both European and U.S. governments are making e-health a priority on their agendas. The technical infrastructure required to support initiatives such as community healthcare integrated networks (CHINs) and telemedicine efforts is often dependent upon connecting different types of computer networks, each running on different types of technologies so as to present to the user the image of a single virtual electronic health highway. It is generally agreed that current software development technology cannot deliver this due to limitations of restricted scalability, fragmented management, and inflexibility in providing business support.

One of the potential solutions may be the use of Object Oriented (OO) technology. This article explores the feasibility of combining OO technologies with healthcare based workflow management systems (WFMS). We introduce the concept of workflow technologies and discuss the main advantages and limitations of WFMS. We detail the circumstances in which the use of WFMS could be considered and the technological factors necessary for its successful implementation.

We also present an Object Management Group (OMG) model, analysing it in the context of the support offered for WFMS. The main advantages and disadvantages of the model are discussed. A workflow management coalition (WFMC) model is then contrasted with the OMG management model in order to identify the architectural differences between them. We focus on the relationship between workflow concepts and the position of the two reference models (WFMC and OMG) and on the use of UML in the design of information systems. We conclude by summarizing our findings on the extent to which OO technology can be used to build collaborative applications in healthcare and medical information systems.

BACKGROUND

During his State of the Union Address in January 2004, President George Bush affirmed the intention of the government to emphasize the role of technology in administration and delivery of healthcare in the United States (Bush, 2004). Similar sentiments have been voiced by the European leaders (Global Medical Forum Foundation, 2005; The Oslo Declaration on Health, 2003), and the World health organization ("E-Health in Eastern Mediterranean," 2005; A Health Telematics Policy, 1997). Both European and U.S. authorities define their initiatives primarily in terms of medical information technology centering on computerized patient record (CPR) or, in more acceptable parlance, the electronic health record (EHR). See Brailer and Terasawa (2003).

WHO's platform statement (A Health Telematics Policy, 1997) speaks of "health telematics policy," an all inclusive term that incorporates not only EHR but essentially all healthcare services provided at a distance and based on the use IT.

While implementation of these concepts is preeminently realistic in the context of EU and the U.S.A., the WHO plan appears, for many reasons, a combination of a list of good ideas and delineation of significant obstacles that make the good ideas seem almost futuristic. In response to the inefficiency of the highly fragmented programs to address even the most urgent aspects of healthcare across the globe, a demand for the development of a new rule set (Banjeri, 2004; Barnett, 2004; Olutimayin, 2002; Onen, 2004) governing the future actions began to emerge—the quest for the "doctrine of global health."

To address this void, von Lubitz and Wickramasinghe developed the doctrine of "networkcentric healthcare" (von Lubitz & Wickramasinghe, 2006a, 2006b, 2006c), which calls for the development of interconnected information grids that, together, constitute a powerful and well-structured network that facilitates information sharing among all participants within the operational continuum (Cebrowski & Garstka, 1998; Stein, 1998). Consequent to improved information sharing is the enhancement of its quality and integrity which, in turn, escalates the level of situational awareness that is the foundation for efficient, real-time collaboration among the involved entities, their self-synchronization, and operational sustainability which leads to a dramatic increase in mission effectiveness (Cebrowski & Garstka, 1998).

As described by von Lubitz and Wickramasinghe (2006a, 2006b, 2006c), networkcentric healthcare operations must be conducted within the intersecting territory of three mutually interconnected and functionally related domains (Garstka, 2000):

- The *physical domain* which encompasses the structure of the entire environment healthcare operations intend to influence directly or indirectly, for example, elimination of disease, fiscal operations, political environment, patient and personnel education, and so forth.
- The *information domain* which contains all elements required for generation, storage, manipulation, dissemination/sharing of information, and its transformation and dissemination/sharing as knowledge in all its forms. It is here that all aspects of command and control are communicated and all sensory inputs gathered.
- The *cognitive domain* relates to all human factors that affect operations, such as education, training, experience, political inclinations, personal engagement (motivation), "open-mindedness," or even intuition of individuals involved in the relevant activities. Difficulties in metrics relevant to the cognitive domain notwithstanding, a body of experimental studies begins to emerge that will, ultimately, provide close quantitative relationships to other domains that govern healthcare operations space (Abel-Smith, 1989; Back & Oppenheim, 2001; Bodner et al., 1986; Newby, 2001; Roberts & Clifton, 1992; Wetherell et al., 2002).

The essential and enabling technology element of NCHO is the Worldwide Healthcare Information Grid (WHIG) that allows full and unhindered sharing of information among individual domains, their constituents, and among constituents across the domains (von Lubitz & Wickramasinghe, 2006a, 2006b, 2006c). In order to perform such a function, the WHIG must consist of an interconnected matrix of ICT systems and capabilities (including communication platforms, data collection, storage, manipulation/dissemination, and sharing), associated processes (such as information and knowledge storage and retrieval, management and their dissemination/sharing), people (e.g., healthcare providers/investigators, administrators, economists, politicians, lawyers, ICT personnel), and agencies (governmental and Non-Governmental Organizations or NGSs) at local/national/international level.

However, von Lubitz and Wickramasinghe have not detailed the technological make up of the WHIG which is the backbone of NCHO. We contend that the ultimate use of Object Oriented (OO) technologies as we discuss in this article will be to provide the technological backbone to such initiatives as NCHO or smaller scale initiatives such as community healthcare integrated networks (CHINs) or e-health and telemedicine applications. To fully appreciate the power and benefits that OO technologies bring to effecting superior healthcare delivery, it is necessary first to understand the evolution of IT applications in healthcare and the key challenges to date.

EVOLUTION OF IT APPLICATIONS IN HEALTHCARE

In the 1970s, the focus of IT applications in healthcare was to facilitate better healthcare administration, particularly in routine administrative tasks such as the calculation of patient charges for reimbursement . In the 1980s, the focus shifted to the development of clinical systems to aid in patient diagnosis and treatment (Johns, 1997; Rao, 2001). This trend continued until the late 1990s. A distinguishing feature of this trend was that most of the IT applications in healthcare were developed for very specific uses such as standalone software applications (Rao, 2001). This lack of interoperability has today become a significant challenge for the healthcare sector.

Simultaneously, in the last 40 years, there has been a significant evolution in system architectures that form the substrate of IT applications. Organizations have evolved from a centralised to a distributed computing architecture (Ganti & Brayman, 1995). This change of emphasis in system architectures has been accompanied by the emergence of client/server and object oriented (OO) technologies. By the 1990s, these two technologies had signalled the coming of age of the distributed computing architecture (Ganti & Brayman, 1995).

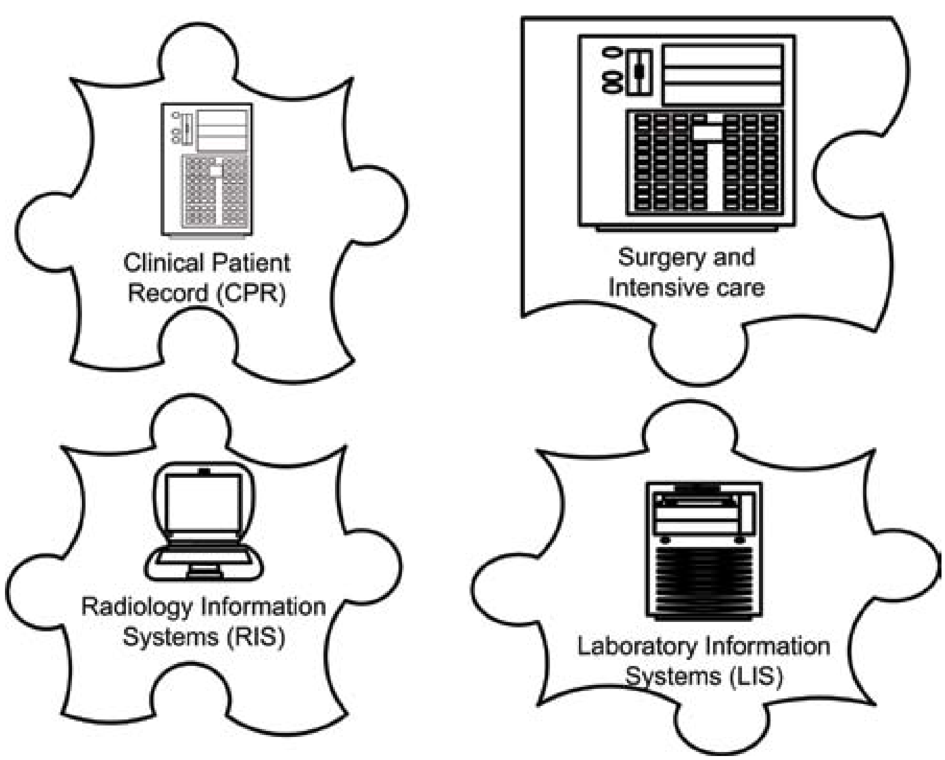
Modern IT applications have evolved to provide basic support for services to aid knowledge processing, problem-solving, and coordination by incorporating concepts such as intelligent design systems, workflow management, and intelligent agents (Ganti & Brayman, 1995). These changes (i.e., evolution from a centralised to a distributed computing architecture technologies) have had implications on the healthcare sector. Even IT applications in healthcare have undergone a drastic change (Ohe, 1998; Pollard & Hammond, 1998; Rao, 2001).

In the centralised computing architecture, IT applications in healthcare were characterised by being written in a proprietary language, specifically made to function on a particular hardware platform, and, most importantly, had very limited interfaces (connections, ability to communicate) with other healthcare information systems (clinical, diagnostic, etc.) (see Figure 1). Moreover, they did not have to ability to interconnect with common desktop applications (word processing, etc.).

This lack of interoperability between different but related healthcare systems (see Figure 1) has been cited as one of the main challenges facing the healthcare sector (Ferrara, 1998; Greenberg & Welcker, 1998; Harrington, 1993). This problem has been further aggravated by the advent of modern IT applications in healthcare that are centred on the power of the Internet (Egger, 2000; Weber, 1999).

The use of OO technologies in conjunction with protocols such as the HyperText Transport Protocol (HTTP) and the Wireless Application Protocol (WAP), with devices such as Personal Digital Assistant (PDA), have allowed patients and doctors to remain in close contact

Figure 1. Limited interfaces between IT healthcare apps



(Dwivedi, Bali, James, & Naguib, 2001; Farkas, 1999; Pollard & Hammond, 1998). These new technologies (OO, HTTP, and WAP) have collectively triggered the connectivity revolution in healthcare. Simultaneously, these new technologies have been accompanied by a revolution in medical electronics and human genome research. It is estimated that in the next 10 years, more then 100,000 medical devices will be launched in the healthcare sector (Egger, 2000).

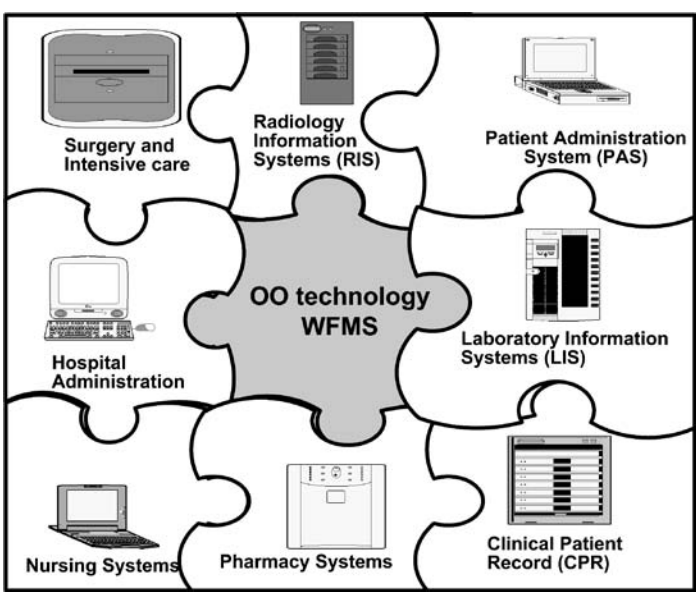
Advances in the application of computer technology have largely driven the biomedicine revolution in the healthcare industry. As a result of the above revolution, modern day healthcare industry is witnessing "the emergence and proliferation of entire new scientific disciplines—molecular biology, economics, bioinformatics and proteomics—which are revealing the secrets of genes, proteins and their functions" (Watanabe, 1999, p. 27). This has implications for the healthcare process.

Advances in pharmaceutical developments will in turn be driven largely by these new scientific disciplines. Our understanding of the human genome could result in the discovery of new treatments based on new pharmaceutical compounds. It has been estimated that in the near future new pharmaceutical compounds could replace 50% of today's in-patient services (Egger, 2000). It is clear that the healthcare system of the new millennium will be computing based and would revolve around Information Technology (Egger, 2000).

The benchmark for survival for healthcare institutions in the future will shift from the current emphasis on "facilities, range of services,or clinicians associated with the organization" to the "experience that the healthcare institution has in providing that care" (Egger, 2000, p. 22), which in turn would require an effective integration of all the different systems associated with healthcare treatment, diagnosis, and delivery. The vision of the healthcare system of the new millennium is one where all the different information systems relating to healthcare delivery are connected seamlessly and appear to the user as a virtual system, see Figure 2 (Johns, 1997; Mercer, 2001).

Object Oriented Technology (OOT) and Workflow Management Systems (WFMS) are the two most promising technologies that stand out from the entire set of all the technologies that can provide a seamless integration for a virtual healthcare system for the future (see Figure 2). We contend that these two technologies, in combination, hold the potential of transforming the vision of the healthcare system of the new millennium into a reality. As mentioned earlier, one of the biggest paradigm shifts in computing was the evolution of system architectures from centralised computing architecture to a distributed computing architecture. This paradigm shift brought out to the forefront the enabling power of client/server computing (Khanna, 1994).

Figure 2. Vision of an integrated healthcare system in the new millennium



EVOLUTION OF OOT

One of the main reasons for the popularity of the client/server revolution is the sharing of data, applications, and the processing power between different clients and the server, thereby improving the efficiency of the system. OOT, and in particular distributed objects, are likely to be the driving force that will transform the vision of an integrated distributed computing architecture into reality; see Table 1 (Orfali, Harkey, & Edwards, 1996).

OOT is a software development methodology that uses a commonly accepted body of knowledge that includes notation diagrams to represent the design of a software application. One of the main advantages of adopting the OO methodology is that it reduces the software development cycle; it offers support in extending the application further by allowing reuse of existent software components.

In addition to the above, OO methodology offers more flexibility in building and interfacing the proposed /existing application with other applications. This not only makes it easier to maintain software applications produced under the OO methodology, but also substantially reduces the cost of software development (Athwall & Moreton, 1995).

Prior to the mid 1980s, all the major types of Hospital Information Systems (HIS) were based on the centralized computing architecture (Khanna, 1994; Ohe, 1998). These legacy HIS used to consist of a number of powerful mainframes which were linked to a very large number of dumb terminals (Ohe, 1998).

One of the main problems in the 1990s was how to utilise these legacy systems with the modern HIS. This gave impetus to the need for having a computing architecture that enabled coordination between different resources (hardware and software) that was available on a network, and the concept of the distributed computing architecture that could enable the above to become a reality (Khanna, 1994).

Table 1. Evolution of client/server with OOT

	1982	1986	1990	1995	1998 +
First Wave	File Servers				
Second Wave		Database Servers			
			Groupware		
Third Wave				Distributed Objects	

DISTRIBUTED COMPUTING BASED CLIENT/SERVER ARCHITECTURE

One of the main disadvantages of early client/server technologies was that there was a clear separation between the two, resulting in the creation of two monoliths instead of one (Orfali et al., 1996). Any vision of a healthcare system in the new millennium would feature knowledge-intensive applications. These applications would evolve from a convergence of digital and multimedia technologies and all of which are likely to run a large number of heterogeneous, autonomous, and distributed information systems (Tsiknakis, Chronaki, Kapidakis, Nikolaoul, & Orphanoudakis, 1997).

This poses severe limitations for existing client/server applications, most of which are based on old technologies (see Table 1). Distributed objects are being regarded as a technology that holds a lot of potential in empowering client/server applications to deal with the challenge of repeatedly integrating a large amount of multimedia clinical data from a wide number of heterogeneous, autonomous, and distributed HIS within a very limited time span (Orfali et al., 1996; Tsiknakis et al., 1997).

Distributed objects through the use of components can achieve the above by subdividing today's monolithic client/server applications into self-managing components that can interact with each other and move across networks and operating systems (Orfali et al., 1996). Distributed objects take full advantage of having the data and business logic which is encapsulated within them to interact with other (old) legacy applications via object wrappers (Orfali et al., 1996). This makes the system more flexible as it takes full advantage of the concept of modularity in software development.

DEFINITION AND INTERRELATIONSHIP BETWEEN DISTRIBUTED OBJECTS AND COMPONENTS

Distributed objects can be defined as an independent piece of created code that is visible to other remote clients irrespective of the language and compiler used to create it. It has the ability to be accessed by other remote clients via method invocation. To put it in simple terms, a distributed object is a blob of intelligence that can live anywhere on the network and which can message each other transparently (Orfali et al., 1996).

There is no precise definition of the term component as it represents diverse features depending upon the perspective taken. However, any definition of components must include the fact that it is a reusable piece of software that is independent of any application (Orfali et al., 1996). Components can be a black box (i.e., they support polymorphism and encapsulation but not inheritance) or white box that supports all three mentioned concepts of traditional objects (Orfali et al., 1996).

A broad overview of the relationship between components and objects could be verbalised to state that each component is an object that is not bound to a particular program, computer language, or implementation (Orfali et al., 1996). The interrelationship between distributed objects and components is that all distributed objects are components but not all components are objects or distributed objects, for example, OLE and black box components (Orfali et al., 1996). This is because components have synergistically evolved from three paradigms (1) the distributed computing architecture, (2) the client/server revolution, and (3) the OO revolution.

Components are different from traditional objects in the sense that components are standalone objects that can plug-and-play across networks, applications, languages, tools, and operating systems (Orfali et al., 1996). As each component has its own intelligence and data, the use of components would allow developers and users to create applications on the fly very easily. Moreover, by using components based on distributed objects on a client/server platform, it is possible to very simply build a large number of customised software applications. The use of components represents the ultimate form of client/server distribution and in the near future almost all desktops would be using client/server distribution (Orfali et al., 1996).

Table 2. Evolution of DBMS

Search capabilities/ multi-user support.	Relational DBMS	Object Relational DBMS
	File Systems	Object Oriented DBMS
	Data complexity/ extensibility	

If we look at the evolution of database management systems (DBMS) in the context of their suitability for multi-user support whilst handling complex data types, the following picture emerges (see Table 2) (Connolly & Begg, 1998).

A previous study has noted that almost all modern day HIS are based on traditional relational database systems. However, it has been acknowledged that relational database systems cannot deal with the large volumes of clinical data that come in different formats (audio, video, images, and multimedia) (Farkas, 1999). This study examined both extended relational and object relational databases (see Table 2) and on their ability to store and access clinical data that is multimedia in nature, and come to the conclusion that in a HIS context, object-oriented databases is the best solution (Farkas, 1999). All the existing HIS use client/server technology with the server running a traditional relational database that cannot store and supply multimedia data (X-ray images, etc.) effectively, while their client side often uses peculiar user interfaces that are difficult to govern and are usually not platform independent (Farkas, 1999). The main rationale behind a relational database application is that it establishes modularity between data—modularity which is not established not because it is an essential requisite, but only because it makes the system easier to implement and manage (Farkas, 1999).

WFMS

A Workflow Management System (WFMS) is an ideal software application that assists in the processing of tasks. At a basic level, workflow can be thought of as a series of actions that help in the automation of tasks.

Since workflow refers to a series of tasks, it implicitly refers to scheduling or routing (i.e., which is the best possible way of performing a particular group of tasks). Since it refers to tasks which have to be performed, it would require responsibility at a basic level. Thus a workflow model can be thought to be a value adding process which is carried out in an efficient and effective manner with clear responsibilities for each of the participants in the process (Workflow Management Coalition, 1995). The WFMS uses process instances to instantiate each business process, and each process instantiation represents a workflow. This gives the WFMS the facility of having several workflows of the identical business process, at the same time. This means that each of them (each process instantiation) can act in a different manner. The advantages here are comparable to the advantages given by multitasking and object orientation (Workflow Management Coalition, 1999).

The Workflow Management Coalition (WFMC) (1995) have provided a Workflow Reference Model (WRM) that has the following five main interfaces:

1. **Process definition tools:** This interface provides specifications for process definition data and interchange.
2. **Other workflow enhancement services:** This interface provides support for interoperability between different workflow systems.
3. **Invoked applications:** This interface provides support for interaction with a variety of IT application types.
4. **Workflow client applications:** This interface provides support for interaction with the user via desktop functions.
5. **Administration and specifications for process definition and data interchange:** This interface provides support for system monitoring and metric functions to facilitate the management of composite workflow application environments.

One of the main weaknesses of the WRM model recommended by the WFMC is that it does not support workflow implementation "across a heterogeneous, distributed infrastructure" (Santanu, Edwin, & Jarir, 2001).

This drawback forces the workflow system architecture to be a client/server system architecture where all the main workflow services are run from the workflow server and, as such, it becomes "monolithic" and "centralised." The main disadvantage of the centralised workflow system architecture is that it "does not address the needs of distributed workflows on a WAN" and thereby prevents the workflow to function in a distributed manner (Santanu et al., 2001). This is a very serious drawback, particularly considering that the future of workflows is connected with the Web or, at minimum, across multiple sites.

The Object Management Group (OMG) is an international body whose objective is "to promote the theory and practice of OOT" by establishing industry standards (Athwall & Moreton, 1995). OMG has challenged the WRM by providing its own version of workflow systems.

The OMG architecture uses CORBA as middleware (a software that helps in assuring client/server communications) that enables distributed objects to cooperate. The OMG architecture uses Object Request Brokers (ORBs) to provide the basic functionality for establishing communication between objects.

This is achieved via two interfaces: (1) the application specific interface and/or (2) the Domain interface. All the CORBA facilities given by the OMG can be classified into: (1) Object services (OSs), which are families of system services, that are universal and have standardised interfaces, and (2) Common Facilities (CFs), which specify the specific services for a particular application domain (e.g., healthcare) (Pollard & Hammond, 1998). In the OMG model, workflow is a part of its CORBA facilities and falls under common facilities (Leymann & Roller, 2000).

The main difference between these two models is that, under the WFMC model, the workflow engine has a centralist character, while in the OMG architecture workflows are just objects. The WFMC model uses five interfaces whilst the OMG model uses just objects, thus fully exploiting the CORBA facilities (both object services and common facilities).

FUTURE TRENDS

Modern day healthcare organizations have realised that in the future their survival would depend upon their ability to give the caregiver access to such information that would enable the caregiver to deliver personalised clinical diagnosis and treatment in real-time in very specific clinical contexts (a process termed as Information Therapy). Information therapy is defined as the "prescription of specific, evidence-based medical information to a specific patient, caregiver, or consumer just in time to help someone make a specific health decision or behaviour change" (Kemper & Mettler, 2002, p. 17). This vision has been translated into concepts like Integrated Delivery System (IDS) and Community

Health Information Networks (CHIN) (Lang, 1997; Mercer, 2001; Morrissey, 2000).

IDS refers to a HIS that is a business model based on computing technologies such as OO "to share key data, with partners and providers, that will allow faster and more accurate decision making… to deliver care to a broader population with fewer requirements for expensive and scarce resources" (Lang, 1997, p. 18). CHINs are integrated HIS based upon a combination of different technology platforms that are connected to enable support for data sharing amongst different healthcare providers (Mercer, 2001).

Both IDS and CHIN are very similar in nature and both refer to an integrated network for allowing the delivery of personalised healthcare. We argue that in the near future component technology would be the driving force behind all HIS as it would support new ways of combing islands of knowledge, and present the knowledge acquired to the user as an integrated whole. In addition to the above, component technology would also provide support for the use of modern computer techniques (such as Intelligent Data Mining tools, WFMS) to discovering previously undiscovered patterns on a case-to-case basis, thereby bringing to the fore a truly integrated healthcare system that supports delivery of personalised healthcare.

On a grander, global scale, such component technology and the integral role for the OO-platform we have discussed is essential in supporting networkcentric healthcare operations (NCHO) as outlined by von Lubitz and Wickramasinghe (2006a, 2006b, 2006c). The constructing of NCHO is clearly a large task that requires to coordination of several players at a global level. However, the WHIG (as discussed earlier), the world healthcare information grid and backbone of NCHO, cannot be constructed without utilising these component technologies and OO platform. To date actualising the structure of the WHIG has not been discussed.

We contend that the ultimate use of Object Oriented technologies for healthcare as we have discussed in this article will be to provide the technological backbone to such initiatives as NCHO. NCHO represents the new paradigm for healthcare delivery while the OO technologies coupled with the WFMC model is an essential enabling criterion and critical success factor fore realising superior healthcare delivery.

CONCLUSION

Old legacy HIS were predominantly used to allow computerization of information to aid in providing financial information and to assist the healthcare managers in having centralized control over different healthcare activities (Lang, 1997).

Healthcare institutions in the 1990s have realized that the old model does not work as the nature of information required is different. Contemporary healthcare institutions are under ever-increasing pressure to find new ways of reducing healthcare costs whilst simultaneously increasing administrative and clinical efficiency to provide a superior level of quality relating to patient care (Carlos & Comaford, 1998). Modern day HIS have a number of clinical information systems each of which is committed to diverse healthcare providers (nurses, doctors, etc.) in different clinical disciplines (radiology, surgery, etc.) to effectively ensure coordination among these necessitates the integration of hospital-wide available information (Tsiknakis et al., 1997).

There is an increasing realization that an integrated HIS is an infrastructure prerequisite if healthcare institutions are to successfully meet the above mentioned challenge (Farkas, 1999; Ohe, 1998; Pollard & Hammond, 1998; Tsiknakis et al., 1997). The old model of HIS cannot meet the above challenge as the old legacy HIS running monolithic computing applications based upon centralized computing architecture cannot ensure an integrated HIS (Lang, 1997; Tsiknakis et al., 1997).

The distributed computing architecture is the only means of providing the integration between different heterogeneous systems that are autonomous and distributed (Lang, 1997; Pollard & Hammond, 1998; Tsiknakis et al., 1997). Another factor which holds a lot of potential in ensuring that the vision of an integrated HIS becomes a reality is the Unified Modelling Language (UML). Developed by the OMG, UML is a graphical and object-oriented notation methodology for describing processes in a form that helps both developers and users (Botelho, 2000a, 2000b). The advent and acceptance of UML as the defacto industry standard has made possible a standard way to depict graphically the design of an information system that can be understood by all the stakeholders at any stage of the software development cycle (Botelho, 2000b). Despite being of OMG specification, UML is independent of any middleware technology, that is, OMG's-CORBA, Microsoft's Component Object Model (COM), and Sun's Enterprises JavaBeans (EJB) (Sutherland, 1998). It is clear that, in the new millennium, an innovative approach would have to be adopted to ensure that the vision of a virtual integrated HIS becomes a reality. We conclude by reiterating that the current gap between different islands of heterogeneous HIS can be bridged if the technologies discussed above (OO, Component Technology, Distributed Computing, WFMS, and UML) are concurrently adopted.

INTRODUCTION

Telemedicine aims at equal access to medical expertise irrespective of the geographical location of the person in need. New developments in Information and Communication Technologies (ICT) have enabled the transmission of medical images in sufficiently high quality, which allows for a reliable diagnosis to be determined by the expert at the receiving site (Pande, Patel, Powers, D'Ancona & Karamanoukian, 2003; Lacroix et al., 2002).

At the same time, however, these innovative developments in ICT over the last decade bear the risk of creating and amplifying a digital divide in the world, creating a disparity between the northern and southern Euro-Mediterranean areas (Dario et al., 2005; Graschew, Rakowsky, Roelofs & Schlag, 2003a; Graschew, Roelofs, Rakowsky & Schlag, 2004).

In recent years, various institutions have started Euro-Mediterranean telemedicine projects (EMISPHER, www.emispher.org/; BURNET, www.burnet.org/; PARADIGMA, www.paradigmamed.org; EMPHIS, www.emphis.org/; EUMEDGEN, www.eurogene.org; ODISEAME, www.odiseame.org; EUMEDCONNECT, www.eumedconnect.net/; GALENOS, www.rrk-berlin.de/op2000/Deutsch/projekte/galenos.html), which were intended to foster a cooperation between the European EU-Member countries and the Mediterranean countries (Graschew, Roelofs, Rakowsky, & Schlag, 2002; Graschew, Roelofs, Rakowsky, & Schlag, 2003b; Rheuban & Sullivan, 2005; Wootton, Jebamani, & Dow, 2005).

All these projects have demonstrated how the digital divide is only part of a more complex problem: the need for integration. Therefore, provision of the same advanced technologies to the European, Mediterranean, and Adhering countries should be the final goal for contributing to their better dialogue for integration.

BACKGROUND

Already in the framework of the EMISPHER project (Euro-Mediterranean Internet-Satellite Platform for Health, Medical Education and Research, EUMEDIS pilot project 110, see www.emispher.org, 9/2002-12/2004, cofinanced by the EU in the framework of the EUMEDIS program), an Internet-satellite platform for telemedicine in the Euro-Mediterranean region was established and put into operation (Graschew, Roelofs, Rakowsky & Schlag, 2005). Other telemedicine systems are used; for example, for tele-ultrasound in rural areas where telementoring by live videoconferencing allowed guiding the ultrasound technician to record additional images of the patient (O`Neill, Allen & Brockway, 2000); for clinical assessment of pediatric burns, which showed a good agreement between the face-to-face consultation and seeing the patient via videoconference (Smith, Kimble, Mill, Bailey, O'Rourke & Wootton, 2004); and for home telecare services likely to improve quality of health services

(Guillen et al., 2002). Other systems are described in Sable (2002); Latifi, Peck, Porter, Poropatich, Geare & Nassi (2004); and Eadie, Seifalian & Davidson (2003). Currently the network consists of 10 partners in Morocco, Algeria, Tunisia, Egypt, Turkey, Italy, Greece, Cyprus, France, and Germany (see Figure 1) and offers applications in the domains of medical e-Learning (courses for undergraduates, graduates, young medical doctors, etc., in real time and asynchronously), real-time telemedicine (second opinion, demonstration and dissemination of new techniques, telementoring, etc.), and e-Health (medical assistance for tourists and expatriates). The EMISPHER network serves as a basis for the introduction of a virtual hospital in the Euro-Mediterranean region.

Due to the experience in the exploitation of previous European telemedicine projects and, in particular, to activities carried out in the framework of the EUMEDIS program, an open Euro-Mediterranean consortium would like to propose the Virtual Euro-Mediterranean Hospital (VEMH) initiative.

VEMH aims to facilitate and accelerate the interconnection and interoperability of the various services being developed (by various organizations at various sites) through real integration. This integration must take into account the social, human, and cultural dimensions, and strive toward common approaches but open and respectful of cultural differences: multilateral cooperation instead of aid.

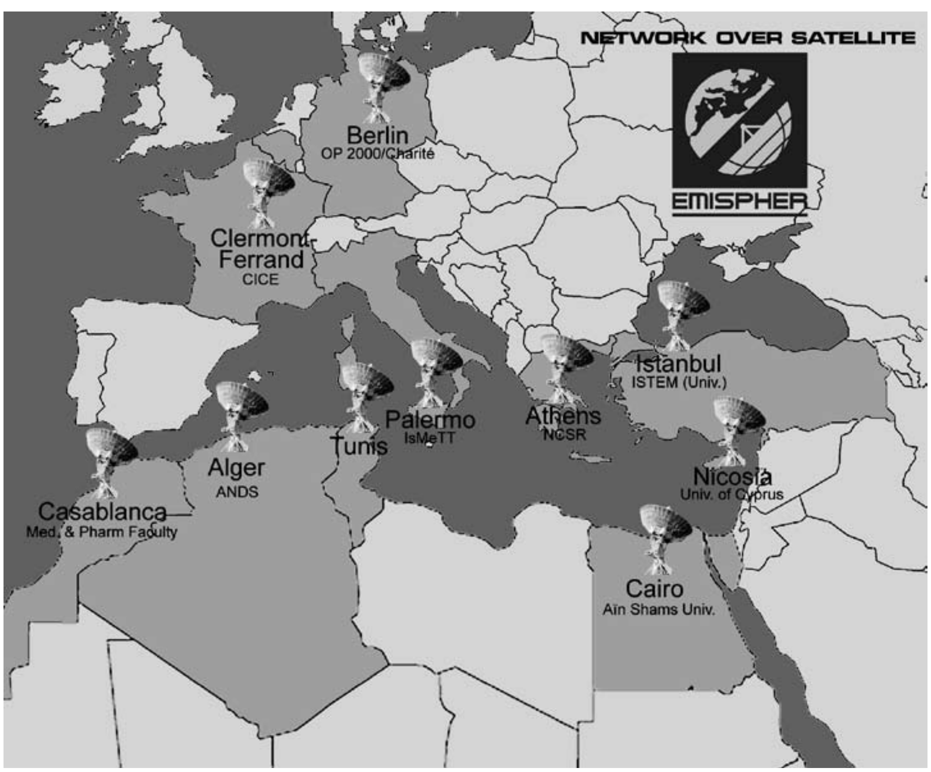
THE VIRTUAL EURO-MEDITERRANEAN HOSPITAL (VEMH)

VEMH will provide a heterogeneous integrated platform consisting of satellite links and terrestrial links for the application of various telemedical services. Evidence-based medicine will be integrated more and more in the following three main dedicated medical services.

E-Learning

In the project, the Mediterranean Medical University (MeMU) will be developed. The leading medical centers

Figure 1. Centers of excellence in the EMISPHER project interconnected by a satellite-based network for bridging the digital divide in the Euro-Mediterranean health care area



integrated in the network provide pedagogical material and modules for synchronous and asynchronous e-learning in their medical specialties: endoscopic surgery, gynecology-obstetrics, infectious diseases, liver and multi-organ transplantation, and so forth. The exchange among the partners of various countries allows for improved qualification of undergraduate and graduate students, hospital staff, general practitioners, and so forth (see Figure 2).

Real-Time Telemedicine

VEMH offers second opinions, tele-teaching and tele-training, tele-mentoring, and optimization of the learning curve. These real-time interactive telemedical applications contribute to improved quality of patient care and to accelerated qualification of medical doctors in their respective specialty. Thus, this international network of distributed but integrated competence contributes directly and indirectly to improved health care (see Figures 3 and 4).

Medical Assistance

As tourism constitutes a substantial economical factor in the Mediterranean region, and because of the increasing mobility of the population, continuity of care through improved medical assistance is of major importance for improved health care in the Euro-Mediterranean region. The introduction of standardized procedures, integration of the platform with various local and national communication systems, and training of medical staff involved in medical assistance allow for shared management of files related to medical assistance (medical images, diagnosis, workflow, etc.).

Evidence-Based Medicine

The next service in VEMH will be Evidence-Based Medicine (EBM). EBM cannot substitute the agreement on concrete and individual therapeutic procedures to be followed; however, even for the individual patient, EBM provides a more solid base for individual decisions. EBM contributes to better disease management.

Figure 2. Interactive tele-education session between IsMeTT (Palermo) and UCY (Cyprus) in the EMISPHER Project

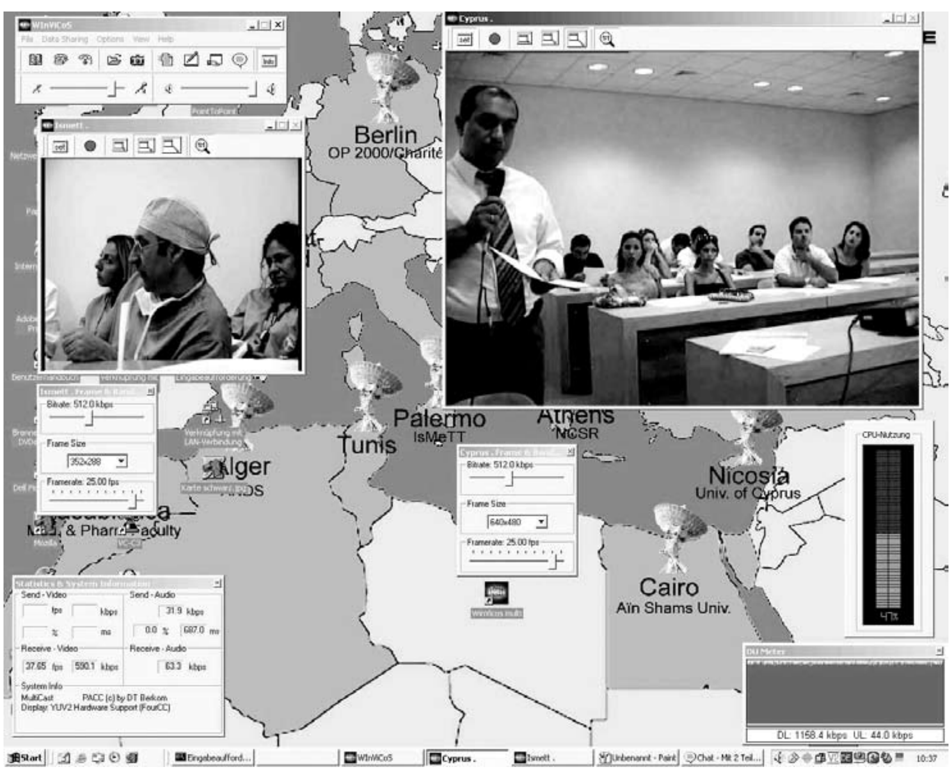


Figure 3. Interactive multipoint tele-consultation during laparoscopy (OP 2000 (Berlin), FMPC (Casablanca), and CICE (Clermont-Ferrand) in the EMISPHER Project

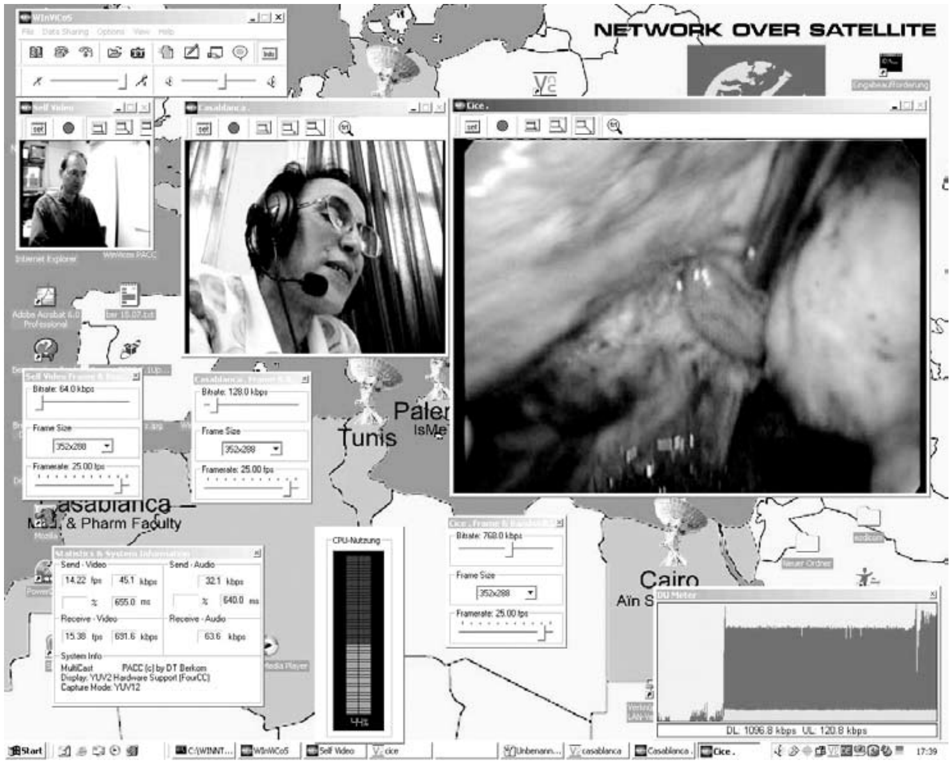

Figure 4. Teleconsultation between OP 2000 (Berlin), ANDS (Algiers), and IsMeTT (Palermo); a live video sequence of an ultrasound investigation is transmitted and diagnosed by the connected experts

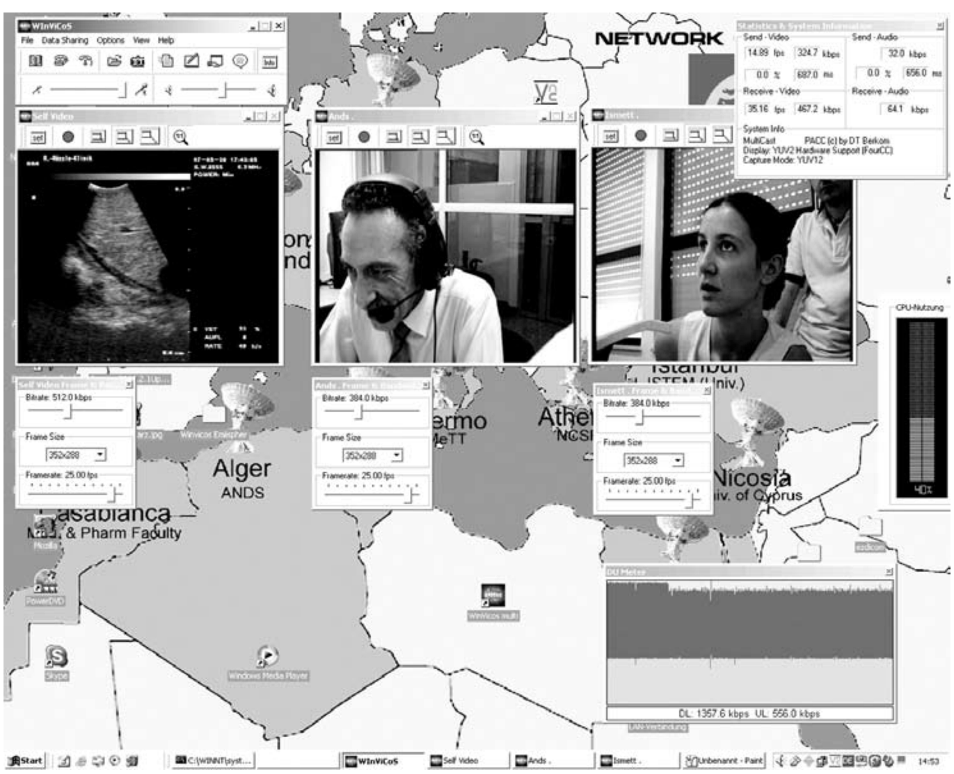

Health care policymakers can also expect great potential from EBM.

Fellowship Program

VEMH will offer individual grants to young medical doctors for training in clinical and scientific organizations of the network. The scope of the fellowship program is to allow young medical doctors to develop and gain experience in a multicultural and multidisciplinary environment.

Methodology and System Architecture of VEMH

Improvement of the methodology of the VEMH network of competence is based on the management of clinical outcomes as well as the integration of various telemedical solutions in one platform to support many medical applications. The individual requirements of the user can be represented as matrix columns and the various applications with integrated technological solutions as matrix rows, while low access costs serve as selection criteria.

A modular network for the integration and optimization of various applications is created. The newly developed methodologies should be usable for more than one disease. The orientation from technique-oriented toward medical-need-oriented solutions serves as optimization criteria.

To approach the identified telemedicine services, the following requirements need to be considered:

- **Traffic:** Intensive applications such as teleconsultation, telediagnosis, and teletraining require real-time interactivity of the audio and video stream
- **High quality of images and video transmission:** Min. 386 kbps up to 1 Mbps
- **Guaranteed bandwidth:** Transmission of medical data does not allow for transfer delay and quality loss
- **Guaranteed confidentiality of patient data.**

Therefore, satellites, also considering the non-fully operating terrestrial infrastructures of the relevant sites and the bandwidth requirements, are the most fitting infrastructure for the envisaged set of VEMH services.

Given the use of already installed terminals and the already defined procedures for the network adaptation and configuration, it will be possible to start the VEMH activities at the beginning of the project.

Evaluation of the VEMH

The justification of the various VEMH services and applications will be assessed by using a comprehensive evaluation methodology. In particular, this will examine various outcomes, including clinical, organizational, and economic outcomes. The criteria under which such services can be evaluated are based upon the work of Bashshur (1995) and displayed in Table 1. The rationale for using this type of methodology is to ensure that the services or applications are capable of having an

Table 1. Criteria for the evaluation of VEMH services/applications

	Criteria							
	Evaluation of Service or Application							
Variables	**Safety**	**Reliability**	**Acceptability**	**Design**	**Effectiveness**	**Efficiency**	**Cost**	**Impact**
Clinical	✓	✓			✓	✓		✓
Economic					✓	✓	✓	✓

Technical/Standards	✓	✓	✓	✓				✓
Organizational	✓	✓	✓			✓		✓
Social/Political			✓		✓			
Medicolegal/Ethical	✓		✓					

immediate and positive impact upon patient care in the VEMH region.

Each service or application will be properly evaluated using the appropriate quantitative/qualitative tools and measurement processes. The quantitative assessment tools that will be used are cost-benefit analysis and cost-effectiveness analysis. Cost-benefit analysis compares the discounted future streams of incremental program benefits with incremental service or application costs; the difference between these two streams is the net social benefit of the service or application. The aim of the analysis is to identify whether a service or application's benefits exceed its costs. Cost-effectiveness analysis is designed to find the minimum cost of meeting a given target, and, unlike cost-benefit analyses, no attempt is made to estimate the benefits.

Both tools are required for a rational appraisal of the case for adoption, or ongoing use, of various services or applications. Failure to conduct these analyses can result in a waste of human and financial resources that ultimately have an effect on patient care.

Risks, Barriers, and Facilitators

Although the market is promising and the technology is ready (or nearly ready) to be used, the take-up and commercialization of telemedicine services are still uncertain due to a number of barriers:

External:

- Decision-making in health is fragmented with respect to procurement policies, which hinders progress.
- Establishing and building confidence with physicians takes time.
- It still seems that it will be one to two years more before full deployment and therefore a critical mass can be built.
- How the services are packaged and attitudinal changes from within the health sector are also necessary.
- There are numerous organizational issues.

Economic:

- It is difficult to predict the break-even level of services and therefore to determine the minimum level of investment required for break-even services.
- There is a lack of investment in health, and therefore, significant investment is still required.
- Considerable investment in improved management, training and education of personnel, redesigning of care, and logistic processes is necessary.

Legal:

- Ethical issues
- Regulatory framework issues
- Reimbursement issues
- Lack of standardization

Technical:

- Software development is still evolving.
- IP levels of connectivity are also required as a minimum.
- All the services need to be fully integrated into one platform.

In various pilot projects, the technology has been put into place, the necessary applications have been developed, and they proved to be used successfully and meet the needs of its end users. Yet numerous trials and demonstrations carried out during the projects have also highlighted a certain number of issues that potentially could hinder the commercialization process of e-services in the medical sector.

In fact, a market analysis report, "The Emerging European Health Telematics Industry" (February 2000, prepared by Deloitte & Touche for the European Commission Directorate General for the Information Society), also insists that the telemedicine market growth will be dependent upon a number of vital conditions and enabling factors already noted. The report also proposes that four key action lines should be initiated in parallel: consolidation on the supply side, technical integration, investment on the demand side, and accompanying measures that could be the enabling factors required to allow the health telematics market to achieve substantial and exponential growth.

The solutions to such barriers to commercialization do not lie within the scope of the technology and appear to be generic to those up and running telehealth activities worldwide. It is only in North America that new legislation has been introduced to respond to the particular needs of this practice; this legislation is not yet being applied on a federal level, but rather on a state-by-state basis. However, the organizational and cultural aspects that must accompany any new form of practice need the input of other actors both on the governmental, legal, and political scale. Telehealth is not a simple extension of current health systems and cannot be perceived as such.

Solutions to the barriers can be consolidated under the following three main categories:

- Awareness of telemedicine and telehealth as a medical practice
- The need for common standards and norms
- The need for specific legislation

FUTURE TRENDS

The application of advanced telecommunications networks and services to health care practices is still evolving and maturing, and hence, telemedicine has yet to become an established part of day-to-day health care practice in many regions and countries. The main barriers to the development of the telehealth market relate to the organization of health care services and, consequently, support to the connection to and usage of advanced telecommunications networks and services by health care establishments, which is primarily a matter for the public health authorities to consider.

However, the promise of telemedicine to provide equal access to medical expertise irrespective of the geographical location can only be met when not merely the patient's data are transferred, but also a telepresence is created bringing patient and remote experts together using ICT. Besides general interactivity between the two sites, features like telehaptic, telesensation, and remote control of medical devices (e.g., telerobotics) are prerequisites for a real telepresence.

Due to the distributed character of VEMH, data, computing resources as well as the need for these are distributed over many sites in the Virtual Hospital. Therefore, Grid infrastructures and services become inevitable for successful deployment of services such as acquisition and processing of medical images (3D patient models), data storage, archiving and retrieval, and data mining (especially for evidence-based medicine). In order to achieve this, conventional Grid technology has to be expanded to cover not only local computing resources but to a dimension of organization-spanning integrated networks.

CONCLUSION

VEMH will foster cross-Mediterranean cooperation among the leading medical centers of the participating countries by establishing a permanent medical and scientific link. Through the deployment and operation of an integrated satellite and terrestrial interactive communication platform, VEMH will provide medical professionals in the whole Euro-Mediterranean area access to the required quality of medical services, depending on the individual needs of each of the partners.

The applications in the areas of e-Learning, real-time telemedicine, and improved medical assistance contribute to an improved level of health care in the whole Euro-Mediterranean region and build the basis for the introduction of Evidence-Based Medicine.

KEY TERMS

Digital Divide: The explosive developments of Information and Communication Technology (ICT) in the last 10 years have led to a digital divide of the world. Those regions not having access to modern ICT will also lag behind in other fields.

E-Learning: The term e-learning is largely used for continuous medical education, both remote and local. Elementary basic information is usually given for free, whereas more structured and complete information is charged.

EMISPHER: Euro-Mediterranean Internet-Satellite Platform for Health, Medical Education and Research. The main objective of the EMISPHER project is to establish a telemedicine service platform integrating Internet-based and highly interactive applications via satellite to foster networking among all health care professionals in Euro-Mediterranean countries.

Evidence-Based Medicine: Selection of preventive, diagnostic, or therapeutic methods on the basis of scientifically based empirical evidence.

Medical Assistance: Collaborative access to medical images, electronic patient files, and so forth to assist treatment of patients who are abroad for holidays or work.

Quality of Service: The optimal design of networks for telemedicine should meet technical aspects such as transmission bandwidth, delay, jitter, data loss, and so forth (quality of service).

Real-Time Telemedicine: Telemedical applications with real-time transmission of live medical video allowing to work interactively.

Virtual Hospital: The objective needs of the heterogeneous partners in a telemedicine network can only be joined by a real integration of the various platforms and services. A virtual combination of applications serves as the basic idea for the Virtual Hospital.

Visual Methods for Analyzing Human Health Data

C. Tominski

H. Schumann
Institute for Computer Science, University of Rostock, Germany

INTRODUCTION

Day by day, large volumes of health-related data are collected by physicians, health insurance companies, and public authorities. These data are potentially useful to understand the history, monitor the present, and predict the future of the health situation in order to ensure a high level of human health protection. To take advantage of this potential, it is necessary to analyze the data. However, this is a demanding task when facing constantly growing volumes of data.

One approach to tackle the analysis of human health data is the application of **visual methods**. In recent years, visualization of data has become a commonly accepted and widely used tool for the extraction of relevant information from arbitrary data. In many cases, a better insight into complex processes and phenomena can be gained by means of visual representation.

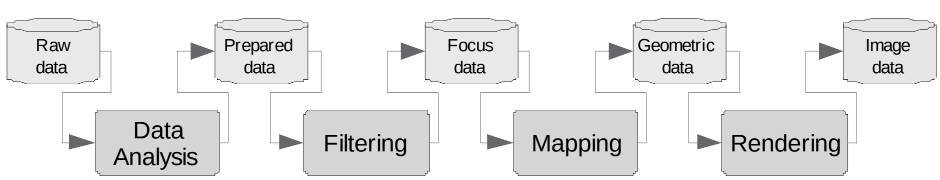
This chapter focuses on the **visual analysis** of human health data that describe the number of cases of different diagnoses in a spatial and temporal frame of reference. To build a common basis for the later description of different visualization methods, basic concepts of visualization as well as an abstract data model are illustrated in Background. In the main part of this chapter, we describe the visualization of human health data at various levels (see Visualizing Human Health Data). Whereas basic visual methods for representing human health data are presented only briefly, the visualization of data with respect to space and time is described in more detail. This chapter concludes with remarks on future work and trends in Future Trends and a brief summary of the key issues described in this article (see Conclusion).

BACKGROUND

Thanks to the capabilities of the human visual system, visualization is a promising tool to analyze larger volumes of data. If visualization is done properly, relevant information can be perceived intuitively, and the underlying data can be understood more easily. By proper visualization, it is meant that a visual representation has to be *expressive*, *effective*, and *appropriate*. Expressiveness relates to the requirement that all relevant information must be expressed in a visualization. Effectiveness depends on the degree to which a visualization supports easy and intuitive interpretation of the visualized facts. A visual representation is appropriate if gained benefit and required effort are balanced with respect to the task at hand.

Technically, the visualization process is implemented in four main steps: *data analysis*, *filtering*, *mapping*, and *rendering* (see Figure 1). They make up the **visualization pipeline** (dos Santos & Brodlie,

Figure 1. The visualization pipeline (dos Santos & Brodlie, 2004)

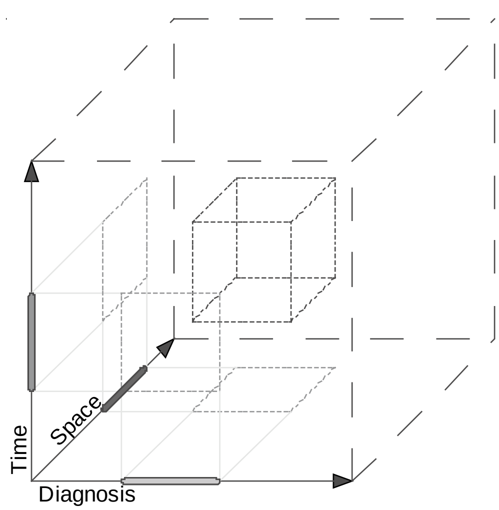


2004). To create a visual representation, a dataset is processed as follows. In the data analysis step, data are prepared for visualization (e.g., by applying a smoothing filter, interpolating missing values, or correcting erroneous measurements). The filtering step selects the data portions to be visualized (denoted as focus data). In the mapping step, focus data are mapped to geometric primitives (e.g., points, lines) and their attributes (e.g., color, position, size). The mapping step is the most critical one for achieving expressiveness and effectiveness, and hence, it is the most interesting one to visualization designers. Finally, geometric data are transformed to visual representations (e.g., images or animations).

Visualization aims at gaining insight by visually representing data. This implies that data characteristics are fundamental for any visualization. For this reason, research on visualization techniques, concepts, or methodologies must be grounded on a description of the addressed kind of data.

In this chapter, we address **human health data** that describe the number of cases of various diagnoses collected in a spatio-temporal frame of reference. Our data describe on a daily basis how many cases occur per diagnosis and per geographical region. From an abstract point of view, the data can be modeled as a data-cube (see Figure 2) that is constituted of three dimensions: time, space, and diagnosis. All these dimensions are of a hierarchical nature. Time uses days, months, quarters, and years; the spatial dimension comprises different administrative partitions of space (i.e., federal state, counties, and municipalities). The diagnoses are linked to the International Classification of Diseases (ICD10), which is hierarchical by definition. By relying on the data-cube model, it is relatively easy to reduce the volume of data to be visualized (e.g., by selecting only subranges of the dimensions [see Figure 2], or by using different levels of hierarchical abstraction). By this, only relevant data have to be extracted from the database. We will see in the next section that different visualization techniques vary in their usefulness for analyzing human health data depending on which dimensions of the data-cube are considered to what extent.

Figure 2. Different dimensions of health data modeled as a data-cube



VISUALIZING HUMAN HEALTH DATA

In the previous section, we indicated that human health data can be analyzed quite efficiently using visual methods. In this section, we suggest concrete **visualization techniques**. Depending on which dimensions of the described data-cube are addressed, different ways of representing human health data are possible:

- Multivariate representation of diagnoses
- Representation of diagnoses with respect to space
- Representation of diagnoses with respect to time
- Representation of diagnoses in time and space

Multivariate Representation of Diagnoses

In this first case, human health data are interpreted without spatio-temporal dependencies (i.e., only the diagnosis dimension of the data-cube is considered). In addition to diagnoses, it is also possible to enhance this abstract interpretation with derived statistics (e.g., maximum, minimum, average, and mean). The advantage of this interpretation is that classic visualization techniques can be applied to represent diagnoses and/or derived statistical characteristics visually. Simple diagram techniques (Harris, 1999) can be used to visualize frequencies of diagnoses (e.g., histograms for absolute frequency, pie charts for relative frequency). More sophisticated multivariate techniques such as Scatter Plot Matrices (Cleveland, 1993) or Parallel Coordinates (Inselberg, 1998) can be used to compare several diagnoses to reveal correlations among them (see Figure 3).

Although these first visual representations are quite abstract, they are nonetheless an initial step toward insight into the underlying data. The general number of cases as well as outliers can be recognized. The drawback is that the data's frame of reference is not considered (e.g., where is a peak in the number of influenza cases?).

Representing Diagnoses in Space

A representation of the spatial frame of reference is necessary to allow an easy interpretation of data features in their geographical context. Maps have been used for ages to illustrate information with respect to geographic realties. Maps have the advantage that they enable the representation of data with respect to natural or manmade spatial phenomena like continents or states, which in our case are given as irregular-shaped regions at different spatial granularities.

If only one diagnosis has to be represented on a map, Choropleth Maps are commonly applied. In Choropleth Maps, each geographical region is color-coded according to the number of cases that occurred for the respective region (see Figure 4a). If multiple diagnoses must be visualized, icon-based techniques are a good choice. Icons are small graphical primitives capable of encoding multiple attributes simultaneously. Furthermore, icons can be placed on maps to communicate spatial dependencies of diagnoses. Figure 4b shows icons representing three different diagnoses for user-selected regions. A challenge that arises when using icons on maps is to avoid occlusion of icons. Particularly for areas with many small regions, this is a demanding task (Fuchs & Schumann, 2004).

Representing Diagnoses in Time

To gain better understanding of the data, it makes sense to consider temporal dependencies. Even though visualization of time-related data is a challenge in its own right (Aigner, 2006), a compact overview of

Figure 3. Health data represented as (a) Scatter Plot Matrix and (b) Parrallel Coordinates

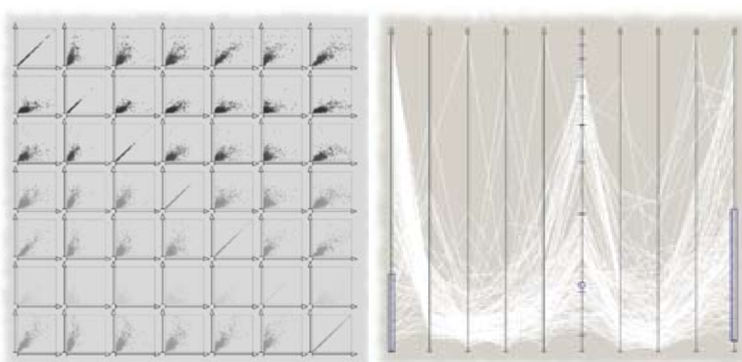


Figure 4. Health data represented via Chorpleth Map (a) and via icons positioned on a map (b)

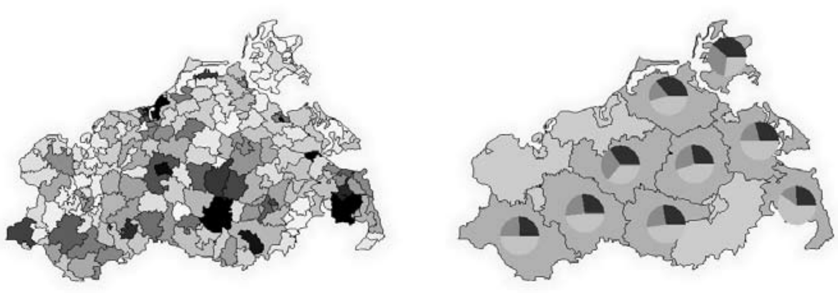

(a) **(b)**

visualization techniques suitable for health data will be given.

A differentiation that must be made when visualizing temporal data regards the elements used for modeling the temporal dimension. Basically, a temporal domain is made up of either time points or time intervals[1]. Frank (1998) suggests a further categorization of time that regards the "shape" of the time axis. Frank distinguishes between linear, cyclic, or branching time. Whereas linear time considers a straight time axis from the past to the future, a cyclic time axis comprises recurring temporal elements (e.g., seasons of the year). Branching time axes are used to describe alternative scenarios of which only one will actually happen. These distinctions imply that, for instance, diagnoses that show cyclically recurring patterns (e.g., influenza) should be represented differently from illnesses that do not show such behavior (e.g., bone illnesses). Whereas techniques for visualizing health data with respect to time intervals or branching time are rare (e.g., (Plaisant, Mushlin, Snyder, Li, Heller & Shneiderman, 1998)), the visual representation with respect to time points given on linear or cyclic time axes is considered in various visualization approaches. From simple yet expressive diagram techniques (Harris, 1999) to more sophisticated techniques such as Spiral Displays (Weber, Alexa & Müller, 2001), TimeSearcher (Hochheiser, 2002) or parallel 3D bar charts (Chitarro, Combi & Trapasso, 2003), a broad range of tools for visually analyzing human health data is available.

A natural goal when representing human health data with respect to time is to reveal relations, and by this, to find correlations in the underlying dataset. How this goal can be accomplished is illustrated by the example of two visualization techniques: time diagrams and spiral displays. A time diagram is useful to compare different diagnoses with respect to a linear time axis (see Figure 5a). A simple line-plot is used to facilitate an intuitive interpretation of the evolution of diagnoses in time. However, for detecting periodic

Figure 5. A single diagnosis represented a time diagram (a) and as a spiral display (b)

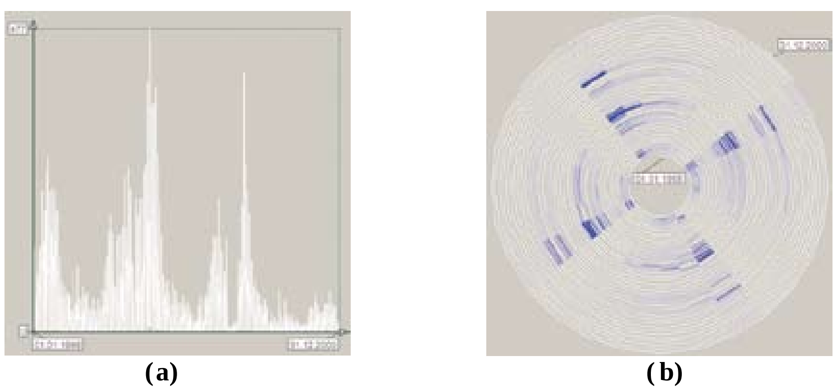

Figure 6. A TimeWheel (a) or a Kiviat Tube (b) can be used to visualize multiple diagnoses with respect to time

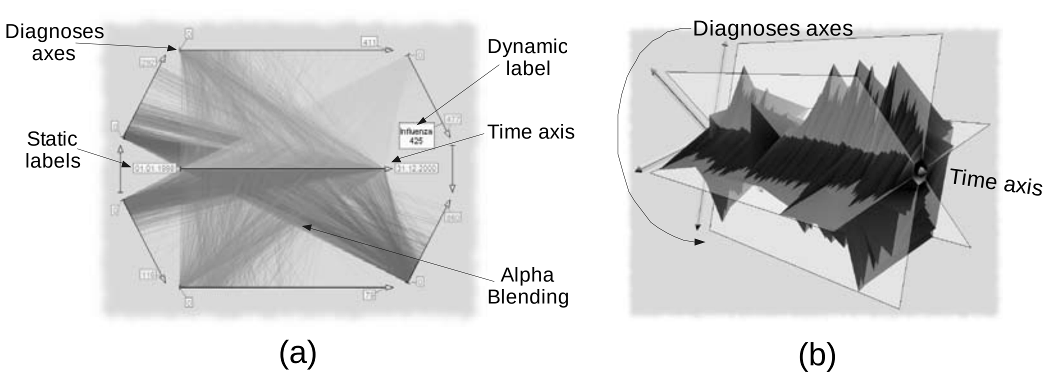


patterns, Spiral Displays are better suited. Spiral Displays represent the time domain as a spiral-shaped time axis (see Figure 5b). To enable the detection of periodic patterns of different length, Spiral Displays allow users to interactively adjust the number of time points encoded per spiral cycle.

Since the two illustrated visualizations and also most of the techniques known in the literature allow the visualization of only a few diagnoses, there is the need to restrict the visualization to important portions of the data. It makes sense to apply statistical analyses in the filtering step of the visualization pipeline to predetermine diagnoses that potentially correlate, and choose highly correlated diagnoses for visualization.

Techniques that are suited for representing multiple diagnoses with respect to a linear time axis are, for instance, the TimeWheel and the KiviatTube (Tominski et al., 2005). The TimeWheel comprises a central, horizontally aligned time axis around which several axes (representing diagnoses) are arranged (see Figure 6a). To represent data values in a TimeWheel, lines descend from the time axis to all other axes. Clearly speaking, for each time step, individual line segments establish direct visual connections between time and all corresponding time-dependent values. The TimeWheel enables users to easily discern the number of cases of the represented diagnoses with respect to a particular time step. The TimeWheel also allows determining where in time certain numbers were measured. Correlations among the diagnoses can be revealed using the KiviatTube. It is constituted by a central time axis and several axes (representing diagnoses) that emanate perpendicular to the time axis. This arrangement of axes makes it possible to render a dataset as a closed three-dimensional surface (see Figure 6b). The KiviatTube can be understood as a data representation that has been extruded along the time axis in 3D (similar to expanding an accordion). As such, the Kiviat Tube encodes not only the evolution of diagnoses over time, but also correlations among diagnoses.

Representing Diagnoses in Time and Space

Even though it is sufficient in certain analysis scenarios to consider time and space separately, it is more often the case that both spatial and temporal aspects have to be visualized. To consider all three dimensions of the data-cube (see Background), three basic tasks must be addressed:

1. Represent the spatial frame of reference as map
2. Create visual representations of the temporal aspects of the data
3. Embed representations of time (2) into the representations of space (1)

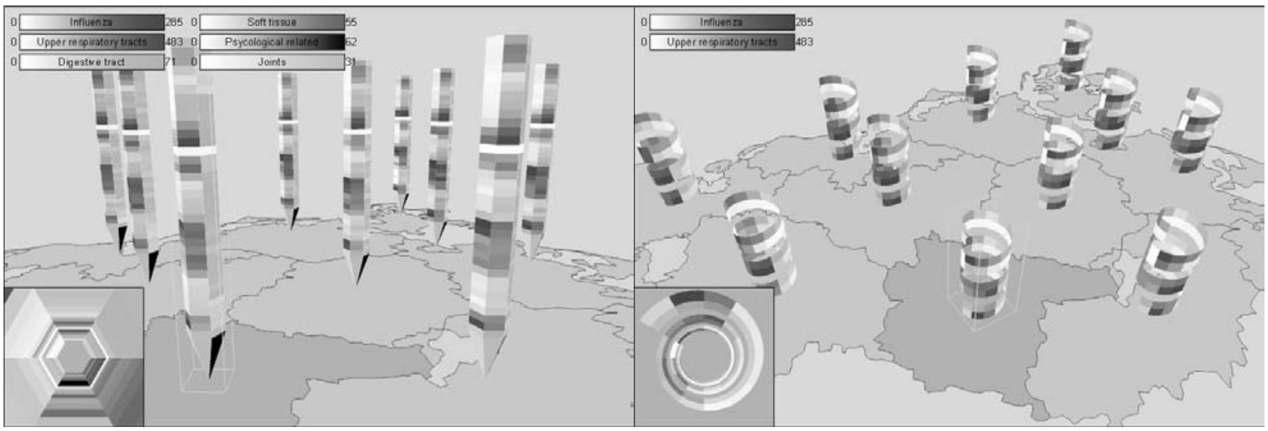
To represent the spatial frame of reference, the two-dimensional map (as introduced in Representing Diagnoses in Space) is represented in a 3D presentation space in which the map can be zoomed and rotated using common 3D interaction. Users that prefer a two-dimensional map representation can switch easily to a respective map projection.

To visualize temporal aspects, pencil icons are used for linear time axes, and helix icons are applied for cyclic time (Tominski et al., 2005):

- **Pencil icons:** Since everybody is familiar with the shape of a pencil, it is a very useful visual metaphor. The natural shape of a pencil provides multiple faces that evolve from a common tip. This shape excellently serves as a 3D icon for visualizing multiple diagnoses with dependencies on linear time. To map data onto a pencil icon, linear time is encoded along the pencil's faces starting from the common tip. Each face of a pencil is used to color-code one diagnosis (cp. Figure 7a). The number of faces of a pencil can be adjusted according to the number of diagnoses to be visualized.
- **Helix icons:** A spiral helix provides a geometric shape that allows an emphasis of the cyclic character of diagnoses. In order to construct a helix icon, a ribbon is created: For each time step the ribbon extends in angle and height depending on the number of temporal primitives per cycle and the number of cyclic passes. Again, color-coding is used to encode data values along the ribbon (cp. Figure 7b). In order to represent multiple diagnoses, the ribbon can be divided into narrower subribbons.

The described pencil and helix icons can be easily embedded into a 3D map display. This can be realized by positioning 3D icons at the centroids of geographical regions and aligning them with the z-axis of the 3D

Figure 7. Visualizing monthly health data by means of 3D icons on a map: (a) Pencil icons representing the number of cases of six diagnoses; some diagnoses show a certain pattern over time; (b) Helix icons clearly reveal the cyclic characteristic of two selected diagnoses. Additional "tunnel views" mitigate, for a selected icon, the problem of hidden information



(a) (b)

presentation space. By doing so, the representation of the temporal dependencies is shifted from the map to a dedicated dimension in the 3D presentation space. However, the embedding in 3D involves new problems compared to a 2D representation:

- Undesired changes of the icon view upon user interaction
- Loss of information due to icon occlusion and hidden surfaces

Applying all interactions allowed in the 3D presentation space (i.e., rotation, translation, scaling) to both the map and the icons is disadvantageous, since it implies visual inconsistencies during the visual analysis. If users rotate the map while analyzing diagnoses represented by a pencil icon, the faces of the pencil are rotated as well (i.e., the view of diagnoses changes). An alternative is to unlink map interactions and icon interactions on demand. This can be achieved by aligning the icons with respect to the user's current view into the 3D scene. This ensures that the icon view is preserved during map navigation. Users are allowed to change the icon view via separate icon rotation.

The second problem that must be addressed is loss of information due to occlusion of icons and on back faces of 3D icons. To alleviate this problem, the crude procedure of positioning icons at the areas' centroids must be improved. An iterative approach that calculates occlusion conflicts and alters the positions of icons locally can help to reduce occlusion. By applying an iterative algorithm that runs until no conflicts occur or until a maximum number of iterations has been exceeded, enhanced icon positions can be achieved, and interactive frame rates are ensured. To mitigate the problems imposed by information lost on back faces, it makes sense to provide the possibility to switch to special designated viewpoints. These viewpoints are located directly underneath each icon, and the view directions are aligned with the icons' axes. Switching to one of these viewpoints results in a "tunnel view" that reveals all data values represented by a selected 3D icon. Figure 7 shows how tunnel views support visual analysis in a 3D presentation space.

These enhanced viewing and interaction techniques in combination with common 3D interactions provide a rich basis for a visual exploration of multiple time and space dependent diagnoses. Furthermore, it is possible to emphasize linear or cyclic characteristics of data by using dedicated 3D pencil or helix icons, respectively.

FUTURE TRENDS

We presented a variety of visual methods for analyzing human health data. However, in light of large datasets, visualizing all data in a comprehensible manner without burying possibly important information becomes more and more challenging. This challenge can be dealt with by conducting additional data analysis steps. Statistical and *data mining* methods such as Principle Component Analysis or clustering are helpful analytical tools to support the identification of what is important in human health data. Although the analysis step is indispensable, it is yet mainly data-driven. In the future, the interests of users should also be considered. This will allow for providing automatically adjusted visualizations that emphasize relevant parts or hiding of nonrelevant data. A further particularly challenging problem is to find new ways to describe tasks of the visual exploration process and to automatically adapt the whole analysis procedure according to the users' tasks at hand. This also includes providing specific interaction functions for investigating health data.

CONCLUSION

The analysis of human health data can be supported by interactive visual interfaces and appropriate visualization techniques. To achieve the main goal of visualization—gaining deeper insights into larger datasets—it is crucial to consider the characteristics of the data and the needs of the analyst. In this chapter, we investigated the role of visualization in the context of human health data. We elaborated on choosing visualization techniques properly with respect to characteristics of the data. In particular, we described techniques for visually analyzing multivariate human health data in time and space. Although the explained techniques are promising tools to support better health care, more work (as indicated in Future Trends) has to be done to fully exploit the usefulness of visual analysis methods.

KEY TERMS

Appropriateness: A visual representation is appropriate if its benefit and creation effort are balanced.

Data Cube: The dimensions of a dataset can be modeled as a hyper-cube, which allows an easy selection of relevant parts of the data.

Effectiveness: A visual representation is effective if it has been generated in accordance with the capabilities of the human visual system.

Expressiveness: A visual representation is expressive if it communicates all information that is relevant with respect to the current analysis task.

Interaction: Denotes the use of specific techniques to adjust visual representations according to the task at hand.

Multivariate Data: Data that contain multiple attributes measured in some observations space are denoted multivariate data.

Visualization: A visual approach to gaining insight into data.

Visualization Pipeline: Describes data analysis, filtering, mapping, and rendering as steps of visualization.

ENDNOTE

1 Since it can be assumed that the reader has a natural understanding of the terms “time point” and “time interval,” a formal description will not be presented here; interested readers are referred to Hajnicz (1996) or Aigner (2006).

INTRODUCTION

Near infrared (NIR) light (700 ~ 900 nm) possesses the capability of penetrating living tissues several centimeters due to the low absorbance of tissue intrinsic chromophores such as oxy- and deoxy-hemoglobin (the main absorber of visible light), melanin, water, and lipid (the principal absorber of infrared light). Featured with the deeper tissue penetration as well as nonionizing and nonradioactive, NIR light attracts extensive attentions on the development of noninvasive techniques for *in vivo* real time monitoring/tracing of biological signals in living tissues. Hitherto, *NIR techniques* have permeated to almost all aspects of health care, such as diagnosing disease (Nahum, Skippen, Gagnon, Macnab, & Skarsgard, 2006), designing the targeted molecular or drug carrier (Hsu et al., 2006), monitoring the response to therapeutic treatment (Tachtsidis et al., 2007), evaluating the rehabilitation, and so on. With the rapid development of various NIR techniques and more cooperation with clinic studies, more potential applications in health care will be exploited in the near future.

Characterized with the virtue of high physiological activity, specificity, and low toxicity, *protein drugs* are becoming mainstream therapeutic agents and constitute a substantial portion of the compounds under preclinical and clinical development in the global pharmaceutical industry (Baumann, 2006). And the *in vivo* evaluation of drug properties, from animal models to human subjects, becomes a crucial in the *protein drug* development. It involves drug screening, drug delivery, drug biodistribution, pharmacokinetics, pharmacodynamics, and so on. Each of these processes requires *quantitative* monitoring of *drug concentrations* in the specific organ/tissue or *qualitative imaging* of *drug distribution* in whole subjects. Thus, a number of analytical techniques were exploited to analyze the *protein drug* process within the experimental subjects. Immunoassay, bioassay, and isotope labeling are the most commonly used methods for quantification of macromolecule in biological fluid (Marshall, Macintyre, James, Krams, & Jonsson, 2006). Immunoassay is based on the specific antibody–antigen reaction. The response signal is generated from a label (e.g., enzymatic, fluorescent, and radio isotopic) attached to either antigen or antibody. This method, including radioimmunoassay (RIA), immunoradiometric assays (IRMA), and enzyme-linked immunosorbent assays (ELISA), is rapid and sensitive as well as economical, but it is heavily affected by a variety of endogenous and exogenous substances. Bioassay provides an indirect method by using living system to measure the biological activity of a drug. This method is expensive, time consuming, and lacks specificity and sensitivity. Isotope labeling is an alternative approach to *in vivo* quantification of protein drug (Liu, Dreher, Chow, Zalutsky, & Chilkoti, 2006). Although it is sensitive, some disadvantages regarding the complex preparation and radioactivity limited its broad application. Beside the aforementioned analytical methods, techniques such as chromatography and electrophoresis are usually used for *protein drug measurements*. However, all the listed techniques, except isotope labeling, are unable to perform the *in vivo* measurement of *protein drug* in biological matrices. They require the tedious and intricate process of sample preparation such as sample collection and purification. Furthermore, the clearance of protein drugs from the specific tissue/organ is quick and the above analytical techniques cannot catch up with its dynamic changes.

Therefore, a noninvasive *in vivo* real time monitoring modality for protein drugs in biological matrices will timely meet the needs and greatly expedite the step of *protein drug* development.

Near infrared techniques contributed considerably to the development of protein drugs by performing noninvasive *in vivo* real time *measurements* on experimental subjects. In this chapter, we will first present the fundamental theory of NIR techniques, followed by the summary of NIR *fluorescence probes*. Emphasis will be placed on the practical applications of NIR techniques on drug development. Future trends and conclusions will be given at the end.

BACKGROUND

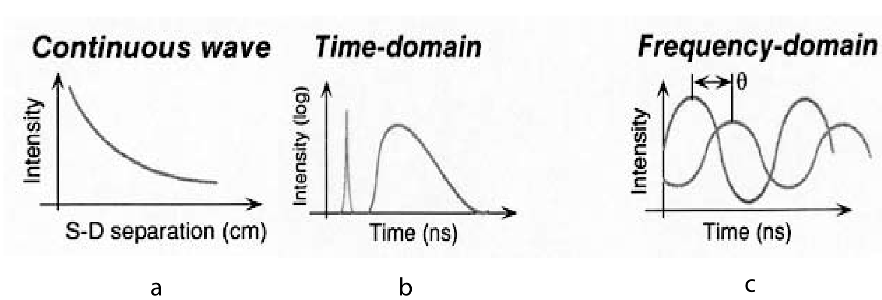
Near Infrared Techniques: Spectroscopy and Imaging

Near infrared light (700 to 900 nm), where photon transport in tissue is dominated by scattering rather than absorption, has the maximal penetration depth of several centimeters, therefore enabling *in vivo* sampling of large tissue volumes, for example, breast, brain, skeletal muscles, or tumors. The absorptions of NIR light by endogenous chromospheres, that is, oxygenated and deoxygenated hemoglobins, and exogenous contrast agents have been used to determine important physiological characteristics of tissues.

In the last decade, extensive investigations in noninvasive NIR techniques have been conducted for both *quantitative* and *qualitative* determination of biological signal in tissues. Based on the profile of the incident light, three main near infrared systems, that is, time-domain (TD), frequency-domain (FD), and continuous wave (CW) photon migration system, have been developed for various *measurements*. Figure 1 illustrates the profiles of the incident light (red line) and tissue diffused light (blue line) for the three systems.

Usually, CW techniques employ illumination with a constant intensity. The diffused light attenuates exponentially with the source-detector (S-D) separation, section (a) of Figure 1, and with the depth of the tissue according to the tissue optical properties. Although having limited penetration depth and only intensity retrieved, CW system is the most easily implemented system and the most widely used in various *measurements* on small *animal models*. In contrast to CW techniques, TD approaches employ a source with a femto-picosecond pulse of light, which is broadened and attenuated as it propagates through the tissue, see section (b) of Figure 1. The diffused light intensity, transient time, and pulse shape are recorded to determine the tissue optical properties. The measurement from a TD system is more accurate and usually used as calibration for other newly developed systems. However, its high cost has limited its wide application. FD techniques offer a compromised approach to the determination of tissue optical properties. The incident light on an FD system is modulated at radiofrequency range (namely, 70 MHz—several hundred MHz). The diffused photon wave propagates through tissue and becomes amplitude-attenuated and phase-shifted relative to the incident light. After demodulation, the changes in amplitude and phase are retrieved for the determination of tissue optical properties. Various forms of heterodyne or homodyne demodulation systems have been utilized to implement FD system. Because the detected amplitude and phase are insensitive to the ambient light, FD system enables greater sensitivity and

Figure 1. Profiles of the incident light (red line) and the diffused light (blue line) for the continuous wave system, the time-domain system, and the frequency-domain system



penetration depth than CW measurements. For all the above systems, multiple NIR wavelengths were usually applied to distinguish the different chromophores in tissues based on the modified Beer-Lambert's Law. The propagation of NIR fluorescence follows the same rule as the excitation light as long as the lifetime of the dye is less than or comparable to the timescale of excitation light propagation.

No matter which incident light applied, the NIR system can be implemented as *spectroscopy* and *imaging*. Figure 2 illustrates the schematic diagram of a near infrared spectroscopy (NIRS) system. The processing circuit is matched to the light sources via a coupling mechanism depending on the type of modulation used. The geometry of delivering and collecting fiber bundles is flexible and can be adjusted as reflectance, transmittance or fluorescence modes according to practical applications.

NIR spectroscopy is usually used for quantitative determination of chromophores concentration in specific region of the subjects. Oxygenated and deoxygenated hemoglobins are the most common physiological parameters to be measured by NIRS for evaluation of vascular hemodynamic properties (Gu, Bourke, Kim, Constantinescu, Mason, & Liu, 2003; Liu, Song, Worden, Jiang, Constantinescu, & Mason, 2000) and disease diagnosis. However, efforts in applying NIRS to *in vivo* monitoring of *drug concentration* are very limited and preliminary, which holds great promising in drug development. While intrinsic chromophores absorption yields significant information on tissue characteristics, extrinsic fluorescence markers attract tremendous attention for *in vivo* monitoring of biological signal in tissue, which is particularly useful in drug development.

The need of tissue observation facilitates the rapid development of near infrared *imaging*. And the extrinsic fluorescence markers bring NIR imaging a prodigious achievement in all the aspects of health care. Currently, reflectance mode and tomography are the two most common NIR imaging approaches used for observing tissue properties. The schematic diagrams are shown in Figure 3. NIR reflectance *imaging* is usually equipped with a continual wave light source (either a laser at an appropriate wavelength or a white light furnished with a bandpass filter) and a high sensitivity CCD camera with a filter for capturing the emitted fluorescence from the tissue. It is currently the typical method for accessing the distribution of fluorescent marker in biological matrices, including in drug development. Together with biological marker, NIR reflectance *imaging* offers additional insights into the determinants of disease progression and therapeutic response. Although NIR reflectance imaging is an ideal tool for imaging and screening of molecular events close to the surface, it has fundamental limitations on the penetration depth and quantitative measurement. To resolve and quantify fluorochromes deep inside the tissue, NIR tomographic methods, section (b) of Figure 3, are developed to fill the gap. Except for the hardware furnished with the multiple source-detector pairs, mathematical algorithms based on photon migration are crucial for reconstructing fluorochromes *imaging* inside deep tissue with better spatial resolution. Up until now, various tomographic *imaging* systems, that is, frequency-domain, time-domain, and continuous-wave imaging, have been implemented and applied mostly in brain function and breast cancer study. There is little report on quantification of drug concentrations from NIR imaging approaches.

Extrinsic NIR Fluorescent Markers: Organic and Inorganic Dyes

Due to the fact that most of the protein drugs lack unique optical properties within the near infrared range, the extrinsic NIR fluorescent labeling makes the *in vivo* study of *protein drug* possible. For a long time, extrinsic fluorescent agents were limited to organic fluorophores, most of which are pentamethine and hepamethines cyanines comprising bezoxazole, benzothaizole, indolyl, 2-quinoline or 4-quinoline. Recently, several new NIR dyes with functional groups, for instance, active ester, carboxyl group, sulfochloride, and so on, were synthesized for covalent conjugation to biological molecules. A part of them is listed in Table 1, including structures and fluorescent spectral properties. Their biodistributions, pharmacokinetics, and applications as extrinsic contrast agent have been summarized by Ballou, Ernst, and Waggoner (2005) and Licha and Olbrich (2005). These agents are always conjugated to biomolecules, including antibodies, peptides, saccharides, drug carriers, and so on for drug development.

Although conventional organic fluorophores have achieved great progress in the development of clinic medicine, their unfavorable characteristics, such as low quantum yield, difficult to manipulate the fluorescent wavelength, and susceptible to photobleaching, limited their applications in some cases. Inorganic fluorescent semiconductor nanocrystals, namely quantum dots (QDs), have the potential to overcome most of the drawbacks of organic fluorophores. Typically, QDs have a core/shell structure of 3-20 nm in diameter and may be multifunctionalized by many ligands and probes. With favorable properties, such as high absorbency, high quantum yield, narrow emission bands, large Stokes shifts, and high resistance to photobleaching, fluorescence quantum dots have been successfully applied to the study of cell and animal biology, immunofluorescence assays, DNA array technology, and so on. The red shift of fluorescence emission to NIR range is believed to have great promising for the *in vivo* study of drug development.

METHODOLOGY

NIR Techniques Applied in Drug Development

With the help of NIR fluorescence agents, *near infrared techniques* provide a valuable noninvasive tool to *in vivo* real time monitoring of the route/distribution or the efficacy of drugs on small *animal models*. In general, NIR *spectroscopy* offers a *quantitative* way to measure the *drug concentrations* in specific tissue/organs, while NIR imaging can image the distribution of drug/carrier in *animal models*. Although the drug quantification by NIR techniques is limited, the results from our group give us more confidence on the potential perspective of NIR techniques in drug developments.

Quantitative Measurements of Protein Drug Concentration for Pharmacokinetics

Dynamic *drug concentration* in *animal models* is the most crucial parameter in drug development, especially

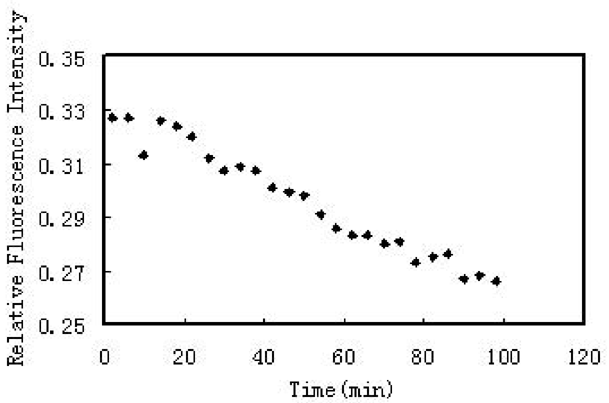
for the study of pharmacokinetics. As mentioned above, it's difficult to perform *in vivo* measurements for *protein drug* without extrinsic labeling. NIR dyes usually have a molecular weight of about 600 and are conjugated to protein drugs that have a larger molecular weight than those of dyes. The conjugation will not change the delivery properties of protein drugs. Therefore, the dye labeling enables the *in vivo* noninvasive measurements of *protein drug* dynamics. Furthermore, the dye labeling may enhance the drug to background ratio and, thus, improve the sensitivity and specificity of the measurements.

In our study, cypate, one of the NIR dyes provided by Dr. Achilefu (Ye, Bloch, Kao, & Achilefu, 2005), was covalently conjugated to a protein model drug L-asparaginase for *in vivo* concentration quantification. L-asparaginase is a remarkably effective therapy *protein drug* for those specific cases where blood cells become cancerous, such as in acute lymphoblastic leukemia. In the process of cypate conjugation to L-asparaginase, many factors including catalyzing system, *p*H condition, temperature, reacting duration, and feed ratio of different components were intensively investigated to achieve an optimal labeling result (Qian & Gu, 2006). In particular, the labeling efficiency, characterized by the dye-to-protein molecular ratio, and the enzyme activity of L-Asparaginase, evaluated by the Nessler's reagent photometric method, were carefully considered

Figure 4. Time profile of relative fluorescence intensity emitted from cypate-labeled L-Asparaginase in blood stream



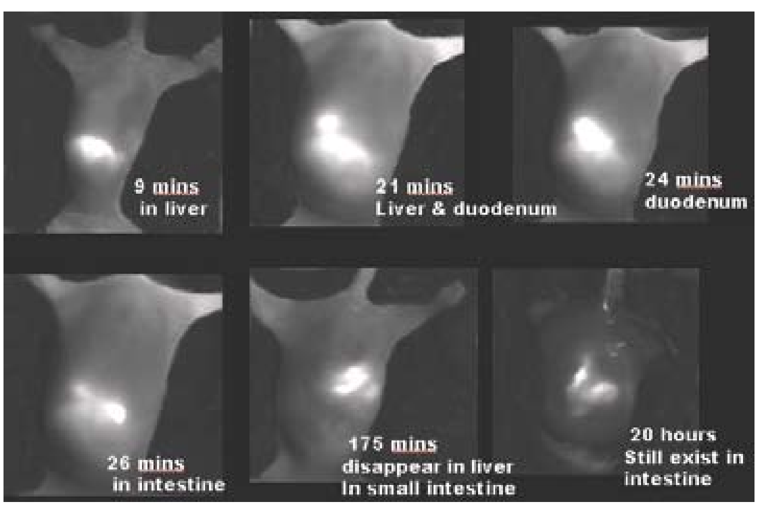
for higher monitoring sensitivity and better therapeutic efficacy.

The optimal conjugation of cypate-labeled L-Asparaginase, with higher labeling efficiency and enzyme activity, was administrated through a tail vein into the blood stream of mouse. The blood dynamic concentrations of L-Asparaginases were *in vivo* monitored by a NIR CW *spectroscopy* whose experimental setup is similar to that in Figure 2. Here, only fluorescence was directly recorded to quantify the cypate in blood. And the concentrations of L-Asparaginase were obtained by applying a precalibrated curve. A laser diode with a wavelength of 760 nm was used to excite the cypate to emit fluorescence at around 820 nm. A high pass filter (> 800 nm) was placed in front of PMT to block the incident light. The delivering and collecting fiber bundles were positioned in a perpendicular geometry in the leg area that contains abundant vasculature. Figure 4 shows the time profile of relative fluorescence intensity emitted from cypate-labeled L-Asparaginase in blood stream. The concentration of L-Asparaginase can be accurately quantified by the calibration. The experimental result from NIRS is consistent with the parallel measurement from radioisotopic labeling, which demonstrated the practicability and reliability of NIR *spectroscopy* as a quantitative monitoring tool. The detecting sensitivity on the dye-labeled drug is much higher than the measurement from the drug itself. The quantitative information of drug dynamics on small *animal models* speeds up greatly the pharmacokinetic study.

Qualitative Imaging of Protein Drug in Small Animal for Drug Development

NIR reflectance imaging is the most prevalent method applied to follow/trace the distribution of dye-labeled macromolecular compound in *animal models* for drug development. Similarly, we also utilized the NIR reflectance imaging system, section (b) of Figure 3, to successfully trace the route of cypate-labeled lysozyme in mouse, as shown in Figure 5. Cypate was covalently bound to lysozyme via two carboxyel groups with higher labeling efficiency and enzyme activity. The optimal conjugation of cypate-labeled lysozyme was

Figure 5. Dynamic route of cypate-labeled lysozyme in mouse. Model monitored by reflectance NIR imaging.



administrated through a tail vein into the blood stream of mouse. The distributions of lysozyme were qualitatively imaged at certain time intervals by reflectance NIR *imaging* furnished with a high pass filter before CCD camera. As demonstrated in Figure 5, cypate-labeled lysozyme was first accumulated in liver (9 minutes after administration) and then sequestered in duodenum and intestines. The back and forth moving of cypate-labeled lysozyme in duodenum and intestines was observed during the experiment. Most of the dye-labeled drug was cleared from liver at about 175 minutes, but still observed in intestines 20 hours after administration. These images revealed the clearance route of cypate-labeled lysozyme, providing important information for *protein drug* development and drug discovery.

FUTURE TRENDS

Despite advances in applying *in vivo* NIR techniques to facilitate the process of drug development, we are currently still limited in many aspects. First, most of the currently available NIR probes/contrast agents have a molecular weight of around 600. If the NIR agent is attached to a selected drug, it may change the delivery properties of the drug with a small molecular weight. This may be the reason why most of the studies on *in vivo* NIR techniques just involved in macromolecular compounds. Second, the quantitative measurement of *drug concentration* by NIR techniques is very limited and preliminary, which may be one of the major obstacles for the wider application of NIR techniques in drug development. Third, although the qualitative imaging of *drug distribution* by NIR imager in small *animal models* is very popular, there are few reports on the precise localization of drugs in a specific tissue. To accelerate the widespread utilization of NIR techniques in drug development, we need to overcome these limitations and explore more potential applications. Therefore, many investigators focus their research on the following directions:

1. Development of more and better NIR agents, with higher fluorescence quantum yield, more stable and less photobleaching, attachable not only to macromolecular drugs, but also to small molecular drugs; Synthesis of smart NIR agents with functional groups acting as targeted drug carrier (Ye, Bloch, Xu, & Achilefu, 2006); Conjugation of current NIR dyes to the existing probes such as radiotracers, MR markers to form multifunctional labeling agents for parallel measurements by using different modalities.
2. Improvement of high sensitive NIR systems. In particular, enabling NIR *spectroscopy* to be a commonly used quantitative monitoring tool for *drug concentration* determination in specific tissues at pico- to femto-mole accumulations, thus providing quantitative information for drug development.
3. Development of better algorithms for multiple source-detectors tomographic *imaging* system to precisely localize drug contents in deeper organ/tissue/cells, thus leading to quick drug screening and drug discovery.
4. Integration of NIR techniques with other mature modalities to perform parallel measurement for better understanding of drug-tissue interactions.

CONCLUSION

The emergence of NIR techniques offers great potential to expedite drug discovery and development. Although there are three typical NIR techniques based on the intensity profile of the incident light, spectroscopy and imaging are the most widely implemented systems for noninvasive *in vivo* real time monitoring of optical signals in biological matrices. Usually, NIR *spectroscopy* offers a quantitative way to determine the endogenous and exogenous chromophores in living body, while the NIR *imaging* provides a qualitative method to image the distributions of biomarkers in whole animal body. With the increasing availability of NIR fluorescent agents, NIR techniques have achieved exciting progress in many aspects of health care, particularly in drug development. Although having some drawbacks such as low quantum yield, inconvenience to manipulate the wavelength, susceptible to photobleaching, and organic NIR fluorescent dyes are still the most commonly used fluorescent agents for molecular imaging. Inorganic fluorescence agent, namely quantum dots, possesses some important advantages over organic agents and brings bright perspective in biological detection.

The results obtained from NIR *spectroscopy* and *imaging* in our experiments and from literatures demonstrated that NIR technique is a practical and reliable monitoring modality for *in vivo* tracing of *drug* *concentration* and distribution in small *animal models*. The widespread application of NIR technique will significantly expedite the step of drug development.

KEY TERMS

Drug Distribution: A different amount of drugs will be accumulated in different organs or tissues when administrated in the living subjects.

Fluorescence Probe: A specific agent that emits fluorescence with longer wavelength when excited by the light within its absorption range.

***In Vivo* Measurement:** Measurements are performed on the body of living subject (human or animal) without taking the sample out of the living subject.

Near Infrared: Electromagnetic wave whose wavelength ranges from 700 nm to 900 nm. These lights have higher penetration depth in living tissue due to low absorption coefficient to hemoglobin in blood.

Pharmacokinetics: A study for the dynamic change of drug concentration in blood. This parameter can help researchers and clinicians to understand the properties of the drug.

Protein Drug: A type of drugs made of protein. These drugs usually have large molecular weight with protein characteristics.

Volumetric Analysis and Modeling of the Heart Using Active Appearance Model

INTRODUCTION

Echocardiography is the fastest, least expensive, and least invasive heart imaging method. Accordingly, it is one of the most commonly used techniques to quantify the ventricular systolic function in patients. The examination is based on visual analysis of myocardial wall motion and deformation by an experienced and trained physiologist. This investigation is subjective, experience dependent, and the obtained results are only partially quantitative. The segmentation of the measured image sequences focuses on finding the exact boundaries of particular objects of interest, but it usually requires manual assistance.

Besides their several advantages, ultrasound images have the following drawbacks:

- They include not only the reflections from tissue transitions, but also several interference patterns (speckle noise). Consequently, tissues can hardly be distinguished by the intensity of their representing pixels.
- Image data highly depend on the position and angle of incidence of the ultrasound beam.
- A wide scale of imaging artifacts are frequently present, so still-frame images might contain only partial information.

In order to deal with these kinds of deficiencies, several automated segmentation techniques have been developed and reported. Geiser, Wilson, Wang, Conetta, Murphy, and Hutson (1998) proposed arc filtering for boundary detection, while Brotherton, Pollard, Simpson, and DeMaria (1994) gave a hierarchical fuzzy neural network solution. Dias and Leitão (1996) introduced an iterative multigrid dynamic programming technique based on Rayleigh distributed random variables and a probabilistic model formulated within Bayesian framework. Belohlavek, Manduca, Behrenbeck, Seward, and Greenleaf (1996) proposed the automated segmentation using a modified self-organizing map. Chalana, Linker, Haynor, and Kim (1996) traced the epi- and endocardial border using active contour models. In spite of their significant merits, these methods still neglect the following aspects:

- Sought boundaries are not always represented by the strongest edges.
- They use no a priori information concerning the allowable shapes and ranges of the segmented object.
- Segmented boundaries should be consistent with the cardiac cycle.

In the last decade, advances have been made in the content-based retrieval of medical images, such as extraction of boundaries of cardiac objects from echocardiography image sequences (Duncan & Ayache, 2000). Montagnat, Delingette, and Malandain (1999) used a two simplex mesh-based cylindrical deformable surface to produce time-continuous segmentation of 3-D sequences. Angelini, Laine, Takuma, Holmes, and Homma (2001) proposed a feature enhancement and noise suppression using a wavelet-like decomposition of the spatial frequency domain. A snake-based segmentation is carried out later on the denoised data.

Active appearance models (AAM), introduced by Cootes, Edwards, and Taylor (2001), are promising image segmentation tools that may provide solutions to most pending problems of echocardiography, as they rely on both shape and appearance (intensity and/or texture) information. Bosch et al. (2002) proposed a robust and time-continuous delineation of 2-D endocardial contours along a full cardiac cycle, using an extended AAM, trained on phase-normalized four-chamber sequences.

To understand the physiology and patho-physiology of the heart, not only the electrical activity and spatial distribution of its structures are important, but also their movement during normal and abnormal cardiac cycles. The ECG signal is measured simultaneously with echocardiography sequence recording in order to localize the investigated events. We developed an algorithm that reconstructs the heart wall boundaries and motion in order to determine the spatial and temporal cardiac activity.

In this article we present our algorithm that reconstructs the heart wall boundaries and motion in order to determine the spatial and temporal cardiac activity.

Several papers in the literature have already reported the usage of spatial AAM (Mitchell, Lelieveldt, Bosch, van der Geest, Reiber, & Sonka, 2002; Stegmann & Pedersen, 2005). The present work has the following contributions:

- Reported techniques classify ultrasound images only as belonging to systolic or diastolic interval. Our approach distinguishes normal and extra beats, and processes the corresponding images accordingly.
- ECG event classification makes possible the investigation of several pathological cases (e.g., volumetric effect of a given extra beat). Comparisons were made between normal and pathological cardiac cycles of the same patient.

MATERIALS AND METHODS

The echocardiography measurements were carried out as presented in the article with title "Echocardiographic Image Sequence Compression Based On Spatial Active Appearance Model" (see Figure 1).

The necessary minimal duration of the recorded image sequences was restricted by the semi-periodic behavior of the ECG signal. The spatial movement of the heart is constrained by the course of the depolarization repolarization cycle (Szilágyi, Benyó, & Szilágyi, 2005). For example, normal and ectopic beats imply different spatial heart movements. The studied ECG parameters, as presented in Figure 2, were: shape of QRS beat, QT, and RR distances. These parameters characterize the nature of a QRS complex, and were determined as presented in (Szilágyi, Benyó, & Szilágyi, 2003).

As the measurements were made with known spatial coordinates *x*, *y*, *z*, time *t*, and direction represented by angle α, the selected image sequences could be concomitantly processed with the measured ECG signal. All selected images that correspond to the same depolarization-repolarization phase and had almost the same ECG pattern (same QRS class, low QT, and RR difference) were included into calculations. Let $c(cl,t)$ be the clustering function that determines the appertainity coefficient to a cluster *cl* of a given ECG period measured at moment *t*. These clusters were determined with hermitage functions and self-organizing maps as presented in Lagerholm, Peterson, Braccini, Edenbrandt, and Sörnmo (2000).

The strength of the relation between a given wall segment and cluster *cl* is determined by function *f* with form:

$$f\left(x,y,z,cl,t\right)=\frac{c\left(cl,t\right)}{dist\left(x,y,z,t\right)}$$

where Box 1 represents the spatial distance at moment *t* of the sensor *s* from the studied wall piece *w*. The angle α of the sensor and the wall place at the image measured at moment *t* determinates the spatial coordinates of the muscle segment. In this way, each wall

Box 1.

$$dist(x,y,z,t)=\sqrt{\left(x_s\left(t\right)-x_w\left(t\right)\right)^2+\left(y_s\left(t\right)-y_w\left(t\right)\right)^2+\left(z_s\left(t\right)-z_w\left(t\right)\right)^2}$$

Figure 1. Various positions of the parallel cross sections and the orientation of the transducer: (a) Horizontal plane(s), (b) left rotated plane(s), (c) right rotated plane(s). Various positions of planes with common axis: (d) front view, (e) back view

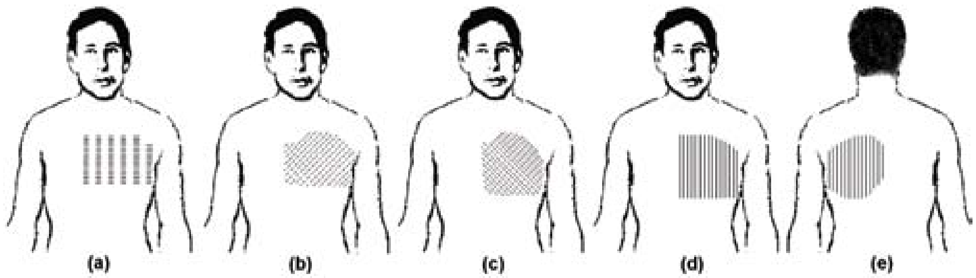

Figure 2. Normal (N) QRS and extra ventricular QRS beat (V), with indicated RR and QT distances. Dotted lines denoted by C (maximal contraction) represent the minimal volume moment of heart during normal cardiac cycle

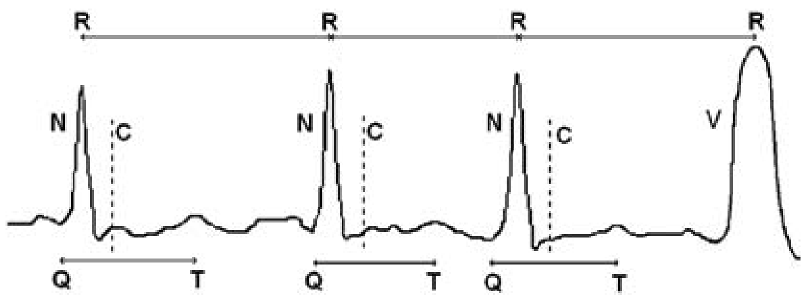

movement was studied in time and the heart's spatial movement could be reconstructed.

Ultrasound is a particularly harder imaging modality for interpretation than CT and MRI, because it suffers from several specific drawbacks which impede automated analysis. The absence of a relation between pixel intensity and any physical property of the visualized tissue demands a deeper usage of the a priori information. The sensibility to noise and reflections implies an intelligent filtering. Even the definition of border position may be direction dependent (Vuille & Weyman, 1994).

Albeit these afore-named problems, the huge amount of recorded images demands the usage of automatic border detection (ABD) algorithms. We will refrain from a direct comparison of these methods, as there are no standard test data sets neither for this purpose nor standard test criteria (Sher, Revankar, & Rosenthal, 1992). The clinically most widespread algorithm is based on acoustic quantification (AQ) that is involved in several ultrasound machine models. However, this method suffers from high sensitivity to image quality. A typical ABD algorithm contains the following steps:

- Preprocessing (smoothing, contrast checking)
- Edge or region detection (thresholds, edge detectors)
- Geometric object models (for example radial search)
- Anatomical structure model
- Interpretation (based on high-level knowledge)

An excellent example of a structure-based method was published by Geiser and Wilson (Geiser et al., 1998; Sheehan et al., 2000) for automatically detecting endocardial and epicardial borders in short-axis echocardiograms. This method is practically useful and it was validated on a large set of patients. In this method, a great advantage over classic algorithms is the involvement of the a priori information and the usage of a feed-back between a high-level model of a short-axis cross section and a low-level feature data.

Figure 3. Schematic representation of the data recording and analyzing procedure. All echocardiography and ECG data go through the same processing module. The AAM is constructed from the measurements of series 1, and fine tuned afterward using the patient specific data resulting from series 2 stage 1. Stage 2 data serve for the detailed cardiac volumetric analysis. Reconstructed 3-D objects are finally aligned using an iterative LMS-based algorithm.

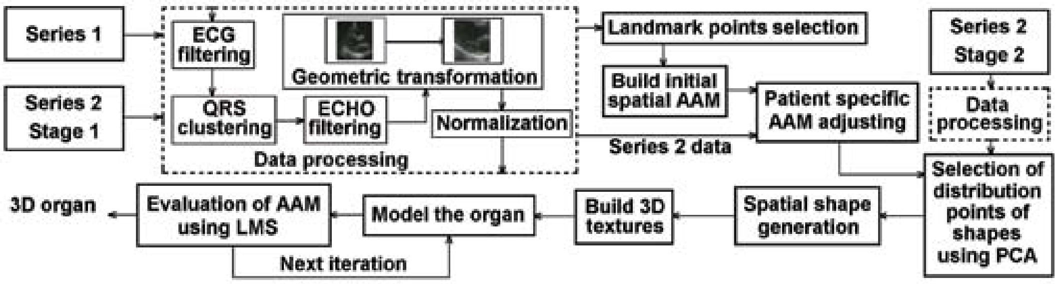

Figure 4. Results of shape reconstruction: (a) Time varying 2-D contour of the left ventricle (2nd patient), (b) reconstructed 3-D structure of the left ventricle

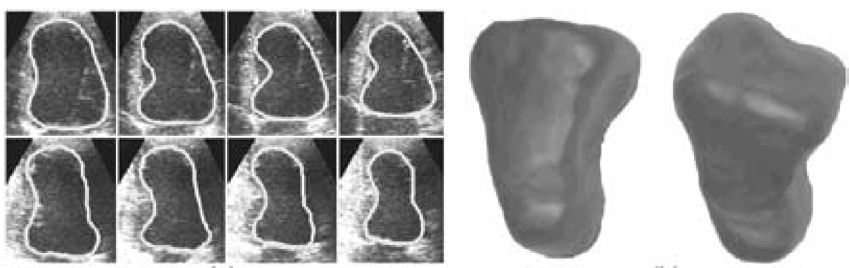

The main weakness lies in its cascade dependent steps that can fail and cause the process to break down.

The enrolled disadvantages convinced us to use an Active Appearance Model that was developed by Edwards, Taylor, and Cootes (1998) for facial recognition and medical image analysis (Edwards et al., 1998) (see Figure 3). This technique can be considered as an extension of the Active Shape Model (ASM) and derives the typical shape and appearance of an echocardiogram from a large set of example images with expert-drawn contours (Bosch et al., 2002; Mitchell et al., 2002).

Its main steps are:

- Extract the average organ shape
- Extract the principal shape variations
- Create the appearance model
- Generate probable echocardiographic image
- Find the desired structure by error minimization technique

This technique has some important advantages: it models average organ shape and variation and can model complete organ appearance including artefact cases. The detailed description of the AAM may be found in an article entitled "Echocardiographic Image Sequence Compression Based On Spatial Active Appearance Model."

RESULTS

Section (a) of Figure 4 presents two series of ultrasound slices indicating the contour of the left ventricle of the second patient, detected during a ventricular contraction. The two rows of slices show two different angle views, having 60° angle difference. The four slices in each row represent subsequent images of the sequence, showing the approximately 100 ms duration of the ventricular contraction. Section (b) of Figure 4 shows two different reconstructed 3-D shapes of the left ventricle, which were obtained using 1527 distribution points.

Figure 5. Variation of heart volume during a normal cardiac cycle (a), and during a ventricular extra cycle (b)

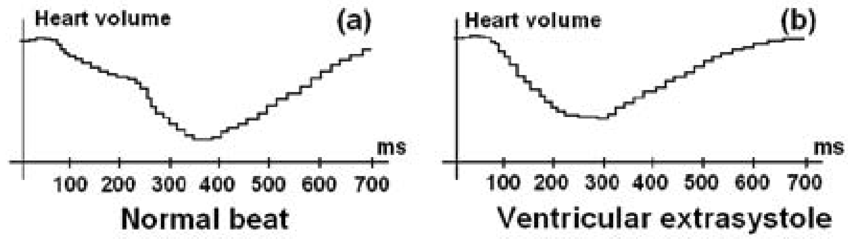

Figure 6. Sensibility of QRS complex recognition algorithm to: (a) Variations of RR distances, (b) variations of QT distances (both with respect to their average), (c) QRS shape correlation with average template.

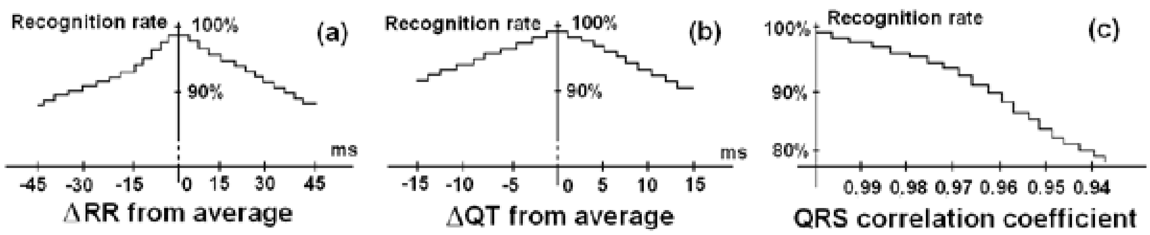

The evolution in time of the heart volume during a normal and an ectopic (ventricular extra) RR period is presented by Figure 5, sections (a) and (b). As the depolarization wave in case of an ectopic beat starts from the ventricular area, the minimal volume is obtained earlier (the delay caused by the AV-node is skipped), and at a higher value compared to normal beats (the contraction of the heart is not optimally synchronized). The first moment of LV volumetric calculation (t=0 ms) was considered at the moment of maximal positive deflection of the ECG signal.

Figure 6 presents a sensibility analysis of the QRS recognition algorithm. Figure 6, section (a), shows how the variation of the RR distances (shorter or longer than average) influences the recognition rate: the algorithm is more sensible for shorter RR periods. The effect of the variation of QT distances around the average value is shown in section (b) of Figure 6: the same absolute difference makes significantly more damage if it occurs in positive direction. Section (c) of Figure 6 reflects the relation between the shape of QRS complexes and recognition performance. The correlation coefficient of the QRS beat with the cluster averaged shape is directly proportional with the performance of the algorithm.

Table 1 presents the patient-dependent recognition rates for normal beats (average duration 707 ms) and ventricular beats (average duration 671 ms). The measurements were effectuated on four patients, and three of them produced ventricular extra-systolic beats.

The recognition of the relation between echocardiographic image and simultaneously recorded ECG signal is a key element in wall movement detection. This relation can be partially hidden by various events, such as aspiration and expiration. These phenomena may influence the measured heart rate, as presented in Table 2.

The measurement circumstances were selected optimal (average QRS wave shape, average RR and QT distances) for performance values presented in Table 1. As Table 1 reflects, the fourth patient did not produce any ventricular beats. We can observe a pronounced performance advantage of the algorithm for normal beats due its higher incidence.

DISCUSSION

From Figure 6, section (a), we could observe that the variation of the RR distances (shortenings and lengthening) influences the recognition rate in different ways. The relation (connection recognition of the image and electric signal) construction algorithm is more sensible for shorter than average normal RR periods. As Figure

Table 1. Patient-dependent recognition rate of various QRS beats in case of optimal circumstances (average QRS shape, average RR and QT distances)

Patient\ QRS type	Normal QRS beat	Ventricular extra-systole
1st- patient	99.2%	97.6%
2nd- patient	99.4%	92.4%
3rd- patient	98.4%	95.2%
4th- patient	98.6%	Not available data

Table 2. Patient-dependent averaged percentual heart rate modification during aspiration and expiration. The obtained variance is presented for normal and ventricular beats. The fourth patient had no ventricular beats.

Patient\ HR variance	Normal QRS beat	Ventricular extra-systole
1st- patient aspiration	6.2%	6.6%
2nd- patient aspiration	5.5%	3.4%
3rd- patient aspiration	9.2%	7.8%
4th- patient aspiration	5.6%	Not available data
1st- patient expiration	- 4.5%	- 5.7%
2nd- patient expiration	- 5.2%	- 3.4%
3rd- patient expiration	- 6.7%	- 5.9%
4th- patient expiration	- 4.3%	Not available data

6, section (b) presents, the lengthened QT distances deteriorate the recognition performance much more than shortened ones where all QT distances are related to average QT distances for normal beats.

Figure 6, section (c) reflects the relation between the shape of QRS beats and recognition performance. The correlation coefficient of the QRS beat with cluster averaged shape is directly proportional with the algorithm's performance. The identification of a wall segment from an image, measured in time of depolarization (before or in first part of systole) is easier than during repolarization. During a normal RR period, about 21-22 images were recorded, so from such an image sequence the first 7-9 images that are related to depolarization stage could be investigated with higher performance.

The recognition of the relation between echocardiography images and simultaneously recorded ECG signal is a key element in wall movement detection. Various events, such as aspiration and expiration influence the measured heart rate. During a whole cardiac cycle, the shape and volume of the left ventricle changes considerably.

It is difficult to determine the performance of the reconstruction method for the sporadically occurred ventricular extra-systolic beats. Even for patients that produce at least five extra beats with similar shapes in each minute, that are included in the same cluster, the reconstruction performance remains well below the normal QRS cluster's accuracy, due to the sparse distribution of the processable slices.

This relatively smaller population in the cluster of ventricular beats, compared to the normal ones, implies a lower reconstruction performance. The measurement circumstances were selected optimal (average QRS wave shape, average RR, and QT distances) for performance values presented in Table 1. As this table reflects, the fourth patient did not produce any ventricular beats. We can observe a pronounced performance advantage of the algorithm for normal beats due its higher incidence.

The volumetric variance of the heart during normal and ectopic (ventricular extra) RR period is presented by Figure 5, sections (a) and (b). As the depolarization wave in case of ectopic beats starts from ventricular area, the minimal volume is obtained earlier (the AV-node caused delay is skipped) but at a higher value (the contraction of the heart is not optimally synchronized), compared to normal beats.

The visual aspect of the heart and its environment varies in time, due to their mutual motion. AAM models include information concerning inner texture only. It would be beneficial to build another AAM for the modeling of the environment, but the invisibility of the pericardium and lung tissues represents an enormous obstacle.

As we know, the left ventricular (LV) hypertrophy has been identified as a strong and independent predictor of various adverse cardiac events even in patients without associated cardiovascular disease (Benjamin & Levy, 1999). This important clinical parameter has been subject to extensive scientific investigation (Haider, Larson, Genjamin, & Levy, 1998). The conventional 2-D echocardiography is the most commonly used imaging modality that supports LV wall mass determination. However, this method is based on geometric assumptions that do not include some possible abnormal ventricular shapes and variability in the distribution of LV mass, that hardens the development of an accurate, easily reproducible method for the quantification of ventricular mass.

Evaluation of intracardiac anatomy from two dimensional echocardiography image sequences requires a mental conceptualization process that is hardened by cardiac dynamics (MacLeod & Brooks, 1998). The dynamic modeling and visualization systems can help with the spatial interpretation of 3-D data of the heart, and make it possible to build the 3-D model of the heart (Issenberg, Gordon, Gordon, Safford, & Hart, 2001).

This study is an attempt to evaluate whether a virtual modeling and visualizing method is feasible for echocardiography, and if ultrasound images in a virtual reality can advance to a clinically useful tool in the technological process of the future. Unfortunately, the low number of patients and the long processing time reflect that the applicability and benefits of the presented volumetric analyzer and heart modeling method in clinical practice is still limited.

The spatial texture around voxels belonging to a dynamic organ suffers a deformation during contraction. Under such circumstances, a compensation mechanism would be necessary, which is situated beyond the scope of the present article.

CONCLUSION

The investigation of simultaneously recorded ECG and echocardiography images enables us to study the relations between the electrical and mechanical phenomena concerning the heart. The method presented in this article performs correctly in case of normal and ventricular beats, that is, we can monitor the volumetric variance of the heart and its main components. This kind of approach of the problem may result in deeper understanding of several pathological cases like:

- Effects of ectopic beats on the heart's pumping activity
- Risk of development of arrhythmias and fibrillation in case of pathological LV wall thickening
- Mechanical effects of Wolff-Parkinson-White syndrome.

KEY TERMS

Active Appearance Model (AAM): A computer vision algorithm for matching a statistical model of object shape and appearance to a new image.

Active Shape Model (ASM): The statistical model of the shape of objects which iteratively deforms to fit to an example of the object in a new image.

Anatomical Structure Model: An anatomical model of the studied organ.

ECG Analysis: The collection of ECG signal processing methods aiming at the determination of medical parameters.

Echocardiogram: The image of the heart created with ultrasound imaging technology.

QRS Complex: A structure on the ECG signal that corresponds to the depolarization of the ventricles.

Spatio-Temporal Modeling: Modeling in both time and space.

Volumetric Analysis: The analysis of the volume variance in time.

Weakness of Modern Hospitals

Roberto Setola
Università Campus Bio-Medico di Roma, Italy

INTRODUCTION

Until some decades ago, health care services were primarily supplied inside hospitals. The patient had to move from his or her home to the hospital, where various diagnostic and therapeutic treatments were provided. Moreover, inside the same hospital, the various tools and processes were insulated and autonomous. Patients and doctors had to move from one tool to another, often placed in different areas, to acquire the different resources. Information provided by these tools was generally collected via paper records. These records were then physically moved (generally in a very inefficient way) from one place to another in order to exchange information. In many situations, these records represented the most critical element in the health system due to misunderstanding, errors, and loss of information caused by their use. Nevertheless, its main drawback was the difficulty, or even the impossibility, to retrieve information from paper records when there were needs in the future and/or outside the hospital.

This situation was largely inefficient, especially from the patient's point of view. Indeed, he or she had to spend a lot of time moving to and from the hospital and supporting a great deal of stress to supply time and again the same information (often in an incomplete, vague, or erroneous manner), and eventually suffering for errors and/or unavailability of information previously stored in other records.

To overcome this drawback, in the past few years, the health care systems has largely changed the way in which their services are produced and supplied. In order to improve the quality (e.g., better diagnosis and treatments), guarantee more comfort to the patients, increase the efficiency of the systems (e.g., reducing time in hospital and, more generally, any type of side-effects), and have a more rational use of the money, ICT (information and communication technologies) has spread throughout fields of health care. Indeed, due to the power of ICT to make interoperable the different elements and actors, useful synergies have been exploited to better use any resource.

This contributes to improve the quality of the services (qualified and specialized services may be provided in spite of geographical location) and, at the same time, to improve efficiency (because it is possible to better distribute loads and to exploit synergy and scale economy).

To achieve this result, the various apparatuses, components, and systems (once autonomous entities) are no longer insulated but rather are grouped into networks to allow sharing information, to support cooperation, to exploit complementary, and to implement supplementary strategies.

In this framework, from the patient's point of view, any single element of the system is less and less important owing to the network as a whole providing the services. This is obtained by integrating multichannels delivery strategies into the front-ends and making interoperable the various back-end elements.

Implicitly in this change of paradigm is the increased rule played by technological infrastructures in the health care systems. These infrastructures that, until few years ago, were not strictly related with the core business (i.e., supply care) but rather confined to complementary activities, today are becoming the backbone of any health care system.

Unfortunately, this introduces many *dependency* and *interdependency* links among the various components. This represents the real weakness of this scenario. Indeed, even if a network-based health care system is more robust than a model composed by single "asset" with respect to a component's failure, it appears more fragile to "catastrophic" events. The presence of these interdependencies (many of them not designed or considered at implementation time and actually poorly known or even completely hidden) exposes the system to a huge variety of threats. Moreover, it makes the system susceptible, due to domino and cascade effects, to simultaneous failures of many services, as dramatically emphasized in health care and other sectors by the blackouts of 2003 (Italian Government Working Group, 2004).

Then, moving from a traditional health care scenario to a network-centered framework, we improve our capabilities to provide efficient, effective, and economic services, but at the same time, we also need to consider the side-effects so introduced. This chapter is devoted specifically to pinning down some of them and to stimulating great attention to this topic.

BACKGROUND

To analyze the amplification of negative consequences of a failure owing to the presence of interdependencies among the various infrastructures used inside a modern hospital, we have used the Input-output Inoperability Model (IIM). IIM is a simple tool, proposed by Haimes and Jiang (2001), to emphasize how the presence of dependencies and interdependencies among the various components of a complex system may facilitate the spreading of degradation.

Haimes and Jiang (2001) set up this model, building on the well-known theory on market equilibrium by Nobel Prize winner Wassily Leontief. The IIM uses the same framework proposed by Leontief but instead considers how the production of goods or services of a firm influences the level of production of the other firms; it focuses its attention on the spreading of "degradation" into a networked system. To this end, the authors introduce the concept of *inoperability*, defined as the inability of a system to perform its intended functions and analyze how a given amount of inoperability inside one element influences the other components of the network.

Haimes, Horowotz, Lambert, Santos, Lian, and Crowther (2005) use this approach to analyze how inoperability induced by a High Altitude Electromagnetic Pulse (HEMP) affects the various sectors of the U.S. economy and to estimate the recovery time under various hypotheses. In Reed, Chang, and McDaniels (2006), this approach has been used to provide a tool for resource allocation for postevent recovery considering the Katrina hurricane scenario, while in Panzieri and Setola (2008), the approach is modified to also explicitly consider the spreading of failures.

The great interest in this approach is related to its simplicity, even if the results that it provides are, for many aspects, largely qualitatively and oversimplified.

The idea at the base of IIM is that an event (e.g., a failure) that reduces the capability of the *i*-th infrastructure to correctly operate induces degradation also in other infrastructures that use services or goods produced by the *i*-th one. This degradation may further propagate involving other infrastructures (cascade phenomena) or even exacerbate the negative consequences into the *i*-th one (feedback effect).

Mathematically, IIM describes these phenomena on the basis of the level of inoperability associated with the various infrastructures. Specifically, the inoperability of the *i*-th infrastructure is coded via the variable x_i defined in the range [0, 1], where $x_i = 0$ means that the infrastructure is fully operative, while $x_i = 1$ means that the infrastructure is completely inoperable.

The inoperability induced on the system due to persistent external causes u_i is calculated via the following dynamic equation:

$$\mathbf{X}(k+1) = \max\left\{\mathbf{A}\,\mathbf{X}(k) + \mathbf{U}, \mathbf{1}\right\} \tag{1}$$

where $\mathbf{X} \in \mathbb{R}^n$ and $\mathbf{U} \in \mathbb{R}^n$ are vectors composed, respectively, by the level of inoperability and external failure associated with each one of the *n* infrastructures considered in the scenario. $\mathbf{A} \in \mathbb{R}^{n\times n}$ is the Leontief matrix, which entry a_{ij} represents the level of influence that the inoperability of the *j*-th infrastructure has on the *i*-th one.

We impose that $a_{ii} = 0 \;\; \forall i$ because we do not consider any recovery phenomena. Notice that in the model, $a_{ij} = 1$ means that the *i*-th infrastructure is completely dependent on the *j*-th one, because a given amount of failure in the latter will directly induce an equal level of degradation into the *i*-th infrastructure.

In order to evaluate the level of dependencies of an infrastructure, we introduce the *dependency index*, defined as the sum of the Leontief coefficient along a single row:

$$\delta_i = \sum_j a_{ij} \quad \text{(row summation)} \tag{2}$$

This index represents a measurement of the robustness of the corresponding infrastructure with respect to the inoperability of the others. If this quantity is less than 1, then the *i*-th infrastructure preserves some working capabilities (e.g., thanks to the presence of buffers, UPS, etc.) in spite of the level of inoperability of its suppliers. On the other side, when $\delta_i > 1$, the operability of the *i*-th infrastructure may be completely nullified, even if the supplier infrastructures show some residual capabilities.

The influence that a specific infrastructure has on the global system may be evaluated, considering the *influence gain* (i.e., the sum of the Leontief coefficients along a single column)

$$\rho_j = \sum_i a_{ij} \quad \text{(column summation)} \qquad (3)$$

A large value for this index means that the inoperability of *j*-th infrastructure will induce significant degradation into the whole system. When $\rho_j > 1$, the negative effects induced by cascade phenomena on the other infrastructures are more relevant in terms of inoperability than that affecting the *j*-th one. The opposite happens when $\rho_j < 1$.

FRAGILITY OF A MODERN HOSPITAL

We use IIM to analyze the impact of a failure in the *IP-network* of a hospital comparing the consequences induced in a modern hospital with that registered in a traditional one.

Specifically, we applied this model to the actual and to the in-building hospital of our university. Indeed, actually the CAMPUS has a traditional hospital, but it is building a new one with a very strong modern idea.

We adopt a very crude approximation modelling each technological infrastructure presents inside the hospital as an entity that the level of operability depends, further to external causes, on the availability of "resources" supplied by other infrastructures. The technological infrastructures on which we focus our analysis are reported on the right of Figure 1.

In a modern hospital, as reported in Figure 1, technological infrastructures figure out a very complicated web of reciprocal influences. Inside this *Electric network* (L), *Infrastructure monitoring* (M) and *IP network* (E) represent hubs with the highest out-degree (i.e., number of outgoing links that are 10, 9, and 8, respectively). This means that these infrastructures have a large influence on the others (they have many non-null terms in the influence gain). On the other side, *Bio-medical apparatus monitoring* (H) has the highest in-degree (i.e., number of ingoing links that is equal to 9). Then the capability of this infrastructure to operate correctly largely depends on the operability of the other infrastructures. Consequently, in the corresponding row of the Leontief matrix, as shown in Table 1, many elements are different from zero, which suggests that the corresponding *dependency index* is quite large, making more "concrete" the risk that this

infrastructure exhibits large degradations owing to failures in other infrastructures.

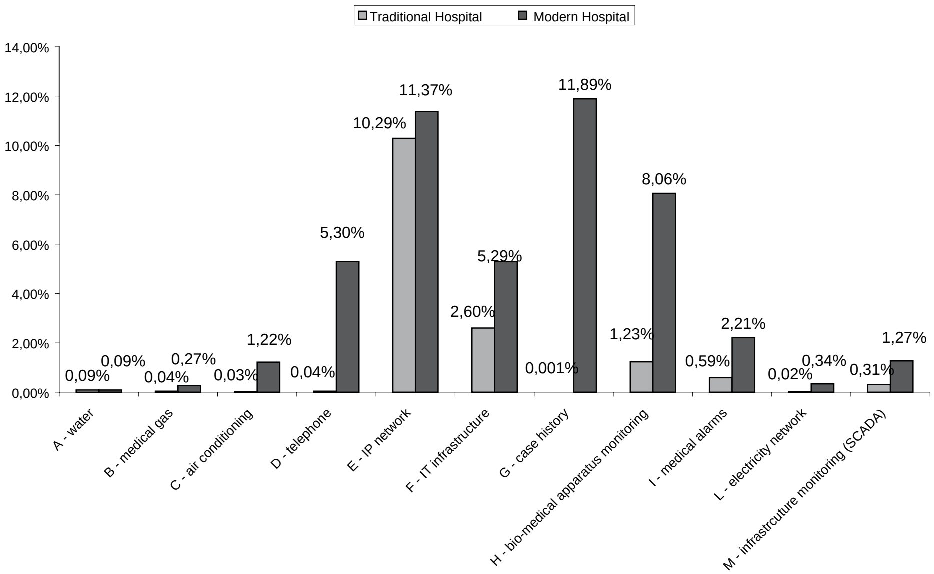
However, to better understand the role played by the various infrastructures and to identify the most critical elements, we have to also consider the degree of influence that characterizes the various links.

This represents the hardest task to be performed in order to apply IIM. In Haimes, et al. (2005), the Leontief matrix **A** is evaluated using the economical statistical data provided by the Bureau of Economic Analysis (BEA). In this chapter, we follow a different strategy evaluating these coefficients on the basis of information collected directly on the field.

To this end, we interviewed managers, architects, engineers, and technicians involved in the design of the various infrastructures for the new hospital. This information has been merged with "experiences" coming from doctors and medical assistants. Moreover, as proposed in Panzieri and Setola (2008), we also used schemas and maps of the infrastructures to also evaluate physical, geographical, and cyber interdependencies (for more information on this taxonomy, see Rinaldi, Peerenboom, and Kelly, 2001).

W

Figure 2. Impact induced by a failure that reduces 10% of the operability of the IP-network (E) in a traditional and a modern hospital. Notice that in the traditional hospital, the case history (G) is paper-based, while in the modern hospital, it is electronic.



Comparing the Leontief matrices of Tables 1 and 2, one can notice that in the modern hospital, there are more no-null elements, and that except for the relevance of the *telephone network (D)*, there is a generalized augment of the influence coefficients.

In Table 1, the *dependency index* δ_i varies from 0,05 (associated with the paper-based *Case history* (G)) to 0,95 (of the *Biomedical apparatus monitoring* (H)). Because this quantity is considerably less than 1 for quite all the infrastructures, we may infer that in a traditional hospital, the various infrastructures were substantially autonomous and able to correctly supply their services without the need of resources supplied by the other infrastructures.

On the other side, in a modern hospital (Table 2), this quantity varies from 0,11, corresponding to *Water infrastructure* (A), to 1,89 related with the *Electronic case history* (G). Moreover, *Biomedical apparatus monitoring* (H) shows a very high value (1,69). This means that there is a generalized interdependencies increment but also an augment of fragility because the failure of any infrastructure has a direct influence on the capability of the other infrastructures to correctly perform their own works.

Curiously, the case history infrastructure that in the traditional hospital is one of the less sensitive elements with respect to infrastructures' failures, becomes in the modern hospital (where the electronic version has been adopted) one of the most sensitive ones.

The level of influence varies for the traditional hospital, from 0 (*Case history* (G) and *Biomedical apparatus monitoring* (H) have no impact on the other infrastructures) to 2,23 of the *Electric network* (L). The large value of this last coefficient emphasizes the cornerstone role played by electricity in the traditional hospital.

If we look to the modern hospital, we see that the influence gain varies from 0,02 (associated with the *Bi-medical apparatus monitoring* (H)) to the value 3 of the *Electric network* (L). However, in this scenario, the influence gain associated with the *IP-network* (E) and that of the *IT-infrastructure* (F) are 1,93 and 1,34, respectively. This pins down two elements. First, the importance of the electric network is increased, and it is still the most critical infrastructure within the hospital. Second, as mentioned before, the capability of each infrastructure to autonomously operate has been reduced due to the need to use services provided by the others. Obviously, this makes the whole system more prone to amplify negative consequences owing cascade phenomena.

To compare the behavior of the two configurations, we analyze the overall consequences induced by a persistent failure that reduces 10% of the operability of the *IP network* (E) evaluating the steady-state solution of equation (1). The results are reported in Figure 2.

Looking to the traditional hospital, one observes that the other infrastructures are only marginally influenced by the failure in the *IP-network* (E). Only *IT Infrastructure* (F) and *Biomedical apparatus monitoring* (H) show a degradation greater than 1%. Moreover, due to the presence of feedbacks, the inoperability of the *IP network (E)* is slightly increased.

On the other side, the consequences of the same failure in the modern hospital are more relevant. It is evident that in this case there is considerable increment in the *IP-network (E)* inoperability (due to feedback) but also a generalized diffusion of inoperability. Indeed, except for *Water* (A), *Medical Gas* (B), and *Electricity* (L), all the infrastructures show an inoperability level greater than 1%. The highest rate of inoperability is shown by the *Electronic case history* infrastructure (G). It reaches a degradation of about 12%.

Looking to Table 3, one can recognize that the direct influence of the *IP-network* (E) on the *Electronic case history* (G) is $a_{GE} = 0,63$. Then, neglecting interdependency phenomena, we should have predicted a degradation of about 6%. Nevertheless, as shown, the presence of the interdependencies amplifies the consequences of the failure, producing an inoperability level that is quite the double of that foreseen in an atomistic analysis.

Obviously, modern infrastructures are designed, conducted, and managed with higher standards in order to improve their efficiency but also their robustness and business continuity. Then it is very difficult that the same "event" may cause similar consequences in both scenarios. Indeed, in everyday activities, we observe that in modern hospitals, quite all the consequences of negative events that affect, as in our example, IP-networks are absorbed without any appreciable degradation (thanks to redundancy, backup elements, etc.). However, as our analysis and different real-world episodes have shown, if an event is able to induce tangible degradation into a single infrastructure, it is largely amplified due to interdependencies and domino effects to a point that it may induce generalized inoperability in the whole system.

FUTURE TRENDS

It is evident that the in the next years, any system, including hospitals and health care systems, will use more and more ICT and other technological infrastructures. This will increment their networked-centered profile and, consequently, the presence of a huge number of dependencies and interdependencies within any element. This will contribute to improve the capability to provide very efficient services, but at the same time, as emphasized, it will make the system more prone to very catastrophic failures.

Then, it is mandatory to correctly figure out this complex scenario in order to understand the possible side-effects induced by the spread of ICT. Unfortunately, this represents a very difficult task, because actual methodological tools appear largely unaffected due to the complexity that characterizes interdependent frameworks. However, we should quickly learn how to approach this scenario in order to adequately manage its behavior.

This will represent one of the most important challenges for the next millennium.

CONCLUSION

An emergent paradigm in developed countries is the increased relevance of networked systems in any sectors. Indeed, technological, economical, sociological, and political reasons suggest, or better impose, to adopt a service-oriented paradigm where the customer (the patient) is collocated in the center of a complex web of technological infrastructures.

Specifically, in the health care framework, exploiting the facilities provided by ICT, it is possible to supply customized health services with very high quality, and better comfort for the patient; at the same time, we are able to reduce their costs.

However, this scenario, mainly dominated by the interdependencies phenomena, has to be carefully understood in order to manage its side-effects. Indeed, even if this framework appears very robust with respect to "normal" accidents, it is prone to some "rare" events (actually neither identifiable nor predictable) that may induce catastrophic and generalized failure in the whole system.

KEY TERMS

Asset: Element able to supply a specific service to an easily identifiable set of users (generally located in the proximity of the asset itself).

Dependency: The capability of an infrastructure to influence the state of another infrastructure; a *unidirectional* relationship.

Infrastructure: System composed by many interoperable elements, geographically dispersed, able to supply generalist products (that have to be specialized by the end-user) to an unforeseen set of users, difficult to identify and to estimate.

Inoperability: The inability of a system to perform its intended functions.

Interdependency: A *bidirectional* relationship between two infrastructures through which the state of each infrastructure is influenced or is correlated to the state of the other.

Service: Any activity identifiable by a tangible benefit for the end-user.

Wearable Kinesthetic System for Joint Knee Flexion-Extension Monitoring in Gait Analysis

INTRODUCTION

Posture and motion of body segments are the result of a mutual interaction of several physiological systems such as nervous, muscle-skeletal, and sensorial. Patients who suffer from neuromuscular diseases have great difficulties in moving and walking, therefore motion or gait analysis are widely considered matter of investigation by the clinicians for diagnostic purposes. By means of specific *performance tests*, it could be possible to identify the severity of a neuromuscular pathology and outline possible rehabilitation planes. *The main challenge is to quantify a motion anomaly, rather than to identify it during the test.* At first, visual inspection of a video showing motion or walking activity is the simplest mode of examining movement ability in the clinical environment. It allows us to collect qualitative and bidimensional data, but it does not provide neither quantitative information about motion performance modalities (for instance about dynamics and muscle activity), nor about its changes. Moreover, the interpretation of recorded motion pattern is demanded to medical personnel who make a diagnosis on the basis of subjective experience and expertise. A considerable improvement in this analysis is given by a technical contribution to quantitatively analyse body posture and gesture. Advanced technologies allow us to investigate on anatomic segments from biomechanics and kinematics point of view, providing a wide set of quantitative variables to be used in multi-factorial motion analysis. A personal computer enables a real-time 3D reconstruction of motion and digitalizes data for storage and off-line elaboration. For this reason, the clinicians have a detailed description of the patient status and they can choose a specific rehabilitation path and verify the subject progress.

In this context, the Gait Analysis has grown up and currently provided a rich library about walking ability.

In a typical Motion Analysis Lab (MAL), multiple devices work together during walking performance, focusing on different motion aspects, such as kinematics, dynamics, and muscular activity.

The core of the equipment used in the MAL is a stereophotogrammetric system that measures 3D coordinates of reflecting markers placed on specific anatomic "repere" on the body (Capozzo, Della Croce, Leardini, & Chiari, 2005). This instrumentation permits to compute angles, velocities, and accelerations.

The MAL is also equipped with force platforms, which reveal force profiles exchanged with ground on landing.

The electromyographic unit is deputed to measure muscle contraction activity by using surface electrodes. Pressure distributions can be obtained by means of baropodometric platforms, made up of a matrix of appropriately shaped sensors. A unique software interface helps the operator to simply manage data from the complex equipment.

BACKGROUND

Although its remarkable advantages, the Quantitative Gait Analysis require large spaces, appropriate environments, and cumbersome and expensive equipment that limit the use to restricted applications.

Moreover, the stereophotogrammetric system requires a pretest calibration and complex procedure which consists in the placement of reflecting markers on the subject body.

Electromyography may be obtrusive if needle electrodes are used to investigate deeper muscles or single motor unit activity. Because of this, although it is a widely accepted methodology, Gait Analysis is still quite difficult to be used in clinical contexts.

For these motivations, in the last few years technological research accepted the challenge of transferring any support and high level information close to the patient, better on the patient himself, by creating a *user friendly* patient-device interface. This means that health services can be brought out of their classic places with a remarkable improvement in health service and in health care based on prevention. Patient can be monitorized for longer time, ensuring the same high service quality at lower costs. A profitable combination of expertise and know how from electronic engineering, materials science and textile industry led to develop effective *Wearable Health Care Systems* (or simply *Wearable Systems*) (Lymberis & De Rossi, 2004). These latter ones had electronics integrated on traditional clothes, like on a breadboard. In order to allow subjects to freely move without constraints, improvements in materials manufacture, microelectronics, and nanotechnologies allowed us to develop a new generation of wearable sensing systems characterized by multifunctional fabrics (referred to as *e-textiles* or *smart textiles*), where electronic components are made up of polymeric materials, weaved or impressed on the fabric itself, without losing their original mechanical and electrical properties.

The main advantages of this advanced technology consist of:

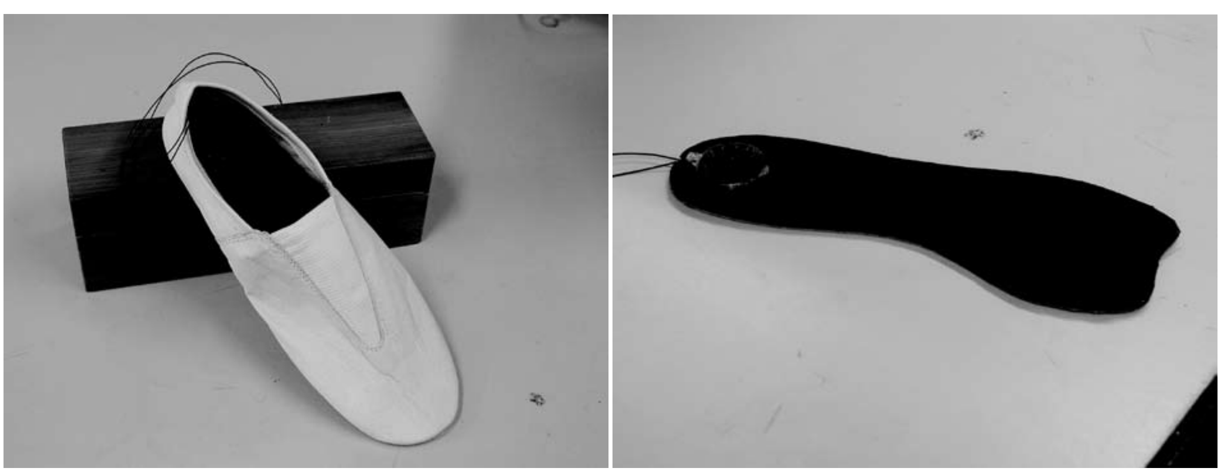
- Strict contact of fabric with skin, the natural human body interface
- Flexibility and good adherence to the body, which helps avoiding motion artefacts affecting the measurement
- Washability to be reused
- Lightness and unobtrusivity, so the patient can naturally move in his usual environment

By means of wearable systems, a large set of physiological variables (ECG, blood pressure, cardiac frequency, etc.) can constantly be monitored and quantitative parameters can be computed, from motion sensing, by dedicated software. Important applications related to health care deal with Ergonomics, Telemedicine, Rehabilitation, and any health service (elderly or impaired people).

MATERIALS AND METHODS

As described in the introductive section, Gait Analysis is usually performed for measuring kinematic variables

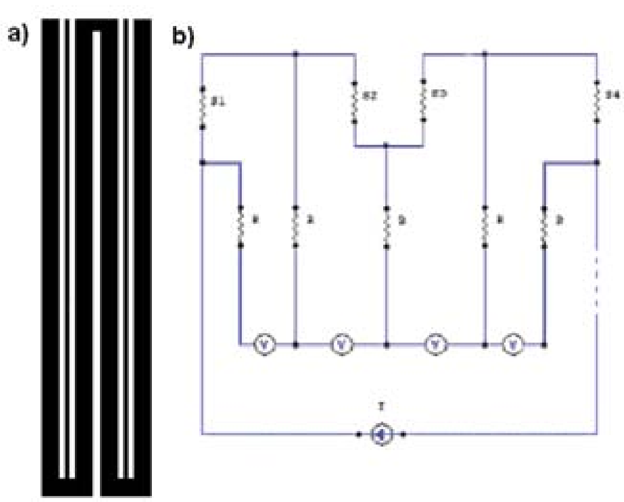
Figure 1. Sensorized shoe for marking the gait cycle



of anatomic segments with tracking devices, which have their main disadvantages in being complex, expensive, and not easy to be used in clinical environments. Thanks to the development of wearable systems, a new class of smart textiles (De Rossi, Santa, Mazzoldi, 1999) allows us to design and produce special garments using electrically conductive elastomer composites (CEs) (Post, Orth, Russo, & Gershenfeld, 2000). CEs show piezoresistive properties when a stress is applied, and in several applications they can be integrated into fabrics or other flexible substrates acting as strain sensors (Scilingo, Lorussi, Mazzoldi, & De Rossi, 2003). Such a sensors are just applied in sportive medicine for rehabilitation in soccer post-strokes, for athletic gesture analysis, for angles measurement, and for lower limb force analysis. We used a wearable prototype based on CEs sensors for the first time in a clinical environment. It consists of a sensorized fabric bend wrapped around the knee, very light, well adherent and elastic, hence very suitable for the chosen application. A sensing garment has been realized deposing the CEs over a sublayer of cotton Lycra® and building a sensorized shoe devoted to the gait cycle synchronism. The sensorized shoe consists of a pressure sensor realized of the same material of the knee-band (KB), and is placed on the sole near the heel, as shown in Figure 1.

The CEs mixture is smeared on the fabric previously covered by an adhesive mask cut by a laser milling machine. The mask is designed according to the shape and the dimension desired for sensors and wires. After smearing the solution, the mask is removed. Then the treated fabric is placed in an oven at a temperature of about 130 centigrade degrees. During this phase, the cross-linking of the solution speeds up, and in about 10 minutes the sensing fabric is ready to be employed. This methodology is used both for sensing areas and connection paths, thus avoiding employing metallic wires to interconnect sensors or link them to the electronic acquisition unit (Lorussi, Rocchia, Scilingo, Tognetti, & De Rossi, 2004). In this way, no rigid constraints or linkages are present and movements are unbounded (Tognetti et al., 2005).

Figure 2. (a) The mask used for the sensorised KB. (b) The equivalent electric scheme of the KB.

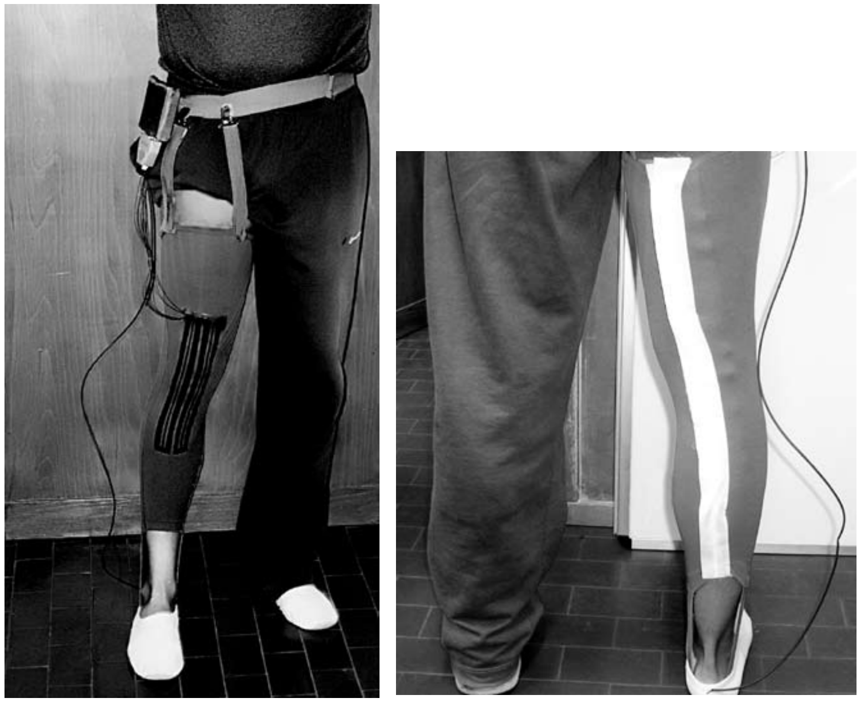


Section (a) of Figure 2 shows the mask for the realization of the KB; the bold black track represents four sensors connected in series and covers the knee joint. The thin tracks represent the connection between the sensors and the electronic acquisition system. Being the thin tracks are made of the same piezorestive mixture, they undergo a not negligible (and unknown) change in their resistance when the knee bends. To face this inconvenience, the analog front-end of the electronic unit is designed to compensate the resistance variation of the thin tracks during the deformations of the fabric. The electric scheme is shown in section (b) of Figure 2. While a generator supplies the series of sensors S_i with a constant current I, the acquisition system is provided by a high input impedance stage realized by instrumentation amplifiers and represented in section (b) of Figure 2 by the set of voltmeters. The voltages measured by the instrumentation amplifiers are equal to the voltages which fall on the S_i that is related to resistances of the sensors. In this way, the thin tracks perfectly substitute the traditional metallic wires and a sensor consisting of a segment of the bold track between two thin tracks can be smeared in any position to detect the movements of a joint. The KB acquires information on the flexion-extension of the knee from four sensors spread on a leotard and a step-signal from the sensorized shoe (Morris & Paradiso, 2002). Moreover, the prototype consisted of an "on body unit" dedicated to the acquisition of signals from the KB and the Bluetooth transmission to a remote PC as shown in Figure 3.

EXPERIMENTAL PROTOCOL

The prototype was used in a clinical application consisting of the gait monitoring on subjects affected by

Figure 3. The overall prototype consisting of a KB, sensorized shoe and an "on body unit." Front (left side) and back (right side) views



venous ulcers localized in the lower limbs. A test for discriminating between pathologic and normal walking was performed by the acquisition of flexion-extension signals from the knee joint during movement. Next, experimental data were validated in order to assess goodness of the methodology. Nine subjects, five females and four males, volunteered to participate in the study. The "normal" sample was made of four voluntaries, three males and one female, belonging to university context with a mean age of 32 years. Each subject was required to fill in a suitable anamnesis questionnaire in order to verify they did not undergo lower-limb injuries, disease, or trauma.

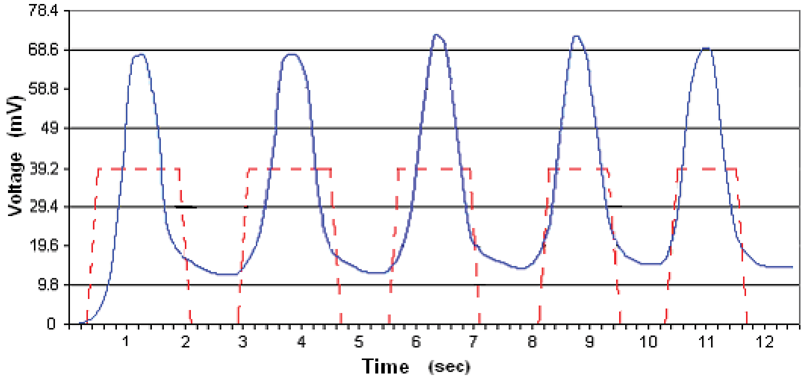
The "pathologic" sample consisted of five patients, four females and one male (mean age about 73 years), in-patient in a clinic specialized in vascular diseases, with special competences in cutaneous ulcers treatment (the medical partner in this work). The presence of the pathology under study was certified by consulting clinical folders.

After the measurement system was correctly applied, taking care of arranging the sensors upon the knee articulation, each subject was required to walk freely on a level ground. By means of a wireless communication system, based on Bluetooth protocol, data were transferred in real time from an on-body unit to a personal computer, where a software interface let the operator monitorize signals from the sensorized garment, including diagnostics and current settings. In a five-gait cycle observation interval the flexion-extension signals were acquired and the correspondent files stored for off-line elaboration.

DATA ANALYSIS

In the typical signal from a sensor of KB (continuous curve in Figure 4), resistance increases during flexion and decreases while the articulation extends, according to the piezoresistive effect. Voltage shows the same behaviour because the supply current was fixed for this kind of measurement. The synchronized matching with step-signal acquired from the sensorized shoe (dashed line) allowed us to detect the "gait cycle," or the elemental reference interval of the analysis. A single step-signal is an "on-off" signal where the low-level indicates that the foot is in contact with the ground, while the high-level indicates lifting.

Figure 4. Flexion-extension of the central sensor of KB (continuous curve) and signal coming from the shoe sensor (dashed curve) which marks the gait cycle



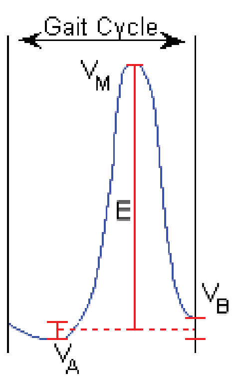
In order to extract significant variables for discrimination, two different approaches were studied. The first one, based on the evaluation of flexion-extension capability, was referred to as the *width excursion* parameter E, defined in Equation (1).

$$E = \left| V_M - \left(\frac{(|V_A - V_B|)}{2} + V_A \right) \right|. \tag{1}$$

V_M represents the maximum voltage width in the maximum flexion instant; V_A is the voltage value when flexion starts; V_B indicates the voltage value in the maximum extension instant such as shown in Figure 5. The second approach proposes to analyze gait discontinuity during the observed interval.

To do this we referred to the standard deviation over a sample made up of average width excursion (E) values, on the five-gait cycles. This parameter called *irregularity* (IR) was calculated both for central (IR_c) and lateral (IRL) sensors. In order to integrate information coming from each couple of sensors, a standard deviation was calculated with respect to their average value:

Figure 5. Graphical representation of the width excursion



$$E_{m_C} = \frac{E_{C_1} + E_{C_2}}{2}. \tag{2}$$

$$E_{m_L} = \frac{E_{L_1} + E_{L_2}}{2}. \tag{3}$$

E_{Ci} (i = 1, 2) indicates the width excursion regarding to central sensor i, while E_{Li} represents the width excursion related to lateral sensor i. IR parameters were computed by “nondistortion” method such as shown in Equation (4):

$$IR = \sqrt{\frac{\sum (x - \bar{x})^2}{(n-1)}}. \tag{4}$$

where x represents the sample arithmetical mean, while n is the dimension of the sample.

RESULTS

According to graphic representation of both IR_c and IR_L parameters over the entire recruited population (see Figure 6), several important issues have to be addressed:

- IR values showed fundamentally to be higher for pathologic subjects than for normal ones, confirming how they reveal an irregular knee flexion-extension during normal walking.
- A good discrimination between the two populations was obtained.
- IR values is higher in patients 5 and 1, which have a larger ulcer size, as it is known in clinical folder.
- Figure 6 reports on the discrimination on the basis of the irregularity of the mean value of central sensors IR_c and Figure 7 shows the graphical discrimination of subjects according to the irregularity of the mean value of lateral sensors IR_L. The graph IR_c reports a normal subject (normal 4) classified as belonging to the pathologic group, while in IR_L graph he is rightly recognized as normal. This means that, for our application, lateral sensors of KB resulted more specific than the central ones.

TEST EVALUATION

The test validity has to be intended as the capability by the test to discriminate between normal and pathological subjects within the recruited population. Receiver Operative Characteristic (R.O.C.) curves analysis provided its scientific support in this evaluation, mainly to decide the best cut-off value of parameters for discrimination. A R.O.C. curve is a graphic representation of sensitivity vs. false positive rate (FPR) for different cut-off levels of the measurement variable.

The best decisional value ensures maximum of sensitivity to the minimum FPR. By this method, optimal cut-off value of irregularity was detected both for central sensors and for lateral ones (see Figure 8) and the test characteristic parameters were computed, in terms of sensibility, specificity and positive predictive value (PPV), as shown in the Table 1. Positive predictive value is directly proportional to disease prevalence in the study population. For a good test a high PPV is more significant if prevalence is high too. In our study, prevalence was high enough (55%), so PPV values of 80% and 100% gave to the test a good validity score, together with high sensibility and specificity. Lateral sensors showed to be equally sensitive but better specific and predictive than central ones. However these results should be verified over a wider population.

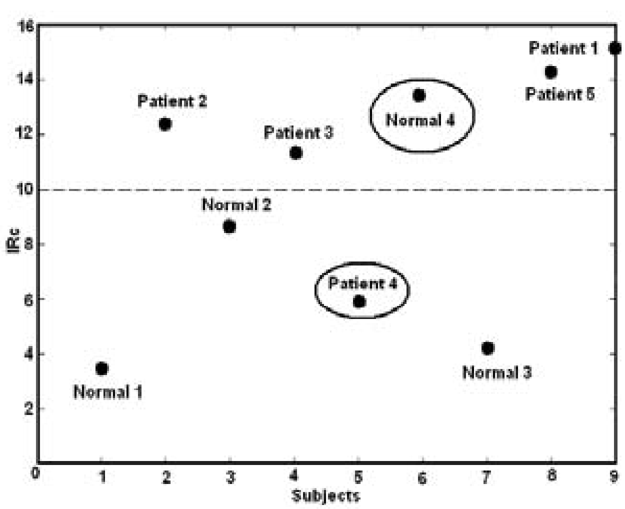

Figure 7. Graphical representation of IR_L parameter

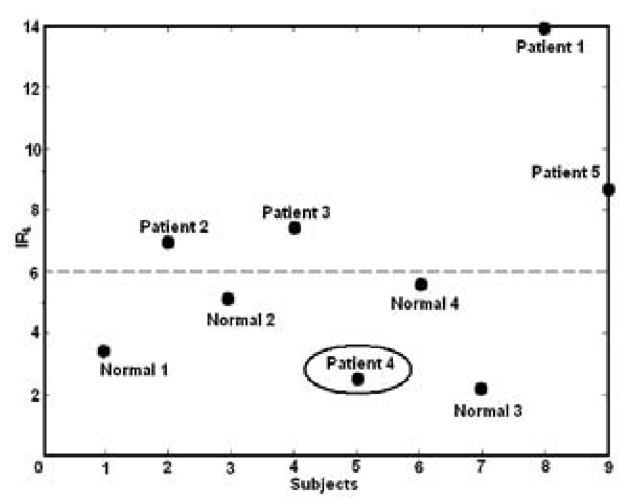

CONCLUSION

In this article, we reported on the possibility of using a wearable kinesthetic system for monitoring through gait analysis the improvement of patients suffering from venous ulcers after undergoing surgical operation. As a validation tool, a preliminary pilot test has been realized, which reports a good capability of discriminating health from injured subjects. Furthermore, results demonstrated the possibility of identifying the severity of the disease in the pathologic group by analyzing of walking activity.

Commonly in the clinical practice, these patients are monitored by means of obtrusive instrumentation aimed at evaluating how the circumference of a thigh increases over time. We used an alternative approach to investigate the illness progress. As patients suffering from this illness exhibit an irregular gait, we customized a sensing garment in order to analyze the gait discontinuity.

Therefore this prototype could be a means that allows clinicians to monitor patients without causing any discomfort during the recovery process after a surgical operation.

Next, developments aim at extending this application to the study of hip motion. Finally, it has been pointed out that the use of these sensorized garments can be considered a valid alternative and comfortable instrumentation applicable in several rehabilitation areas, such as in sport disciplines and in multimedia fields.

Table 1. Sensitivity, specificity, ppv and vpn value of the sensors central and lateral

Central sensors		**Lateral Sensors**	
Sensitivity	80%	Sensitivity	80%
Specificity	75%	Specificity	100%
PPV	80%	PPV	100%
VPN	75%	VPN	80%

KEY TERMS

Anatomical Repere: A prominent structure or feature of the human body that can be located and described by visual inspection or palpation at the body's surface; used to define movements and postures. Also known as anatomical landmark.

Conductive Elastomer Composites: A rubberlike silicone material in which suspended metal particles conduct electricity.

Piezoresistive Effect: The changing electrical resistance of a material due to applied mechanical stress.

Quantitative Gait Analysis: Useful in objective documentation of walking ability as well as identifying the underlying causes for walking abnormalities in patients with cerebral palsy, stroke, head injury, and other neuromuscular problems

Wearable Systems: Devices that are worn on the body. They have been applied to areas such as behavioral modeling, health monitoring systems, information technologies, and media development.

Web-Enabled System Design for Managing Clinical Information

INTRODUCTION

Healthcare is characterized by a highly complex environment where the process of patient care requires an unusual amount of communication between different healthcare professionals (HCPs). For a better patient care, the various HCPs have to cooperate, a processed often called shared care (Garde & Knaup, 2006; Schabetsberger, Ammenwerth, Andreatta, Gratl, Haux, & Lechleitner, 2006). Nowadays, there is an increasing incorporation of a heterogeneous set of Information Systems (ISs)—paper-based and computer-based—on the daily work of HCPs, in order to retrieve information about patients (Coiera, 2003; Van-Bemmel & Musen, 1997). The complexity of the patient care process combined with the heterogeneity of the information resources leads to a paradigm of data redundancy in the healthcare services in general, and hemophilia care in particular.

Hemophilia is a chronic disease that affects about 400,000 people worldwide; however, most of these people do not have access to adequate treatment (Evatt, 2005). A system for patient registry is a critical tool for monitoring, identification, and diagnosis of these patients; furthermore, it serves as an essential tool for managing their treatment. A registry is a database or a collection of records of people identified as having hemophilia or inherited bleeding disorders (Evatt, 2005). The purpose of a registry is to define the population demographics and collect observational data on specific hemophilia health concerns such as the prevalence of viral infections, factor inhibitors, implementation of prophylaxis for children or different product usage (Baker et al., 2004).

Portugal, in spite of having about 1,000 patients with hemophilia, doesn't have a hemophilia national patient registry, and most hemophilia treatment centers (HTCs) don't have a specific system to store and manage information concerning this pathology.

In order to help the management of this information at the *Hematology Service of Coimbra Hospital Center* (HS_CHC), as well as to facilitate communication between HCPs and patients, and improve the utility and quality of clinical data and treatment information, a Web-based IS under study is briefly presented in this work. To guide this study, namely along its design process, we followed an approach that combines a *grounded theory* approach with evolutionary design based on constant development, evaluation, and refinement of the generic domain model.

BACKGROUND: HEMOPHILIA CARE, INFORMATION AND TECHNOLOGIES

Hemophilia is an inherited bleeding disorder caused by low concentrations of specific coagulation factors (Bolton-Maggs & John-Pasi, 2003). With proper treatment, people with this disease can live healthy lives; otherwise, hemophilia causes crippling pain, severe joint damage, disability, and death (Baker et al., 2004).

Around 30 years ago, the development of coagulation-factor concentrates changed the life of these patients and allowed to treat them at home maintaining a high level of independence; thus, currently, most people with severe hemophilia are on therapy at home with infusion of the coagulation-factor concentrate. While some studies demonstrated significant quality of life benefits associated with home therapy using coagulation-factor concentrates (Teitel et al., 2004), this increased the difficulty to monitor their treatment and progress as well as to detect complications. For instance, many patients arrive at their care center without their home treatment record. Even when they have completed a paper record, uncertainties are often expressed as to the validity of the data, because it is possible that much of the data is entered retrospectively immediately prior to the clinic visit. Thus, there is an urgent need for the collection of meaningful outcome data for hemophilia, and in turn this means being able to obtain accurate records of home administration of coagulation-factor concentrates (Baker et al., 2004).

Web-based IS have the potential to support the ongoing care needs of patients as well as the collaborative management of with a chronic disease, like hemophilia. According to Baker et al. (2004) and Walker et al. (2004), one of the most relevant applications of electronic recording through the Web is the identification of early episodes of bleeding in the home setting, which otherwise would not have become apparent until the time of the patient's next clinic visit. A Web-based IS is also particularly helpful in identifying inappropriate use of coagulation-factor concentrates during home therapy.

Since hemophilia care is very expensive, cost-effective use of resources is extremely important; however, ensuring better data quality requires a continuous improvement process that includes the adoption of new information technologies, timely data entry, and rigorous audit and definition of data fields (Baker et al., 2004; Haux, 2006). Improving communication between patients and hemophilia center HCPs and the quality and timeliness of data collection and manipulation gives a better opportunity to improve long-term clinical outcomes in a cost-effective way (Collins et al., 2003). Moreover, improved communication pathways with HTCs can help minimizing the sense of isolation that patients with this disease may experience.

WEB-BASED INFORMATION SYSTEM TO SUPPORT HEMOPHILIA CARE

Motivation and Problem Context

The HS_CHC (one HTC in Portugal) requested the present study in order to evaluate the feasibility and usefulness of a Web-based IS to collect, record, and manage hemophilia patient data, based on the previous mentioned reasons. This HTC provides assistance to patients in three integrated Hospitals (*Central Hospital*, *Bissaya Barreto Maternity Hospital* and *Pediatric Hospital*) and provides clinical and laboratorial support to other hospitals all over Portugal.

Nowadays, the Portuguese Health Service uses several different computer-based ISs, in order to support the information flow and communication between different HCPs. The computer-based ISs used in HS_CHC are, basically: (i) *Integrated Hospital Information Systems* (IHIS)—which allow to visualize, manage and archive the administrative information while creating a clinical process; (ii) *Medical Support Information System* (MIS)—which allows to visualize, manage, and archive the clinical information during the medical appointment; (iii) *Nursing Support Information System* (NIS)—which allows to visualize, manage and archive nursing information during treatments; (iv) *ClinidataXXI*—to archive clinical analysis results and laboratorial information providing online service at the three aforementioned hospitals.

These computer-based ISs represent generic solutions, since they were developed to support general requirements of hospitals and cannot respond to the specific needs of hemophilia care. However, hemophilia center HCPs generate a lot of information when they observe their patients. Part of this information is in electronic format and is stored in computer-based ISs, but another part (i.e., home treatment records) is on paper format and is stored in paper files.

At present, patients record the result of hemophilia home therapy in paper diaries and send them to the HTCs by post, or bring them when they attend routine review appointments. This system has a number of weaknesses, as often paper records are incomplete or not returned. Furthermore, the period between individual infusions of treatments and receipt data may be long, which is undesirable, since that data is very important for clinical decisions about treatments. In this pathology, the information result of home therapy is more than a resource, since clinical decisions about patients' treatment depend on it.

The fact that the information concerning hemophilia patients is spread throughout different ISs is an obstacle for quality of data, fast retrieval of information, and thus healthcare quality. The need of an integrated IS for this specific pathology is obvious, and new technology has an important role in this field for developing a Web-based IS.

Our Proposal and Approach Followed in to Design

As mentioned, the goal of this proposal is to develop a Web-based IS to support the management of inherited bleeding disorders, which integrates, distributes, and archives large sets of information from heterogeneous sources in the scope of hemophilia care at HS_CHC.

To conduct this study, we followed an approach that combines a *grounded theory* approach with evolutionary design based on the constant development and refinement of the generic domain model, as shown in Figure 1.

Without constant and rigorous evaluation, the impact of new systems on the quality of care is unknown, and it is possible that badly designed systems could significantly harm patients (Cysneiros, 2002). To overcome these limitations we followed a specific approach to design the hemophilia Web-based IS. The main idea of our approach was the use of *grounded theory* to support the process of requirement engineering in a complex environment on the basis of a comprehensive domain model.

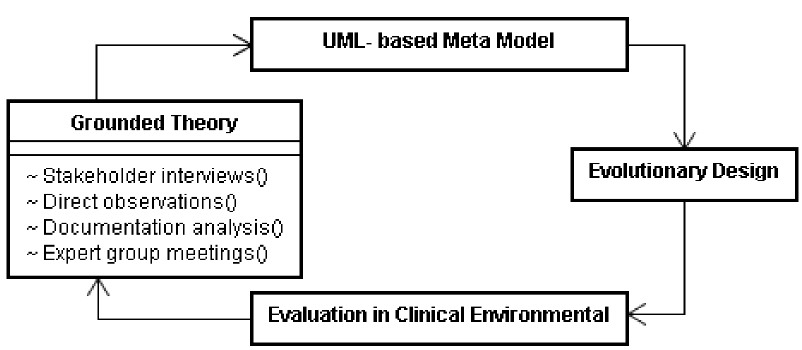
The *grounded theory* approach was published by Glaser and Strauss (1967) as a qualitative method in social research. It supports the inductive development of theories which are grounded in data to explain a phenomenon (Denzin & Lincoln, 2000; Strauss & Corbin, 1998), in the present context, the clinical practice in the HS_CHC. A theory is developed by systematically recording and analyzing data related to the phenomenon, in a process called constant comparison.

For the development of this domain model, we used the methods of software engineering, basically in two stages: requirement analysis and modeling. Requirement analysis is an important part of the software engineering process, where the needs or requirements of the system are identified (Maciaszek, 2005; Teixeira, Ferreira, & Sousa Santos, 2005). During the first step of the requirement analysis phase, we analyzed the clinical practice in typical environments of HS_CHC, in order to stimulate basic research, as well as understand the information flow and the management process of clinical data (Teixeira, Ferreira, & Sousa Santos, 2007). This analysis indicated that even though departmental information systems have sometimes been interfaced in order to transfer some data among a patient registration system, laboratory system, and medical system, this was usually based on ad-hoc activities without the implementation of a global communication concept.

In the second step of the requirement analysis, we tried to have a clear and detailed specification of the actors' functional requirements. The aim of this stage was to identify the characteristics of information, the users' needs, the key tasks they will perform with the system and the system functionality.

Basically, we started with a systematic analysis of the clinical practice, using direct observation, documentation analysis and unstructured interviews, in order to understand the particular characteristics of

Figure 1. High-level overview of the steps followed in design [adapted - Garde & Knaup, 2006]



this specific practice. Based on this, we developed a first domain model. In order to validate and improve it and to develop a valid theory (triangulation), this method was complemented with other gathering data techniques. We systematically collected, structured, and discussed the results in regular meetings with the expert physicians. From the experience and feedback of human actors we refined our domain model.

Having identified these requirements, appropriated modeling techniques had to be used. An object-oriented environment of design was selected, since it would allow to incorporate new components based, for instance, on decision support methods or techniques for formulating complex queries on the stored data. Thus, we applied the *Unified Modeling Language* (UML) to create a comprehensive domain model for capturing the requirements. We have chosen UML since it is an object-oriented design technique representing a standard language for specifying, visualizing, constructing, and documenting the artifacts of systems (Booch, Rumbaugh, & Jacobson, 1999; Whitten, Bentley, & Dittman, 2004).

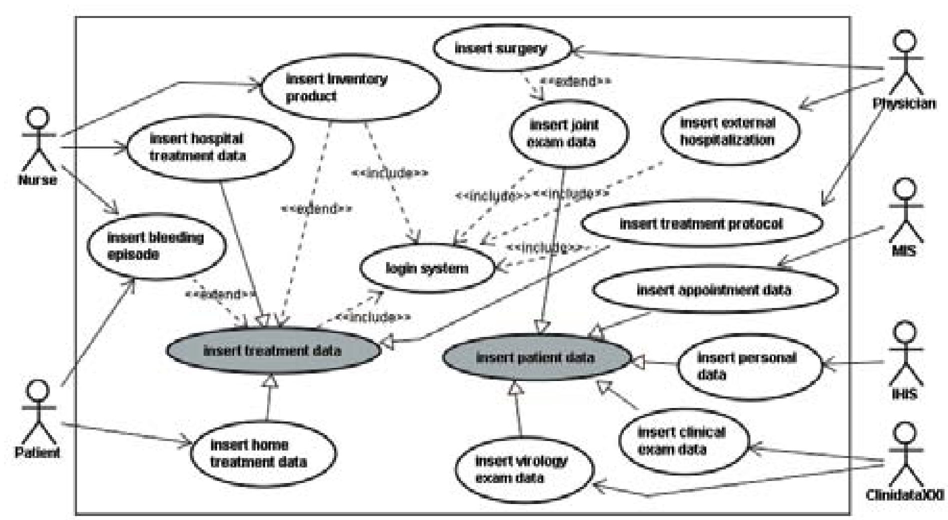
As a result of the requirement analysis step we identified the actors, functionalities of the system, and main classes of information for modeling the domain. We used the *use case* diagram of UML to describe external elements (actors) and main functionality (*use cases*); they are generally regarded as an excellent technique for capturing the functional requirements of a system (Fowler & Scott, 1997). The identified actors are the physician, nurse, patient (human users), and IHIS, MIS, ClinidataXXI (other systems). Figure 2 shows which actors interact with each *use case* for the main functionality, as well as the key processes involved in information introduction.

Patients have an individualized password protected home page, which can only be accessed by themselves or, in case of children, old people or illiterates, by a caregiver. For example, when a patient receive a treatment (infusion of coagulation-factor concentrate), they can access their personal page and enter details about treatment, symptoms of bleeding episodes associated, and the amount and batch number of coagulation-factor concentrate. If the treatment takes place in HCT, these data could be inserted by a nurse that has an individualized password too. The patient's page shows a recommended treatment regimen for prophylaxis and management of bleeding episodes. These treatment protocols are entered by a physician and can be updated at any time. Patient clinical evolution can be assessed trough the system in graphical and table formats. The HIS, MIS, and ClinidataXXI represent no-human actors and insert some data as personal data, clinical and virology exam data, and appointment data.

In order to detail the dynamic aspects of collaboration for the identified functionality, we used de sequence diagrams of UML. *Sequence* diagrams are interaction diagrams that specify how functionalities are carried out (what messages are sent and when).

For example, the diagram shown in Figure 3, was used to describe how objects (actor and classes) collaborate to execute the "insert treatment" functionality.

Figure 2. High-level overview of the UML use case diagram (including insertion tasks only)



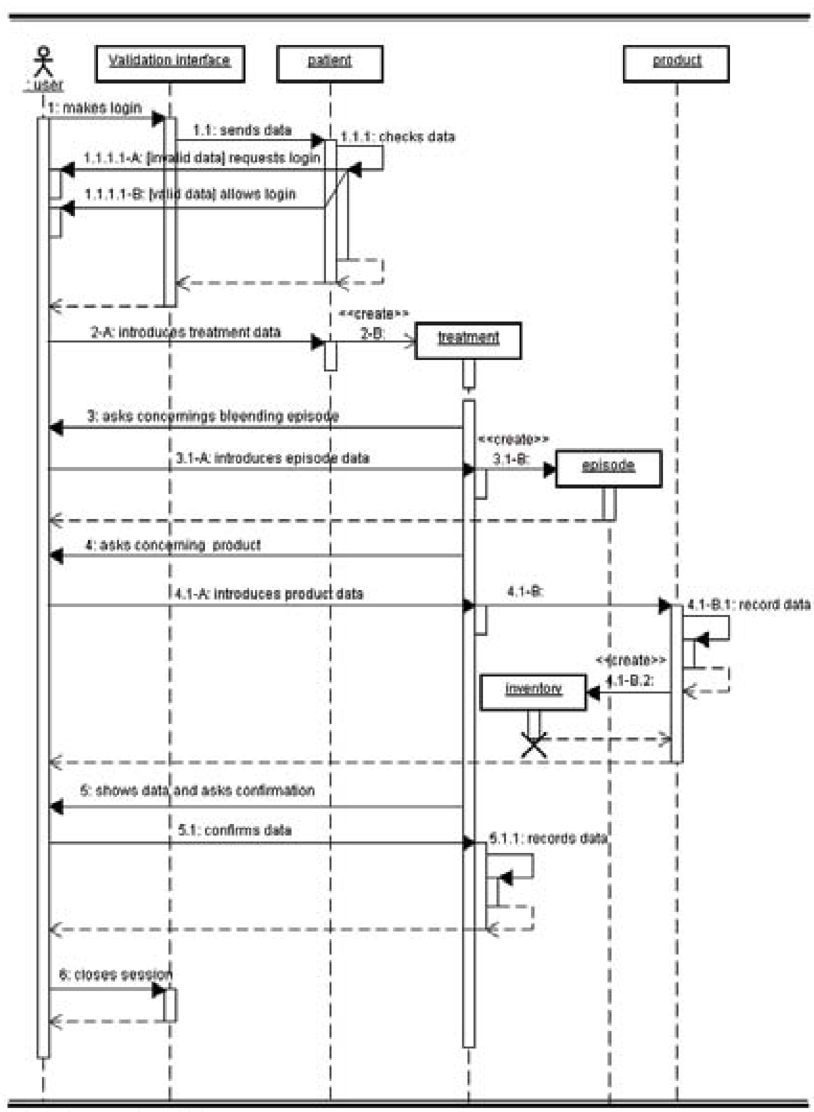
In order to represent the static structure showing object classes, attributes as well as relationships between those object classes, a *class* diagram of UML was used (Figure 4).

Besides patients' personal data, it is also important to record the data obtained from the medical program routines (appointments) and medical diagnosis. Patients' data are stored with a unique identification; each patient has a virology history, as well as a history concerning clinical analysis, external hospitalization, and so on. Also regarding the patient, it's necessary to store additional data obtained during the first medical appointment and routine review appointments, such as family tree and family history, joint condition, treatment history, and life quality.

Each patient can undergo many treatments. The treatments can be on-demand or prophylactic. On-demand treatments have associated bleeding episodes (in a joint, muscle, or mucosa). On the other hand, treatments can be made at home, at HTCs or at another hospital.

Usually, treatments consist of infusion of blood products (coagulation-factor concentrates), which are

Figure 3. UML sequence diagram of the "insert treatment" task



Note: user can be a patient or a nurse

Figure 4. UML class diagram (giving overview of domain model information)

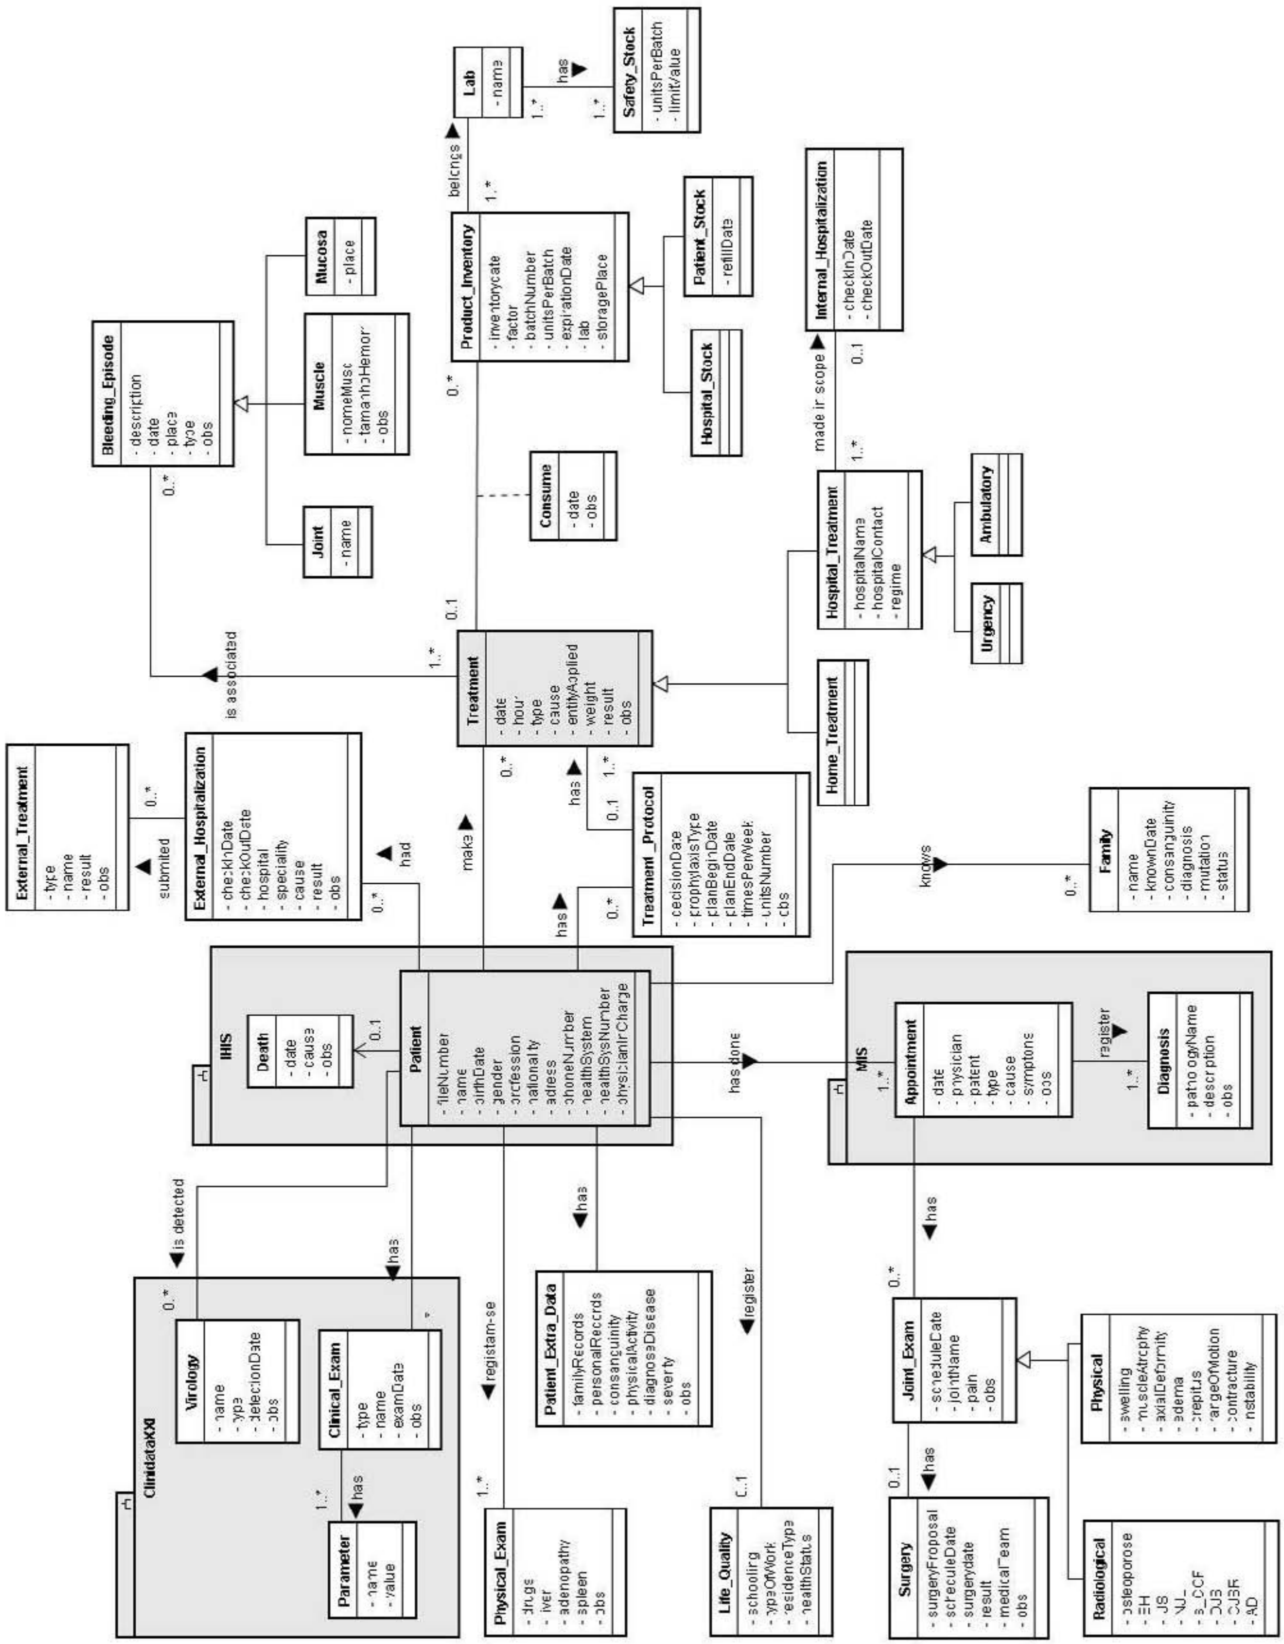


Table 1. Relationship between the functionality (presented in the use case diagram) information classes (presented in the class diagram) and corresponding permissions

Actor	Funcionality	Information Classes (permission)
Patient	+ insert treatment data - home treatment + insert bleedind episode	+ Patient (read) + Treatment (write) + Product_Inventory (update) + Bleeding_Episode (write)
Nurse	+ insert treatment data - hospital treatment + insert bleedind episode + insert product inventory	+ Patient (read) + Treatment (write) + Bleeding_Episode (write) + Product_Inventory (write, update)
Physician	+ insert patient data - joint exam + insert surgery + insert ext hospitalization + insert treatment data - insert treat protocol	+ Patient (read) + Family (write, update) + Diagnosis (write) + Physical_Exam (write) + Patient_Extra_Data(write) + Life_Quality (write, update) + Joint_Exam (write) + External_Hospitalization (write) + Treatment_Protocol (write, update)
MIS	+ insert patient data - appointment	+ Appointment (write) + Diagnosis (write)
IHIS	+ insert patient data - personal data	+ Patient (write)
ClinicadaXXI	+ insert patient data - clinical exam - virology exam	+ Clinical_Exam (write) + Virology (write)

Note: write permission receives by inheritance read permission.

in stock; thus, functionality concerning the management of the blood products inventory should also be integrated. When a blood product arrives at HTC, a nurse inserts its data into the system (name of product, data of reception, batch number, number of units per batch, validity); on the other hand, a blood product can be in different places, as it can be given to patients for home treatment or to a distant treatment center. When a blood product is consumed in the sequence of a treatment, the system should register this occurrence, and automatically update the stock.

All this information can be visualized (*read*), inserted (*write*), and updated (*update*) by different actors through different functionality (as shown in Table 1).

FUTURE TRENDS

We are currently implementing, for the *Hematology Service of Coimbra Hospital Center*, a prototype of a Web-based IS according to the above described domain model. If this Web-based IS proves to be a good tool for delivering hemophilia information services in this center, we would like o extend this solution to other HTCs in Portugal, in order to contribute to the development of a hemophilia national patient registry. Moreover, we should also take into consideration that there are significant technical and regulatory issues surrounding the privacy, security, and confidentiality of individually identifiable health information, which need to be settled.

CONCLUSION

The use of electronic records within healthcare systems is increasing and the quality, usefulness and availability of patient information is potentially improved by this approach. Particularly in the hemophilia care, the availability of specialized IS within this community is gaining more importance.

Due to the decentralization of the staff working places, an efficient and effective integrated system can provide the necessary link between data collection, storage, and analysis. The ISs together with the Internet offer presently significant opportunities to HCPs and patients to improve their communication and joint management of chronic diseases, as hemophilia, at the same time, they offer to HCPs analytical tools to transform data into information and mine relevant information through data queries. On the other hand, using a Web-based IS, patients can have direct access to the system, to view their clinical history, as well as insert treatment data. The management and stock control of the products used in treatments can also be improved.

In this work, we described the design process of a Web-based IS for managing clinical information in hemophilia care to support patients assisted at the *Hematology Service of Coimbra Hospital Center*.

In order to collect the data and gather knowledge about domain of the *Hematology Service of Coimbra Hospital Center*, a *grounded theory* approach was conducted using techniques such as interviews, direct observations, expert group meetings, and analysis of existing documentation. The first phase was to identify the information gaps in the service. Then, we proceeded to the requirement analysis with business process assessment, direct, and indirect observation techniques and interviews with HCPs. Six actors were identified: patient, physician, nurse, and three already-existing ISs (MIS, IHIS and ClinidataXXI). Based on the identified actors and needs, a generic conceptual model was developed using *Unified Modeling Language*.

Healthcare industry is characterized for highly complex environments and information technologies can have a significant influence on the patient's health. However, technology misconception and/or misuse can be risky, and in severe cases, it can lead to the patient death. For this reason, any new systems have to be carefully validated and verified before becoming a part of routine patient care. For this reason, a good design process can give a major contribution, and we believe that by using a *grounded theory* based approach for the requirements engineering phase, we were able to design a Web-based IS, we deem will fulfill the needs of the Hemophilia Service. A prototype is currently under development and has already passed a first evaluation cycle.

ACKNOWLEDGMENT

The authors are grateful to Doctor Natália Martins of *Hematology Service of Coimbra Hospital Center* for providing us access to data and information systems, as well as for all the help in the requirement analysis and discussion of the proposed model.

KEY TERMS

Grounded Theory: Research method most often associated with the social sciences.

Healthcare Actors: Individual or group with an interest in the healthcare system, including patients and their families, nurses, physicians, laboratorial technical staff, and other external entities as regulators, insurance companies, and healthcare organizations.

Home Therapy: Process where the hemophilic patients receive treatment with coagulation-factor concentrates in their homes.

Modeling Process: Definition of the details of a business process flow, modeling all the data, and other relevant elements.

Requirement Analysis: All tasks that go into determining the requirements of a new or altered system, taking in account users' needs.

Requirement Engineering: Systematic requirement analysis.

Shared Care: Continuous, patient-oriented cooperation of hospitals, general practitioners, specialists, and other healthcare professionals (HCPs) during patient care.

Software Engineering: Application of a systematic, disciplined, quantifiable approach to the development of Information Systems/Software.

Unified Modeling Language (UML): A standardized specification language for object modeling that includes a graphical notation used for visualizing, specifying, constructing, and documenting the artifacts of a system.

Web-Based Information System: Information System that is accessed with a Web browser over a network such as the Internet or an intranet.

INTRODUCTION

The care of patients suffering from chronic diseases is a growing source of expense for health care services around the world. The implementation of new models for patients' treatment and follow-up needs to be faced in order to increase patients' quality of life, and to reduce the costs associated. In this article, we propose a point-of-care for home care scenarios that is based on the remote monitoring of biomedical parameters.

BACKGROUND

Research experiences in the past have proved that home care can maintain or even improve old or chronically ill people's quality of life, as well as decrease health care costs associated. Home care delivery can still be improved through advances in human-machine interfaces that enable users (i.e., mostly old people) to deal easily and nonintrusively with technology (Ades, 2000; Hernandez, Casas, Escarrabill et al., 2003; Morlion, Knoop, Paiva, & Estenne, 2002). Many limitations brought on by aging are expected to be overcome by innovation in the area of Ambient Intelligence (AmI) (Cucchiara, Grana, Prati, & Vezzani, 2005; Trivedi, Huang, & Mikic, 2005), and focused on the design of devices easy to use and easy to learn that work transparently and pervasively to aid the user (Remagnino & Foresti, 2005).

Therefore, next generation home care and follow-up systems have important challenges to face, such as the development of nonintrusive systems that provide the right medical services on a highly-usable basis or systems that require minimum human-machine interaction to promote an augmented environment while making computers disappear in the background. Of course, it is important to make these necessities possible by means of developing affordable solutions for public and private health care institutions, only achievable with low cost structures easy to install and to maintain.

In order to achieve these requirements, we propose a Wireless Sensor Network, based on a Home Area Network (HAN), featuring a gateway, several biomedical sensors (pulse oximeter, electrocardiograph, and accelerometer to quantify daily activity) that the doctor recommends to the patient to control his/her health and a user interface, key element to inform the user of events registered (such as start of the exam, low battery supply, etc.). All network nodes are provided with wireless capabilities to allow full mobility (ISTAG, 2002).

THE BIOMEDICAL WIRELESS SENSOR NETWORK

Requirements

The requirements taken into account when designing the home care point-of-care have been mainly: self-management, context awareness, plug-and-play features, and security. Due to the need to achieve wearable and low cost sensors, limited resources in processing power have also been taken into account.

Regarding self-management and plug-and-play capabilities, the point-of-care has been designed to automatically route data packets. That is to say that the user does not have to consider nodes' breakup, or the addition of new nodes/sensors to the network, as they are transparently recognized and managed. For security reasons, data coming from new sensors is not sent to the telemedicine server until approved by it.

The nodes of the wireless network have to be context aware to adapt their behavior accordingly to environmental variables that govern the system, such as the actor of the system and the actor's preferences, the moment of the day when usage takes place, season, and so forth.

Once again, it is important to achieve these goals by means of low cost systems, as these points-of-care will not be deployed massively or used in clinical routine if they are not cost-efficient and provide benefits over traditional health care delivery. Of course, as costs are reduced, limitations arise, such as processing power, tight memory sizes, or low power consumption (batteries are required to last long enough to allow several measures to take place, as well as to support the wireless radio link power consumption).

Above all, there are security issues to be considered. For real scenario setups where sensitive and personal data will be in transit through the network, refusing intrusions, avoiding denial of service, driving the system into a safe state in case of failure, and so forth, are a must.

Functionality

Based on the requirements stated above, the wireless sensor network consists of three different elements: a gateway (center of the point-of-care), the sensors (used to monitor the patient's vital signs), and the user interface (to inform of upcoming exams, problems, etc.).

The functionality of the different elements follows. The gateway has twofold capability: (1) it is used to communicate with the sensors that the patient has, and (2) it is needed to send data to and from the health care institutions (i.e., hospital, primary care, etc.). The information regarding the doctor's prescription of medical exams is sent to the gateway where it is stored, processed, and routed to the specific sensor, stating the duration, sample rate, quality of the measure, amplification factor, or any precise parameter needed to collect the data.

The sensors have been developed as stand alone wireless devices and have been provided of automatic start of the measure, auto-discovery, and auto-configuration facilities. That is to say that the patient does not need to take care of configuring nor connecting them, for instance, to upload or download the data collected. It is important to note that the user does not need to ensure either that the sensors are powered on and off, as they are suspended and resume automatically after a given time. When resume is done every half minute, several tasks take place:

1. Checking the state of the sensor to become aware of the patient's willingness to start an exam. When the user wants to commence it, the user places the sensor on, so that the device is able to collect data. This situation takes place no matter whether the doctor programmed the test or the patient decided to take it (because of not feeling alright).
2. Connecting to the gateway. The radiofrequency module is powered on and a "keep alive" message is sent to the gateway. If there is information that needs to be transmitted to the node, as imminent exams that need to take place, it is sent at this moment. Afterwards, if data are still stored in the sensor, the data are forwarded to the gateway.
3. Checking battery level. When batteries are close to being used up, an alarm is sent to the gateway and the user is notified so that the user can recharge them. This check is performed every 10 minutes instead of every half minute.
4. Checking network failures.

Once all these tasks have been performed, the device is suspended again to save batteries. Using this method, battery consumption is decreased up to a maximum of 60%.

Results

The abovementioned approach has led to the definition and development of a home point-of-care that aims to foster independent living of the elderly or chronically ill featuring high usability and minimum human machine interaction and remote monitoring.

This has been achieved using a gateway to route information from the house to outside institutions (hospitals, private institutions, etc.), and also within the home environment, through a network of monitoring sensors. In order to minimize maintenance and installation costs, as well as to improve usability, a wireless network (LR-WPAN) has been used to interconnect the sensors and the hub (Jimenez-Fernandez et al., 2006).

Each node (i.e., sensing device) has three different parts. First, the biomedical sensor itself: an off-the-shelf OEM board (ECG, pulse oximeter) or an ad-hoc module (accelerometer) that has been provided with a second component, an autonomous power supply. As the power requirements of each sensor are different, customized supply stages have been designed using a standard interface with commercial AAA batteries, and always looking for the highest efficiency that maximizes sensors' life time. Finally, the third part that has been added provides the "intelligence" explained in the requirements section: awareness of patient's willingness to perform a measurement, network functionality (e.g., routing, reconfiguration), and so forth. The main component of this stage is a radio transceiver in the ISM band of 2.4 GHz that implements the physical layer and the MAC layer of the IEEE 802.15.4 wireless standard. The main characteristics featured are:

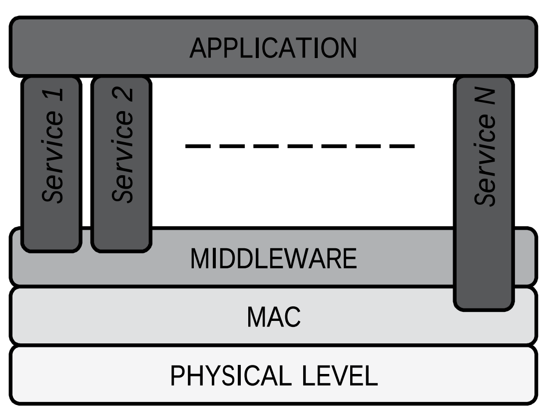
- Possible bit rates: 250 Kbps, 40 Kbps or 20 Kbps. We are using 250Kbps.
- Possible network topologies: mesh, star, or point to point. We are using star topology because it is more efficient for this propose.
- Support for low latency devices.
- Channel access using CSMA-CD (Carrier Sense Multiple Access/Collision Detection).
- Low power consumption.

Therefore, our network requirements and functionality suit perfectly with the given standard. In order to implement the remaining layers of the protocol stack, a low-cost PIC 16F microcontroller that connects to the radio transceiver through a SPI communication interface has been attached to each node. The commonly used OSI architecture has been refused in favor of an architecture based on services. The goal pursued with this design is the implementation of applications that arise as a mere aggregation of services and relations between services, rather than a node-focused orientation, simplifying the development of user applications (Sgroi, Wolisz, Sangiovanni-Vincentelli, & Rabaey, 2003). Our services are built on top of a communication middleware (Coleri, Puri, & Varaiya, 2003; Heinzelman, Murphy, Carvalho, & Perillo, 2004; Ranganathan & Campbell, 2003) that abstracts network or hardware specific tasks to the application. This middleware allows sending data to any node of the network without considering its location, sending broadcast messages, and so forth, and all this happens using a simple and unique interface (based on query-response) that can be dynamically instantiated in any node at any time. This allows us to easily compose applications taking into account many complex aspects, such as privacy, safety, load balancing, low energy consumption, and so forth (Coleri et al., 2003; Rabaey et al., 2000), and in a totally transparent way to the user. The protocol stack can be depicted in Figure 1.

The idea behind this approach is to isolate common behavior that can be reused from other applications and to encapsulate it as system services, so that once the system is running the addition of a new application becomes easy.

Another important fact that has to be emphasized is that, in contrast to traditional architectures, service oriented architectures do not force all services to access all middleware/layers available (as can be seen

Figure 1. Protocol stack



in Figure 1). For instance, in order to check battery levels, communication protocols can be bypassed and access to the physical level directly used, making signal processing more efficient.

All in all, an interoperable, reliable system, abstracting the hardware from the applications, has been designed, developed, and implemented. It is important to highlight that the size of the prototype is not comparable to that of wearable devices, but the aim of this work was just to emulate the behavior that wearable sensors will have in the future, not to miniaturize existing ones.

FUTURE TRENDS

This article has presented a system that addresses usability issues, plug-and-play interoperability, reconfigurability, and wireless communication between the different devices of the home's point-of-care. Emerging trends on the field of research are focused on applying standards to these issues in order to facilitate vendor interoperability and so avoid closed solutions. At the moment, there is a family of standards, ISO11073/IEEE 1073, that aims to increase interoperability at the hospital's point-of-care. Although it is not specifically designed to undertake the problem of integrating monitoring devices in the patient's house, it may be useful in our environment.

All in all, the aforementioned approach aims to solve the difficulties of device replacements and upgrades that usually lead to reconsidering the design of the whole system or, at least, to the modification of important software coding or hardware development. By applying these standards, communications between the different devices and the gateway will be transparent and universal no matter whom the vendor is.

CONCLUSION

The point-of-care described hereby has focused on usability concepts, aiming to develop intelligent and intuitive nodes able to respond to the activities and situations recognized in the user's environment.

The primary objective of this platform is to examine whether a system of basic biomedical sensors (motion sensors, ecg, pulse oximetry, blood pressure, etc.) is able to detect behavioral patterns and help aging and ill populations with everyday activities and health care follow up; that is to say, to provide the foundation for an Ambient Intelligence approach.

Finally, a flexible, dynamic, and easy to program architecture has been implemented, enabling software developers to focus on application level without paying attention to network and hardware levels.

KEY TERMS

Embedded System: Special-purpose system in which the computer is completely encapsulated by or dedicated to the device or system it controls.

Home Area Network (HAN): The interconnection of information technology devices within the range of a house.

Home Care: Health care given to a person at home that aims to enable people to remain at home rather than use residential, long-term, or institutional-based nursing care.

LR-WPAN: Low Rate Wireless Personal Area Network.

Point-of-Care: Care at the bedside or anywhere else where the patient might be, or where the caregiver makes the decisions.

Usability: Perception of a target user of the effectiveness (fit for purpose), efficiency (work or time required to use), and ease of use of a device, interface, computer program, Web site, and so forth.

Wearable Sensors: Biomedical sensors that, due to their small size and weight, can be worn on the body.

Wireless Communication: Communication that takes place via airwaves as opposed to cables.

Workflow Management Systems for Healthcare Processes

C. Combi
Università degli Studi di Verona, Italy

G. Pozzi
Politecnico di Milano, Italy

INTRODUCTION

Organizations achieve their goals by executing processes, which can be physical processes to produce goods (e.g., assembling components of a PC), information processes to manage information (e.g., to collect information about facts), or business processes (e.g., to produce goods, to provide services, and to manage information). Final goals are achieved by executing atomic work units (tasks), by coordinating them, by assigning them to executors (agents) that can be human or automatic ones.

A workflow management system (WfMS) is a software system that supports the execution of such processes inside organizations. A WfMS requires a formal description, known as schema or process model or workflow, for every process it has to manage: many instances (or cases) of a process can be executed at the same time, sharing the same schema, while each case has its specific data, like patient's name, insurance claim, and so on.

A WfMS has to manage a huge amount of data: to do that, it relies on a Database Management System (DBMS), which is mostly based on the relational data model. A WfMS is also tightly coupled to the Information Systems (IS) of the organization, and may be even more tightly coupled to the Decision Support System (DSS) of the same organization. In fact, the IS mainly focuses on data and data flows, without considering in detail the processes that produce/manage/consume data; the DSS, instead, helps the management to identify strategies for the organization, considering aggregated data possibly stored in a data warehouse.

At the early 2000s, the term of "scientific workflow" has also been introduced, mostly in the fields of bioinformatics and chemical informatics. However, scientific workflows do not refer to the specific context of processes and activities that can be suitably managed by a traditional WfMS, as defined above: scientific workflows rather refer to the need for multiple interconnected tools to handle large quantities of data, like those coming from different monitoring systems, with multiple data formats, and for interoperability purposes.

BACKGROUND

A WfMS supporting the coordinated execution of tasks by agents requires (Grefen, Pernici, & Sanchez, 1999) a formal description of the process (process model), a formal description of the organization where the process is executed, and whose agents will be assigned for the execution of tasks (organizational model), and a formal description of the information related to every case (information model).

The workflow designer is responsible for the definition of the process model, generally performed via graphical design tools, producing the formal description in a Process Definition Language (PDL) format. Every WfMS features its own PDL. The Workflow Management Coalition – WfMC – (http://wfmc.org), which is a nonprofit organization involving producers, vendors, and consultants, as well as users of WfMSs, defined a standard process definition language, namely X-PDL, based on the XML format of documents: recently, some WfMSs and some Workflow Designer Tools have been released, declaring themselves to be X-PDL compliant.

The organizational model describes the structure of the organization where the process is executed, and considers agents available inside that organization. Typically, information stored for every agent, beyond traditional ones, relate to the skills of the agent (e.g., secretary, nurse, physician, head of the department, CEO), authorizations granted to the agent (e.g., responsibility for a surgery intervention), localization of the agent (e.g., NIH at Bethesda, MD), working hours, and so on: these information are relevant for the scheduling and assignment of tasks to agents, balancing the workloads among available agents and maintaining constraints of tasks (e.g., deadlines for the completion of a task or the need of having two distinct executors for two tasks, like when one agent makes a proposal and a different ones approves or rejects).

The information model describes the data that are relevant for the process itself, like the patient's name, the patient's choices, the preferred food or diet (e.g., vegetarian) and so on: every case owns its data, which thus are case-specific. Data from the information model are also used to identify execution paths inside the process model. For example, if the patient suffers from diabetes, the task PrepareSugarFreeMeal will be executed; otherwise, the task PrepareNormalMeal will be executed. Data from the information model are stored by the underlying DBMS and, in some cases, can be shared with the IS and with the DSS.

The Architecture of a WfMS

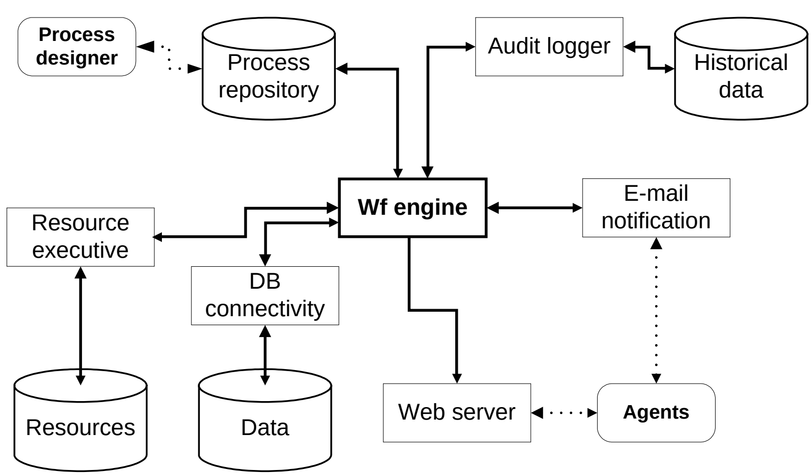
In order to support the coordinated execution of tasks by different agents, the Scheduler of the WfMS, which is a software component inside the engine of the WfMS, reads from the process repository the process model of currently active cases, and identifies the current status of execution and the next task(s) to be scheduled. The workflow engine asks the resource executive to read the organizational model and to identify the suitable agents to entrust for the execution of the task: the resource executive has to compare the skills and the authorizations of the selected agent with the minimum skills and authorizations required for the task, beyond providing workload balancing among the agents. The Scheduler also has to check for the completion of tasks within the prescribed deadlines, detecting and signaling possible anomalies and delays (Combi & Pozzi, 2003; Combi & Pozzi, 2004; Duftschmid, Miksch, & Gall, 2002).

Other components inside a WfMS are the e-mail feeder (to send and to receive e-mail messages and communications to/from agents), the Web server (to provide a html-based interface to the WfMS and to the worklists for every user), the DBMS connectivity (to access data related to current cases), and the Audit logger (to access historical data about past cases). Figure 1 depicts a general architecture for a WfMS.

WORKFLOW MANAGEMENT SYSTEMS FOR HEALTHCARE

WfMSs can be useful in coordinating any process that is "workflowable" (i.e., that can be suitably described by a process model). In order to be workflowable, a

Figure 1. A general architecture for a workflow management system (WfMS), highlighting the software components belonging to a WfMS; rectangles represent software programs; cylinders represent databases; rectangles with smoothed corners represent human executors.



process must be composed of single atomic work units, possibly assignable to different agents, and it must be repeatable and predictable. In such a way, after the process model has been identified and described, the WfMS can suitably coordinate the execution of the work units, assuring that any instance of that process will be executed according to the identified process model and within the expected deadlines.

Several applications of WfMSs can de identified in the area of healthcare, and they can be classified according to many criteria. At a very high-level view, processes managed by a WfMS can be classified according to their main goals: in the following, we assume to classify processes as self-administration processes, daily practice processes, research, and experimentation processes.

Processes for the Self-Administration

WfMSs can support typical processes which aim at self-administering the organization. For instance, a WfMS can manage the process of enrolling personnel (assigning Ids, e-mail addresses, desks, phone numbers, and so on), or of requesting authorizations to travel abroad, or of going on holiday. Generally, these processes are not strictly related to the main mission of the organization, and thus are somehow organization-independent.

Processes for the Daily Practice

WfMSs can support several processes typical of the daily practice in healthcare. Processes can be related to the treatment of patients focusing on medical aspects, and to the management of the patient dealing with organizational aspects as adhering to the recommendations from the dietician or billing the patient at discharge time.

Among some of the typical medical processes, we can consider the decision process of the physician to formulate the correct diagnosis for the patient under examination: in fact, some guidelines are defined, and can enable the physician to achieve the correct diagnosis in the shortest time, and in the less-expensive way possible. Another process can be that of adhering to the clinical guidelines specified for the identified diagnosis: in fact, after a diagnosis has been formulated, the treatment of the patient should adhere as much as possible to a standardized treatment, in order to achieve the best result in the shortest time, and to ensure that the patient has been treated according to the top-most and up-to-date criteria. These can also avoid some legal issues that could be attributed to malpractice.

As a more general process of the daily practice, we can consider the billing procedure which must be started immediately as one patient is discharged, in order to obtain the payment from the patient as soon as possible, and to allow him/her to start the reimbursement procedure from the insurance company. This process may require to collect data from different sources and from different departments, to analyze them, and to produce the final bill.

Processes for the Clinical Research

WfMSs can also support several processes for the clinical and medical research. For instance, processes can be related to the validation of treatments for patients suffering from a particular disease. In order to compare results from different experimenting centers in a uniform way, all the patients must be treated according to a common protocol, and data must be collected according to a common standard. The coordination by a WfMS is needed both to achieve the correct diagnosis and to execute the correct treatments as described by the protocol.

Moreover, WfMS could suitably support the experimental application of clinical guidelines. Clinical guidelines are recommendations, usually specified by scientific/clinical committees or associations, and based on a wide consensus from specialists, on the appropriate treatment/prevention and care of patients with specific diseases. As an example, we may consider a fragment of a guideline for stroke prevention (Inzitari, 2000):

For the treatment of endocranial hypertension, mannitol should be administered (0.25 to 0.5 g/kg for 4 hours) for patients with elevated endocranial hypertension; forthermore, glycerol should usually be administered by parenteral route (250 mL of 10% glycerol in 30-60 min every 6 hours); during therapy with glycerol, haematology should be systematically controlled since it may induce haemolysis.

According to this scenario, WfMSs could help physicians and nurses to properly manage the suitable sequence of therapeutic actions on a given patient, as well as to assign the clinical tasks to the personnel of the health organization having the right skills and roles. Moreover, WfMSs would manage possible repetitions of actions (e.g., *every 6 hours*) and exceptional conditions which do not allow the staff to follow the clinical guideline (e.g., how to deal with possible allergies of the patient to the administered drug).

FUTURE TRENDS

WfMSs still have some lacks that hurdle the widespread adoption of WfMSs themselves to manage extremely critical processes in application domains featuring such a great variability as the medical domain does.

One of the key issues to assure wide diffusion of WfMSs in managing medical processes for healthcare is that of achieving a common standard to share information (data, but mostly process definitions) among the different centers involved both in the daily practice and in research and experimentation activities. In fact, every WfMS has its own proprietary language to define processes, and no portability is assured for process definitions among different vendors: thus, the same process must be implemented in several languages, in order to enable users of different WfMSs to run the same process. Instead, the adoption of a common process definition language, like X-PDL standard language recommended by the Workflow Management Coalition, will greatly increase the ease of portability (refer to WfM Coalition Web site).

Another key issue in the adoption of WfMSs in healthcare is the need of suitably managing exceptions, which may occur during case execution (Casati, Ceri, Paraboschi, & Pozzi, 1999; Combi, Daniel, & Pozzi, 2006). In fact, the sudden worsening in the conditions of a patient cannot be neglected and—very often—may require a prompt intervention. These exceptions may lead to an immediate rescue surgery of an admitted patient or to the immediate admission to a hospital for an out-patient. Moreover, the hospital where the out-patient is admitted, due to the sudden worsening of his/her conditions can be a different hospital from the one that was taking care of that patient: the use of a treatment protocol commonly shared by the two hospitals could be very useful. The definition of such expected exceptions inside the process model will thus greatly improve and benefit the usage of a WfMS in the daily practice, as well as in the clinical research.

One more key issue, which, however, does not cover the area of WfMSs only, but spreads over information systems and decision support system, is the correct management of temporal information: in no other application domain like in healthcare a suitable management of temporal information is extremely useful. Temporal representation and temporal reasoning are some of the leading research activities in the area of temporal information management with an immediate outfall on WfMSs (Bettini, Wang, & Jajodia, 2002). Temporal representation enables one to suitably and correctly represent data over time; temporal reasoning enables one to correctly infer knowledge (including diagnosis, prognostic indices, and therapy administration) from temporal series, and from data collected in the past (Adlassnig, Combi, Das, Keravnou, & Pozzi, 2006). Both representation and reasoning over temporal information have immediate influence on modeling of decisional activities in DSSs and WfMSs.

CONCLUSION

Workflow Management Systems (WfMSs) are gaining more and more popularity and relevance, as they appear suitable to model both generic processes and specific healthcare processes. In healthcare, WfMSs can help physicians in their daily practice with well-defined treatment and diagnosing protocols. WfMSs can also help physicians in their clinical research and experimentations, especially when different research centers are involved: in fact, WfMSs provide a standardized definition of the process to be followed by the different centers involved in the validation of new treatments and therapies.

With particular relevance to healthcare, one of the major requests and expectations from WfMSs is related to the adoption of a standard language to describe the processes, while at present, no common process definition language exists.

KEY TERMS

Data Model: A formal description of data managed by a business process. In most cases, these data are stored via a Database Management System (DBMS), and are also referenced by an Information System (IS) and, possibly, by a Decision Support Systems (DSS)

Exception: An event that may occur during the execution of a business process, and can—if the exception is expected and has suitably been modeled by the workflow designer—force the process to deviate from its normal flow of execution.

Organizational Model: A formal description of an organization, including agents and resources. The organizational model is used by a WfMS to assign activities to agents.

Process/Business Process: Any activity executed within an organization, requiring the coordinated execution of simple atomic activities (task) by executing agents. A business process is described by a workflow.

Process Model: A formal description of a business process. The definition is performed via a process definition language (PDL), which in most cases is WfMS-dependent.

Workflow Management Coalition (WfMC): A nonprofit organization collecting researchers, developers, users, and consultants in the area of business process automation.

Workflow Management System (WfMS): A software systems that helps to execute, automate, and enact business processes described by workflows.

X-PDL: A language, defined and standardized by the Workflow Management Coalition (WfMC) to describe business processes. X-PDL is vendor-independent, and aims at becoming a standard way for exchanging process definitions among WfMSs from different vendors.
