A technology gap separates developing countries from the developed world: from manufacturing processes to information technology provision in business, government, and higher education, poorer countries lag behind richer ones. One reflection of this gap is the high concentration of global research and development (R&D) in developed countries: in 2002, developed countries accounted for more than 90 percent of global R&D expenditures (UNCTAD 2005). The transfer of technology from developed to developing countries helps close the international technology gap and contributes to productivity growth in developing countries. Such technology transfer makes much economic sense, since it keeps poorer countries from having to spend already scarce resources on reinventing the wheel.

The results of R&D undertaken in developed countries are transferred globally through many channels, perhaps the most important of which is foreign direct investment (FDI) investment projects whose ownership and control lie in the hands of overseas investors. The establishment of production facilities by foreign companies usually results in the introduction of new production processes and techniques to the local economy, making FDI a major channel of technology transfer. FDI also has come to play an increasingly important role in helping disperse R&D activities globally: during the period 1993 2002, R&D expenditures by foreign subsidiaries of multinational firms increased from $30 billion to $67 billion, representing a rise from 10 percent to 16 percent of global business R&D.

This article examines several questions related to international technology transfer. How do technologies originating in industrialized countries take hold in developing countries? What role does FDI play in this process? What benefits do developing countries enjoy from FDI? And how, if at all, can international organizations such as the World Trade Organization (WTO) facilitate the process of technology transfer?

International Technology Transfer and the Role of FDI While much FDI occurs between industrialized countries, developing countries are becoming increasingly important hosts for such investment flows. In fact, during 2001 5, average net FDI inflows equaled $754.3 billion, of which $212.4 billion (approximately 29 percent) went to developing countries. The global stock of FDI in 2004 stood at approximately $9 trillion with approximately 25 percent of it being in developing countries (UNCTAD 2005).

FDI is undoubtedly one of the primary channels of international technology transfer. It is well known that multinational activity occurs primarily in industries that are characterized by a high ratio of R&D to sales and by large shares of professional, scientific, and technical workers (Markusen 1995). In fact, a basic tenet of the theory of the multinational firm is that such firms rely heavily on their technology-based assets and well-established brand names to offset the logistical disadvantages of operating in multiple counties as well as to successfully compete with local firms that are usually more familiar with the local environment. In 1995, of all transactions in royalty and license fees, transactions within the same firm made up in excess of 80 percent, so most explicit

trade in technology takes place within multinational firms (UNCTAD 1997).

Other private sector channels for technology transfer include technology licensing and joint ventures. With technology licensing, a licensee will pay royalties and fixed fees to a foreign licensor in exchange for the right to use its technology. Joint ventures, on the other hand, are typically organized as partnerships between foreign and local companies. Then there are the so-called indirect routes for technology transfer, which include international trade in goods and services and the movement of labor between countries. Another such route is the imitation or "reverse engineering" of technological products, which essentially involves taking them apart for analysis and then independently reproducing them — a practice that allows local entrepreneurs and companies to replicate products and technologies from abroad without paying any royalties or fees.

The usage of the word *transfer* in the phrase *technology transfer* conveys the impression that the process is smooth and costless. Such is hardly the case. The fact that developing countries lag behind the technology frontier merely creates the potential for technology transfer. For this process actually to occur, providers and acquirers of new technologies have to undertake deliberate and often significantly large investments. Substantial empirical evidence indicates that international technology transfer does not come cheap. Economists regard knowledge (and its application in the form of technology) as a nonrival good, meaning that it can be accessed by more than one person. The nonrival nature of knowledge does not mean, however, that it can be transferred free of cost. Rather, it simply implies that if two people are willing to pay the cost of adopting a new idea or a technology, they can do so without interfering with each other's decisions.

Analyses of FDI must always bear in mind one basic observation: multinational firms engage in the transfer of technology primarily to maximize profits and value for their stockholders. Thus any technology transfer activity that does not contribute to profit-making will typically not be attractive for a multinational company. For example, if transferring a technology runs the risk of strengthening a company's local rivals, the company should be expected to try to thwart the process of technology diffusion to some degree: it may choose not to invest locally and may simply export the product from its home market or may transfer only peripheral technologies as opposed to core ones.

Despite such concerns, FDI often generates benefits for both consumers and local companies in developing countries. Benefits to consumers include access to higher-quality goods or completely new goods that were not produced locally. Benefits to local companies include what is known as the "demonstration effect," in which local firms adopt a technology from overseas after observing its successful introduction by a multinational. People trained or previously employed by multinational firms can provide added benefit to local business by helping with technology transfer when they change jobs or start new firms.

Multinationals also engage in technology transfer to firms that either supply them or buy their products. An example can be found in Mexico's automobile industry. After the North American Free Trade Agreement (NAFTA) was ratified in 1992, U.S. car companies set up manufacturing plants in Mexico. Within five years this had led to hundreds of domestic producers of car parts and accessories springing up (Moran 1998). United States and other multinational corporations transferred technology to these Mexican suppliers, who, as a direct result, gained expertise in industry best practices and quality control. The Mexican story is by no means unique. A rich body of evidence indicates that Mexico's experience has been replicated across the world (Saggi 2002).

Policy Implications The earlier discussion suggests that the process of technology transfer via FDI may not always work smoothly. But does this necessarily create a role for government support or regulation of such activities? Historical experience of countries such as Japan, South Korea, and China suggests that many national governments perceive this to be the case. These countries have considerable experience in attracting and regulating private

sector international technology transfer. Both Japan and South Korea have been deliberately selective in their choice of technology transfer method, preferring technology licensing over FDI. Their experiences have been studied in some depth. It is well known that during the 1960s and 1970s, Japan's Ministry of International Trade and Industry (MITI) limited competition between potential local buyers of foreign technologies to keep the prices they paid for it low. Furthermore, MITI never formally encouraged FDI and instead encouraged local companies to license technology from overseas. It even insisted that foreign firms share their technology with local firms as a precondition for doing business in Japan. South Korea presents a similar story. In fact, discouraging FDI while encouraging technology licensing was a central theme of South Korea's industrial policy.

There are several reasons why such countries may prefer technology licensing to FDI. They may share a fear that FDI may lead to a transfer of what are called "black box" technologies, in which local companies do not learn very much about how the technology was developed. Another perception is that FDI gives the foreign companies that supply the technologies a stronger bargaining position than the local ones receiving it. Governments also believe that FDI has fewer of what are called "spillover" benefits for local businesses, compared with technology licensing and joint ventures between local and foreign firms.

The evidence for these views remains quite thin, however. In fact, several studies have found that the opposite is true. For example, technology licensing may offer fewer opportunities for profit-making than is sometimes perceived. In addition, a licensee may need additional permission from the license holder to export the technology to a new country. Or it may need permission to make additional modifications or improvements. This shows that, if anything, technology licensing can carry a number of restrictions that may hamper technological development and growth of the licensee's businesses.

Because of these limitations, governments in many developing countries have come to adopt a more liberal approach to FDI than in the past. In fact, today most countries compete with one another to attract more FDI by providing a range of fiscal and other financial incentives. This is more relevant for manufacturing than for services, however. For example, in recent years, while China has been the biggest recipient of FDI in the world, its services sector has not been particularly open to FDI. This was, in fact, an important sticking point during China's negotiations regarding its entry into the WTO.

For international technology transfer to work well, policies need to take into account the needs of both buyers and sellers of foreign technology. As we have seen, the point of technology transfer from the perspective of developing countries is to save them from having to reinvent the wheel. At the same time, the costs of new technologies need to be kept low. From a policy point of view, this means that governments need to invest in education, infrastructure, and local expertise to adopt and adapt new technologies.

From the perspective of technology suppliers, transferring technologies to poorer countries comes with risks, which can be mitigated by appropriate (but not excessive) regulation. Historically, developing countries have not always appreciated the fact that suppliers of foreign technology need to profit from their endeavors. But today, the pendulum is in danger of swinging too far in the other direction. Developing countries may have become overeager to attract FDI into manufacturing, even while still restricting it in services. But this is problematic, as policies that favor one sector over another distort the flow of FDI relative to what would occur as a result of purely market forces. Few developing countries have comparative advantage in world-class manufacturing, and favoring the manufacturing sector can deprive the development of the service sector, leading to a misallocation to inward FDI as well as complementary domestic resources.

The Role of International Institutions Most international treaties at the United Nations level make some reference to the need for rich countries to help developing countries meet their treaty obliga-

tions by transferring technologies under favorable conditions. For example, Article 7 of the WTO's Trade-Related Aspects of Intellectual Property Rights (TRIPS) agreement notes that intellectual property protection should "contribute to the promotion of technological innovation and to the transfer and dissemination of technology, to the mutual advantage of producers and users of technological knowledge and in a manner conducive to social and economic welfare, and to a balance of rights and obligations." Article 66 of the same agreement commits developed countries to find ways to encourage international technology transfer to developing countries and to help improve their technological base.

Governments of industrialized countries are less enthusiastic about subsidizing technology transfer, however, in part because they are reluctant to interfere with what is now an activity dominated by the private sector. Their earlier pledges to transfer technology to help developing countries with international agreements on biodiversity and global climate change remained mired in debate at the end of 2007, as did discussion on concrete steps to implement Article 66 of TRIPS.

The WTO has a working group on trade and technology transfer, but through the end of 2007, it had focused primarily on information exchange between representatives of the group's member countries. And even here, the information provided had been little more than what is freely available in the academic literature.

The potential certainly exists for countries in the group with more experience, such as Japan and South Korea, to provide a mentoring role to less developed ones. Developing country members would benefit from practical case studies from Japan, for instance, that show its reasons for adopting certain technology transfer policies, and how these helped to strengthen local industry.

Poorer countries can also benefit from guidance on the structure of international technology transfer contracts, including, for instance, information on reasonable royalty rates, the conditions sellers of technology have been willing to accept, and the types of contract clauses that have proved helpful in encouraging local technological development.

It is a staple of today's development thinking that technology transfer from developed to developing countries is important for generating sustained economic growth. But historical experience shows that, to be innovators themselves, countries must first learn to absorb foreign technologies and adapt them to local conditions.

Because of government intervention, in several Asian countries technologies in the private sector were frequently transferred through technology licensing rather than FDI. This may have allowed some countries such as South Korea to obtain foreign technologies at relatively low prices. Although such policies are not necessarily the most desirable ones, they were more successful than the policies of countries such as India that focused on achieving self-reliance by fostering imitation and adoption of foreign technologies under a regime that protected local industries from foreign competition.

Today's multilateral trading system is a markedly different one, and it seems unlikely that developing countries can adopt the interventionist policies used by even Japan and South Korea, let alone India: several multilateral agreements of the WTO explicitly forbid governments from pursuing such policies. Furthermore, policies supporting technology licensing require an effective bureaucracy, which some of the poorest developing countries lack.

Developing countries are likely to maximize the benefits of technology transfer by investing more in local education and infrastructure development while giving multinational firms relatively unrestricted access to their markets. In particular, policies that favor one sector (such as manufacturing) at the expense of another (such as services) seem counterproductive. As an example, it is worth noting that the development and success of India's software sector has far outpaced its manufacturing sector despite the fact that the Indian government has always been rather keen to promote local manufacturing via the pursuit of a restrictive trade policy. In fact, it seems quite likely that the software sector succeeded because it was able to draw on India's investment in

education (as evidenced by the fact that the Indian Institutes of Technology are considered on a par with the best universities in developed countries) and because the government did not (some would say it could not) restrict international trade in the sector.

In addition, governments in rich countries and international institutions such as the WTO have the potential to do more to encourage technology transfer. Similarly, the governments of advanced developing countries can play a more active role in sharing their own experiences of managing technology transfer from developed countries.

■ foreign direct investment and labor markets

Private cross-border capital inflows are made up of foreign direct investment (FDI) and portfolio equity and debt flows. *Direct* investments are defined as those which wield a significant influence on the management of the firm. FDI flows therefore comprise the financing of overseas greenfield investments (where new operational facilities are constructed from the ground up) and further expansions, and of cross-border mergers and acquisitions by multinational enterprises (MNEs). The total direct capital owned by nonresidents in a given country in a particular year constitutes the stock of FDI.

The regional and sectoral destination of FDI flows has changed substantially over the decades. At the outbreak of World War I, more than 80 percent of the foreign capital stock was located in developing economies, reflecting the importance of railway building, the extractive industries, and the colonial control of international trade at that time. In the early 21st century, by contrast, almost 80 percent of the global FDI stock is located in the developed world, and FDI is associated with a different range of activities. The transnationality of an industry today is associated with the sectoral importance of knowledge capital such as "patents, blueprints, formulae, managerial and work procedures, marketing knowledge, reputations and trademarks" (Markusen 1998). Knowledge spillovers are likely to be associated primarily with such knowledge-intensive industries. Within services the sector which currently accounts for the bulk of the global FDI stock the predominant subsectors are finance and business activities. Within manufacturing, the chemical industry is predominant, followed by motor vehicles and electronics. Primary activities account for only a small proportion of global FDI.

In discussing the labor-market effects of FDI, one clearly needs to distinguish between the effects on the host, or destination, economy and those on the home, or source, economy. The following two major subsections follow this distinction.

FDI and the Host-Economy Labor Market How might FDI affect the labor market of the host economy? Obviously, in the presence of unemployment, an FDI inflow might simply lead to new job creation, without further complications. If the inflow is large enough relative to the size of the economy, it might also bid up wages and improve the economy's terms of trade, generating gains even in the absence of market failures. For a small economy like Ireland, which had an unemployment rate of 17 percent before the substantial increase in export-platform FDI of the "Celtic Tiger" era of the 1990s and beyond, both of these considerations apply.

In general however, the matter is less straightforward, and indeed, cross-country growth regressions that attempt to isolate the effects of inward FDI yield inconclusive results. One problem with these studies is that they fail to distinguish between the different characteristics of FDI projects associated with import substituting and outward-oriented regimes. Case study investigations of FDI in the automotive and high-performance electronics industries in developing economies show that the effects depend very much on whether local subsidiaries are integrated into the parent firm's international sourcing networks (as under outward orientation) or whether they are oriented toward protected domestic markets. Foreign direct investment projects of the first type motivated by "global sourcing" considerations have been found to differ from "tariff-jumping" FDI projects of the second type in terms of the size of the local plant, its proximity to the technological frontier, the rapidity with which technology and quality control procedures are upgraded, and the general efficiency of the operations. In each case, the tariff-jumping FDI projects exhibit less desirable characteristics. Nor do they represent an effective infant-industry strategy, while many prominent domestic component producers in outward-oriented

regimes are known to have originated as contract manufacturers to foreign plants (Moran, Graham, and Blomström 2005).

The cross-country studies on FDI also typically do not specify the precise microeconomic channels through which FDI might be thought to influence growth. Besides the direct first-round employment effects of an FDI project, second-round effects will arise through the impact of FDI on local firms, while third-round effects will arise through the impact on public-goods provision and expenditure of any increased tax revenues that might be associated with FDI.

MNE entry can crowd out local firms in the product market, though this outcome is less likely with export-platform FDI, while benefits can arise through the erosion of local monopoly power and the inducement to reduce internal inefficiencies. The investment might also raise the productivity of local firms through knowledge spillovers, deeper markets in specialized factors, and increased scope for backward and forward linkages between customer and supplier firms   the classic "Marshallian externalities."

In the labor market itself, while the short-term value of an FDI project will depend on the extent to which other jobs are crowded out, productivity growth and hence wage growth over the longer term may be higher in multinational firms. The characteristics of the jobs created are also important. If some interindustry wage differences are associated with industry rather than worker characteristics (as in efficiency-wage models, for example), an FDI-induced change in industrial structure can yield benefits in terms of increased wages. Labor-market volatility might also increase, however, because of the ease with which MNEs can switch activities across plants. The latter possibility, however, might also serve to make local labor markets more competitive.

In general, the second-round labor-market effects arise either because MNEs differ in a number of key aspects from the domestic firms they may replace or because FDI induces changes in the behavior of domestic firms.

All the international evidence suggests that MNEs on average are more productive than domestic firms — in terms of both output and value added per employee — and that they exhibit higher productivity growth. These findings are largely accounted for by the fact that MNEs are larger (in terms of output, employment, and value added), they invest more, and they use more intermediate inputs per employee than purely domestic firms. When these differences are controlled for, the productivity gap largely disappears, though the fact that some small element remains suggests that multinationality per se is associated with somewhat greater efficiency in terms of input usage. From a policy perspective, however, the fact that MNEs differ from local firms in these key characteristics is important in that it means that they bring to the host country a set of characteristics and techniques that would otherwise be difficult to establish locally.

The literature is virtually unanimous in its finding — from both developed countries such as the United States, the United Kingdom, and Ireland, and developing countries such as Côte d'Ivoire, Morocco, Venezuela, and Indonesia — that foreign firms pay higher wages than privately owned domestic firms (see, e.g., Aitken, Harrison, and Lipsey 1996; Harrison 1996; Scheve and Slaughter 2005). Part of the reason is undoubtedly that foreign MNEs employ more highly skilled labor than domestic firms do. It is difficult to determine whether this difference fully accounts for the wage differential as skills are often imperfectly measurable. There are a number of reasons, however, why MNEs might pay higher wages than domestic firms for equivalently skilled workers. MNEs may want to minimize the risk that their proprietary knowledge is dissipated through frequent labor turnover or they may wish to avoid excessive geographical disparities. Higher wages might also be required to compensate for perceived disadvantages such as greater employment volatility. Foreign firms also generally provide higher levels of training than domestic firms, resulting in higher subsequent wage growth.

Compared to the other topics discussed, little research has been carried out on the question of the relative volatility of employment in MNEs and domestic firms. Contrary to the presumption that MNEs might be more willing to switch activities across locations in response to wage pressures, the available research suggests that MNE employment levels are less affected by wage changes than is the case for domestic firms. This finding appears likely to arise because of the bundle of characteristics other than ownership per se that distinguishes them from local firms.

A recent study on Irish data adds a new element to the research on volatility. It finds that while the higher-technology MNE-dominated sectors exhibit faster employment growth than the traditional lower-technology sectors populated primarily by domestic firms, employment growth in the former sectors is also more volatile. The application of portfolio theory demonstrates however that the diversification resulting from the attraction of MNEs has allowed the aggregate manufacturing sector to grow more rapidly without a commensurate increase in overall volatility and risk (Barry and Kearney 2006).

We now turn to the question of whether and why FDI might induce changes in the behavior of domestic firms. Multinational and domestic firms interact in a number of ways, some beneficial and some harmful to the latter. The beneficial effects can arise through market transactions or via externalities while the adverse consequences arise through increased competition. The overall effect will determine the second-round employment consequences of foreign direct investment.

The transfer of proprietary assets from MNEs to domestic firms can take place via transactions deliberately negotiated between the parties, as in the case of technology licensing agreements or the provision of direct support for the upgrading of locally provided inputs, which is relatively common in developing countries. Alternatively, technology transfer can take place through externalities that do not bring any direct return to the MNE. Interactions between different firms can generate more knowledge flows than are contracted for. Indeed the inability to write complete contracts is a prime reason

why MNEs frequently prefer to carry out such transactions internally. Even in this case, though, MNE employees who move to local firms will bring with them much of what they have learned in their earlier positions.

Pecuniary as opposed to technological externalities arise when the presence of MNEs leads to increased local investment in increasing-returns activities. There is widespread evidence that MNEs, by making use of local suppliers, have expanded both the quality and the output of the latter. MNE presence can also lead to an expanded provision of public goods such as infrastructure and education, investment in which might not be cost effective unless demand is sufficiently large. Enhanced provision of public goods clearly expands the development potential of the host economy.

MNEs also represent increased competition for domestic firms, however. If market structure is imperfectly competitive, local profit margins are reduced. In increasing-returns sectors, the reduction in market share can force local firms up their average cost curve and away from the minimum efficient scale level of output, possibly causing exit. These negative competitive effects can offset any favorable technological externalities for local firms but are nevertheless likely to be beneficial for the overall economy.

How do these two opposing forces play out in reality? The many empirical studies on the topic do not provide an unambiguous answer to the question. The message that does emerge, however, is that the likelihood of positive second-round employment effects depends on the size of the technological gap between MNEs and domestic firms, the extent of vertical linkages between the two, and the nature of competition in the industries concerned.

Earlier studies based largely on cross-section data almost always found MNE presence to be associated with higher domestic-firm productivity. This correlation might simply be a consequence of the fact that foreign firms tend to invest in higher productivity sectors. Hence more detailed analysis is required.

The importance of the technology gap between foreign and domestic firms is attested to in a number of ways. The gap is likely to be smaller in more developed economies. In line with this, a number of studies find that spillovers are concentrated in middle-income developing countries, with no evidence of such effects in the poorest developing countries. The type of technology and the amount imported by MNEs is also found to be greater in countries and industries where the local labor force is better educated. Beneficial effects on domestic firms are also found to be especially likely to occur when there are vertical linkages between local firms and MNEs, and particularly with upstream local suppliers.

While spillover effects appear strongest in technology-intensive sectors where local firms' capabilities are above a threshold level, competition effects appear to dominate in less technology-intensive sectors. Here, the entry of MNEs tends to lead to an initial decline in the profit margin of local firms, though these can bounce back in the event of competition-induced efficiency gains. A number of studies have also found that MNE presence helps local firms to break into new export markets.

FDI and the Source-Economy Labor Market
Similar questions arise in the case of source-economy labor markets. Here we are interested in the effect of *outward* direct investment (ODI) on employment, production, wages, and the skill mix of the economy, and on the productivity of the firms themselves.

The four channels through which source-economy effects arise are: (1) the redeployment of source-economy labor, if displaced by outward FDI, (2) increased imports of source-economy goods and services by the economies hosting increased FDI, (3) savings accruing to source-economy investors and customers if activities shift to lower-cost locations, and (4) profit repatriation by foreign affiliate companies. All of these will have knock-on effects on the labor market.

The short-term employment effect will depend on whether the overseas and domestic activities of the firm are complements or substitutes. The qualitative employment effects on the home base may differ between the short term and the longer term also, in that an ODI-induced expansion in the market share of the MNE can strengthen home-economy opera-

tions even if home activities appear to be substitutable for the firm's foreign operations in the short run. The counterfactual also should be taken into account, in that even if ODI leads to a contraction in home-location operations, the alternative to ODI may be the complete closure of these operations.

The question of whether home and host-economy activities are substitutes or complements is related to whether FDI is vertical or horizontal in nature. Vertical FDI entails the geographic fragmentation of the production process, while investments undertaken in order to gain an advantage in supplying local or regional markets are classified as horizontal. In general, vertical FDI (typically from developed to outward-oriented developing economies) is associated with complementarity between home and host activities. It might be thought that horizontal FDI (typically between developed economies) will be associated with substitutability as it can displace home exports. Foreign plants however frequently import inputs or other complementary products from the MNE's home base, and studies of U.S., Japanese, Swedish, and other European MNEs have found foreign-affiliate sales to be associated with an increase in the exports of the home-based parent MNE (see, e.g., Lipsey, Ramstetter, and Blomström 2000). Higher capital expenditures on the part of foreign affiliates of U.S. MNEs have also been found to be associated with higher U.S. investments by the parent companies (Desai, Foley, and Hines 2005). The overall implication is that home and foreign production are combined to generate final output at lower cost than would be possible without ODI. Thus production is ultimately increased in both locations. Even if this were not true at the level of the individual firm, labor-market flexibility can serve to ensure that the home economy remains at or close to full employment.

We now turn to the effect of outward FDI on the relative demand for skilled and unskilled labor. If firms in high-income countries fragment their production process and outsource labor-intensive stages to lower-wage countries, this outsourcing leads to a relative increase in the demand for skilled labor at home. Headquarters services are a particularly highly skilled segment, comprising R&D, design, marketing, finance, and strategic management. An increase in demand for such services will show up as an increase in the relative wages of more highly skilled labor, as has been seen in the developed world over recent decades.

The offshoring of unskilled-labor-intensive segments of the production process does entail real welfare losses for displaced workers, however. Evidence from the United States shows that about one-third of displaced workers will not have found a job one year after displacement, though most will have found new jobs after a further lag. Frequently, however, the new jobs found by such workers are at reduced wage levels. The types of workers who suffer most in the structural adjustment process are those of advancing age with low educational attainment, and those who have had a long period of tenure in the lost job (reflecting the depreciated value of their firm-specific and industry-specific skills). There is widespread agreement that public intervention to minimize dislocation resulting from structural change should be focused on providing the displaced with new skills and training and ensuring that they do not become detached from the labor market. While the economy gains in the long run, the adverse adjustment costs will be higher if labor-market rigidities hinder employment growth.

MNEs also establish foreign operations in order to source new technology, which tends to benefit both the companies themselves and the home economy. National productivity has been shown to be increased by outward investments in other R&D-intensive economies, while other research suggests that the international networks that MNEs establish can provide other home-based companies with links — through interaction with these firms — to innovation in other areas of the globe.

The evidence summarized here leads to generally positive conclusions. Inward FDI can yield positive benefits for domestic firms through externalities and other channels, while, to the extent that it causes exit of the least efficient incumbent local firms, this elimination of inefficient firms is itself associated with an increase in productivity and hence in wages.

In the case of outward FDI, foreign-affiliate output and employment are frequently complementary to parent-firm home activities and, even when they are not, ODI tends to boost domestic productivity so that home-economy wages rise even if new employment opportunities are located outside the original firm.

As in all cases of structural adjustment, labor-market flexibility is important to ensure that new employment opportunities materialize as existing jobs disappear. The benefits of structural adjustment frequently accrue to workers with different characteristics from those displaced in the adjustment process. Hence the discussion on labor-market interventions to deal with displaced workers raises issues similar to those encountered in the policy discussion on trade adjustment assistance (see, e.g., Baicker and Rehavi 2004; Kletzer 2004).

■ foreign direct investment and tax revenues

Does foreign direct investment (FDI) expand tax revenues? It is commonly believed that FDI enhances economic growth, both directly by increasing the stock of physical capital in the recipient economy, and indirectly by inducing human capital development and promoting technological upgrading. Based on evidence of positive effects of FDI on economic growth, international trade, and domestic investment (under certain conditions), it is then claimed that FDI also expands government tax revenues. The reasoning is that higher levels of economic activity generate higher levels of production, and consequently higher levels of government tax revenue, all else being equal. This perceived additional benefit of greater tax revenues has led host countries to expand their attraction packages to include firm-specific incentives such as tax holidays, tax breaks, and subsidies.

These potential benefits have given multinational corporations (MNCs) a strong bargaining position to negotiate favorable conditions for their entry into new markets. As a result, MNCs are often able to extract additional concessions in the negotiation process, in some cases even long-lived tax breaks and exemptions. Even if FDI has the potential to expand government tax revenues by enhancing economic growth, the fact that MNCs receive such tax incentives creates distortions that can contradict the main goals of tax policy. It can also affect the competitiveness of domestic firms and, consequently, influence the collection of tax revenues. Therefore, a direct link between FDI and economic growth does not necessarily translate directly to expanded government tax revenues.

The performance of government tax revenues is determined by three main aspects: *structural characteristics* (factors that influence the tax handles of an economy), such as income level, population size, the existence of informal or subsistence sectors, and the dependence on taxation of trade; *macroeconomic characteristics*, such as the governmental debt stance, the government's current and past budget position, and the degree of reliance on inflationary tax to generate revenue; and *external characteristics*, such as the terms of trade, exchange rate volatility, and the degree of trade liberalization of the economy. Changes in one or more of these factors can affect the performance of tax revenues; given that FDI can affect some of these factors, it can also potentially affect the collection of tax revenues. FDI's effect on government tax revenues in the host country may also differ from the effect on the source country.

FDI's Effect on the Source Country's Tax Revenues Even if FDI directs investment into foreign countries, the parent enterprises still maintain headquarter activities in the source country and thus generate tax responsibilities that affect the collection of tax revenues. Although FDI generates economic growth and spillovers in the countries that attract it, it mainly benefits the owners of the MNCs. Subsidiaries repatriate profits to their respective parent companies through dividends, interest, and royalty payments, which are taxed by the source country. In addition, most research and development is conducted in the source country, which generates significant taxable economic activity in the country of origin, thus again affecting the collection of tax revenues.

Most countries also offer relief from double taxation to MNCs participating in outward foreign investment. Some countries allow foreign tax credits to be applied to domestic tax liabilities, deductions of

taxes paid to foreign governments from their tax liabilities, exemptions for the foreign earnings of their MNCs from domestic taxation, or some combination of the three. Although this relief from double taxation tends to lower the collection of tax revenues from production abroad, it protects the health of the MNCs of the host country.

Furthermore, since the performance of the MNCs affects the citizens of the source country   the owners of the firm   and MNCs bear the risk of expropriation that is inherent in foreign investment, there is an incentive for both the government and MNCs to protect and enhance the revenues from FDI through bilateral treaties. These treaties lower trade barriers, protect foreign investment, reduce tax rates abroad, and reduce tax uncertainty over the long term (Chisik and Davies 2004).

FDI's Effect on the Host Country's Tax Revenues FDI inflows are expected to fuel economic growth and generate higher levels of output in the host country. Conventional wisdom presumes that FDI would consequently increase government tax revenues. FDI can affect government tax revenues in a variety of ways: it can directly increase domestic taxes on income and goods and services if the higher levels of foreign investment increase production and employment; it can indirectly increase (1) taxes on international trade if the product is sold abroad or if imported inputs are used in the production process, (2) taxes on income and goods and services if it fosters greater activity in domestic firms participating in the production chain, and (3) overall taxes if higher or better incomes emanating from the previous points find their way back into the economy (multiplier effect); or it can affect the collection of tax revenues through the formalization of economic activity brought about by the existence or addition of foreign investment.

Although such considerations could have a positive impact on the collection of tax revenues, the intensive use of tax incentives to attract FDI may introduce potential distortion to this link, which can belie the conventional wisdom. In addition, although the greater economic activity brought about by FDI

should raise tax revenues in the long run, tax incentives tend to reduce tax revenues in the short run.

Since FDI goes hand in hand with trade liberalization   MNCs account for two-thirds of all cross-border sales   it is this area that has received the most attention. Trade tax revenues usually decrease with trade liberalization, and liberalization's effect on overall taxes depends on the efficiency of the transition toward domestic taxes (on goods and services), the resulting volatility of the exchange rate (and its effect on import and export bases), and the adjustment of exports and imports due to changes in the terms of trade.

FDI can also affect government tax revenues through formalization of the economy. Since greater foreign investment increases production in the formal sector, it also formalizes the production of domestic firms supplying inputs to the MNC, thus contributing to the collection of tax revenues. It also strengthens tax compliance of domestic companies by exposing them to the best business practices and corporate governance of the MNCs.

Although the potential impact of FDI on government tax revenues is considerable, empirical research in this area is almost nonexistent, with the exception of the work of Braunstein and Epstein (2004) and Vacaflores (2006). The former find that inward FDI has a negative impact on tax revenue in Chinese provinces   which is ameliorated by its positive impact on trade   while the latter shows that FDI has a positive impact on total tax revenues in Latin America, which is channeled through its impact on the main component, taxes on goods and services.

Despite this lack of conclusive empirical results, host countries are increasingly complaining about the tax evasion that tax treaties sometimes allow, the detrimental tax breaks that they were forced to give in the capitalization/privatization process, and the manipulation of intrafirm prices, all of which are perceived as detrimental to the tax collection of host countries.

Policy Implications The anticipation that a country's tax structure affects the MNC's choice to locate in a particular country has led most countries to adjust their tax system, making it more flexible to

international firms, becoming in many cases even more attractive for MNCs than domestic firms. This subsidization of FDI through tax incentives brings to light the potential harm that greater foreign participation can inflict on domestic firms, as the partial or total crowding out of domestic firms increases the possibility that some domestic factors of production may lose with higher levels of FDI. Glass and Saggi (1999) show that if the impact of MNCs on the profitability of domestic firms is sufficiently negative, FDI may lower host-country welfare to a degree that the optimal policy toward FDI should instead be a higher level of taxation. So the degree of substitutability of production between domestic and foreign firms and/or complementarities in their production processes become important in the overall collection of tax revenues.

To better understand the overall effects of FDI, more needs to be known about the effects of FDI on government tax revenues. Theoretical studies suggest that this effect should be positive, at least in the long run once tax incentives have expired. However, the inherent adjustments in tax systems and potential impact on the performance of domestic investment require further research to establish the direction and magnitude of such effect more conclusively.

DIEGO E. VACAFLORES

foreign direct investment: the OLI framework

The OLI, or "eclectic," approach to the study of foreign direct investment (FDI), developed by John Dunning, has proved to be an extremely fruitful way of thinking about multinational enterprises (MNEs) and has inspired a great deal of applied work in economics and international business. In itself it does not constitute a formal theory that can be confronted with data in a scientific way, but it nevertheless provides a helpful framework for categorizing much (though not all) recent analytical and empirical research on FDI. This survey first summarizes the OLI paradigm and then uses it as a lens through which to review some of the highlights of this research, while also noting some important issues that it neglects.

OLI stands for ownership, location, and internalization, three potential sources of advantage that may underlie a firm's decision to become a multinational. Ownership advantages address the question of why some firms but not others go abroad, and suggest that a successful MNE has some firm-specific advantages that allow it to overcome the costs of operating in a foreign country. Location advantages focus on the question of where an MNE chooses to locate. Finally, internalization advantages influence how a firm chooses to operate in a foreign country, trading off the savings in transactions, hold-up, and monitoring costs of a wholly owned subsidiary against the advantages of other entry modes such as exports, licensing, or joint venture. A key feature of this approach is that it focuses on the incentives facing individual firms. This is now standard in mainstream international trade theory but was not at all so in the 1970s, when FDI was typically seen through a Heckscher-Ohlin lens as an international movement of physical capital in search of higher returns (see, for example, Mundell 1957).

Ownership Ownership advantages are key to explaining the existence of MNEs. A central idea is that firms are collections of assets, and that candidate MNEs possess higher-than-average levels of assets having the character of internal public goods. These assets can be applied to production at different locations without reducing their effectiveness. Examples include product development, managerial structures, patents, and marketing skills, all of which are encompassed by Helpman's (1984) catchall term *headquarter services*. Although this is clearly a multidimensional factor, it is common to model it in terms of a single index of firm productivity. The most sophisticated treatment along these lines is found in work on heterogeneous firms by Helpman, Melitz, and Yeaple (2004), which combines the simplest version of the horizontal motive for FDI (to be discussed later in this article) with the assumption that firms differ in their productivities. A potential firm must pay a sunk cost to determine its productivity, and when this is revealed, active firms sort themselves into different modes of production. Low-productivity firms produce only for the home mar-

ket; medium-productivity firms choose to pay the fixed costs of exporting; but only the most productive firms choose to pay the higher fixed costs of engaging in FDI. These predictions are consistent with the evidence. As a further contribution, the paper derives from the model the prediction that industries with greater firm heterogeneity will have relatively more firms engaged in FDI and shows that this prediction is confirmed by the data. This work and others like it do not explore, however, why firm productivities differ in the first place. Prior investment in research and development (both process and product) and in marketing presumably account for the disproportionately greater productivity of most MNEs.

Location While international trade theory has tended to take ownership advantages for granted or else to model them in fairly obvious ways, rather more attention has been devoted to exploring alternative motives for MNEs to locate abroad. A key issue that has attracted much attention is the distinction between "horizontal" and "vertical" FDI. Horizontal FDI occurs when a firm locates a plant abroad in order to improve its market access to foreign consumers. In its purest form, this simply replicates its domestic production facilities at a foreign location. Vertical FDI, by contrast, is not primarily or even necessarily aimed at production for sale in the foreign market, but rather seeks to take advantage of lower production costs there. Since in almost all cases the parent firm retains its headquarters in the home country, and the firm-specific or ownership advantages can be seen as generating a flow of headquarter services to the host-country plant, there is a sense in which all FDI is vertical. Nevertheless, the distinction between market-access and cost motives for FDI is an important one.

The horizontal motive for FDI reflects what Brainard (1997) has called a "proximity-concentration trade-off": building a local plant saves on trade costs and so has the advantage of proximity; but it loses the benefits of concentrating production in the firm's home plant. Let $\pi^*(t^*)$ denote the operating profits that a potential MNE can earn from selling in a foreign market subject to per unit trade costs t^* (which can include both tariffs and transportation

costs). These operating profits are decreasing in t^*: higher trade costs reduce operating profits. Constructing a local plant avoids the trade costs, leading to higher operating profits of $\pi^*(0)$; however, it requires an additional fixed cost f. Hence the trade-cost-jumping gain, the difference between the total profits from FDI, Π^F, and those from exporting, Π^X, equals:

$$\gamma(\underset{+}{t^*}, f) \equiv \Pi^F - \Pi^X = \pi^*(0) - f - \pi^*(t^*) \quad (1)$$

Thus FDI is encouraged relative to exports by proximity (lower trade costs t^*) but discouraged by the benefits of concentration (higher fixed costs f).

The vertical motive for FDI implies a very different view of the determinants and implications of FDI. Now the focus is on how a firm can serve its home market: either by producing at home, or by vertically disintegrating and moving its production facilities to a cheaper foreign location. Assuming for simplicity that each unit of output requires a single unit of labor, we can write the operating profits of serving the home-country market as $\pi(c)$, where c includes both factor costs and trade costs. If the firm remains a domestic firm and supplies its home market from its parent plant, where w is the local wage rate, it incurs no trade costs so its profits Π^D will equal $\pi(w)$. Alternatively, it can engage in FDI and locate a new plant in the host country, exporting all its output back to the source country and incurring a trade cost of t. In that case, it incurs a plant-specific fixed cost f as in the case of horizontal FDI, and earns operating profits of $\pi(w^* + t)$, where w^* is the host-country wage. The relative profitability of FDI is therefore:

$$\Pi^F - \Pi^D = \mu(w^* + t, w) - f$$
$$\text{where:} \quad \mu(w^* + t, \underset{+}{w})$$
$$\equiv \pi(w^* + t) - \pi(w) \quad (2)$$

Now the decision to engage in FDI depends on the trade-off between the benefits of concentration, on the one hand, and the cost savings from offshoring, on the other, where the latter are denoted by the term $\mu(w^* + t, w)$. This offshoring gain depends negatively on the host-country wage w^* and positively on the source-country wage w: the vertical

motive for FDI attaches great importance to comparative costs of production. In addition, the gain is decreasing in the source-country trade costs t, implying plausibly that trade liberalization will encourage FDI.

Empirical studies of FDI have until recently tended to favor the horizontal over the vertical motive. For example, many case studies have shown that "tariff-jumping" has been important in many historical episodes. It has also been noted that the bulk of FDI is between high-income countries with relatively similar wage costs (though much of this is likely to be neither vertical nor horizontal FDI, but rather cross-border mergers and acquisitions, to be discussed further later). More formal econometric studies have shown that the horizontal motive provides a good explanation for FDI (see, for example, Brainard 1997; Markusen 2002). On the other hand, there is no clear evidence that FDI falls in importance with distance, as the horizontal model implies. In addition, more recent empirical work by Yeaple (2003b) and others, based on data at the level of individual firms, suggests that both motives are important. It is easy to see why this might be so even in the simple two-country case discussed above. If the foreign market is sizable, then the total gain from FDI as opposed to producing at home (in each case serving both domestic and foreign customers from a single plant) is given by the sum of (1) and (2) above: both trade-cost-jumping and offshoring gains have to be taken into account. More generally, with many countries there are additional reasons for FDI, and the two motives are likely to interact in complicated ways. For example, even for vertically integrated firms, proximity and concentration are not in conflict where serving a group of foreign countries is concerned. The reduction of trade costs between European countries in the 1990s encouraged American and Asian firms serving European markets to concentrate their production in European plants and so engage in "export-platform" FDI. Similarly, Yeaple (2003a) has shown that the horizontal and vertical motives may reinforce each other if a parent firm wishes both to serve foreign markets in similar high-income countries and to avail itself of lower

production costs in low-income countries. In general, therefore, the pattern of location of foreign plants is likely to reflect the complex integration strategies of firms having both vertical and horizontal motives for engaging in FDI.

Internalization Internalization, the third strand of Dunning's taxonomy, is often seen as the most important; in the words of Ethier (1986), "Internalization appears to be emerging as the Caesar of the OLI triumvirate." Explaining why some activities are carried on within firms and others through arm's-length transactions is a major research topic for microeconomics as a whole, not just for the economics of FDI. A pioneering 1937 paper by Ronald Coase argued that the optimal scale of the firm, or the optimal degree of internalization, reflects a balance between the transactions costs of using the market and the organizational costs of running a firm. In recent decades, economists working in information economics have tried to endogenize these two sources of costs, emphasizing the inability of agents to write complete contracts. An early application of this approach to FDI was by Ethier (1986). In his model production requires prior research, the results of which can either be carried out within a vertically integrated firm (in the MNE case) or sold to downstream users. The end user must agree to purchase the research before its outcome is known, however. Ethier shows that a greater degree of uncertainty about the likely success of research efforts makes it more costly for the upstream and downstream firms to write a contract, which because of the complexity of the research process must necessarily be independent of the outcome. Hence more uncertainty raises the likelihood that production will be vertically integrated through MNEs. Moreover, the emergence of MNEs does not require international differences in factor prices, unlike other models of vertical FDI.

A different approach to endogenizing the internalization decision, though also relying on incomplete contracts, is taken by Antras and Helpman (2004). Following the Grossman-Hart-Moore property-rights approach to the problem of bargaining between a firm owner and a potential supplier/employee, ex post efficiency is greater when residual ownership rights are allocated to the party that contributes more to the final output. Embedded in a model of product differentiation and trade, this implies that more efficient firms and firms for which headquarter services are more important should exhibit internalization (the owner contracts with the supplier, who becomes an employee), while less efficient firms should exhibit arm's-length trade (the supplier remains a separate legal entity). In addition the model assumes that final-goods producers are located only in one country, the North of a two-country North-South model. Such producers are assumed to have a twofold choice: on the one hand, they have to choose between vertical integration, which solves the hold-up problem but at the cost of reducing incentives to the provider of the input, and an arm's-length relationship; on the other hand, they could locate their production in either country, trading off higher wages in the North against lower contract protection in the South. The full range of potential outcomes is shown in table 1, and Antras and Helpman show how heterogeneous firms will sort into these different modes, based on their productivity, on the share of headquarter services in the value of output, and on the differences in costs between home and foreign locations.

Cross-Border Mergers Both the OLI framework and the bulk of academic work on FDI until very recently have concentrated on the "greenfield" mode of FDI, where the parent firm constructs a new plant in the host country. Yet in reality the bulk of FDI, especially between developed countries, takes the form of cross-border mergers and acquisitions (M&As), in which the parent firm acquires a con-

Table 1
Taxonomy of location internalization modes

	Location	
	Home	Abroad
Internal	Integrated national firm	FDI
External	Outsourcing	Offshoring

trolling interest in an existing host-country firm. (UNCTAD estimates suggest that M&As accounted for more than 80 percent of worldwide FDI in the 1990s.) The distinction matters, since recent research suggests that the determinants and implications of cross-border M&As are very different from those of greenfield FDI.

Domestic M&As have been extensively studied by scholars in finance and industrial organization, and these literatures suggest two principal motives for them. A "synergy" motive arises in any market where an acquired firm has assets that are complementary to those of the acquirer, whereas a "strategic" motive arises in oligopolistic markets (i.e., markets in which the number of competitors is small), since a firm gains from absorbing a rival and so increasing its own market power.

Postmerger synergies can arise from many sources, including cost savings via internal technology transfer, reductions of overhead and other fixed costs, and the integration of pricing and marketing decisions on differentiated products. In an open-economy context, a particularly plausible kind of synergy is between the "O" and "L" advantages of different firms: the superior productivity and international networks of an acquiring MNE, on the one hand, combined with the local knowledge and distribution network of a potential target firm, on the other. Nocke and Yeaple (2008) develop a model that captures this kind of synergy: a competitive international market for corporate assets allows firms to match with suitable affiliates. Their model predicts that efficient matching occurs: more efficient parent firms acquire more efficient targets. They also show, however, that the most efficient firms engage in greenfield FDI rather than in cross-border M&As, a result consistent with the evidence.

Mergers driven by synergies may be expected to raise world welfare, provided the synergies are realized in practice. By contrast, mergers driven by strategic considerations might be expected to reduce welfare since they increase concentration. Neary (2007) shows, however, that this intuition is incomplete for two reasons. First, in the absence of synergies, the only mergers that will occur in equi-

librium are those in which the acquirer can afford to buy out the target firm. This implies that the target firm must be considerably smaller, and therefore eliminating it is likely to enhance global efficiency. Second, in general equilibrium, the expansion of more efficient acquiring firms and the elimination of less efficient target firms puts downward pressure on wages, thus encouraging increased output and lower prices in all sectors. Hence mergers are likely to raise overall welfare, although income distribution shifts in favor of profits at the expense of wages. Neary's model also makes the positive prediction that mergers take place in the same direction as trade and therefore they are encouraged rather than (as in the horizontal model of greenfield FDI) discouraged by decreases in trade costs. In line with empirical evidence, cross-border mergers thus serve as "instruments of comparative advantage," encouraging more specialization and trade along comparative advantage lines.

The OLI Framework: An Overall Assessment
In conclusion, the OLI framework does not directly address one of the key issues that has dominated economists' thinking about FDI, the distinction between horizontal and vertical motives for locating production facilities in foreign countries. Nor does it address the increasingly important distinction between greenfield and M&A modes of engaging in FDI. Nevertheless it remains a helpful way of organizing thinking about one of the most important features of the world economy.

■ foreign direct investment under monopolistic competition

Central questions in the study of foreign direct in vestment (FDI) are: Where do firms choose to locate their production? To what extent do firms become multinational and supply foreign markets through production by local subsidiaries rather than through trade? What are the associated levels of FDI and

patterns of trade? Theories of FDI under monopolistic competition provide a framework to address these questions. They analyze firms' choices on where to locate production, and also endogenize the number of active firms operating in each country.

Monopolistic competition models typically focus on horizontal rather than vertical FDI. That is, they look at situations where FDI involves producing the same good (or at least undertaking the same stage of production) in several locations. This is in contrast to vertical FDI, where FDI takes the form of offshoring different parts of the production process, although a monopolistic competition framework has also been used to address this issue (for example, Helpman and Krugman 1985).

Theory There are three main elements in a model of monopolistic competition and FDI: equilibrium of the firm, equilibrium of the industry, and general equilibrium of the economy. This review focuses on the first two of these. Each firm has increasing returns to scale, typically modeled by two components: increasing returns at the level of the firm and increasing returns at the level of the plant. At the firm level, increasing returns may derive from the costs of headquarters operations or research and development (R&D); these can be represented by fixed cost F. Plant-level operations have increasing returns to scale, modeled by fixed costs associated with setting up a plant, P. Unit operating costs are typically assumed constant (equal to marginal costs), but contain two different components, production costs and costs of trading internationally, such as transportation costs or trade taxes.

The trade-off faced by firms is clear. If they supply all markets from a single country (and single plant) they save the fixed costs of setting up a new plant but incur additional trade costs. Conversely, FDI means paying for a new plant, but saving trade costs. This is sometimes referred to as the proximity-concentration trade-off. Firms' decisions depend on the levels of these various costs and since fixed costs are involved also on expected sales volumes.

Turning to the industry equilibrium, there is free entry and exit of firms, so the equilibrium number of firms in each country is determined by zero profit

conditions. Competition is imperfect and firms set a markup of price over marginal cost, thus covering their fixed costs. Imperfect competition is typically modeled via product differentiation, often using the Dixit-Stiglitz (1977) framework so that price-cost markups are constant. In the simplest cases all firms in the industry have identical cost and demand functions (e.g., Markusen and Venables 2000).

What equilibrium outcomes are possible? Suppose first that there are two countries of similar size and with similar factor prices. Then the two key parameters are trade costs and the plant fixed cost relative to the firm-level fixed cost, (P/F). If trade costs are low relative to P/F then each firm will operate in a single country (with just one plant) and export to the other country. There will be no FDI, but there will be large volumes of intraindustry trade. If the two countries are identical, intraindustry trade will be balanced; otherwise the larger country will be the net exporter of output from this sector, since trade costs tend to cause firms to locate in the larger market.

If trade costs are high relative to plant fixed costs (or to the ratio P/F), then firms substitute FDI for exports. In the case where the two countries are identical, there is two-way FDI, and each market is supplied by domestic firms and foreign affiliates. There is no trade in goods, although there is trade in services, in the sense that affiliates' earnings cover some of the firm-level fixed costs and can be viewed as payment for headquarters' services. If the two countries are of different sizes, equilibrium has the following pattern: the smaller country may be supplied only by multinationals, while the larger is supplied by both multinational firms and "national" firms producing in a single country. In a multi-country model country size should be interpreted to include the market access of each country. For example, a firm may use a small country as an export platform to supply a larger neighborhood (Ireland and the EU being the obvious example).

In the model sketched earlier, all firms based in one country have the same behavior, this property following from the assumption that they all have the same technologies and face the same demand functions. This has the unattractive consequence that no

country will both export and have outward FDI in the same product. There are a number of ways of generalizing the model to get away from this stark result. One is to make firms within each country heterogeneous, and this approach has been pursued by Helpman, Melitz, and Yeaple (2004). All firms in a particular country face the same fixed costs, but there are now four such fixed costs incurred: by entry, by commencing production, by exporting, and by undertaking FDI. When the firm enters it learns its unit production cost (drawn from a distribution, and therefore varying across firms), and trade costs are a constant multiple of this. Each firm has to make three decisions. The first is whether to produce at all, or to exit; the second is whether or not to supply the foreign market; the third is whether to do so by exports or by FDI. Each of these decisions depends, in a natural way, on the level of the fixed costs associated with each activity relative to the per-unit cost.

The industry equilibrium, with free entry of firms, may now involve some firms exporting and others engaging in FDI. If there are two identical economies, then the following outcomes arise. Firms that commence production but have relatively high unit costs will produce only for the local market, neither exporting nor undertaking FDI. To see the reason for this, recall that the fixed costs of different activities are assumed to be the same for all firms, but the ability to cover these fixed costs depends on volume sold. High marginal cost firms will have small sales, and it is not profitable for them to incur the fixed costs of either exporting or FDI.

Firms with an intermediate level of unit costs will export but not undertake FDI, since the fixed costs of exporting are assumed to be less than those of FDI. Firms that have unit costs below some critical value switch from exporting to FDI, since they are able to sell at sufficient volume to cover the additional fixed costs. This critical value of unit costs is greater the higher are trade costs.

The model therefore predicts a size distribution of firms in each country, with firms engaging in a range of strategies some selling just in their domestic market, some exporting, and the largest engaging in FDI. The volume of affiliate sales relative to exports will be larger the higher are trade costs. Country differences can be added to the model, with results similar to those in the simpler model outlined above.

One further empirical prediction comes from this model, that the volume of FDI relative to exports will be larger the greater the degree of heterogeneity among firms. The intuition is that, other things being equal, exporting is a strategy associated with the middle of the distribution of unit costs, and increasing the dispersion of this distribution empties out this middle relative to the tails.

Empirical Evidence A number of papers have conducted empirical investigations of the hypotheses outlined above. An early and influential study by Brainard (1997) looks at the exports and affiliate sales of U.S.-based firms to 27 countries and in 63 industries. Trade costs are measured by freight and insurance charges and by import tariffs. Plant scale economies are proxied by plant-level employment, and firm-level scale economies by total nonproduction workers (capturing headquarters activities). Industry measures of R&D and advertising intensity are used to capture internalization advantages. Brainard finds that the share of affiliate sales in total foreign sales (affiliate sales plus exports) increases with trade barriers, transportation costs, and firm-level scale economies, and decreases with plant-scale economies, offering support to the predictions of the monopolistic competition model. Helpman, Melitz, and Yeaple (2004) undertake a similar exercise, with an extended data set and including a measure of the dispersion of firm size (and thereby dispersion of operating costs). Their results confirm those of Brainard, and additionally they find that dispersion has a negative effect on exports relative to affiliate sales, consistent with the predictions of their model of FDI with heterogeneous firms.

Policy Issues Many countries seek to attract FDI in the belief that it brings both employment and beneficial spillover effects, either through productivity spillovers or by stimulating related sectors. But at the same time, entry of FDI to a sector may crowd out local firms, and many countries restrict FDI inflow to sensitive sectors in order to protect local firms. How do these forces balance out?

Models of FDI and monopolistic competition are well placed to address these issues, because they allow for changes in the number of firms operating in a country and industry, and because they can be used to analyze linkages between related sectors (Rodriguez-Clare 1996; Markusen and Venables 1999). Suppose that a multinational firm enters a "downstream" industry (production of a final good). Its initial impact on local competitors is negative and, if the industry is monopolistically competitive, some of the firms in this industry may exit. However, the multinational will use inputs and these generate "backwards linkages," that is, create demand for intermediate goods supplied by upstream industries. Adjustment in these upstream industries may involve entry of new firms, and this can create a positive feedback mechanism. If these new upstream firms produce new (or better) varieties of intermediate goods, then costs in the downstream industry will fall (a "forward linkage"). This is a pecuniary externality the greater variety of intermediates benefits all firms in the downstream industry. It is then possible that entry of the multinational leads to a substantial increase in the industry's output essentially, it acts as a catalyst for formation of a cluster of activity. Whether this outcome happens depends on a number of parameters of the model and is more likely the more the multinational sources its inputs from the local economy rather than from imports, and the greater are the potential pecuniary externalities arising perhaps from variety effects, or also from direct knowledge spillovers or technological externalities.

These examples are illustrative of the rich set of possibilities that can be explored in models of FDI and monopolistic competition. There is potential for further work in several areas. For example, specification of sources of increasing returns needs to move beyond the simple characterization of fixed cost and constant unit cost. Richer modeling of firm heterogeneity would be desirable. A good deal of work needs to be done to further develop applications of the approach to policy, particularly in the context of understanding the contribution of FDI to the de-velopment of clusters of economic activity in developing countries and regions.

■ foreign direct investment under oligopoly

An oligopoly is a concentrated industry in which only a few firms compete. The extreme case of oligopoly is duopoly, where just two firms exist in the market. The key qualitative characteristic of oligopoly is that there is significant interdependence between rival firms. Each firm is sufficiently large in relation to the overall product market for its actions (e.g., levels of research and development, plant investment, and pricing decisions) to have a significant effect on its rivals' profits.

Profit-maximizing firms in an oligopoly will recognize their interdependence and take account of the likely reactions of rival firms when making their own business choices. Accounting for strategic responses complicates the analysis of firm decision-making under oligopoly compared to monopoly and perfect or monopolistic competition, where firms typically act in isolation. Therefore, noncooperative game theory, which analyzes how independent, self-interested players behave in situations of mutual interdependence, is often used to predict the outcome ("equilibrium") of oligopolistic competition.

In an "international oligopoly," consumers are distributed over several countries, and a small number of firms populate the industry at a global level. Competition occurs on two levels: as well as producing output for each national product market, a key strategic decision for firms in an international oligopoly is the mode of market access. Firms choose whether to serve a given national product market through international trade (exports from a plant elsewhere) or local production. Foreign direct investment (FDI) is the name given to the funds that flow across national borders in order to establish production facilities abroad. A firm that undertakes FDI to set up plants outside its home country becomes a multinational enterprise (MNE), also known as a transnational corporation or a multinational corporation.

Empirical and Theoretical Points of Departure
Modern analysis of firms' plant location decisions in international oligopolies started with Stephen Hymer's famous PhD thesis, *The International Operations of National Firms* (submitted to MIT in 1960, but not published until 1976). Hymer began by noting that the predictions of the then-dominant theoretical approach to FDI flows, which treated FDI as an international flow of portfolio capital in a perfectly competitive global financial market, were strikingly contradicted by the data. In the traditional perspective Hymer critiqued, the rate of return to capital is given by its marginal product, which is itself a decreasing function of a nation's stock of capital relative to other factors of production. Therefore, the return to capital will tend to be low in capital-abundant (developed) countries and high in capital-scarce (developing) countries. Moreover, if capital is freely mobile internationally, then one would expect to observe FDI flowing from developed to developing countries.

Several representative features of the data (empirical "stylized facts") are strongly inconsistent with the traditional perspective. At the macro level, developed countries are the recipients of the majority of global FDI flows as well as being the majority source, of course. Developing nations are left largely out of the global FDI loop. In this vein, Hymer observed in 1960 that the most popular locations for postwar U.S. outward FDI were Canada and the United Kingdom, both developed nations whose capital stocks survived the war much less depleted

than those on the European continent. Moreover, two-way flows of FDI between pairs of countries ("cross-hauling") are common even at the industry level. Another robust and awkward empirical result comes from econometric studies of the macroeconomic determinants of FDI flows, which generally find little or no explanatory role for national measures of capital intensity or the return to capital. For excellent surveys of the empirical findings, see the introductory chapters of Barba Navaretti and Venables (2004), and Markusen (2002).

Hymer concluded that the traditional macroeconomic account of FDI flows under the assumption of perfect competition was inadequate, and that a microeconomic study of FDI emphasizing the special characteristics of MNEs and the markets they inhabit offered fresh hope. At the microeconomic level, Hymer and subsequent applied theorists highlighted two stylized facts for particular attention:

- MNEs are prevalent in relatively concentrated industries that seem to fit the theoretical category of oligopoly; and
- MNEs are most likely to be observed in industries where proprietary, knowledge-based assets (usually related to the production process or the product) are important. Moreover, within an industry, MNEs are generally the firms with the largest stocks of such assets. It seems intuitively obvious that industries where proprietary, knowledge-based assets are important should also be concentrated. The fixed costs of developing such assets generate significant economies of scale for incumbent firms, which means that there is only room for a few firms to operate profitably in the industry.

Moreover, because knowledge-based assets are nonrival within the firm (their so-called public good aspect), it is natural to expect multiplant firms to arise in industries where they are important. Of course, horizontal MNEs are a special case of multiplant firms, and Markusen (1984) examines their welfare consequences in a model where production requires both firm- and plant-level activities. The firm-level activity, which produces a joint input across all the firm's factories, might be research and development (R&D) investment. Markusen assumes a two-country world where each country hosts a single plant to produce the final good. The two plants may be owned by competing national firms or integrated within a single MNE. As Markusen shows, that organizational choice involves a trade-off between technical and allocative efficiency. Integrating the plants into a single MNE avoids duplication of firm-level activities and boosts profits, but it also creates a monopoly in the product market.

Dunning's popular OLI (ownership-location-internalization) framework suggests further reasons why FDI might be observed in knowledge-intensive industries. Given that a firm has chosen to produce abroad, Dunning argues that FDI is favored over licensing production to a foreign firm if the transactions costs of writing and enforcing contracts create sufficient "internalization advantages." The OLI approach also assumes that, in order to undertake FDI profitably, a firm must possess "ownership advantages" over its industry rivals (e.g., superior technology). We return to this point later.

Models of International Oligopoly Having established that knowledge-intensive industries are likely to be both oligopolistic and FDI-intensive, we now consider the direct relationship between FDI and oligopoly. The seminal early analysis of the implications of oligopoly for FDI behavior is Knickerbocker (1973). Knickerbocker documented follow-the-leader patterns in the data on firms' FDI behavior within given industries, most evident at intermediate levels of concentration. He claimed that tacit collusion lay behind this relationship: tacit collusion often leads to imitative, follow-the-leader behavior, and it naturally arises at intermediate levels of concentration ("loose-knit" oligopolies in his terminology). In contrast, if concentration is low, firms are too numerous to coordinate their activities; and if concentration is high (a "tight-knit" oligopoly), firms can coordinate to maximize industry profits and so surpass imitative behavior.

Graham (1998) uses game-theoretic techniques to formalize Knickerbocker's follow-the-leader story. In Graham's model, FDI is used as a threat to

maintain collusion. In an international duopoly where the firms originate from different countries (and, for simplicity, international trade is ruled out), each firm tacitly agrees not to enter its rival's home market via FDI, thereby granting its rival a domestic monopoly. If one firm breaks the understanding by undertaking FDI, its rival reciprocates, thus producing follow-the-leader behavior. (Graham's theoretical framework is an infinitely repeated Prisoner's Dilemma game.)

The modern game-theoretic literature has suggested other direct linkages between oligopoly and FDI. If technology diffuses slowly, then incumbent firms have first-mover advantages over potential entrants into the industry. These can facilitate preemptive FDI to keep host-country product markets concentrated and deter entry by local firms. The mechanism is that, compared to international trade, inward FDI allows foreign industry incumbents to compete more aggressively with local entrants on host-country product markets. The possibility of preemption creates a strategic motivation for FDI in addition to considerations of demand and cost. (Formal models are presented by Markusen 2002, chapter 4; Motta 1992.)

In this preemption story, FDI sustains market power, whereas the *threat* of FDI is key under tacit collusion. Both scenarios seem quite intricate, however: Do firms really think like that? The results of the formal models of tacit collusion and preemptive FDI are also highly sensitive to assumptions: for example, if the local firm in the preemption setup described earlier could move before the foreign industry incumbent, then it could enter the host-country market to preempt inward FDI! Such fragility is, however, a common feature of game-theoretic models.

Recent game-theoretic analyses of international oligopolies have uncovered further reasons for the emergence of MNEs. In an important paper, Horstmann and Markusen (1992) use a symmetric two-firm, two-country framework to examine firms' choices between horizontal FDI and exporting. In the model, the firms originate from different countries, and competition takes place in two stages. First,

the firms choose between not entering the industry and entering either as a national firm or as a horizontal MNE. If it enters, a firm incurs a firm-specific fixed cost, which represents its headquarters and other joint-input activities such as R&D. Firms also incur a plant-specific fixed cost on each factory they establish. Therefore, choosing between entering as an MNE or a national firm (i.e., FDI versus exporting to the foreign market) involves a trade-off between fixed and marginal costs. FDI entails the fixed cost of an additional plant, but it allows the firm to "jump" the international trade cost that must be paid on exports. After having chosen the location of production, the firms compete (in Cournot fashion) on both national product markets. As is conventional, Horstmann and Markusen solve their model backwards to isolate its subgame perfect Nash equilibrium, thus capturing the idea that firms consider how their FDI choices will affect subsequent product-market competition.

Two results from the Horstmann-Markusen model are especially noteworthy. First, MNEs become more likely to arise in equilibrium as the firm-specific fixed cost rises relative to that for plants. This result echoes Markusen (1984): integrating national firms into an MNE economizes on firm-specific costs. Moreover, FDI cross-hauling occurs in equilibrium when the national markets are large enough to support the total fixed costs of two MNEs. This explanation of cross-hauling reciprocal FDI flows within a given industry is a major contribution because such flows are both empirically common and difficult to rationalize within other frameworks, such as OLI. Recall that a precondition for FDI in the OLI framework is that a firm possess "advantages" over its rivals. Therefore, FDI cross-hauling within an international duopoly suggests that firm A has advantages over B and B over A clearly an impossibility.

A second key result from Horstmann and Markusen (1992) is their prediction on how changes in international trade costs affect firms' choices between horizontal FDI and exporting. Because the benefit of FDI to firms is the avoidance ("jumping") of trade costs, Horstmann and Markusen find that national firms tend to displace MNEs as trade costs fall. This

prediction seems strikingly counterfactual, as we discuss later.

Markusen and Venables (1998) extend the analysis of firms' FDI decisions by allowing for entry into the industry and differences between the two host countries. They find that MNEs tend to displace national (exporting) firms in equilibrium as countries become more similar (both in size and in relative factor endowments), and as world income grows. These results fit the stylized facts well because a large proportion of global FDI flows between "similar" developed countries. Intuitively, similarities between the host countries encourage two-way FDI flows because they mean that MNEs from different countries are able to compete on similar terms.

A final area where oligopoly theory has been applied to FDI is in the analysis of horizontal cross-border mergers and acquisitions (M&As). Quantitatively, international M&As are more important in FDI flows than greenfield investment, the name given to the building of new production facilities abroad. Moreover, analysis of international M&As helps address a well-known paradox. As confirmed by Horstmann and Markusen (1992), intuition suggests that reductions in international trade costs should discourage FDI in favor of exports and, within FDI, the share of vertical should grow because it involves some international trade, whereas horizontal FDI involves none. There has been dramatic growth in global FDI flows in recent decades, however, and the majority of FDI remains horizontal, despite the large reduction in international trade costs, due in part to ongoing trade liberalization.

Neary (2006) considers possible resolutions of this paradox. Unlike horizontal greenfield FDI, he shows that trade liberalization can increase the profitability of horizontal mergers. The profitability gain from a merger arises because it removes the competition that would otherwise have occurred between the participating firms. Moreover, competition in the global market is more intense, the lower are trade barriers. With high trade barriers, import competition is limited and, for example, isolated national firms can earn almost monopoly profits at home. Therefore, the profitability gain from reducing competition through merger/acquisition rises as trade costs fall, and we expect trade liberalization to encourage horizontal cross-border M&As.

Another potential resolution of the paradox is to allow for intrabloc trade liberalization, for example, the launch of the European Single Market or the North American Free Trade Agreement (NAFTA). These liberalizations might make horizontal inward FDI from the rest of the world to serve the whole bloc profitable, where previously inward FDI to serve primarily just one bloc member was not.

This survey has aimed to show how oligopoly theory can cast light on strategic motivations for FDI that are absent in other market structures. In the process, some empirical observations such as FDI cross-hauling at the industry level become easier to explain. Finally, we should note that although this survey has ignored policy issues, there are lively debates concerning oligopoly and FDI. One, for example, concerns whether large MNEs are able to "divide and rule" national governments and cause a "race to the bottom" in corporate taxes. Such controversies highlight what a fruitful area this is for further research.

■ foreign equity restrictions

A foreign equity restriction is a measure that imposes more stringent requirements on foreign investors than domestic investors and thereby influences de cisions about where to invest and in what form. In some economies, such as Switzerland, private com panies impose limits on foreign holdings of their own shares (Bailey, Chung, and Kang 1999), but in most cases foreign equity restrictions are the result of government policy.

The aim of regulatory restrictions on foreign eq uity ownership is to maintain the independence of domestic firms for reasons of sovereignty, national security, and economic stability. In particular, the measures are often intended to prevent the acquisi tion of controlling stakes in domestic companies by large multinational corporations, over which na tional governments and other stakeholders have little influence. Sectors that are frequently subject to for eign equity restrictions are telecommunications and media, air and maritime transportation, finance, public utilities, and defense electronics.

Resource Allocation Implications Foreign direct investment (FDI) is a form of international eco nomic integration that can bring substantial gains to both investor and investment-receiver by fostering intrafirm trade and transactions in intangible assets, such as knowledge and product brands. Beyond the standard gains from trade, FDI inflows can provide dynamic spillovers from technology transfer and skill-building. These benefits are especially impor tant in developing countries where advanced tech nology and managerial expertise are in short supply.

Barriers to FDI reduce or eliminate these benefits by distorting the allocation of capital among different economies, between foreign and domestic invest ment, among different sectors, and between tem porarily held portfolio and longer-term direct in vestment. As a result, products and services may cost more than they would without the foreign equity restrictions and assets may not be used in the most productive way. The effects may manifest themselves through a variety of channels, such as higher prices, less consumer choice, lower capital stock, and lower productivity. The resulting costs of the foreign equity

restrictions in terms of forgone economic welfare improvements have to be weighed against their noneconomic benefits in terms of sovereignty, security, and stability to arrive at an overall assessment of the rationale for such measures.

Types of Restrictions and Measurement Measures to control or influence FDI range from simple requirements that investments be registered and screened, with virtually automatic approval, to complete bans on foreign ownership in some sectors or countries. Restrictions also vary with respect to the level at which they are applied. For example, measures may affect market entry, ownership and control, or operations. Another classification of re-

strictions pertains to the way in which they are applied for example, through legislation that clearly specifies ownership limits, or case-by-case assessments of whether entry will be allowed and the conditions that may apply (Hardin and Holmes 1997).

Assessing the relative prevalence and restrictiveness of different foreign equity restrictions presents major challenges, similar to those encountered when trying to measure other nontariff barriers. Relatively simple ways of summarizing the extent of foreign equity restrictions are based on counts of the number of measures in a sector or economy, or on indicators that reflect the proportion of investments covered by

Table 1

Coefficients on FDI restrictions (maximum 1.0)

Type of restriction	Scores
Foreign equity limits	
No foreign equity allowed	1
1 to 19% foreign equity allowed	0.6
20 34% foreign equity allowed	0.4
35 49% foreign equity allowed	0.3
50 74% foreign equity allowed	0.2
75 99% foreign equity allowed	0.1
no restriction but unbound	0.05
Screening and approval	
Investor must show economic benefits	0.2
Approval unless contrary to national interest	0.1
Notification (pre or post)	0.05
Other restrictions	
Board of directors/managers	
majority must be nationals or residents	0.1
at least one must be national or resident	0.05
must be locally licensed	0.025
Movement of people	
no entry	0.1
less than one year	0.075
one to two years	0.05
three to four years	0.025
Input and operational restrictions	
domestic content must be more than 50%	0.1
other	0.05
Total[a]	Between 0 and 1

[a]If foreign equity is banned, then the other criteria become irrelevant, so that the index is at 1.0. It is possible that various scores sum to slightly more than 1.0 when foreign equity is not totally banned, and in such cases, the index is capped at 1.0.

barriers (Hoekman 1995). Although such frequency and coverage indexes have the advantages of simplicity and lack of arbitrariness, some measures are more constraining than others. It therefore seems desirable for analysts to attempt to weight different restrictions according to their significance, even though such a procedure entails some subjective judgments and possible errors (Golub 2003).

One weighting scheme that has been used by Organisation for Economic Co-operation and Development (OECD) researchers is shown in table 1. The overall restrictiveness of FDI barriers is derived for each industry and country, based on regulations in three areas: equity limits, screening and approval, and other restrictions. Area scores are added up to yield an overall indicator that ranges from 0 to 1. Equity limitations and screening are related to an investor's right of establishment, whereas measures affecting management structures, movement of people, and operational restrictions pertain to national treatment of established firms.

This line of analysis focuses on statutory restrictions, but many countries retain informal public or private barriers to foreign equity acquisition, which can in some cases be more restrictive than formal regulations. Nonformalized FDI impediments are by nature difficult to capture and compare, however.

Policy Reform Many economies have liberalized their foreign investment policies since the 1980s such that equity restrictions in manufacturing have virtually disappeared in OECD countries. Developing and emerging economies maintain on average more restrictive policies, but large variations across countries and sectors exist. While service sector privatizations have led to increased market openness in many economies, reforms have often involved limits on acquisitions by foreigners. Yet there are some notable differences between OECD and non-OECD countries. In particular, transportation and tourism are relatively less restricted in non-OECD countries, while electricity, wholesale and retail distribution, and finance are relatively highly restricted in non-OECD countries (Koyama and Golub 2006).

The general, broad-based trend toward removal of foreign equity restrictions suggests that policymakers have increasingly been persuaded of the merits of inward FDI over concerns related to sovereignty, security, and stability, as well as the partisan interests of entrenched lobbies. From an economic point of view, nondiscrimination between domestic and foreign investors is generally the best policy in the absence of a clear-cut market failure or threat to national interests. Neutrality involves both right of establishment for foreign firms and national treatment of such firms once they are established. Right of establishment signifies that there are no discriminatory obstacles to foreign greenfield investment or mergers and acquisitions, while national treatment involves nondiscrimination in conducting business (Golub 2003).

Progress toward liberalization of remaining restrictions can be facilitated by continued discussion in international forums on development of codes, guidelines, and best practices in areas with direct impact on public- and private-sector governance practices. Moreover, reforms do not necessarily have to involve the immediate and complete removal of foreign equity restrictions. In some cases, more direct measures that, for example, clearly specify quantity or value constraints on foreign investors' market access or operations will tend to achieve the policy goal at a lower cost than a regulation that tries to achieve the same objective but in a less direct and transparent way.

■ foreign exchange intervention

Foreign exchange intervention refers to the purchase and sale of currencies in the foreign exchange market by a country's monetary authority, such as its central bank. In many countries with managed exchange rates, intervention is used routinely to target the for eign exchange value of the country's currency. For example, a central bank with a currency whose value is dipping below its target range typically will sell some of its holdings of foreign currency in exchange for purchases of its own currency. This process reduces the supply of the country's own currency and thereby increases its value in the foreign exchange market.

In countries without exchange rate targets, foreign exchange intervention is used at times to try to in fluence other aspects of the foreign exchange market or to directly alter domestic macroeconomic condi tions. Many central banks intervene in an attempt to dampen the volatility of the exchange rate, to slow the rate of change of the currency's foreign exchange value, to calm disorderly markets, or to manage the official holdings of foreign exchange reserves. In a few countries, foreign exchange intervention is a standard tool for addressing important domestic macroeco nomic concerns, such as the rate of inflation. Some of these domestic concerns may be linked only indi rectly to the foreign exchange market itself. In prin ciple, a monetary authority can use intervention to achieve any number of objectives.

When managing foreign reserves or influencing any aspect of the foreign exchange market is the ob jective of intervention, the monetary authorities face several choices in its implementation. Most impor tant, a monetary authority must decide to what extent the foreign exchange intervention should be allowed to affect domestic monetary conditions. Foreign ex change intervention can be undertaken in tandem with offsetting domestic monetary operations. An intervention's effect on domestic monetary conditions thereby will be "sterilized"   that is, there will be no net direct effect on domestic monetary conditions. Alternatively, intervention can be undertaken by itself, without countervailing domestic operations. Such intervention is called "unsterilized" intervention.

A monetary authority must also choose how much information about its intervention to divulge to foreign exchange market participants. It may in tervene in secret, it may reveal some of its informa tion about intervention, or it may intervene openly. Finally, a monetary authority may choose to inter vene in concert with others, in which case its inter vention is said to be "concerted," or it may intervene unilaterally. The efficacy of foreign exchange inter vention is thought to vary depending on these key aspects of its implementation   whether it is steril ized or unsterilized, secret or transparent, and uni lateral or concerted.

Effectiveness of Foreign Exchange Interven tion Intervention is quite effective in modifying the foreign exchange value of currencies when it is un sterilized. Since it is not offset by countervailing domestic operations, unsterilized intervention alters the amount of reserves in the banking system. When a central bank, for example, sells some of its foreign currency holdings, the reserves in the banking system

decline correspondingly. Foreign exchange sales themselves are thus a form of monetary policy tightening. This type of intervention has a direct effect on the foreign exchange value of a country's currency: tighter monetary conditions strengthen a currency's foreign exchange value. Its effectiveness is apparent even for currencies with high turnover in deep markets. When exchange rate concerns dominate monetary policy, foreign exchange intervention is effective.

Sterilizing foreign exchange intervention means preventing it from bringing about a domestic monetary condition change the very thing that would have the most direct effect on the currency's value. Therefore, in order for sterilized intervention to have an effect on the exchange rate, its effectiveness must come about through some other channel.

One important potential channel is known as the signaling channel. In this channel, intervention affects exchange rates when it signals a change in future monetary policy. In theory, such signals are credible (and intervention effective) only if intervention tends to be followed by consistent changes in monetary policy. Thus the signaling channel allows for an effect on exchange rates when the intervention, though initially sterilized, is expected ultimately to be unsterilized.

The microstructural approach to foreign exchange has recently provided other new insights into the efficacy of intervention. Microstructure models focus on the informational structure of foreign exchange markets. Because they are explicit about the informational structure, these models are well-equipped to show how an individual agent (such as the monetary authority) reveals its information when it initiates a transaction. This makes the microstructural approach particularly suitable both for understanding the role that intervention might play in coordinating exchange rate expectations and for sorting out some of the key aspects of the intervention's actual implementation. For example, microstructure models can provide precise answers to questions such as why intervention is carried out secretly, or why intervention, rather than an announcement, is used to convey information. The

intervention's optimal implementation is shown in these models to depend on the precise nature of the informational asymmetries in the market.

Practice of Foreign Exchange Intervention In most mature economies with floating exchange rates and open capital markets, intervention now occurs only infrequently. Although central banks engaged in more frequent unilateral and concerted intervention during some earlier periods, such as the 1980s, their intervention in the early 21st century was quite limited. For the central banks that issue the major international currencies, intervention when it does occur is usually small relative to the overall size of the foreign exchange market. It also typically takes the form of sterilized intervention. The only notable exception is the Bank of Japan, which has intervened frequently, and sometimes extensively. The European Central Bank and the U.S. Federal Reserve Board, for example, may let years go by without carrying out any intervention at all; and, when they do intervene, their intervention is sterilized routinely. Even the Bank of Canada, which had a policy of regular and automatic intervention until the mid-1990s, countenances intervention only in exceptional circumstances. For mature economies, extended central bank absence from the foreign exchange market is the norm.

The monetary authorities in many emerging economies, on the other hand, still intervene heavily in the foreign exchange market. In 2000 2006, the monetary authorities in China, in several of the oil exporting countries, and in a handful of emerging market countries sold off large quantities of their own currencies. In doing so, they accumulated immense holdings of foreign currency reserves.

Intervention among emerging market countries is most prevalent in those with exchange rate targets. Their intervention in some cases is unsterilized, and the corresponding changes in monetary conditions affect the exchange rate directly. In other cases, particularly where intervention occurs in a setting with significant barriers to capital mobility, it is sterilized. This combination of sterilized intervention and barriers to capital mobility is thought to enable a country to maintain a relatively weak exchange rate

without engendering domestic inflation. It is also exactly this combination of sterilized intervention and capital controls that so frustrates the trading partners of a few emerging market countries and provokes accusations of excessive currency manipulation.

Research Challenges The practice of foreign exchange intervention has moved along in fits and starts. It has varied across both time and countries in nearly every way in its objectives, in its implementation, and in its perceived effectiveness. This variation is mirrored in the dissonance of research on intervention, which as of the first decade of the 21st century provided little in the way of sure-footed guidance to monetary authorities. (In fact, the extent of any consensus arguably diminished since earlier decades, when a deeper skepticism about intervention prevailed.) Researchers face daunting empirical and theoretical challenges, and definitive conclusions remain a long way off.

On the empirical front, researchers face a scarcity of reliable, detailed data on actual intervention for all but a few countries. Foreign exchange market news reports have been used in lieu of actual intervention, but these reports have been found to be inaccurate. They can be used to measure at best only what the exchange rate response is to reports of intervention, not actual intervention. The reports are particularly unhelpful in exploring the role of secrecy in intervention. In addition, key pieces of intervention's implementation, such as whether or not it is sterilized or is concerted, often are not directly observable. This is problematic since theory tells us that intervention's effectiveness depends on these key pieces of its implementation. Moreover, intervention policy even its objective does not appear to be stable over time. This structural instability is generally, though not always, difficult to detect. When undetected, it means that atheoretical empirical studies are likely to conflate measures of effectiveness from different policy eras. Such conflated measures are difficult to interpret.

Empirical work on the intervention's exchange rate effectiveness also faces a serious simultaneity problem: foreign exchange intervention is carried out in response to changes in the exchange rate and in response to the conditions that affect the exchange rate. Thus intervention's effect on the exchange rate must be disentangled from the exchange rate's effect on intervention. Credible empirical studies must begin with plausible strategies to identify the effect of intervention by itself and that is a tall order. The most common identification strategy has relied on assumptions about the timing of the effects: the strategy is to assume that intervention affects the exchange rate instantly, while the exchange rate affects intervention only slowly. Unfortunately, to the extent that monetary authorities "lean against the wind," their response to the exchange rate is automatic. Thus the assumption of a slow response is often rendered implausible and the problem of disentangling the effects reemerges.

Further complicating the empirical work are the important theoretical challenges to a clear understanding of foreign exchange intervention. For example, while some models provide good descriptions of the implications of asymmetric information, only a few address the source of the informational asymmetry. It is easy enough, at one level, to say that a monetary authority has privileged information about its own intervention objectives and about future monetary policy. However, that is a remarkably static explanation for work in a field that generally demands attention to dynamics. It calls for further explanation of why such an informational advantage might not erode over time. A dynamically consistent account of the informational asymmetry will pave the way for a more complete understanding of the role of foreign exchange intervention.

■ foreign market entry

Foreign market entry is an important strategy for multinational enterprises (MNEs) to expand their global reach and establish an international network of interdependent business units. Within this net work, each subsidiary has a specific role, such as to provide access to local resources or markets. The design of an entry strategy has to match the needs and resources of the MNE with the opportunities and constraints in the local environment. Entry strategies are thus adapted to the local resource endowment, market demand, and institutional environment, though the degree of such adaptation varies across firms, industries, and locations.

Setting up a new business operation requires several strategic decisions, including the entry mode, location, timing, marketing, human resources, and logistics. Most scholarly research has focused on entry modes: export, contractual cooperation, or foreign direct investment (FDI). The FDI mode is further distinguished by the investors' share of equity ownership, and whether to build an operation from scratch, a greenfield project, or acquire an existing firm. These decisions are interdependent though economic analysts often prefer to analyze them ce teris paribus to generate more parsimonious theo retical models. Key parameters influencing the entry strategy vary with the objectives of the project; they are here illustrated primarily with a focus on market-seeking FDI.

Foreign entries are undertaken for a reason that is normally specified before the entry strategy is de signed. The motives of FDI relate to the develop ment and exploitation of resources of the MNE across its operations. Hence any specific entry deci sion cannot be viewed in isolation but has to be considered in relation to the overall strategic posture of the MNE. The MNE's global strategy thus sets the framework for specific foreign entries. This article considers the following aspects of foreign entry: entry mode, location, timing, marketing, human resource management, and logistics.

Entry Modes Foreign entry modes are classified in multiple ways. First, nonequity modes are dis tinguished from equity modes; the former include exports with and without trade intermediaries, as well as contractual forms of business such as licens ing, franchising, outsourcing, and turn-key projects. Equity modes are distinguished by the ownership stake taken by the foreign investor: portfolio invest ment, joint venture (JV), and wholly owned sub sidiary (Young, Hamill, Wheeler, and Davies, 1989; Welch, Benito, and Petersen 2007).

Portfolio investment involves the acquisition of a small equity stake as a financial investor, yet without influencing the strategy of the firm. Joint ventures are created by two or more partner firms each contributing resources and sharing the con trol of the operation. They are differentiated by ownership levels taken by the foreign investor; the higher the equity stake and the more dispersed the

residual ownership the more the investor has control over the operation. Wholly owned subsidiaries provide the investor with full control.

Theoretical models of the choice of foreign equity focus on the internalization of transactions and control over operations (Buckley and Casson 1996; Brouthers and Hennart 2007). Transaction costs economics and internalization theory suggest that a JV would be chosen if three conditions are met: (1) the new business unit depends on resource contributions from two or more firms, (2) the transfer of these resources or the expected benefits for the investors are subject to high transaction costs, and (3) it is not feasible for the entire parent firms to be integrated into one firm, for instance because they are big relative to the envisaged project, or one of them is a state-owned enterprise.

High transaction costs are in particular likely to arise for investors who transfer intangible assets. This issue is particularly pertinent for MNEs because their ability to achieve competitive advantages in foreign markets is often based on the deployment of intangible assets. They face asymmetric information regarding the content, value, and usage of these assets, which are classic sources of market failures. Thus the more markets are characterized by information asymmetries, the more likely MNEs prefer to internalize an operation and establish a wholly owned subsidiary. Moreover, Kogut and Zander (1993), and other scholars, argue that knowledge to be transferred is often tacit and thus requires "learning by doing" and therefore an intraorganizational mode of transfer. This requirement provides an alternative explanation for why knowledge-intensive firms would abstain from licensing or JVs as modes of foreign entry. Thus the more MNEs compete on the basis of technology, brand names, or other intangible assets, the more likely they would enter foreign markets with wholly owned subsidiaries.

A different source of transaction costs is interdependence of business activities and thus high asset specificity. These transaction costs lead in particular to vertical JVs in industries that require large investments in assets specific to a business relationship, as in the mining and processing of certain natural resources.

Yet, transaction costs also depend on the institutional environment governing the market, notably the feasibility and cost of enforcing contracts. Where these institutions are weak, investors would abstain from relying on contracts; at the same time, local partners may be helpful in interacting with other local businesses in such contexts. Joint ventures may provide an avenue to operate in unfamiliar contexts, especially where market supporting institutions are weak.

A different distinction of investment modes concerns the make-or-buy decision, namely the establishment of a greenfield operation versus an acquisition of (a stake in) an existing company. This decision is primarily driven by the investor's need for local resources: an acquisition provides local organizationally embedded resources, such as human capital and networks with local authorities. A greenfield operation, in contrast, allows investors to create a new operation from scratch according to their own designs, and thus to replicate organizational procedures and practices. The greenfield option is preferred in particular by investors whose competitive advantages are grounded in the firm's organizational structure and culture. Acquisitions are preferred by those who need complementary local resources.

Location Location concerns both the choice of country to invest in and the selection of a specific site. For resource- or efficiency-seeking projects aiming to create an export platform, the primary concern is costs of production. Hence the key determinants for location decisions are the costs and quality of the local factor endowment. Entrants would consider the specific inputs that they require for their operations, including natural assets such as cost of the local workforce and natural resources and "created assets" such as intermediate goods, human capital, and infrastructure.

Created assets are often of primary concern in industrialized countries, but they are also of increasing importance in emerging economies. Created assets are often provided by other businesses, which is one cause of the agglomeration of FDI:

foreign entrants invest where a strong community of local and foreign-owned businesses already exists.

Market-seeking investors are primarily concerned with access to distribution channels and potential customers. They identify the relevant market and then seek a central location for sales, marketing, and distribution operations. In some industries, the actual production needs to be located close to the customer or the point of consumption, notably in service industries such as hotels and financial services, and for manufactured goods that face high transportation costs. Thus location decisions by market-seeking investors are a function of the expected market size and of transportation costs of bringing products to the customer. For consumer goods, market demand may be predicted based on demographic data such as per capita incomes and population size. For business-to-business operators, size and growth of the local customer industry are crucial. A special case is "follow-the-customer" entrants, which set up operations to best supply a specific customer, as commonly observed, for instance, in the automotive industry.

In addition to the primary considerations of factor costs and markets, location decisions are often moderated by the institutional environment. For instance, investors are concerned about regulation of the industry, political risk, and law enforcement, especially with regard to intellectual property rights. Moreover, they may prefer locations in cultural proximity because cultural differences between existing and new operations may reduce the efficiency of communication and coordination.

Location decisions may be made in two stages, first the country and then the site, but businesses may also compare alternative sites in different countries. The relevant parameters for both between-country and within-country location choice tend to be similar. MNEs may shortlist alternative sites and then negotiate with the pertinent national and local authorities in parallel. At this stage, investment incentives such as provision of specific local infrastructure or subsidies and financial incentives may tip the balance for a particular site, especially if competition for FDI is strong.

Timing of Entry Market-seeking foreign investors normally aim to be number one or two in their industry or market segment, especially if the industry tends toward oligopolistic market structures. Such market leadership may best be achieved by taking an early lead, or by taking over a local market leader (Lieberman and Montgomery 1988). Thus market-oriented investors often pursue first-mover advantages, while others enter the host country shortly after the first mover, aiming to challenge the first mover before its position is too strong.

Early entrants may attain a lead in building reputation and consumer loyalty, and in establishing relationships with major suppliers and customers. First movers may thus be able to lock their partners and customers into a relationship, and raise barriers to entry for later entrants. Moreover, first movers may build goodwill with local authorities, slide down the learning curve, and acquire unique local resources, such as distribution channels, local brands, and raw material sources.

Followers, on the other hand, may benefit from a less uncertain business environment, from observing the experiences of the first mover, and from customers and local authorities already familiar with the product and the practices of the industry. In particular, "fast seconds" may benefit from these advantages, while challenging the first mover before the market structure has stabilized. Empirical evidence suggests that first movers can maintain their leadership position if they continuously commit resources and focus on learning about the local environment. Yet evidence also points to many first movers who did not succeed in creating sustained market leadership.

Related to timing is the question of how fast to accelerate commitment to a market. In some industries, heavy up-front investment is required to establish a strong position in view of (potential) competitors, as for branded consumer goods, or because of the capital intensity of the industry, as for oil exploration. In other industries, a "platform strategy" may be appropriate as investors establish a small foothold from which to observe the local industry and to flexibly react to business opportunities if and when they emerge.

Marketing The marketing literature on foreign entry has focused on standardization versus local adaptation (Meyer and Tran 2006). A standardization strategy would use the same product, brand, and processes in all countries. Advantages of such a strategy include economies of scale in product development, production, and marketing. It is most likely to be appropriate in industries that are technology intensive and face little variation in consumer preferences. In contrast, a local adaptation strategy would emphasize localization of products to accommodate local needs and preferences. This may in particular include the creation or acquisition of local brands for the mass market. Such localization is important for instance in the food and beverage industry.

Standardization and localization are not exclusive, as MNEs may combine a high degree of standardization for their internal processes, such as product development and production, with adaptation of products and customer interfaces, notably marketing practices. Others pursue a multi-tier strategy and offer both an international product positioned in the premium segment and a local brand aimed at the mass market. Such a strategy allows synergies, for instance, in the use of distribution channels.

Human Resources and Logistics A foreign entry depends on qualified and motivated people to implement the strategy. Human resources management is particularly important to manage knowledge sharing within the organization, both to transmit key organizational practices to the new operation and to inform decision-makers at headquarters about the local business. Thus along with the establishment of a new subsidiary, expatriate managers have to be selected and prepared for their assignment, and local staff needs to be recruited and trained. Expatriates play a pivotal role in this process, as do training programs for local staff that may include learning by doing in other operations of the MNE. Other human resource management challenges include leadership of a workforce in a culturally different context and adaptation of systems for recruitment, performance assessment, and remuneration of local staff.

An important aspect of a foreign entry strategy that is little analyzed in the literature but of great importance for management practice is logistics. Lower labor costs are valuable for a business only if the products can be transported to the customer in good time at acceptable costs. Modern transportation infrastructure and information technology systems are designed to allow MNEs to optimize the integration of their internal operations as well as supplier relations. Specialist intermediaries offer services that may include not only warehousing, shipping, and door-to-door delivery but also processing of customer orders and identification of appropriate suppliers. A foreign entry often triggers changes in these systems, especially if it involves the relocation of production.

Interdependencies An entry strategy consists of many elements; entry strategy is, therefore, a multidimensional construct. Any decision has to take account of other dimensions. Take, for example, the choice of entry mode. If timing and speed of entry are crucial for an investor   as they are for those pursuing a first-mover advantage   an acquisition or a JV may offer quick market access. However, an acquisition poses greater challenges for the integration of the local operation with the global company in terms of, for instance, marketing, logistics, and human resource management. Thus foreign market entry decisions have to reflect the complex interdependence of multiple dimensions.

■ forward premium puzzle

Interest rates, the exchange rate, and the forward rate are all linked together by expectations and individual attempts to obtain the highest rates of return. The forward premium puzzle is closely related to the failure of uncovered interest parity (UIP) to hold, and the phenomenon of forward rate bias, which refers to the tendency for the forward exchange rate (the price of foreign currency agreed to today for a transaction some specific time in the future) to sys tematically mispredict the future spot exchange rate (the exchange rate in transactions in which one cur rency is directly exchanged for another). The puzzle is the finding that the forward premium the gap be tween the spot exchange rate and the forward rate usually points in the wrong direction for the subse quent actual movement in the spot exchange rate. Uncovered interest parity states that if the covered interest parity holds for a pair of currencies, then the forward discount, and hence the interest differential between the two countries, should be an unbiased predictor of the subsequent change in the spot rate, assuming that actors make guesses about the future

that are on average correct (what is sometimes termed "rational expectations"). The puzzle arises from the fact that, if market participants were risk neutral, the forward rate should equal the future expected spot exchange rate; yet when the forward rate suggests depreciation, typically the exchange rate appreciates, and vice versa.

The puzzle is of importance for what it suggests about the workings of international financial mar kets. To the extent that the puzzle reflects the failure of rational expectations to hold, then interest rate differentials will be poor guides to future exchange rate movements. In addition, the implied lack of market efficiency suggests a potential role for gov ernment intervention in foreign exchange markets. On the other hand, if the puzzle reflects the presence of a premium to compensate for the riskiness of specific currencies, then capital may not be so ready to migrate from one currency to another.

Explaining the Forward Premium Puzzle To fix concepts and terms, define the forward rate at time t for a trade to occur at time k as F_t^k and the spot rate at time t as S_t. Further, let the subjective expectation of the spot rate at time $t+k$, based on time t informa tion, be defined as $\varepsilon_t(S_{t+k})$. Assume for the moment rational expectations, namely, $E_t(S_{t+k})$. Then one should expect:

$$S_{t+k} = F_t^k + \tilde{u}_{t+k} \qquad (1)$$

where the error term is an expectational error.

In reality, regression estimates do not obtain a regression coefficient of unity, although the point estimate is often not statistically significantly far from the posited value.

The forward premium puzzle can be identified by assuming that the error term is log normally dis tributed, so that (1) can be rewritten as:

$$s_{t+k} = \beta_0 + \beta_1 f_t^k + \tilde{u}_{t+k} \qquad (2)$$

where under the null hypothesis, $\beta_1 = 1$, and β_0 is allowed to equal some constant impounding some Jensens Inequality terms.

Notice that one can subtract the current log spot rate s_t from both sides, since under the null $\beta_1 = 1$. This yields:

$$s_{t+k} - s_t = \beta_0 + \beta_1(f_t^k - s_t) + \tilde{u}_{t+k} \qquad (3)$$

The left hand side of equation (3) is ex post depreci-ation, while the term in the parentheses is the forward discount (or the inverse of the forward premium).

The puzzle is that estimates of β_1 are not only different from the value of unity, and statistically significantly, but also that the coefficient estimates are typically *negative*. This suggests that agents could make substantial profits by arbitraging. To be con-crete, individuals could borrow in the low interest currency and lend in the high interest currency, in a process termed "the carry trade." This well-known strategy can be highly profitable, although the profits are particularly vulnerable to sharp movements in the exchange rate.

This issue is linked up to uncovered interest parity in the following sense. If covered interest parity holds, then:

$$(f_t^k - s_t) = (i_t^k - i_t^{k*}) \qquad (4)$$

Substituting this no-arbitrage-profits condition into (3), one finds that (3) can be rewritten as:

$$s_{t+k} - s_t = \beta_0 + \beta_1(i_t^k - i_t^{k*}) + \tilde{u}_{t+k} \qquad (5)$$

The equation above is the regression used to test the joint null hypothesis of uncovered interest parity and rational expectations. The finding of a negative slope coefficient in equation (5) is equivalent to the finding of a negative slope coefficient in (3), for instances where covered interest parity holds.

Reasons behind the Puzzle A number of papers have investigated a wide variety of different econo-metric issues, but overall it appears that the negative slope coefficient cannot be entirely explained by the time series characteristics of the variables. Leaving aside these econometric issues, the forward premium puzzle might exist even when capital is perfectly mobile according to the covered interest parity cri-terion, either because of the invalidity of the rational expectations hypothesis or the existence of an ex-change risk premium.

Estimates of equation (5) using values for k that range up to one year typically reject the unbiasedness restriction on the slope parameter. For instance, the survey by Kenneth Froot and Robert Thaler (1990) finds an average estimate for β of 0.88. Menzie

Chinn and Guy Meredith (2004) document that this result holds for more recent periods extending up to 2000. They also show that the bias decreases at longer horizons.

It is important to recall that uncovered interest parity, properly defined as relating to expected de-preciation, is untestable. Estimation of the standard UIP regression equation relies on the rational ex-pectations methodology embodied in equation (1). Of course, reliance on the assumption of rational expectations is by no means uncontroversial. In a number of papers, Kenneth Froot and Jeffrey Frankel (1989) demonstrate that the standard tests for UIP yield radically different results when one uses survey-based measures of exchange rate depreciation. They find that most of the variation of the forward dis-count appears to be related to expected depreciation, rather than a time-varying risk premium, thereby lending credence to UIP.

Menzie Chinn and Jeffrey Frankel (1994) docu-ment the fact that it is difficult to reject UIP for a broader set of currencies, although there is some evidence of a risk premium at the 12-month horizon. The authors interpret the differing results as arising from a wider set of currencies they examine 17 currencies as opposed to the 5 or so examined by Jeffrey Frankel and Kenneth Froot (1987) where the assumption of perfect substitutability of debt instruments is less likely to hold. As these authors have emphasized, rejection of the rational expecta-tions hypothesis does not necessarily mean one ac-cepts the proposition that agents are irrational. It may be that agents are constantly learning about the economic environment such that their forecasts are biased for long stretches of time.

Perhaps the most natural explanation for why the forward premium predicts the wrong direction of exchange rate movements is that a risk premium drives a wedge between expected changes and actual changes. However, the modeling of the risk premium has proven quite challenging. A standard model motivates the risk premium as a function of the correlation between relative returns on assets denom-inated in the two currencies, and the ratio of mar-

ginal utilities of consumption in the two respective countries. While the theory is quite straightforward, an implausibly high degree of risk aversion is necessary to rationalize the observed volatility of the risk premium. Some recent work has had success relying on different utility functions. For instance, Moore and Roche (2002) assume that the amount of utility that consumers gain from consumption depends in part on the amount of consumption undertaken in the previous period. This approach rationalizes the observed volatility with the seemingly small changes in consumption.

■ fragmentation

Fragmentation involves the decomposition of a production process into its constituent activities and the dispersion of those activities across national borders. It gives rise to cross-country production sharing and production networks. Under fragmentation, traded goods and services contain value added from more than one nation.

The ability to be "fragmented" into "production blocks," each capable of being carried out in a physically separate location, is in the first instance a matter of technology. Whether or not to take advantage of this facility, however, is an economic decision that depends on location-specific advantages, such as proximity to raw materials, factors of production, and markets. While the physical nature of production may remain largely unchanged, its organization undergoes significant transformation.

In addition to choosing locations for constituent activities, firms provide "service links" in order to facilitate communication and coordination and to allow for efficient and on-time transportation of parts and components within the network (Jones and Kierzkowski 1990). Hence, fragmentation will take place only where savings in production cost exceed the costs associated with service links.

When making their choices, firms must also determine whether to keep the dispersed activities under company management or to outsource them to independent contractors in so-called arm's-length relationships. The choice depends on economic as well as legal and institutional considerations; it involves trust, enforceability of contracts, and protection of intellectual property (Helpman 2006; Barba Navaretti and Venables 2004). A substantial proportion of cross-border production involves the foreign operations of the affiliates of multinational corporations, implying that a rising share of international trade is intrafirm trade.

Fragmentation, which has also been described as "breaking up the value-added chain," works particularly well between advanced and emerging economies and has grown rapidly in industries such as electronics, machinery, and textiles and apparel. Key factors facilitating this development have been reductions in trade restrictions and other barriers and cost-cutting innovations in transportation and communications technologies. The rapid spread of international production sharing is changing trade patterns, trade balance accounting, and the interaction between trade, the exchange rate, and other macroeconomic variables.

The spread of production sharing implies that traded products increasingly contain parts and components from more than one country. Hence domestic value added to a country's exports is often significantly less than the value of those exports. Chinese exports of electronic machinery, for example, incorporate imported components. Similarly, the imports of many countries contain components made in those countries. United States imports of automobiles from Mexico, for example, carry large amounts of U.S.-made components.

Production sharing gives rise to a new form of intraindustry trade, in which parts and components and finished products belonging to the same industry or sector pass back and forth among countries. This vertical intraindustry trade differs from the more

traditional horizontal intraindustry trade of different varieties of the same end product.

Analytical Issues The term *fragmentation* was first used in this context by Jones and Kierzkowski (1990). Alternative terminology includes intraproduct specialization and vertical specialization. The effects and implications of cross-border fragmentation may be examined from a variety of theoretical perspectives, including Ricardian, Heckscher-Ohlin (H-O), and imperfect competition (Arndt and Kierzkowski 2001). The first two are the workhorses of trade theory. In the Ricardian model, countries are differentiated by technology, so intraproduct specialization among countries participating in production sharing is determined by location-specific technological know-how. Countries with limited technological development will engage in low-tech production, while more advanced components and assembly will be produced in countries possessing the necessary technologies.

In the Heckscher-Ohlin framework, differences in factor endowments provide the basis for specialization, such that countries will specialize in activities that make intensive use of locally abundant factors of production. Labor-intensive component production and assembly will, therefore, be carried out in labor-abundant countries, other things being the same, while skill- and capital-intensive activities will be performed in more advanced countries. In that framework, fragmentation has effects on output, factor prices, trade, and welfare analogous to those associated with technological progress (Arndt 1997).

The factor-proportions view of vertical intra-industry specialization and trade is a key contribution of the H-O approach, which had been criticized in years past for its inability to explain horizontal specialization and trade. Indeed, it was this shortcoming that prompted the development of imperfect-competition models of international specialization and trade, in which consumers value variety and monopolistically competitive firms specialize in the production of variety. Intraindustry trade associated with production networks, on the other hand, consists of the movement across borders of parts, components, and end products belonging to the same industry.

Factor endowments, however, are not the only type of location advantage. Others include distance, border, country size, infrastructure, legal and financial systems, and regulatory and other policies. The effects of these variables on trade in general have been studied with the aid of gravity models, which posit that trade between two countries will fall with distance and the thickness of the border; that country size measured in various ways affects bilateral trade positively; and that strong and transparent legal and institutional structures, ample infrastructure, and protrade regulatory policies increase trade.

The gravity equation is now beginning to be employed in the context of production networks, for the purpose of which it must be amended in a variety of ways. There is, for example, more than one distance to be accounted for. In addition to the distance between the importer and exporter of the final product, there is distance between countries supplying parts and components and the country in which the final good is assembled. Regional clustering of supplier nations (as in Southeast Asia) is a distinct location advantage.

Foreign Direct Investment Production networks with developing economies typically require up-front capital formation, financed at least in part by inflows of foreign direct investment (FDI) and technology from advanced countries. Foreign investors erect production facilities and install infrastructure, bring in skilled workers, and transfer technology at levels of sophistication beyond those available in the country. While such activities violate several assumptions of the H-O model, that model is nevertheless useful in predicting the pattern of FDI flows.

The investment involved is vertical (VFDI), intended to support vertical or intraproduct specialization. In a world of cross-border production fragmentation, the H-O model predicts that VFDI will tend to flow from capital- and skill-abundant, labor-scarce countries to labor-abundant economies. The Ricardian model predicts that such flows will move from technologically advanced to technologically emerging economies.

As already noted, factor endowments are only one type of location advantage, and therefore cannot fully explain movements of FDI. Once again, the gravity model offers a way of accounting for additional location-specific considerations   including distance, country size, border effects, and various institutional and policy-related factors. The bulk of the existing empirical literature on FDI, however, covers periods dominated by horizontal foreign direct investment (HFDI), which prevails among advanced countries and which continues to be the dominant form of FDI.

According to this evidence, FDI responds positively to distance. The explanation lies in the fact that in horizontal specialization FDI is a substitute for exports. As distance and its costs increase, exports are replaced by on-site production for the local market and hence FDI flows rise. Vertical FDI, on the other hand, moves to support production sharing. Hence, when distance raises the costs associated with servicing a network, production sharing becomes unprofitable and FDI declines.

Multinational Companies While many multinationals go abroad to produce for the local market, an increasing number have become involved in production networks, a process in which affiliate operations play a key role. Often, the initial organizational structure follows a "hub-and-spoke" pattern, with affiliates in several countries trading directly with the parent company, but less with one another. As interactions become more sophisticated and infrastructure is developed, true networks evolve in which trade takes place among affiliates located in various countries, as well as between affiliates and local firms. This pattern is exemplified by Japanese multinationals operating in Southeast Asia (Kimura and Ando 2003).

Agglomeration of activities is important in this context, because it generates positive externalities. Clusters of multinationals operating in a given country or in several adjacent countries attract and train workers, improve access to finance and other services, and generate knowledge spillovers that raise productivity and reduce costs. The creation of such an environment benefits from supportive public policies and public investment in infrastructure. A classic example is Ireland and the electronics industry. Such an environment generates positive agglomeration effects, as workers with industry-specific skills migrate into the area and knowledge spillovers occur.

In this setting, local producers are encouraged to enter the industry as suppliers of goods and services to the multinationals. There is evidence that arm's-length trade is growing in Southeast Asia as foreign multinationals rely increasingly on local suppliers. For developing countries, this opens another path to industrialization.

Scale economies are important in production networks and are exploited by multinationals. Since neither the Ricardo nor Heckscher-Ohlin framework is capable of handling scale economies and externalities, the imperfect competition literature provides important insights. Scale economies come into play on both the production side and in the provision of service links among production blocks. If production of each part or component is concentrated in one location, for example, longer runs permit exploitation of internal scale economies at each location. Meanwhile, agglomeration and clustering of producers generate economies that are external to plant and firm.

In the provision of service links, the fixed costs associated with establishing a communications network can be spread over larger numbers of units and firms as the size of the network and the number of participating entities expand. Access to a service network encourages agglomeration of firms in a country or region. Where individual countries tend to be small, cooperative policies among countries are required to reap the benefits of agglomeration.

Productivity, Employment, and Wages The spread of fragmentation has sounded political alarm bells in advanced countries about jobs and wages not only in manufacturing, but in services industries, as "offshoring" of call centers, help desks, programming, and ticketing operations has proliferated. There is no doubt that jobs of workers whose functions are shifted to foreign locations are lost. But if cross-border sourcing of components raises competitiveness and lowers prices of final products or

services, thereby increasing sales and thus output, then jobs will be created elsewhere in the industry or more generally in the economy.

With respect to wages, there are two concerns. First, production sharing with low-wage countries may exert downward pressure not only on the wages of workers whose jobs are lost, but on wages generally in a "race to the bottom." Second, it may change the wage distribution against low-skilled workers and widen the wage gap between skilled and unskilled workers.

The available evidence is mixed, in part because it is not easy to separate the effects of fragmentation from those of technological change and of other factors affecting employment and wages (Feenstra 1998). The outcome further depends on the sector in which fragmentation occurs, on the skill ratios in the affected industries, and on the relationship of each skill category to capital. In a framework in which fragmentation occurs in many industries, moreover, there will be "onshoring" as well as "offshoring," so that jobs lost in one sector must be balanced against jobs gained in others. Under such circumstances, the problem is mainly one of matching unemployed workers with emerging jobs. This is the familiar trade-adjustment problem.

Regional Integration In recent years, regional production sharing and trade in parts and components has grown rapidly. This growth has been facilitated by preferential trade liberalization. While production sharing is generally welfare-improving under free trade and in preferential trade areas (PTAs), rules of origin that restrict the movement of components from outside the PTA can introduce significant elements of trade diversion.

Production sharing is changing the nature of regional integration, in that it requires deeper integration than the removal of tariffs and other restrictions on the flow of goods and services. It calls for liberalization of investment and for the cross-border movement of persons, as well as harmonization of technical standards, regulatory policies, and dispute settlement procedures. To the extent that cross-border integration of production at the level of industries reduces asymmetries and promotes conver-

gence of business cycles, it helps pave the way for greater regional monetary cooperation, including monetary union.

When industries become linked across borders, production sharing tends to reduce the sensitivity of trade flows to exchange rate changes. Consider a depreciation of the Mexican peso against the dollar, which raises the price of imports of U.S.-made components for incorporation into passenger vehicles. When these vehicles are exported to the United States, the dollar's appreciation has an offsetting effect. Hence trade flows associated with production sharing are less sensitive to exchange rate movements than other types of trade. This has implications for intraregional exchange-rate arrangements (Arndt and Huemer 2007).

Fragmentation and Interdependence Production sharing allows countries to reap the benefits of increased specialization. In the context of standard trade theory, intraproduct specialization pushes out the production possibility curve and thereby allows countries to reach higher consumption frontiers. In this sense, its effects are analogous to those of technological progress and factor accumulation.

But it also links countries more closely to their trading partners and thereby reduces policy autonomy and increases interdependence. It goes well beyond trade in promoting economic integration by linking industries at the level of production. Countries are more open and thus more exposed to external shocks. A group of countries operating in a production network will experience similar shocks. As more industries become involved in networks, cross-country asymmetries decline. Business cycles tend to converge. The pressures and incentives for policy cooperation increase.

Fragmentation is an important feature of globalization. Products become internationalized, national markets are more closely linked to those abroad, economywide behavior patterns converge, and the domain of overlapping policy interests expands.

■ free trade area

A free trade area (FTA) is created by an agreement among a group of countries to eliminate trade bar riers on most (if not all) goods between them. FTAs can be, and often are, regional and dictated by geo graphical considerations, such as the North Ameri can Free Trade Area, composed of the United States, Canada, and Mexico. They can also occur between countries that are far apart, as with the U.S.-Israel or U.S.-Singapore FTAs. Countries can belong to more than one FTA. The number of FTAs has increased rapidly since the early 1990s. For example, as of October 2007, the World Trade Organization (WTO) reported that approximately 110 notified (that is, officially existing) FTAs (excluding acces sions) were active at that time.

In contrast to a customs union (CU), which sets a common external tariff, FTAs do not necessarily equalize their members' tariffs on nonmembers. With differences in tariffs, rules of origin (ROOs) prevent trade in a product from going through the country with the lowest tariff on it and then being shipped within the FTA, since a good is eligible for zero tariffs in the FTA only if it originates there and ROOs specify the conditions required for origin to be granted.

There are large differences in the effects of an FTA with and without ROOs. In the absence of ROOs, an FTA results in large changes in trade flows as trade seeks the lowest tariff entry point into the FTA. Goods are then transshipped to their final destination in the FTA. Of course this results in large tariff rev enue transfer effects as this trade deflection transfers tariff revenue to the country with the lowest tariff entry point. As pointed out by Richardson (1995), this can result in a race to the bottom in setting tariffs. Moreover, in the presence of transshipment costs, such arbitrage may waste valuable resources: if such waste outweighs the positive effects of lower tariffs,

an FTA without ROOs may even reduce welfare overall.

In the presence of ROOs, however, simple transshipment is not possible. Nevertheless, some trade deflection may still be possible. By shipping domestic production to its FTA partners and meeting domestic demand via imports, the low-tariff country can still attract trade to its ports.

The Legal Basis of FTAs Signatories to the General Agreement on Trade and Tariffs (GATT) accord most-favored-nation (MFN) status to one another. This means that they cannot offer anyone else a more favorable (lower) tariff. How then can FTAs, which are by their very nature discriminatory, be legal? The answer lies in Article XXIV of GATT, which explicitly allows FTAs and CUs as exceptions to this rule as long as substantially all trade is free among members, and trade barriers with nonmembers is not higher on average after the FTA or CU.

The Welfare Effects of FTAs Although one thinks of FTAs as liberalizing of trade, and trade liberalization as welfare improving, neither may be true. If one pictures an FTA as only reducing the tariff on each good to the lowest tariff set by any of the FTA members, one might be inclined to think that such an FTA is welfare improving. Even this is not necessarily so, however. The theory of the second best says that welfare could fall with liberalization if not all distortions are removed, and consequently, even in such a stylized setting, an FTA may reduce welfare.

The usual argument showing the possibility of welfare loss is Viner's (1950). If an FTA is formed with the high-cost supplier, what is called trade diversion occurs. The country imports from its higher-cost FTA partner rather than the lower-cost country outside the FTA, so the gain in consumer surplus or welfare from lower tariffs and resulting lower consumer prices could easily fall short of the loss in tariff revenue. Trade-diverting customs unions could reduce welfare, whereas trade-creating customs unions, those formed with the lowest-cost supplier, would raise welfare.

FTAs need not be liberalizing, since if ROOs are hard enough to meet, they will raise costs by enough that no firm will find it worthwhile to meet them in order to obtain zero tariffs. In this case, FTAs do nothing. It is even worse if ROOs are strict and raise costs a good deal, but are still worth meeting. In this case, even if prices fall a little, the loss from the cost increase due to ROOs, which wastes resources, and the tariff revenue forgone, could easily reduce welfare relative to that prior to an FTA.

Moreover, recent work in this area has shown that the goals of improved market access and welfare may well be in conflict. Ju and Krishna (2000) show that if the excess demand for exported goods does not respond to changes in the prices of imported goods, then any policy that increases imports must also reduce welfare. Anderson and Neary (2007) interpret these results in terms of the generalized mean and variance of tariffs. They show that welfare is negatively related and import volume is positively related to the generalized variance and this causes a tension in the two objectives.

Stepping Stones, Stumbling Blocks, or Building Blocks? Of significant policy relevance is whether FTAs help or hurt the chances of further liberalization along multilateral lines. Bhagwati (1991) has been a vocal opponent of FTAs, arguing that they dampen the enthusiasm of a country for nondiscriminatory reform such as the multilateral trade negotiations held under the auspices of GATT/WTO.

The first question to ask is why multilateral free trade should be seen as more desirable than bilateral free trade. After all, if an FTA is a microcosm of the whole world, then there is not much to gain from global free trade. This argument neglects two factors, however. First, increasing the size of the world does raise welfare when goods are differentiated (as larger economies have greater variety and therefore higher real income and welfare) or there are increasing returns to scale (as larger economies can better exploit economies of scale and therefore have lower prices and higher welfare). Second, bilateral arrangements are not usually of this form but tend to occur between similar countries first, extending to others later. This makes sense, as such FTAs are likely to face less resistance as they have little effect on factor prices and

bring gains from reaping economies of scale and greater product variety.

Levy (1997) argues persuasively that, for political economy reasons, bilateral free-trade agreements can undermine political support for further multilateral trade liberalization. He uses a median voter model where agents have different endowments of capital, and where bilateral free trade could occur before multilateral free trade. With perfect foresight, no proposal that makes the median voter worse off than under multilateral free trade can occur. Thus if multilateral free trade is not possible directly, it cannot become so after a bilateral agreement. As a result, a bilateral agreement cannot be a stepping stone to multilateral free trade. It can, however, be a stumbling block. A free trade area has two effects in his model. It reduces the earnings of the relatively scarce factor in a country via standard Hecksher-Ohlin channels (since via trade, the relatively scarce factor in a country becomes in effect less scarce and so its price falls), and it raises the real income and, hence, welfare of all agents via increased variety. When the latter effect dominates, as it does if the FTA was among similar countries, a bilateral trade agreement makes most agents better off. But by doing so, it raises the reservation utility (the welfare under the status quo) for future multilateral agreements. Multilateral free trade would raise the gains to those with the most capital but reduce the gains to those with little capital, and as a result the median voter could be worse off with multilateral free trade. Thus, even if total welfare is highest under multilateral free trade, bilateral arrangements such as an FTA can prevent it from occurring.

A classic argument by Johnson (1967) is that multilateral reform would dilute existing preferences and therefore would provoke resistance by those adversely affected. For example, Mexican suppliers who are at an advantage under the North American Free Trade Agreement (NAFTA) would lobby against a reduction in the U.S. MFN tariff. Under the EBA (Everything but Arms) agreement of the European Union (EU), the poorest countries are allowed to export all goods other than arms to the EU market free of tariffs. If the EU reduced its MFN tariff, however, these preferences would be diluted and these poorest counties would lose their EU market to more competitive suppliers and would lobby hard against such liberalization on the part of the EU.

Limão (2006) has shown that there is evidence that such concerns are important. Using data on U.S. tariff reductions during the Uruguay Round of WTO negotiations, he shows that tariffs tended to be higher on goods that were traded in NAFTA. Moreover, as a result, the reciprocating tariff cuts tended also to be smaller.

Baldwin (2006) takes the opposing viewpoint. He argues that FTAs are building blocks for multilateral liberalization. He argues for a domino effect: once a group of countries form an FTA, then even if some countries stayed out of the FTA to begin with, once it is large enough, they would find themselves with so few trading partners that they would want to join! As a result, maybe there would be waves of integration: first a regional trading arrangement forms with a core group, then the next tier of countries joins, and so on. What happens more often, however, is that countries belong to many FTAs, and free trade is not a transitive relation. If A has an FTA with B and B has an FTA with C, this is not the same as A having an FTA with B and C. Goods from A will not have origin in B and therefore will not get zero tariffs when exported to C. Some exports from A via B to C could occur, however, with B's production being exported to C and B consuming A's products.

What, then, is the role of FTAs today and what can we expect in the future? Clearly, FTAs are here to stay. We cannot expect overlapping FTAs to do what multilateral free trade would, and there is empirical evidence that they act as stumbling blocks to global free trade. For these reasons, their proliferation is cause for concern. On the plus side, however, it is likely that their formation results in economic gains, both static and dynamic. Since FTAs may be possible (as sensitive sectors can be isolated via the use of restrictive ROOs) when multilateral free trade is not, it is as yet far from obvious what their net welfare effects are.

■ Free Trade Area of the Americas (FTAA)

The United States and Latin America have long resisted what geography would seem to dictate: a special inter-American relationship built around open trade and investment flows. U.S. foreign policy has generally focused on other regions of the world notably Europe and Asia and eschewed regional favorites altogether in favor of a global reach. In Latin America, nationalists of the right and left have preferred to limit their dependence on U.S. power by diversifying their relations through stronger ties to Europe or other Latin American nations. Nevertheless, there have been periods in history when Latin America has reached out to the United States and the United States has responded affirmatively. The 1990s were one such period, and the centerpiece of such inter-American cooperation was the Free Trade Area of the Americas (FTAA).

The idea of a hemispheric free trade zone was not new when policymakers began to discuss it in earnest in the final decade of the 20th century. The goal can be traced back at least to Simón Bolívar (whose integrationist vision sometimes excluded but sometimes seemed to include North America), and it was discussed at the time of the founding of the Pan-American Union at the end of the 19th century. Presidents Ronald Reagan (1981 89) and George H. W. Bush (1989 93) made rhetorical references to the idea of a hemispheric free trade zone. However, this vague aspiration only became a concrete policy option when Latin American governments pressed a reluctant United States to take their free-trade agenda seriously. In 1990, it was Mexican president Carlos Salinas de Gortari who proposed a free trade accord to President Bush the seed that became the North American Free Trade Agreement (NAFTA). It was the Chileans who pressed three successive U.S. administrations for a free trade agreement. It was the Latin Americans who proposed to the Bill Clinton White House that the United States convene a post-NAFTA meeting of hemispheric leaders to spread the spirit of NAFTA southward, and who insisted that the centerpiece of the subsequent 1994 Miami Summit be the Free Trade Area of the Americas (FTAA).

The Latin Americans had good reasons to pursue hemispheric integration. An FTAA would permit them secure access to the world's largest and most dynamic market, and would signal to investors a more stable policy environment and a warmer and more predictable business climate. A regional free trade alliance would focus national policy debates on the next stage of reforms (following on the controversial but generally successful Washington consensus financial stabilization programs) required to promote international competitiveness, including further market liberalization, effective regulation and competition policies, and modern infrastructure in, for example, telecommunications, energy, and transportation. Politically, Latin America's democratic leaders were looking to Washington to bolster their position against the ever-present authoritarian tendencies in Latin American polities.

For the United States, an FTAA would open markets for trade and investment, giving U.S. firms preferential access against competitors from Europe and Asia. It could help Latin American countries to lock in macroeconomic reforms, accelerate steps toward market liberalization, and enhance the legitimacy of still-fragile democratic governments. Furthermore, on issues from counternarcotics to counterterrorism, environmental protection to energy cooperation, free trade was widely understood as generating positive externalities or spillover effects in diplomatic negotiations. Countries linked together in an FTAA could also serve as useful allies in global forums, including in World Trade Organization (WTO) trade negotiations. At the same time, fearing job loss especially in low-wage goods, environmental destruction, and a broad-based lowering of social standards, in a "race to the bottom," powerful, contrary voices in the United States spoke out vociferously against a regional trade accord and accelerating globalization more generally. Still other critics questioned the value of focusing trade negotiations on Latin America, as opposed to larger markets in Asia and Europe, and the WTO.

From 1994 to 2005, hemispheric trade negotiations proceeded on three tracks. As follow-on to the Miami Summit and the launch of the FTAA nego-

tiations, an elaborate web of negotiating committees and working groups evolved into a network of as many as 1,000 officials. But, with a deadline of 2005, negotiations proceeded at a leisurely pace and repeated draft texts left the more contentious issues in brackets. The United States pressed for liberalization in manufacturing and services, while Brazil and other agricultural exporters focused on U.S. protectionism and fiscal subsidies in products such as sugar, beef, cotton, peanuts, and orange juice that undercut the competitiveness of Latin American producers. In 2002, on the eve of off-year elections, the U.S. Congress passed a farm bill that sharply increased such agricultural subsidies, embarrassing U.S. trade officials who for years had been chastising the Europeans and Japanese for protecting their domestic farmers at the expense of global efficiency and developing-country producers.

The two leading countries in the FTAA negotiations, the United States and Brazil, turned to the Doha Development Round of negotiations within the framework of the WTO to help resolve some of the agricultural issues. However, the global WTO seemed no more capable of cutting the Gordian knot of agricultural subsidies than did the regional FTAA forum.

As the Doha Round prospects dimmed and the FTAA negotiations stumbled, many countries turned to less ambitious, more manageable bilateral and subregional trade arrangements. Following NAFTA, the United States ratified similar agreements with Chile and Central America (CAFTA), and concluded negotiations with Panama, Colombia, and Peru (approved by the Colombian and Peruvian legislatures but by the end of 2007 the U.S. Congress had approved only the Peruvian accord). Trade-oriented Mexico and Chile negotiated numerous bilateral accords with other Latin American nations as well as with the European Union and a growing number of Asian nations.

As the FTAA negotiations slowed and the 2005 deadline approached, neither the United States nor Brazil was willing to tackle domestic protectionist interests to close the deal. The Bush administration became embroiled in Iraq and its domestic leverage

declined, just as the Democrats in Congress became emboldened and, increasingly, fell under the influence of organized labor and other voices who demanded a new "fairer" approach to globalization. As the overall U.S. trade deficit ballooned, Democrats held proposed trade accords hostage, as leverage to overhaul other aspects of U.S. trade policy, and to better position the Democrats in upcoming elections. In Brazil, the 2002 election of Luiz Inácio Lula da Silva strengthened the nationalist forces in the powerful foreign ministry, Itamaraty, many of whose diplomats perceived the FTAA as strengthening the geopolitical position of the United States at the expense of Brazil's hegemonic aspirations in South America.

At the 2005 Summit of the Americas at Mar del Plata, Argentina, it became clear that political winds were shifting in South America. Argentine president and summit host Nestor Kirchner allied with Venezuelan president Hugo Chávez in adopting highly critical postures toward the FTAA. Emboldened by strong trade surpluses driven by the global commodity boom, the two outspoken Latin American leaders were critical of U.S. foreign policy and in particular President George W. Bush, attacking "neoliberalism" and the Washington consensus in favor of more state-directed, protectionist domestic economic policies. The 2001 2 crash of the Argentine financial system had embittered relations between Argentina and the United States and the International Monetary Fund (IMF), while the Kirchner administration focused more on domestic recovery than on international trade negotiations. In an overt challenge to the FTAA, Chávez launched his Bolivarian Alternative for the Americas (ALBA), and enlisted Cuba, Bolivia, and Nicaragua in what appeared to be mainly a series of foreign assistance and barter agreements, exchanging subsidized Venezuelan oil for trade and, in the case of Cuba, technical assistance. Kirchner helped Chávez pursue membership in the four-nation Mercosur in part to offset the dominance of Brazil within the South American integration scheme injecting that accord with a more ideological and anti-U.S. flavor.

Thus by 2007 the FTAA seemed to have reached a halfway point. A series of agreements links Canada, the United States, Mexico, the Central American nations, Chile and Peru, and possibly Colombia and Panama (pending U.S. congressional approval). NAFTA has facilitated dramatic increases in trade and investment flows and has generated a number of proposals to deepen the tripartite integration in areas such as infrastructure, energy, education, and immigration; politically, NAFTA weathered the challenge of the hotly contested 2006 presidential elections in Mexico. CAFTA has captured the imaginations of the Central American governments and private sectors; Sandinista leader Daniel Ortega, on regaining the Nicaraguan presidency in 2006, said his nation should take advantage of the market opportunities opened by CAFTA. The NAFTA and CAFTA nations faced the challenge of better integrating those accords (together with Chile and Peru, and possibly Colombia and Panama) to reduce inconsistencies and, possibly, create an umbrella governance mechanism. For its part, South America has become progressively fragmented by conflicting ideologies, economic policy preferences, and leadership styles, and none of the proposed integration schemes the FTAA, Mercosur, ALBA seems capable of bridging the divides. The promise, often voiced by Brazil, that Mercosur could serve as a stepping stone toward the larger FTAA, seems increasingly remote.

The future of the FTAA, therefore, remains uncertain. Has a historic opportunity been lost, or was the hemisphere simply experiencing a pause in the long march toward regional economic integration? One scenario, based on the coalescing of new domestic coalitions forming common cause against local vested interests, envisions a renewed push in the United States and Brazil to complete the deal. In such a scenario, other South American countries might want to avoid being left out and join the Brazilian-U.S. bandwagon, marginalizing Chávez and his ALBA. Alternatively, the hemisphere might become increasingly divided between a northern tier NAFTA plus CAFTA and a southern tier fractured by the simmering rivalries among Venezuela, Brazil,

and Argentina, and the separate path chosen by an increasingly open, globalized Chile.

Considers the debates and procedures in the U.S. Congress and the "readiness" of individual Latin American countries to participate in a hemispherewide free trade zone.

RICHARD FEINBERG

G

gains from trade

The theory of international trade can be viewed as an application of positive economics (economics focused on establishing facts, in contrast with normative economics, which focuses on questions of policy). This theory seeks to determine the prices at which commodities are exchanged on world markets (the so-called terms of trade) and traces the causes of trade to comparative advantage, the principle by which a nation that opens to international trade is led to specialize in and export certain commodities and to import others. From the theory's inception in the early 19th century, economists showed an even stronger interest in the gains from trade, that is, the welfare implications of trade for the countries that participate in it. As Richard E. Caves (1960, 6) points out, "Classical international trade theory was concerned first of all with the gains from trade, and only occasionally with the analysis of international trade by means of a formal, determinate model." Aside from formal modeling, it remains true that gains from trade and causes of trade were closely linked by economists of the classical school because of their strong interest in economic policy. Their main reason for studying the causes of trade is that it benefits countries that engage in it. The intimate connection between trade and its welfare implications is captured in the titles that Jacob Viner assigned to the last two chapters of his magisterial *Studies in the Theory of International Trade*: "Gains from Trade: The Doctrine of Comparative Costs" and "Gains from Trade: The Maximization of Real Income." As Viner states, "Recognition of its 'welfare analysis' orientation is essential to the understanding and appraisal of the classical doctrine" (1937, 437).

Does international trade always benefit the countries that participate in it? Some observers, both economists and statesmen, have expressed skepticism about the existence of "gains" on a national level and believe they can carry a negative sign, in which case they should be labeled "losses from trade." Advocates for or against greater freedom of trade have argued with each other for centuries, and there is no reason to expect such arguments ever to cease. Although it is important to recognize these controversies over the benefits of free trade to the world as a whole, to a subset of countries that contemplate the creation of a free trade area, or to a single country, they can be fully addressed only from a multidisciplinary perspective that includes economic, political, sociological, environmental, labor, and other effects.

The gains from trade are important for understanding the world economy since the perception of what such gains (or losses) consist of has led for centuries to the implementation of trade policies such as trade restrictions (tariffs or quotas), or conversely the liberalization of trade adopted in the forum of bilateral or multilateral negotiations. The term *gains from trade* can apply to various types of economic agents not limited to nation-states, such as regions of a country (economic or geographic) or even smaller units such as firms or individuals. Since nations are regarded in this entry as the main agents of interest, a question immediately arises: If some groups or individuals gain from trade (or from the partial removal of trade restrictions) while others

lose, does "the nation" gain or lose? This issue, which is considered in the next section, explains why trade and trade policies are such controversial issues at both the national and international level. Before examining how the gains from trade were described and quantified by pamphleteers, economists, and schools of economic thought since the early 18th century, it is helpful to set out how contemporary trade theorists define and measure them on the assumption that all individuals in a country are alike, or that any losers from trade are compensated.

Definitions of the Gains from Trade The gains from trade can be measured by either the *compensating variation* (CV) or the *equivalent variation* (EV). Their definitions given here can easily be generalized to economies with multiple commodities, but are best understood in the context of an economy with two commodities (good 1 and good 2). If the superscripts a and t refer to equilibrium values of variables in autarky (a term describing self-sufficiency or no trade) and free trade, the CV is the amount of income that would need to be withdrawn in an economy trading at the free trade prices (p_1^t, p_2^t) so that consumers can buy the same consumption bundle they chose under autarky, (c_1^a, c_2^a), rather than their preferred consumption bundle under free trade, (c_1^t, c_2^t). In algebraic terms,
$$CV = p_1^t c_1^t + p_2^t c_2^t - (p_1^t c_1^a + p_2^t c_2^a). \qquad (1)$$
The EV uses autarky prices rather than free trade prices as reference prices to measure the gain in welfare, so that
$$EV = p_1^a c_1^t + p_2^a c_2^t - (p_1^a c_1^a + p_2^a c_2^a). \qquad (2)$$
The EV can be interpreted as the amount of money that would have to be donated to consumers under autarky to allow them to purchase the same consumption bundle they choose under free trade. Since the consumption bundles (c_1^a, c_2^a) and (c_1^t, c_2^t) are valued at different relative prices in (1) and (2), the magnitudes of the CV and EV are usually different, and there is no reason to believe that either one is a superior measure of the gains from trade.

The CV and EV are illustrated in figure 1. If good 1 is plotted on the horizontal axis and good 2 on the vertical axis, DE is the concave production possibility frontier (PPF) that shows the output combinations

that a neoclassical economy can produce with its given technology and factor endowments. If A is the point of equilibrium in autarky, the autarky price ratio is given by the slope of p^a, a line tangent to DE at A. If trade becomes possible at terms of trade given by the slope of line p^t, the production point moves from A to P, and the consumption point from A to C. The economy's comparative advantage in good 1 leads it to specialize partially in that commodity, and to export BP of good 1 in exchange for CB of good 2. For this reason, CBP is known as the economy's "trade triangle." The exports of good 1, BP or JK, equal production OK minus consumption OJ, and the imports CB of good 2 equal consumption CJ minus production PK ($=$ BJ). If the exportable good 1 is the *numéraire*, or unit of account in which prices are measured, and AF is drawn parallel to p^t, the CV for the passage from autarky to free trade is FP. If CH is drawn parallel to p^a, the EV is GH, which usually differs in length from FP.

The CV and EV represent attempts to measure in terms of good 1 the "distance" between the consumption bundles C and A, or the enhanced welfare of consumers due to trade. A more intuitive way to recognize the existence of gains from trade is to note that the free trade consumption bundle C is located outside the PPF DE and is therefore unavailable to the economy in autarky (Corden 1984). Since C is chosen under free trade in preference to any point on
Figure 1
Gains from trade in a neoclassical economy

DE such as A, consumers are *potentially* better off under free trade since the gainers are always able to compensate the losers while remaining better off than in autarky (Samuelson 1939). In the absence of compensation, and in recognition of the fact that free trade usually produces both gainers and losers, a "social welfare function" is sometimes invoked that weights different persons' utilities according to the tastes of a dictator or decision-maker (benevolent or otherwise). The algebraic sum of these weighted utilities may be higher or lower than in autarky. Samuelson (1939) also made an observation, subsequently confirmed by other economists, that the gains from trade increase with the difference between the autarky and free trade price ratios. If these price ratios are identical, the economy remains in a state of autarky and there are no gains from trade.

If an economy trades according to its comparative advantage, does it always gain from trade? Leaving aside distributional issues, cases of foreign or colonial exploitation, "unequal exchange" and various distortions to which an economy may be subject (which are considered later), the answer is yes in the vast majority of cases. But there are exceptions where welfare under free trade is the same as in autarky, such as the case of an economy whose comparative advantage leads it to export a commodity it was not consuming before trade (Maneschi 1998a). Moreover when a large economy with a linear PPF attempts to trade with a much smaller one, it cannot fully specialize in its export commodity and faces terms of trade identical to its autarky price ratio, with zero gains from trade.

18th-Century Perspectives on the Gains from Trade In the 18th century, economists measured the gains from trade in accordance with what Viner calls the "18th-century rule," which postulates that "it pays to import commodities from abroad whenever they can be obtained in exchange for exports at a smaller real cost than their production at home would entail" (Viner 1937, 440), thus reflecting the benefits of trade as an indirect method of production. The earliest numerical example of the application of this "rule" was given by Henry Martyn (1701, 583): "If nine cannot produce above three Bushels of Wheat in *England*, if by equal Labour they might procure nine Bushels from another Country, to imploy these in agriculture at home, is to imploy nine to do no more work than might be done as well by three; . . . is the loss of six Bushels of Wheat; is therefore the loss of so much value." His numbers can be interpreted in terms of the two-commodity example of the previous section. In response to a cheaper overseas price of wheat (good 2), or terms of trade $(p_1/p_2)^t$ that exceed the autarky price ratio $(p_1/p_2)^a$, the economy tends to specialize in good 1. If $m_2 (= 9)$ bushels of wheat (good 2) are imported in exchange for x_1 units of good 1, balance of trade equilibrium requires that $m_2 = (p_1/p_2)^t x_1$. In autarky, x_1 units of good 1 are valued at $(p_1/p_2)^a x_1$, or 3 bushels of wheat. For every nine workers employed, the gains from trade (or *GT*) in terms of wheat are therefore

$$GT = m_2 - (p_1/p_2)^a x_1$$
$$= [(p_1/p_2)^t - (p_1/p_2)^a]x_1 \qquad (3)$$
$$= 9 - 3 = 6 \text{ bushels.}$$

Martyn's numerical example is a rudimentary attempt to quantify the equivalent variation EV defined earlier, if it is expressed in terms of the importable good 2. If the economy is in a state of autarky, it would have to receive foreign aid amounting to 6 bushels of wheat for every nine of its workers in order for them to reach the same welfare level they would enjoy under free trade.

The 18th-century rule was used to characterize the gains from trade by writers such as the French economist and statesman A.R.J. Turgot and the author of *The Wealth of Nations*, Adam Smith. Smith applied it to trade between tribesmen, between town and countryside, and between two nations. For example, laying great emphasis on the importance of trade between town and countryside, Smith noted that "the inhabitants of the country purchase of the town a greater quantity of manufactured goods, with the produce of a much smaller quantity of their own labour, than they must have employed had they attempted to prepare them themselves" (1776, 376). Since Smith never attempted to illustrate his examples with numbers, Martyn's 1701 numerical

illustration of the gains from trade stands out as a major analytical advance that was not equaled for more than a century, not even by someone as renowned as Smith (Maneschi 2002a).

The gains from trade were viewed in broader terms by the main French and British writers of the Enlightenment. Montesquieu and Voltaire praised commercial activity and luxury goods for their civilizing effects (*doux commerce*) and for promoting the power and military preparedness of nation-states. Smith's mentor and friend David Hume adopted similar views, observing that "commerce with strangers . . . rouses men from their indolence. . . . Imitation soon diffuses all those arts; while domestic manufactures emulate the foreign in their improvements, and work up every home commodity to the utmost perfection of which it is susceptible" (1752, 14). He later argued that "the encrease of riches and commerce in any one nation, instead of hurting, commonly promotes the riches and commerce of all its neighbours. Every improvement, which we have since [two centuries ago] made, has arisen from our imitation of foreigners. . . . Notwithstanding the advanced state of our manufactures, we daily adopt, in every art, the inventions and improvements of our neighbours" (1758, 78 79). Economists continue to maintain that trade encourages the international diffusion of technology, which may be one of its chief benefits. An international demonstration effect stimulates consumer demand for new commodities developed overseas and induces domestic firms to produce them. Hume also argued that the prosperity of neighboring nations promotes domestic prosperity instead of endangering it, as mercantilist writers had maintained.

In addition to using the 18th-century rule in various contexts, Adam Smith also took a broad perspective on the benefits of trade for producers as well as consumers (Maneschi 1998b). Consumers benefited not only from cheaper imports of staples but from the introduction of hitherto unknown commodities from Asia and the Americas. Europe's burgeoning market for manufactured exports allowed it greater scope for the division of labor and hence rising labor productivity. Another benefit that Smith emphasized was subsequently criticized by most classical economists: that trade offered a vent for surplus commodities produced over and above domestic needs. John Stuart Mill (1848, 579) called it "a surviving relic of the Mercantile Theory," since it implies that resources cannot be reallocated so as to avoid the "surplus" commodities whose existence Smith postulates. Smith also echoed Hume and French Enlightenment thinkers in praising trade for promoting economic interdependence. After arguing that "the discovery of America, and that of a passage to the East Indies by the Cape of Good Hope, are the two greatest and most important events recorded in the history of mankind," Smith observed that "by uniting . . . the most distant parts of the world, by enabling them to relieve one another's wants, to increase one another's enjoyments, and to encourage one another's industry, their general tendency would seem to be beneficial" (Smith 1776, 626).

David Ricardo's Twofold Gains from Trade In chapter 7 of his *Principles of Political Economy and Taxation*, Ricardo (1817, 132) claimed that international trade yields two distinct and coequal types of gain: "It is quite as important to the happiness of mankind, that our enjoyments should be increased by the better distribution of labour, by each country producing those commodities for which by its situation, its climate, and its other natural or artificial advantages, it is adapted, and by their exchanging them for the commodities of other countries, as that they should be augmented by a rise in the rate of profits." The first gain, the efficiency advantage arising from the reallocation of resources in accordance with comparative advantage, is unrelated to the second, a rise in the profit rate.

Ricardo quantified the first type of gain for two trading countries, England and Portugal, when he specified the amounts of labor embodied in each country's exports and the labor it would require to produce its imports:

England may be so circumstanced, that to produce the cloth may require the labour of 100 men for one year; and if she attempted to make the wine, it might require the labour of

120 men for the same time. England would therefore find it her interest to import wine, and to purchase it by the exportation of cloth. To produce the wine in Portugal, might require only the labour of 80 men for one year, and to produce the cloth in the same country, might require the labour of 90 men for the same time. It would therefore be advantageous for her to export wine in exchange for cloth. (Ricardo 1817, 135)

England thus saves 120 − 100 = 20 men by importing wine instead of producing it, and Portugal saves 90 − 80 = 10 men by importing cloth instead of producing it (Maneschi 2004). These gains from trade in terms of the labor each country economizes are another example of the "18th-century rule" cited earlier.

The second type of trade gain, incommensurable with the first, represents the increase in the rate of profit that trade may bring about: "It has been my endeavour to shew throughout this work, that the rate of profits can never be increased but by a fall in wages, and that there can be no permanent fall of wages but in consequence of a fall of the necessaries on which wages are expended. If, therefore, by the extension of foreign trade, or by improvements in machinery, the food and necessaries of the labourer can be brought to market at a reduced price, profits will rise" (Ricardo 1817, 132). This second type of gain depends exclusively on the import of commodities consumed by workers and is unaffected by that of luxury goods that do not enter the workers' consumer basket.

The increase in the profit rate achieved by trade was important for Ricardo since he had argued in previous chapters of the *Principles* that the pressure of population on land leads to diminishing returns at both the extensive and intensive margins of cultivation, to an increase in the price of "corn" (grains), to a rise in the money wage, and hence to a fall in the rates of profit and of capital accumulation. In the absence of trade or of technical change, the economy heads toward the stationary state. A trade-induced rise in the profit rate, resulting from the fall in the money wage when cheaper wheat is imported, reverses this trend by boosting the rate of capital accumulation. This "dynamic" gain from trade is additional to the "static" gain resulting from an improved resource allocation. Ricardo and the classical school thus closely associated trade with economic growth, and the gains from trade include those that affect an economy's trajectory over time. To judge from the frequency with which Ricardo referred throughout the *Principles* to the need for England to repeal the Corn Laws that held the price of grain artificially high, this second gain from trade was for him just as important as the saving of labor associated with the principle of comparative advantage (Maneschi 1992).

John Stuart Mill: Splitting the Gains from Trade When Ricardo postulated a trade equilibrium between England and Portugal, he stated each country's gains from trade but never explained how the terms of trade are determined. This task fell on the capable shoulders of John Stuart Mill, the son of James Mill, who had been one of Ricardo's closest supporters and disciples. John Stuart Mill pointed to reciprocal demand, the demand of each country for its trading partner's exports, as the force that determines the terms at which they trade (which he called the "terms of interchange"). His theory was first published in "Of the Laws of Interchange between Nations; and the Distribution of the Gains of Commerce among the Countries of the Commercial World," the first of his *Essays on Some Unsettled Questions of Political Economy* of 1844, and later in his *Principles of Political Economy* first published in 1848, which became the premier textbook of political economy in Great Britain. Mill argued that the gap between two countries' autarky price ratios, which reflect their respective comparative advantages, yields the range within which the terms of trade can settle, and that reciprocal demand determines where they settle within that range and hence how the gains from trade are split between them. According to Mill, "The produce of a country exchanges for the produce of other countries, at such values as are required in order that the whole of her exports may exactly pay for the whole of her imports. . . . So that supply and demand are but another expression for reciprocal

demand: and to say that value will adjust itself so as to equalize demand with supply, is in fact to say that it will adjust itself so as to equalize the demand on one side with the demand on the other" (Mill 1871: 592 93).

The terms of trade favor a country more the closer they lie to the *other* country's autarky price ratio. If the terms of trade coincide with the country's own autarky price ratio, its gains from trade are zero and all gains go to its trading partner. As a corollary of this, Mill observed that large countries gain less from trade than smaller ones "since, having a greater demand for commodities generally, they are likely to have a greater demand for foreign commodities, and thus modify the terms of interchange to their own disadvantage" (1871, 604). A later neoclassical economist, Francis Edgeworth, referred to this finding as "Mill's paradox."

In addition to Mill, other classical economists such as Robert Torrens emphasized the role of reciprocal demand in yielding the terms of trade. Torrens went even further than Mill. Since a foreign country's tariff can turn the terms of trade and the gains from trade in its favor, Torrens demanded reciprocity in trade policy and advocated a defensive tariff. Other economists criticized him for abandoning his previous policy in favor of unilateral free trade (O'Brien 2004). Torrens's important insight gave rise to Francis Edgeworth's argument, expressed more precisely later by Charles Bickerdike, that a "large" economy (one that can affect its terms of trade) maximizes its gains from trade by levying an optimal tariff.

In another chapter of his *Principles*, Mill explored further the nature of the gains from trade by pointing to its "indirect effects, which must be counted as benefits of a high order," including "the tendency of every extension of the market to improve the processes of production." Foreign trade creates a demonstration effect akin to an "industrial revolution" by inducing people to work harder so they can import commodities they were previously not familiar with: "The opening of a foreign trade, by making them acquainted with new objects, or tempting them by the easier acquisition of things which they had not

previously thought attainable, sometimes works a sort of industrial revolution in a country whose resources were previously undeveloped for want of energy and ambition in the people." Moreover, "the economical advantages of commerce are surpassed in importance by those of its effects which are intellectual and moral. It is hardly possible to overrate the value . . . of placing human beings in contact with persons dissimilar to themselves, and with modes of thought and action unlike those with which they are familiar" (1871, 581). For Mill, as for other classical economists such as Smith and Ricardo, the dynamic benefits of trade ranked at least as high as the static benefits emphasized by the neoclassical school that followed them (Maneschi 1998c).

Mill is also remembered as the first orthodox classical economist who, breaking rank with his confreres, advocated the infant-industry argument for protection in carefully restricted circumstances. A "young and rising nation" (he may have had the United States or Germany in mind) should be willing to forgo some of its current gains from trade by protecting a new industry in which other countries have a "present superiority of acquired skill and experience. A country which has this skill and experience yet to acquire, may in other respects be better adapted to the production than those which were earlier in the field" (Mill 1871, 922). In other words, a country may have a *potential* comparative advantage in an industry, but this potential needs to be fostered by temporary protection for it to be realized (other advocates of the "creation" of comparative advantage starting with Alexander Hamilton are discussed in Maneschi 1998b, chapter 5). This policy does not contradict free trade as a policy goal once an industry has matured and can compete in world markets, since protection then can and should be removed. Whether countries have actually followed this exemplary behavior is of course another question.

Neoclassical Depiction of the Gains from Trade
The classical theory of comparative advantage was attacked as based on an incorrect theory of value by economists of the neoclassical school that emerged in the last quarter of the 19th century. The Austrian-

born Gottfried Haberler (1936) argued that the prices of commodities are based not on the classical labor theory of value, but on their opportunity costs as measured by the least-cost combination of the factors that produce them. Diagrammatically he represented them by the slope of a concave production possibility frontier (PPF) such as that shown in figure 1. On this basis, he generalized the Ricardian theory of comparative advantage while retaining some its main policy implications.

Haberler was unaware that, in a long footnote inconspicuously embedded in a textbook of economic principles, the Italian economist Enrico Barone (1908, 88 90) had used a nonlinear PPF to depict in general equilibrium terms the gains accruing to an economy as it passes from autarky to free trade. He thus anticipated similar diagrams presented some 25 years later by Viner, Abba Lerner, and Wassily Leontief (Maneschi and Thweatt 1987). Barone's diagram is shown in figure 2, where AB is the PPF showing all possible combinations of commodities A (on the vertical axis) and B (on the horizontal) that the economy can produce. The dashed curves, now known as community indifference curves (CICs), show the combinations of the two commodities that yield the same societal welfare level. Autarky equilibrium is at M, where the CIC curve 3 is tangent to the PPF. The autarky price ratio is given by the common tangent at M (not shown) to both the PPF and the CIC. If the economy is given the opportunity to trade at terms shown by the slope of the line PC, with a higher relative price of B, it tends to specialize in B. The production point moves from M to P, the consumption point from M to C. The trade triangle CQP shows that exports QP of B exchange for imports CQ of A. The CIC labeled "8," which the economy can attain in free trade and is tangent to CP at C, clearly yields a higher welfare than under autarky, and illustrates the gains from trade.

The Heckscher-Ohlin-Samuelson Theory and Beyond In the 20th century the theory of international trade was revolutionized by Swedish economic historian Eli Heckscher (1949) and his student Bertil Ohlin (1933), who traced the sources of comparative
Figure 2
Barone's 1908 representation of the gains from trade

advantage to differences in relative factor endowments across countries and analyzed the effects of trade on income distribution. While Heckscher's intentions were reformist in nature, in the sense of modifying but not rejecting inherited trade theory, Ohlin aimed to overthrow the dated Ricardian theory and replace it with an explicitly neoclassical theory based on factor endowments. Both Heckscher and Ohlin noted that trade encourages the convergence of factor prices in the trading countries or regions. Ohlin, however, doubted that they could actually be equated and denied the possibility (as Haberler did before him) that a factor such as labor could be hurt by trade even if it is intensively employed in the import-competing industries whose prices are reduced by trade.

In a pathbreaking article, Wolfgang Stolper and Paul Samuelson (1941) showed that both Haberler and Ohlin were mistaken, since trade in fact can reduce the real wage of a factor such as labor if it is intensively used in the import-competing sector of the economy. Stolper and Samuelson proved this by stripping the Heckscher-Ohlin model down to two countries, two commodities, and two factors of production, thus obtaining results impossible to discern in the multicommodity, multifactor context of Heckscher and Ohlin. Samuelson (1948)

complemented this paper by setting out the stripped-down Heckscher-Ohlin model in diagrammatic form and showing how factor endowments and factor intensities affect comparative advantage and the pattern of trade. He proved that factor prices are fully equalized by trade in specific circumstances. The Stolper-Samuelson and factor price equalization theorems are components of what became the Heckscher-Ohlin-Samuelson theory of trade, which revealed the ambiguity in the expression *gains from trade* when applied to a country: if some factors gain while others lose from trade, as the Stolper-Samuelson theorem predicts must happen, how can the "nation" be said to gain? Samuelson showed that it can do so since the gainers can compensate the losers and still be better off than in autarky. While this is an important finding, it is cold comfort to factors that lose from free trade if in reality they are not compensated.

All the models of trade discussed so far postulate perfect competition in product and factor markets. Their conclusions and associated gains from trade are modified if this assumption does not hold. After adopting the Heckscher-Ohlin-Samuelson model as the mainstream theory of trade after World War II, economists analyzed how various types of distortions in factor or commodity markets affect the direction of trade and the welfare conclusions drawn earlier, and how tax or trade policies can be designed to alleviate these distortions. Policies can sometimes be ranked in terms of first-best, second-best, and so on (Bhagwati 1971; Corden 1997). In the absence of offsetting policies, it can be shown that autarky may be preferable to free trade. Economic growth can be immiserizing (Bhagwati 1958) by causing the terms of trade to deteriorate to such an extent that consumers are worse off than before growth. An optimal tariff, however, can avert this outcome. Trade policy is thus crucial in determining the existence and size of the gains from trade.

Starting in the 1970s, economists developed a New Trade Theory based on imperfect or monopolistic competition or oligopoly (see, for example, Krugman 1990). In the models they developed, comparative advantage is dispensed with as the source of trade, its place taken by economies of scale. Even countries identical in all respects can be shown to gain from trade if they specialize in different manufactures and reap the associated economies of scale. The nature of the gains from trade was substantially enriched by the New Trade Theory, since consumers are shown to benefit not only from cheaper commodities but from a greater variety of them than is available in autarky. Moreover trade can provide a dynamic impetus by stimulating innovation, technical change, and learning by doing. Dynamic benefits from trade that include the availability of new commodities and new methods of production are reminiscent of those identified more than a century earlier by classical economists such as Hume, Smith, and Mill (Maneschi 2002b). Even Ohlin (1933) devoted chapter 3 of his book to economies of scale as a secondary cause of trade in addition to factor endowments. The "New" Trade Theory can thus boast of numerous distinguished precursors.

The gains from trade have figured prominently in discussions of the rationale for international trade since mercantilist times and have typically led economists to argue for trade liberalization except in cases where they wished to promote infant industries or exploit monopoly power by turning the terms of trade in a country's favor. Attempts to quantify the gains from trade began in 1701 with Henry Martyn and continued in 1817 with David Ricardo and in the 20th century with the calculation of the compensating and equivalent variations. Classical economists such as David Hume and John Stuart Mill also argued for a broader vision of the gains from trade that includes the dynamic benefits that can be realized from the imitation of foreign ideas and technical improvements. Beginning in the 1970s, the exponents of the New Trade Theory added the availability to consumers of a greater variety of commodities as another important gain from trade.

■ gender

The global work force is largely female. First, at the international level, women make up about 50 percent of migrant workers in Asia, even 75 percent and their share is increasing. These are women from low-income countries, such as the Philippines and Sri Lanka, taking up jobs elsewhere in typically feminine occupations such as domestic work, child care, and nursing. The countries of destination are mainly Western, but also Arab countries, such as the United Arab Emirates. Second, at the national level, the majority of workers in export industries in developing countries is female. Together, these two levels of the global work force imply that more than 50 percent of workers in the global economy that is, in globalized jobs are women. This trend stands in striking contrast with the fact that universally, women's labor force participation is lower than that of men.

Female Employment in Export Manufacturing The female share of employment in export manufacturing reached its peak in the 1970s and

1980s, in particular in countries that pursued an export-led growth strategy. These countries offered export processing zones (EPZs) to (foreign) investors with incentives such as tax holidays and limited enforcement of labor regulations. The countries include Mexico, Taiwan, and South Korea, but also low-income countries such as Bangladesh, Sri Lanka, and Mauritius, that all have shown female shares of export employment between 70 and 90 percent. Since the 1990s this share has declined, but remains above 50 percent for developing countries, whereas the female share in export manufacturing in countries that belong to the Organisation for Economic Co-operation and Development (OECD) has declined and is well below 50 percent. In developed countries, export employment has declined in labor-intensive sectors, which have moved to developing countries due to the wide availability of low-skilled labor and low wages there, as is predicted by the Heckscher-Ohlin model of international trade. Women in OECD countries have particularly lost jobs in female-intensive sectors such as textiles, garments, and leather products.

The high female shares of migration and export employment show that the world economy has provided new opportunities for women in the developing world to find jobs and earn an independent income. The reasons for the predominantly female employment in export industries in developing countries relate to perceived qualities of female labor as well as to labor market discrimination.

Women tend to be regarded by employers as more suitable for work in typical low-skilled jobs in export manufacturing production. This is also referred to as the "nimble fingers" view, which leads many employers in sectors such as garments, toys, microelectronics, and assembly to prefer female over male workers. The "nimble fingers" view of women workers values the typical skills required for detailed but repetitive tasks in mass production, which have not been acquired through formal education but through women's socialization (informal training in sewing for example). In addition, the "nimble fingers" perspective of female workers also extends to the perception of women workers as being socialized as more obedient and less militant than men, which is reflected in women's lower membership in trade unions.

Wage Discrimination Women are the preferred work force in industries that compete at the international level and experience a strong pressure toward cost reduction. Women are hired more often than men in such industries, because women's wages are lower than men's wages. This gender wage gap provides employers with a cost advantage, without much loss of productivity as long as women are hired only for low-skill jobs. Gender analyses of export employment indeed show that women are predominantly found in the lowest skill categories of production, both in wage employment and in subcontracted work, such as piece-rate home work. Econometric analyses have shown that countries with the highest ratio of export earnings to their gross domestic product also have the largest gender wage gaps, even when educational levels of women have moved close to those of men. The Asian tiger economies, the fast growing economies of South Korea, Taiwan, Hong Kong and Singapore, are prominent examples, suggesting that their export success has, at least in part, been built on wage discrimination against women.

Wage discrimination is not specific to export employment, but trade liberalization does tend to put wages in export sectors under pressure, as well as wages in import competing sectors. This makes it difficult to improve women's wages and to reduce the gap with men's wages without a loss in export earnings or a worsening of the competitiveness of domestic goods vis-à-vis imported goods. Moreover, gender norms in labor markets are strong and justify women's low wages on the basis of gender stereotypes. One was mentioned above, the "nimble fingers" view of women workers, in which women's skills are highly valued for export production but not rewarded in wages because the skills are perceived as "natural" and not part of women's formal human capital. Another gender norm that prevents women's wages from catching up with men's is the breadwinner bias in employers' decisions on payment: men are thought to deserve higher wages than

women because of their traditional gender role as breadwinners. This norm, however, doesn't take into account that men's wages are often not sufficient to serve as a family wage and that globally there is an increase in the share of female-headed households, hence, an increase in the number of female breadwinners.

Women as the World's Flexible Work Force
Women are not only the preferred work force in wage employment for exports, but also make up the majority of flexible workers in the global production system. The informal economy, which is largely unregulated, with low or absent labor standards, is expanding. This is partly due to the outsourcing of production by multinational companies to local suppliers in global value chains   production processes with various layers of heavily competing suppliers for well-known brand names. Indeed, the global work force has been increasingly informalized, with women experiencing lower labor standards than men. Jobs in the global production system are increasingly subcontracted, flexible, and temporary. Women therefore find themselves increasingly working informally at the bottom of global value chains, outside the reach of labor laws, labor inspectors, and company codes of conduct.

The explanation for the increase in outsourcing rather than in-company production is, again, the cost pressure experienced by firms that try to survive in highly competitive low-wage sectors of the world economy. Large parts of production in these sectors are subcontracted and end up being done by flexible, irregular female workers in rented factories, small-scale workshops, or at home by individual workers. This process of global cost reduction through hiring cheap female labor is quite different from a process in which companies that are less vulnerable to global competition compete on the basis of productivity increases rather than cost reductions. Such a strategy requires investment in new technology and skills. Even though the educational gap between men and women is narrowing everywhere, and has disappeared in an increasing number of countries, it is men who benefit more often from the on-the-job

training and higher pay in such industries. This is exactly what is reflected in the figures referred to above, showing the defeminization of export employment in mature export industries. Employers prefer men for the higher skill jobs, believing that women would be less reliable workers because of maternity leave and possible career breaks when they have children. In addition, male workers' bargaining power is higher than that of female workers because of the male breadwinner norm and men's higher participation in trade unions. Women workers, therefore, remain at the lower end of export production.

The prospects for a reduction of the gender wage gap and improvement of working conditions are limited, despite women's increased levels of education, as long as labor market discrimination keeps women locked in low-skilled formal and informal employment in highly competitive global industries.

IRENE VAN STAVEREN

General Agreement on Tariffs and Trade (GATT)

From its creation in 1947 to its absorption into the newly created World Trade Organization (WTO) in 1995, the General Agreement on Tariffs and Trade universally referred to as "the GATT" was *the* multilateral agreement governing trade among a growing number of countries, including all of the major trading nations. As such, the GATT served two primary functions for its members. First, it provided a set of multilaterally agreed rules and disciplines governing selected policies affecting countries' trade in goods, in particular, tariffs and quotas on imports. The goal was to encourage international trade by imposing certain disciplines on countries' trade policies, thereby making future access to foreign markets more predictable. Second, it provided a forum for (1) the settlement of trade disputes among members, and (2) negotiations to further liberalize

trade, as well as to strengthen and extend the multilateral rules. Thus the GATT was both an agreement and an institution.

By any standard, the period 1948 to 1994 was an era of unparalleled economic prosperity for the world economy. Adjusted for inflation, output of goods and services grew at an average annual rate of 3.6 percent, with output per person increasing 2 percent a year (compared with an estimated 0.9 percent during 1820 1913). A key factor behind this rapid growth of output was the even more rapid expansion of world merchandise trade, which grew at an average rate of nearly 6 percent a year in real terms from 1948 to 1994. This meant that virtually every year saw a growing share of world production being traded across one or more borders.

It is widely accepted among trade specialists that GATT rules, in combination with periodic GATT-sponsored negotiations, played a major role in this expansion of world trade (Goldstein, Rivers, and Tomz 2006). The GATT has also attracted considerable interest from scholars and policy officials who believe a good case can be made that the GATT was the most successful of the postwar international economic institutions.

Origins of the GATT The immediate origin of the GATT was the UN draft charter for the stillborn International Trade Organization, often referred to as the "Havana Charter." Before going into this, however, it is useful to mention two earlier experiences with international commercial policies that influenced the drafters of the Havana Charter and thus the ultimate design of the GATT.

In the latter half of the 19th century, European treaties increasingly included a provision for most-favored-nation (MFN) trade status. Enshrined in trade agreements such as the Cobden-Chevalier Treaty of 1860 liberalizing trade between Great Britain and France, the MFN provision assured that trade was nondiscriminatory. This meant that trade benefits resulting from subsequent treaties were passed on to previous treaty partners through the promise that they would receive the lowest tariff rate granted to any trade partner. MFN created a

multiplier effect for trade liberalization, leading to significantly lower barriers to trade throughout the continent (Curzon 1965).

More important, the drafters of the Havana Charter shared the experience of the Great Depression, when economic decline brought beggar-thy-neighbor policies, high tariffs, and depreciating currencies, as nations tried to protect their home markets. This, of course, only accentuated the general decline. The extent of the worldwide descent into virtually uncontrolled protectionism is evident from the 25 percent decline in the volume of world trade between 1929 and 1932 (minus 60 percent in dollar terms). By 1936 industrial production had recovered to a level 10 percent *above* its 1929 level, while the volume of world trade was still 15 percent *below* its 1929 level.

It was against this background that, in the closing years of World War II, American and British officials began laying plans for the postwar world economy. Among the most ambitious of those plans was the proposal for a new institution, to be called the International Trade Organization (ITO), that would be the third pillar along with the International Bank for Reconstruction and Development (World Bank) and the International Monetary Fund (IMF), both already agreed to in 1944 underlying the postwar world economy. A preparatory committee established by the UN Economic and Social Council met in London in October November 1946 to discuss a draft charter for the proposed ITO. That meeting also produced a resolution calling for a multilateral trade negotiation, to be held the following year in Geneva at the committee's second session and a recommendation that a "General Agreement on Tariffs and Trade," containing rules and disciplines to protect the value of the tariff concessions, be created.

The first full draft of the GATT, based primarily on text taken from the commercial policy section of the draft ITO charter, was produced at a January February 1947 meeting in Lake Success, New York (Jackson 1969). Two concurrent negotiations began in Geneva in April, one focused on the draft ITO charter and another focused on reductions in tariffs and refinements in the accompanying draft GATT.

On October 30, 1947, 13 developed and 10 developing countries accounting for more than three-quarters of world trade signed the Final Act of the GATT containing (1) a schedule of concessions listing each government's agreed tariff reductions, and (2) rules and procedures regulating nontariff restrictions on trade what Robert Hudec (1987) called a "code of behavior" for governments.

It was assumed that the ITO, whose charter was finalized in Havana in March 1948, would shortly come into force and that the GATT would come under its aegis. That option evaporated in 1950 when it became clear that the U.S. Congress would not ratify the Havana Charter. The provisional GATT became the framework for postwar commercial relations. Noting that the early GATT "was permeated by an atmosphere of impermanence," Richard Gardner (1956) described it as "a slender reed on which to base progress toward a multilateral regime."

The 23 participants in the Geneva trade negotiations were the GATT's first "contracting parties" a term that emphasized both the contractual nature of the GATT and the fact that it was a "provisional agreement" and not a treaty-based organization. With a more or less steady increase in the membership over the period 1948 94, the number of contracting parties stood at 128 when the GATT was absorbed into the WTO in 1995, four-fifths of which were developing or least-developed countries.

Basic Principles Five basic principles some explicit, some implicit informed the rules and guided the activities of the contractual, rules-based GATT system.

Nondiscrimination. This principle embraces two elements. The better-known one is the most-favored-nation (MFN) clause, which prohibits a GATT member from discriminating between imports from other GATT members any concession granted on a product from one contracting party "shall be accorded immediately *and unconditionally* to the like product originating in or destined for the territories of all other contracting parties" (Article I, emphasis added). Adherence to MFN both depoliticizes trade and ensures that a country buys its imports from the cheapest foreign source. Some exceptions were in-

cluded in the GATT from the beginning, most notably for free trade areas and customs unions among small groups of countries. Later the contracting parties agreed to allow preferential treatment of imports from developing countries. By the early 1990s, with the rapid spread of preferential trading areas especially free trade areas many trade experts were openly questioning the relevance of the GATT's MFN provisions.

The second element of nondiscrimination is national treatment, which prohibits discrimination between imports and domestic products once the imports have entered the country. For example, a retail sales tax applied to imported TV sets but not to domestically produced TV sets would violate the national treatment principle (however, imposing a tariff on foreign-made TV sets as they enter the country is not a violation of national treatment).

Tariffs only. The GATT was not a free trade organization. Member countries were not required to participate in trade liberalizing negotiating rounds, and they were free to protect domestic producers by imposing restrictions on imported goods. If they did protect, however, they were required to use tariffs rather than import quotas or other nontariff restrictions to provide that protection. This made good sense. Not only is the level of protection provided by tariffs more transparent than nontariff protection, but tariffs are a less distorting (less inefficient) way of granting protection.

Consensus decision making. Although there were provisions for majority voting on a one-country, one-vote basis, the GATT developed a very strong tradition of making all decisions by consensus (defined as no country present at the meeting when the decision was taken formally objecting to the proposed decision). This often slowed the decision-making process, but considering that many of the decisions resulted in legally binding obligations for all members had important advantages, including adding to the intellectual and diplomatic "legitimacy" of the decisions.

Special treatment for developing countries. There were no special provisions for developing countries in the original GATT. In the 1950s the developing country members began demanding exemptions from GATT's rules and disciplines, to which was added, at the beginning of the 1960s, demands for special and more favorable treatment for their exports in the markets of other GATT members (Hudec 1987). Institutional changes reflecting these demands included special provisions for developing countries in GATT rules and procedures, the creation of a permanent Committee on Trade and Development, the Tokyo Round's "Framework Agreements," and technical assistance provided by the GATT Secretariat. Technical assistance aside, the extent to which these various developments actually benefited rather than harmed developing countries continues to be the subject of debate among trade experts.

Small Secretariat with a limited mandate. The member countries kept the Secretariat very small compared with the other major postwar international economic organizations (such as the World Bank and the IMF). Comparable figures for 1994 are not available, but in 1996, just after GATT's absorption into the WTO, the WTO Secretariat was in 16th place on the list of the 17 largest international economic organizations in terms of budget and number of staff members (Blackhurst 1998).

As for the Secretariat's limited mandate, consider, for example, the following: the Director-General could not initiate a dispute settlement case, no matter how blatant the rule violation; the Secretariat could not interpret GATT rules; the Secretariat was not allowed to report regularly on trade policy developments in member countries until 1977, 30 years after the GATT was signed; and the Secretariat was not allowed to have a formal Office of Legal Affairs until 1983, even though the GATT was based on contractual obligations. In essence, the Secretariat existed to service the meetings and other activities of the member countries. The popular way to describe this situation was to say that the GATT was a "member-driven" institution.

The explanation for the member-driven operation of the GATT and the Secretariat's very small size undoubtedly is the highly politicized nature of trade policies at the national level. Domestic politics meant

that no government and especially no developed country government could be seen advocating a secretariat with any real independence and power. Some analysts argue that this was the secret behind GATT's success (Hudec 1993; Winham 1998).

Dispute Settlement A rules-based agreement is credible only if it includes effective dispute settlement procedures. In GATT's early years, working parties were created to handle disputes. Then in 1952 the contracting parties switched over to a "panel" system in which three (sometimes five) delegates from countries not party to the dispute evaluated submissions by the parties to the dispute and made recommendations or rulings, depending on the issue(s) at stake. The panel's final report was submitted to the GATT Council (a body representing all GATT members) for adoption by consensus, which meant that the country that "lost the case" could block the adoption of the panel report if it so desired. Odd as this may sound, the system worked in the first three decades a substantial proportion of panel reports was adopted because the contracting parties knew that if the dispute settlement system failed, the GATT would fail (blockage of panel reports emerged as a major problem only in the 1980s and was addressed in the Uruguay Round negotiations).

A defendant country that lost a case (and did not block the adoption of the panel's report) had three options: (1) withdrawal of the GATT-inconsistent measure(s), always the required and first-best option; (2) as an interim measure, pay compensation, generally by lowering one or more tariffs (on an MFN basis) on selected exports of interest to the winning plaintiff; or (3) if compensation was not paid, suffer retaliation by the plaintiff country, generally via a discriminatory increase in tariffs on items of export interest to the defendant country. The third option was possible only if it was authorized by the contracting parties a very important proviso since it heavily modified the long-standing "right of unilateral reprisals" in international law. Although retaliation was authorized only once under the GATT, there is no doubt that countries' awareness of this option was crucially important in the enforcement of GATT rules.

In the early years there was a struggle between those countries that favored an approach to dispute settlement that was pragmatic and avoided undue "legalism" and those that favored a more judicial or legalistic approach. Over time the latter approach won out, as evidenced, for example, by the previously mentioned creation of GATT's first ever Office of Legal Affairs in 1983. In the course of providing other examples, Ernst-Ulrich Petersmann (1997) observes that this shift progressively transformed "the GATT into the most frequently used, and most effective, international system for the rule-oriented settlement of disputes among governments."

Beginning in the 1980s, the effectiveness and uniqueness of GATT's dispute settlement system acted as a magnet for issues outside GATT's area of responsibility. In two instances the protection of intellectual property and the enforcement of workers' rights proposals to extend GATT rules and dispute settlement (with trade retaliation a possibility) into new areas were motivated by the lack of effective enforcement mechanisms in the responsible international organizations, while in two others trade in services (banking, insurance, and so forth) and protection of the environment there was no effective international organization. Negotiations on these issues subsequently became key parts of the Uruguay Round (see below).

Negotiating Rounds Although the GATT was not a free trade organization, the underlying "ethos" included a strong belief by many members including all the developed countries that the pursuit of *freer* trade was an important goal for the organization. This is not surprising considering the high tariffs and widespread use of import quotas, inherited from the 1930s, that confronted the early GATT.

During the period 1947 94, GATT's contracting parties held eight rounds of trade liberalizing negotiations. Reciprocal reductions in tariffs I'll reduce my tariff on radios if you reduce your tariff on corn were the exclusive focus of the first five rounds and an important part of the agendas of the three later rounds. By 1994 the average tariff on manufactured goods entering the developed countries had been reduced from around 40 percent in the immediate

postwar period to below 5 percent. Tariffs in many developing countries also started to come down beginning in the late 1960s and early 1970s as these countries adopted more outward-oriented development strategies.

Not only were tariffs reduced, but an increasing number were also "bound" under GATT rules. Binding a particular tariff, say the tariff on radios at 20 percent, meant that you were not permitted to increase it above that level (a lower tariff was okay). Raising it above 20 percent would put you in violation of your GATT obligations and risk a dispute settlement case. Binding members' tariffs was often as important as reducing rates since both increased the predictability of future market access and thus encouraged trade.

In the Kennedy Round (1964 67) anti-dumping measures were added to the agenda. Reflecting both the success in reducing tariffs and the increasing complexity of commercial relations, the Tokyo Round (1973 79) attempted, for the first time, to deal with a range of nontariff measures, including three production subsidies, technical barriers to trade (for example, safety standards), and government procurement that are applied not at the border but domestically in the importing country. The extent to which these initial steps "inside the border" signaled a turning point for the multilateral trading system was perhaps not fully appreciated at the time. Otherwise, little meaningful progress was made in the Tokyo Round, the principal achievement being a series of "codes" that were signed by a minority of the contracting parties, making them plurilateral rather than multilateral agreements.

The Uruguay Round It was not long before pressure to launch a new round began building as a result of both short-term concerns and medium-term goals. The former focused on the worsening trade relations among many of the leading traders in the early 1980s, caused in part by a sharp slowdown in the growth of world production and trade. Launching a new round, it was argued, would help governments to contain protectionist pressures, through the new round's standstill agreement (on new trade barriers) and the demonstration that governments were dealing with the system's perceived shortcomings.

The medium-term goals behind the push for a new round, in turn, fell into two distinct categories. One was based on the widespread perception that the GATT system was in serious trouble and that something had to be done soon. Not only had the postwar liberalization momentum been lost, but even more ominously, the use of GATT-illegal discriminatory quantitative restrictions (often labeled voluntary export restraints, or VERs) by some of the major countries was spreading to ever more products, as was the use of trade-distorting production subsidies. Moreover, after seven rounds of negotiations, agricultural trade was still not subject to GATT's rules, and trade in textiles and clothing a potentially important source of jobs and economic growth in many lower-income developing countries remained heavily restricted by GATT-sanctioned quantitative restrictions.

The other medium-term goal stemmed from the belief on the part of many members especially the developed countries that after nearly 40 years the GATT needed to be updated to be able to deal effectively with the new realities of world trade and the policy frictions they engendered. A key part of this updating involved proposals for writing new GATT rules and disciplines to cover economic activities that had increased greatly in importance since the GATT was drafted. Attention focused on three areas: trade in services, the protection of intellectual property rights, and trade-related investment measures (for example, requiring foreign-owned firms to purchase a certain percentage of their inputs in the host country).

With growing support from the developed countries and many developing countries, momentum for launching a new round began accelerating in the early months of 1985. At the same time, a group of developing countries led by Brazil and India remained strongly opposed to a new round. Proposals to include "new areas" on the negotiating agenda especially trade in services also drew strong opposition from many developing countries. Eventually the countries favoring a new round won out, helped

by a compromise whereby the services negotiations would be on the agenda but kept completely separate from the negotiations on goods.

GATT's eighth and final round of negotiations was launched in September 1986 at a meeting of the contracting parties in Punta del Este, Uruguay. The ministerial declaration launching the Uruguay Round gave the negotiators four years to complete their work. That target was missed when the December 1990 ministerial meeting in Brussels failed to resolve differences that had blocked agreement on a number of difficult issues, of which agricultural trade was by far the most high profile and politically charged. Negotiations continued and, finally, late in November 1993, GATT's new Director-General, Peter Sutherland, decided that there had been enough progress for him to give the negotiators a deadline of December 15 to wind up the round. The strategy worked. Describing the meeting of the Trade Negotiations Committee on December 15, John Croome (1995) observes, "At 7:30 in the evening, to huge applause, Sutherland brought down his gavel to signify approval of the Uruguay Round agreements. . . . It was, he suggested, 'a defining moment in modern economic and political history.'"

On a very general level, the principal achievements of the Uruguay Round can be summarized as follows:

- Agreement to create the World Trade Organization to replace the 1947 GATT provisional agreement.
- A major revision of the dispute settlement system. In a complete reversal of the practice under the GATT, panel decisions are now automatically accepted unless there is a consensus not to do so; this was coupled with the creation of an independent Appellate Body to hear appeals of panel decisions.
- Further liberalization of tariffs and nontariff restrictions on industrial products, and—for the first time—reductions in import barriers and other (domestic) interventions affecting agricultural trade.
- Creation of the General Agreement on Trade in Services (GATS)
- Creation of the Agreement on Trade-Related Aspects of Intellectual Property Rights (the TRIPS Agreement)

Trade ministers met in Marrakesh (Morocco) in April 1994 to sign the Uruguay Round Agreements, and the WTO began its existence on January 1, 1995.

What Became of the GATT? The original agreement, now referred to as GATT 1947, was phased out at the end of 1995. Within the WTO family of agreements, an updated version of the agreement GATT 1994 is the umbrella treaty covering trade in goods.

The GATT played a key role in the economic prosperity of the second half of the 20th century. It also gave us the WTO, modeled on the GATT but with greatly expanded responsibilities in an increasingly globalized world economy. On both counts, we owe a great debt to the architects of the GATT and to the many national officials and Secretariat staff who despite a very inauspicious beginning made it work.

RICHARD BLACKHURST

■ General Agreement on Trade in Services (GATS)

The General Agreement on Trade in Services (GATS), an outcome of the Uruguay Round of trade negotiations, contains the first set of multilateral rules for trade in services. It entered into force on January 1, 1995, nearly fifteen years after it was first put on the multilateral trade agenda at the initiative of the United States (Feketekuty 1988). Developing countries initially resisted negotiating services, but today some, such as India, that have a growing stake in services exports, are the main proponents. After nearly twenty-five years of virtually continuous negotiations, the GATS has helped create a more secure, rule-based environment for services trade, but it has so far failed to generate significant new trade liberalization.

The Scope of the GATS The GATS is extremely wide in scope and covers all measures affecting *trade in services*. Instead of worrying about a precise definition of what a service is, GATS negotiators proceeded to list the entire range of services covered:

1. Business services
2. Communication services
3. Construction services
4. Distribution services
5. Educational services
6. Environmental services
7. Financial services
8. Health-related and social services
9. Tourism and travel-related services
10. Recreational, cultural, and sporting services
11. Transport services

As if this list were not long enough, there is a twelfth residual category, "Other services not elsewhere included."

Since the conventional definition of trade where a product crosses the frontier would miss out on a whole range of international transactions, the GATS also takes an unusually broad view of trade, which is defined (in Article I) to include four modes of supply:

- *Mode 1—Cross-border*: services supplied from the territory of one member into the territory of another. An example is software services supplied by a supplier in one country through mail or electronic means to consumers in another country.
- *Mode 2—Consumption abroad*: services supplied in the territory of one member to the consumers of another. An example is when the consumer moves, for instance, and consumes tourism or education services in another country. Also covered are activities such as ship repair abroad, where only the property of the consumer moves.
- *Mode 3—Commercial presence*: services supplied through any type of business or professional establishment of one member in the territory of another. An example is an insurance company owned by citizens of one country establishing a branch in another country.
- *Mode 4—Presence of natural persons*: services supplied by nationals of one member in the

territory of another. This mode includes both independent service suppliers, and employees of the services supplier of another member. Examples are a doctor of one country supplying through his physical presence services in another country, or the foreign employees of a foreign bank. Note that the GATS does not apply to measures affecting natural persons seeking access to the employment market of a member, or to measures regarding citizenship, residence, or employment on a permanent basis.

Thus any measure affecting the supply of services through any of these modes is covered by the GATS. The inclusion of commercial presence as a mode extends the reach of the agreement to measures affecting foreign direct investment (FDI), and the inclusion of presence of natural persons (at the insistence of developing countries) to measures affecting the entry of foreign nationals, both of which have traditionally been a tightly controlled province of national governments.

The Rules of the GATS The major provisions of the GATS are summarized in table 1. The wide scope of the GATS contrasts with the gentleness of its rules. It is convenient to think of GATS rules as operating at two levels. First, there is a set of general rules that apply across the board to measures affecting trade in services; and second, there are the sector-specific commitments made by members, which determine the liberalizing impact of the agreement.

Key General Rules: The MFN Principle and Transparency Article II of the GATS constitutes a general obligation which is, in principle, applicable across the board by all members to all services sectors. Article II:1 of GATS states: "With respect to any measure covered by this Agreement, each Member shall accord immediately and unconditionally to services and service suppliers of any other Member treatment no less favorable than that it accords to like services and service suppliers of any other country." The GATS and its Most Favored Nation (MFN) obligation came into effect, however, before World Trade Organization (WTO) members were willing to completely eliminate discriminatory measures in services trade.

Table 1
Major provisions of the GATS
(article and main disciplines implied)

I	Definition. Trade in services covers all four modes of supply.
II	Most Favored Nation (MFN) obligation. Option to invoke exemptions on a one time basis.
III	Notification and publication. Obligation to create an enquiry point.
IV	Increasing participation of developing countries. High income countries to take measures to facilitate trade of developing nations.
V	Economic integration. Allows for free trade and similar agreements.
VI	Rules for domestic regulation. Requirements concerning the design and implementation of service sector regulation, including in particular qualification and licensing requirements.
VII	Rules on recognition of qualifications, standards, and certification of suppliers.
VIII	Monopolies and exclusive suppliers. Requires that such entities abide by MFN and specific commitments (Articles XVI and XVII) and do not abuse their dominant position.
IX	Business practices. Recognition that business practices may restrict trade. Call for consultations between members on request.
XIV	General exceptions. Allows measures to achieve noneconomic objectives.
XVI	Market access. Defines a set of policies that may only be used to restrict market access for a scheduled sector if they are listed in a member's specific commitments.
XVII	National treatment. Applies in a sector if a commitment to that effect is made and no limitations or exceptions are listed in a member's schedule.
XVIII	Additional commitments. Allows for any other specific commitment to be made on a sector by sector basis. To date these have been limited primarily to telecommunications, through the so called Reference Paper.
XIX	Calls for successive negotiations to expand coverage of specific commitments (Articles XVI and XVII).
XXIX	States that annexes are an integral part of the GATS.

Specific sectoral sensitivities, such as a large number of bilateral agreements in maritime and road transport, that were revealed in the Uruguay Round raised the specter of wholesale sectoral exclusions from GATS as a means of avoiding the MFN rule. In order to prevent this, it was agreed to permit limited exemptions to MFN under GATS. Such exemptions, however, had to be taken at the time the negotiations were concluded and *in principle* were not meant to last longer than 10 years (that is, not beyond 2004) but at present they show no sign of disappearing.

Apart from services specified in individual MFN exemption lists, the only permitted departure from most-favored-nation treatment under the GATS covers preferential treatment among countries that are members of regional trading arrangements. The GATS rules on "Economic Integration," in Article V, are modeled on those in Article XXIV of the GATT. Article V:1 permits any WTO member to enter into an agreement to further liberalize trade in services with the other countries that are parties to the agreement, provided the agreement has "substantial sectoral coverage," eliminates measures that discriminate against service suppliers of other countries in the group, and prohibits new or more discriminatory measures. An approved agreement must be designed to help trade among its members, and must not result in an increase in the overall barriers faced by nonmembers in trading with the group within the respective sectors or subsectors (Article V:4). If the establishment of the agreement, or its subsequent enlargement, leads to the withdrawal of commitments made to nonmembers, there must be negotiations to provide appropriate compensation (Article V:5). Agreements that have been notified so far include the North American Free Trade Agreement; the European Communities; agreements between the European Union (EU) and the Slovak Republic, Hungary, Poland, the Czech Republic, Romania, Norway, Iceland, Liechtenstein, and Bulgaria (many of which became redundant upon accession of the countries concerned to the EU); and agreements between Canada and Chile and between Australia and New Zealand.

A related exception from the MFN rule, for the movement of natural persons, is permitted by Article V *bis* of the GATS. This allows countries to take part in agreements that establish full integration of labor markets. The only such agreement notified so far is the one involving Denmark, Finland, Iceland, Norway, and Sweden.

Specific Commitments on Market Access and National Treatment The GATS depends to a large extent on the specific commitments on market access and national treatment made by members. Both types of commitments are made for each of the four modes of delivery of service transactions.

Article XVI stipulates that measures restrictive of *market access* that a WTO member cannot maintain or adopt, unless specified in its schedule, include limitations on: (1) the number of service suppliers; (2) the total value of services transactions or assets; (3) the total number of services operations or the total quantity of service output; (4) the total number of natural persons that may be employed in a particular sector; (5) specific types of legal entity through which a service can be supplied; and (6) foreign equity participation (e.g., maximum equity participation). With the exception of (5), the measures covered by Article XVI all take the form of quantitative restrictions.

Three aspects of Article XVI are important. First, the Article XVI list does not include all measures that could restrict market access. Perhaps most significantly, fiscal measures are not covered. Thus, a member could maintain, without being obliged to schedule, a high nondiscriminatory tax on a particular service that severely limits market access. Second, Article XVI has been interpreted to cover both discriminatory and nondiscriminatory measures, that is, measures of the type "only five new *foreign* banks will be granted licenses" and also measures such as "only ten new [*foreign and domestic*] banks will be granted licenses." Finally, the limitations must be read as "minimum guarantees" rather than "maximum quotas," in other words, a country that has promised to allow five foreign banks entry is free to grant entry to more than five.

The other key pillar of the GATS is the *national treatment* obligation. Article XVII:1 states: "In the sectors inscribed in its Schedule, and subject to any conditions and qualifications set out therein, each

Member shall accord to services and service suppliers of any other Member, in respect of all measures affecting the supply of services, treatment no less favorable than that it accords to its own like services and service suppliers." Unlike Article XVI, Article XVII provides no exhaustive list of measures inconsistent with national treatment. Nevertheless, Article XVII:2 makes it clear that limitations on national treatment cover cases of both de jure and de facto discrimination. If domestic suppliers of audiovisual services are given preference in the allocation of frequencies for transmission within the national territory, such a measure discriminates explicitly on the basis of origin of the service supplier and thus constitutes formal, or de jure, denial of national treatment. Alternatively, a measure stipulating that prior residency is required to obtain a license to supply a service does not formally distinguish service suppliers on the basis of national origin, but it may de facto offer less favorable treatment for foreign suppliers because they are less likely to be able to meet a prior residency requirement than like service suppliers of national origin.

A member's specific commitments can be seen as the outcome of a two-step decision. Each member first decides which service sectors will be subject to the GATS market access and national treatment disciplines. It then decides which measures violating market access and/or national treatment respectively will be kept in place for each mode in that sector. Granting unrestricted market access with full national treatment would be equivalent to establishing free trade, and the flexible structure of rules reflects the desire of most governments to adopt a gradual and conditioned approach to opening up their markets. One result of this structure is that the GATS is not a particularly transparent or user-friendly instrument. More important, virtually all commitments made in the Uruguay Round were at best of a standstill nature, that is, a promise not to become more restrictive than already was the case for scheduled sectors (Hoekman 1996).

Doha Agenda and Beyond The negotiations under the Doha agenda show little sign of advancing services liberalization in the manner anticipated in the Uruguay Round. The best current offers of access in services do not even reflect the liberalization that has already taken place. The "request-offer" negotiating process, conducted first bilaterally and then plurilaterally, seems to have resulted in a low-level equilibrium trap where little is expected and less offered.

The WTO's Hong Kong Ministerial in December 2005 did identify the elements of a meaningful outcome in services. Such a package would have three elements. First was a promise not to impose new restrictions on trade in services. This would dispel the specter of protectionism that hangs over outsourcing of business services   which is producing huge cost savings in the North and ever-widening export opportunities for the South. Second was a commitment to eliminate barriers to FDI, either immediately or, in sectors where regulatory inadequacies need to be remedied, in a phased manner. The greatest benefits of securing openness to FDI, especially in infrastructure services, would accrue to the South while offering increased business opportunities to the North. Third was agreement to allow somewhat greater freedom of international movement for individual service providers (mode 4) in order to fulfill specific services contracts. Research, for example, by Winters et al. (2003) shows large potential benefits to both the North and the South from the liberalization of mode 4, as it offers a way to realize the gains from trade while averting social and political costs in host countries and brain drain losses for source countries.

For there to be a reasonable prospect of achieving these goals, more attention needs to be given to the regulatory context in which services liberalization takes place, in three ways. First, it may make sense to focus primarily on securing "national treatment," that is, ending all discrimination on the entry and operation of foreign services providers rather than on creating more intrusive disciplines. This will reassure regulators that multilateral commitments deprive them only of the freedom to discriminate and do not limit their freedom to regulate in any other way or to adopt policies that improve sector performance.

Second, it may be necessary to establish a credible mechanism to provide regulatory assistance to support liberalization commitments by developing

countries. This will reassure developing country policymakers that regulatory inadequacies that could undermine the benefits of liberalization will be remedied before any market-opening commitments take effect.

Third, it should be possible to make temporary entry of foreign services providers conditional on the fulfillment of specific conditions by source countries. Immigration authorities in host economies must be assured that source countries will cooperate to screen services providers, to accept and facilitate their return, and to combat illegal migration.

In essence, these proposals suggest that it may be necessary for services negotiations to be complemented by broader cooperation. The assumption is that poorer developing countries would participate meaningfully in negotiations that offered an opportunity not merely to make binding commitments but also to mobilize assistance for regulatory reform. And migration authorities would engage constructively in negotiations that offered the opportunity not only to untie their hands, but also to secure assistance from source countries to deal with problems they cannot solve on their own.

■ **Global Environment Facility**

The Global Environment Facility (GEF) grew out of an awareness in the 1980s of transboundary environmental problems and the accompanying recognition that efforts to improve matters would be costly (Sjöberg 1994). Launched in 1991 by the World Bank as an experimental facility, the GEF entered a three-year pilot program to test approaches and resolve competing governance schemes. Today it is the single largest grant-making institution for global environmental programs (Clémençon 2006). The GEF has allocated some $5 billion for more than 1,500 projects in 140 countries (GEF 2005). Because of its size, the GEF has great potential for affecting international environmental health, but as of 2007 its clearest results had been short-term, quantifiable projects such as those within the ozone program. The GEF's ability to work with populations around the world to create integrative, sustainable, long-term benefits will bolster its own position as an international environmental lender and promote the health of environments and communities worldwide.

Mission, Funding, and Change GEF projects are developed and financed through three implementing agencies: the World Bank, UN Environment Program (UNEP), and UN Development Program (UNDP). The World Bank is responsible for investments and mobilizing resources from the private

sector. UNEP supports developing scientific and technical analysis, advancing environmental management in GEF financed activities, and managing the Scientific and Technical Advisory Panel. UNDP is responsible for building the human and institutional capacities that enable governmental agencies or nongovernmental organizations to take the actions necessary for global environmental protection. Executing agencies include regional development banks and a number of specialized UN agencies. GEF operations are coordinated by a Secretariat in Washington, DC.

The GEF provides concessional financing to cover the incremental costs necessary to achieve global environmental benefits. Incremental costs are calculated by subtracting the costs of any national or local benefit from the total cost of the project in order to provide financial incentives to create global environmental benefits. Cofunding is expected to cover the "national" benefits of the project. As such, GEF funding is intended to complement traditional development assistance by covering the additional costs or agreed incremental costs incurred when a development project also targets global environmental objectives. As one observer noted, "GEF assistance is not development 'aid' in the traditional sense, but the payment, by a certain group of donors, for the import of environmental services (cleaner air, biodiversity protection, etc.) provided by the South" (Jordan 1995, 306).

Today, the GEF promotes environmentally beneficial projects in developing countries through six focal areas: biological diversity, climate change, international waters, ozone depletion, land degradation, and persistent organic pollutants, as well as multifocal projects (see figure 1). The GEF acts as the financial mechanism for the following global conventions and international agreements: the UN Framework Convention on Biological Diversity, the UN Framework Convention on Climate Change, the Montreal Protocol, the UN Framework Convention on Combating Desertification, and the Stockholm Convention on Persistent Organic Pollutants.

In 2002, the GEF received $2.92 billion for the 2003 6 lending cycle, its largest financial allocation
Figure 1

Distribution of GEF allocations by focal area. Source: GEF 2005.

up to that point in time. The United States is the largest single shareholder, supplying 20 percent of GEF financial contributions. However, since the GEF's first funding cycle, the United States has been holding down GEF funding levels. Most recently, it required the GEF to adopt a new resource allocation framework as a condition of continued U.S. financial support (Clémençon 2006).

Tackling Global Environmental Dilemmas and Achieving Results The GEF Evaluation Office independently monitors and evaluates GEF programs and projects. It periodically publishes its assessments in independent overall performance studies (OPS). The 2005 performance study (OPS3) emphasizes the challenge inherent in such evaluations: while some projects have quantifiable benefits and may be evaluated within immediate, short-term timeframes, most GEF projects are large and require long time frames to see results (GEF 2005b). The success of long-term projects hinges not merely on whether the GEF has completed a checklist of environmental goals, but also on whether the project is sustainable; projects must achieve financial sustainability by the time GEF funding ends (Clémençon 2006).

The Ozone Program is notable for its quantifiable, short-term benefits. Although not officially linked to the Montreal Protocol, the GEF has aided countries with economies in transition in achieving their obligations under the protocol. Consumption

of ozone depleting substances (ODS) chlorofluorocarbons, halons, carbon tetrachloride, and methyl chloroform decreased by 99.8 percent from the 1980s to 2003 (GEF 2005b). Much of the success of this small-budget program is due to external factors such as economic slowdowns, but OPS3 finds that the GEF has essentially achieved its goal of eliminating the consumption and emission of ozone depleting substances in countries with economies in transition (GEF 2005b).

Other programs in the GEF portfolio may contribute to environmental benefits, but their success is dependent on long-term project sustainability and will not be quantifiable for decades. Instead, impacts can be measured in terms of socioeconomic and political achievements. The International Waters Program, which has no global convention to follow, has helped to foster open lines of communication and to jump-start regional cooperation among stakeholders and countries, in part by supporting the development of global and regional conventions (Clémençon 2006). Though less quantifiable than projects in the ozone area, the achievements of International Waters programs are nonetheless significant in terms of effecting positive environmental and socioeconomic conditions (GEF 2005b).

Likewise, GEF's energy efficiency portfolio has played an important role "in developing and transforming the markets for energy and mobility in developing countries" (GEF 2005b). The Climate Change Program has seen some socioeconomic and capacity-building impacts, but clear-cut environmental benefits remain blurry: while a particular Climate Change project may bring about carbon reduction, its effects are negligible in view of overall world emissions. One way to think about GEF interventions is that they may only be successful if they are replicable, lead to more funding, or build capacity that makes possible future policy development and implementation (Clémençon 2006). In this light, the success of the Climate Change projects has been limited.

The resources that GEF directs toward preserving biodiversity are notable. However, the impact of these resources remains ambiguous. The GEF's contribution of more than U.S. $2 billion to biodiversity projects from 1991 to 2005 makes it the largest single benefactor of biodiversity (GEF 2005a). The GEF is thus highly influential for the future of the world's biodiversity, but one study reports that it is "difficult, if not impossible, to determine the impact GEF funding has had on the biodiversity it sought to protect" (Horta, Round, and Young 2002, 18). A recent assessment of some 34 biodiversity conservation projects found that in two-thirds of the projects, important outcomes were not sustained after project completion (Dublin, Volonte, and Braun 2004). The GEF's role in achieving the global goal of placing 10 percent of the world's land area in preservation should not be overlooked, and conservation within protected areas has been impressive, but biodiversity loss outside of protected areas continues unchecked (Clémençon 2006).

Since 1994, evaluations of the GEF have emphasized the necessity of a holistic approach that addresses the root causes of environmental problems (Horta, Round, and Young 2002; GEF 2002). The 2005 performance study (OPS3) echoes this call, specifically with attention to sustainability of natural conditions as well as political and social conditions. A biodiversity project, for example, may successfully establish a protected area in the short term, but the sustainability of that area is necessary in order to reduce biodiversity loss in the long term. Likewise, projects in the International Waters area are expected to take decades to establish the institutional and legal conditions to achieve improved water conditions (Gerlak 2004). Attention to the persistence of natural, political, and social conditions is key to the success of these projects.

In addition to sustainability, the 2006 performance study prescribes a more strategic vision and a clearer definition of performance indicators (GEF 2005b). Because of the complex nature of transboundary environmental projects, numerous agencies, organizations, and stakeholders lobby the GEF and a multiplicity of organizations offer guidance. Established in 2003, GEF's strategic priorities were intended to handle the proliferation of guidance coming from various global conventions and con-

ferences but have actually increased guidance and broadened a strategic focus at the GEF (GEF 2005b). OPS3 envisions a synergistic, strategic approach with focused, coherent, and prioritized goals that could capitalize on areas where projects overlap, thus increasing efficiency. An approach that spans the focal areas as well as the various levels of landscape, ecosystem, country, and region will "allow GEF to fulfill its role as catalyst and facilitator of global environmental sustainability" (GEF 2005b, 4).

The halting or reversal of practices leading to the deterioration of the global environment exceeds the resources the GEF can provide. The GEF can, however, provide stimuli to catalyze local and governmental work toward mitigating environmentally harmful effects of various processes. On the learning curve of environmentally beneficial lending, the GEF has climbed quickly, especially within quantifiable, technical areas. While the learning curve at this point flattens out, the topography of complex, systems-oriented programs becomes unstable. The GEF's ability to navigate this terrain is imperative to its survival as the world economy's largest environmental lending organization and to its ability to affect the health of environments worldwide.

■ global imbalances

Global imbalances are large and unsustainable mismatches in crucial macroeconomic variables in major countries or areas of the world economy. Among the most serious and persistent global imbalances in the early 21st century are (1) the large and unsustainable trade deficits of the United States and surpluses of China, Japan, and some other emerging Asian economies, (2) inadequate national savings of the United States and the excessive savings of China and Japan, (3) high unemployment rate of Europe and inadequate growth of Japan, and (4) dismal poverty and slow growth of some of the world's poorest countries in relation to the very high standards of living in advanced countries. Left uncorrected, these global imbalances can lead to serious economic problems in the countries and regions involved and for the world as a whole.

Persistent large U.S. trade deficits could lead to a collapse, or sharp depreciation, of the dollar, which in turn could result in higher interest rates and recession in the United States, and slower economic growth or recession in the rest of the world. Inadequate U.S. savings and excessive savings in China, Japan, and some other (mostly Asian) emerging market economies are leading to large capital inflows from these countries to the United States and a high level of U.S. international indebtedness; but a sudden sharp reduction in such capital inflows could inflict serious economic damage on the United States and

the entire world economy. High unemployment in Europe and slow growth in Japan due to their somewhat rigid or inflexible economies sharply reduce the economic growth of these economies and push them toward trade protectionism in a vain effort to protect labor and unproductive sectors from world competition, especially from China and other dynamic emerging Asian economies. Finally, dismal poverty and slow growth of some of the poorest countries, especially those of sub-Saharan Africa, lead to strife and political unrest in these countries and ethical conflicts and turmoil in the collective conscience of the rich countries.

Trade Imbalances between the United States and East Asia Table 1 shows the enormous and rapidly growing trade deficits of the United States, on the one hand, and the large trade surpluses of China and Japan, on the other hand, since the mid-1990s. The table shows that the U.S. trade deficit rose sharply from $191 billion dollars or 2.4 percent of the U.S. gross domestic product (GDP) in 1996 to $452 billion or 4.6 percent of the U.S. GDP in 2000, and $782 billion or 6.3 percent of U.S. GDP in 2005. Trade deficits in excess of 2 or 3 percent of GDP are deemed by most economists to be unsustainable in the long run and need to be corrected. Table 1 also shows that almost one half of the U.S. trade deficit is with China and the other emerging markets of East Asia and Japan, and it is against the currencies of these nations that the dollar is overvalued. The situation is different with respect to Europe and the euro. Since 2001 the dollar has depreciated substantially with respect to the euro. Overall, the large and rapidly increasing U.S. trade deficits are the result of extremely low and declining savings (table 2) of the United States and its more rapid growth relative to the euro area and Japan over the past decade.

Inadequate U.S. Savings Another serious global imbalance is given by the inadequate savings of the United States, on the one hand, and the excessive savings of China, Japan, and some other emerging Asian economics (sometimes referred to as a global savings glut). Table 2 shows that the savings rate of the United States declined from an average of 16.3

percent of GDP in the period 1990 99 to 13.3 percent of GDP in 2005, or by 2.9 percentage points from 1991 to 2005, while U.S. investment rose from an average of 18.7 percent of GDP in the period 1990 99 to 20.0 percent of GDP in 2005, or by 1.5 percentage points from 1991 to 2005. As a result, U.S. net borrowing abroad (negative U.S. net savings) increased from an average of 2.4 percent of GDP in the period 1990 99 to 6.7 percent of GDP in 2005, or by 4.4 percentage points (2.9 1.5 in net savings) from 1991 to 2005. The counterpart of the huge U.S. net borrowing was the large foreign net lending to the United States, primarily by Asian countries, with the euro area practically in savings-investment balance.

Most foreign lending to the United States during the 1990s took the form of foreign direct investments (FDI) attracted by high U.S. growth and profitability. During this period, an increasing amount of foreign capital flows to the United States took the form of foreign official purchases of U.S. government securities and accumulation of dollar reserves, mostly by Japan and Asian emerging market economies, especially China. By buying U.S. government securities and accumulating dollar reserves, Asian countries avoided a large depreciation of the dollar vis-à-vis their own currencies and hence a sharp reduction in their exports to the United States and to the rest of the world (which would result from Asian exports becoming much more expensive for consumers and

businesses paying for them in depreciated dollars). Essentially, Asian countries thus followed an export-led growth strategy financed by lending large sums to the United States. This resulted in a dollar overvalued with respect to most Asian currencies and in a large and unsustainable U.S. trade deficit (the counterpart of the large U.S. net borrowing abroad).

Economists disagree over how long this process can continue. But a significant and rapid reduction in net foreign loans (capital inflows) to the United States could lead to a collapse of the dollar, higher interest rates in the United States, and a U.S. and world economic recession and crisis. There is a broad consensus among economists that the medium- and long-term solution to this problem is for the United States to adopt policies to stimulate domestic savings and curb its expenditures. This is not easy to do because, as most economists would agree, American consumers and firms have become accustomed to living with increasing levels of debt, and it is difficult to change this behavior. An increase in the U.S. savings rate would reduce the need for capital inflows, reduce or eliminate the dollar misalignment, and reduce U.S. trade deficits to sustainable levels. The United States, however, is hardly doing enough to overcome its savings-investment imbalance a problem that could not, in any event, be easily or quickly solved. It has been suggested that China and other emerging market economies should increase domestic expenditures while Japan should restructure

Table 2
Savings, investments, and net savings in major economic areas, 1990 2005 (percent of GDP)

its economy to further stimulate its growth. The International Monetary Fund through its new surveillance mandate may encourage the United States, China, and Japan to take cooperative steps to reduce their saving-investment imbalance to sustainable levels.

Structural Imbalances in Europe and Japan
Although savings and investment are in near balance in the euro area (see table 2), this part of the world faces a serious structural imbalance, which has kept its growth rate well below its potential and much lower than the growth rate in the United States since 1996 (see table 3). The restructuring that had taken place in the euro area during the decade from the mid-1990s to the mid-2000s clearly was inadequate, and its economy, especially its labor market, remained excessively rigid by the end of 2007. In addition, some economists argued that the euro area did not pursue the creation of a "new economy" sufficiently aggressively, and it thus was not able to harvest as much benefit as the United States did in the late 20th and early 21st centuries. From 1996 to

2005, the average annual growth rate was 2.0 percent for real (inflation-adjusted) GDP and 0.8 percent for labor productivity in the euro area, as compared with 3.3 percent and 2.2 percent, respectively, in the United States. This has kept the rate of unemployment much higher in the euro area than in the United States and contained European imports over the past decade.

Economists generally agree that the appropriate long-term policy for the euro area to overcome its imbalance would be to accelerate or speed up the restructuring of its economy and liberalize its labor markets, as well as encourage more rapid adoption and spread of new ICT (information and communications technology), and so stimulate labor productivity and growth of its economy. Strong labor opposition, however, has so far prevented European governments from introducing the deep structural reforms necessary. This may be understandable Europe is proud of its high wages and generous social protection benefits, and it seems unwilling to compromise them. It is also difficult to introduce reforms

Table 3

and restructure labor markets when the economy is growing slowly. Furthermore, the benefits of re-structuring generally come only over time, but most of the costs are paid up front. The longer the re-structuring is delayed, however, the more the euro area falls behind the United States in real per capita income. In fact, after rapidly reducing the gap in real per capita income from more than 50 percent in 1950 to approximately 10 percent in the 1980s, the euro area average real per capita income slipped back to about 76 percent of U.S. income in 2005, wid-ening the gap to 24 percent.

The Japanese imbalance is also structural and mostly internal in nature, thus requiring, for the most part, domestic policies to correct it. Specifically, Ja-pan was in recession or slow growth for the entire decade of the 1990s, and by the end of 2007 still faced major structural imbalances. Domestic defla-tion rather than international disturbances was the primary cause of the large undervaluation of the yen with respect to the dollar and thus of the large Jap-anese trade surplus vis-à-vis the United States. By most yardsticks, Japan has a unique situation it saves too much and consumes and invests domesti-cally too little (see table 2).

Japan has followed three policies to correct its domestic deflation and structural imbalance. It has pursued a very powerful expansionary monetary policy, which has kept nominal interest rates at a practically zero level (with real rates negative because of domestic deflation). It has adopted an equally powerful expansionary fiscal policy (evidenced by an average annual budget deficit of 6.4 percent of GDP from 1996 to 2005 and 6.8 from 2001 to 2005 and a public debt equal to 172.1 percent of GDP in 2005). Finally, Japan has actively intervened in foreign ex-change markets to prevent a further yen appreciation and a reduction of its exports. In fact, Japan's foreign exchange dollar reserves increased from about $120 billion in 1996 to $830 billion at the end of 2005. Yet, until 2004, Japanese growth remained very subdued. Despite the fact that growth resumed in 2004, remaining structural imbalances still kept Ja-pan performing below its potential by 2007.

Dismal Poverty and Growing Global Inequality
Still another serious global imbalance in the world today is dismal poverty and slow growth of some of the world's poorest countries, especially those of sub-Saharan Africa. Table 4 gives the population and the per capita income of various countries or groups of

Table 4

Population and economic and health indicators, 1990 2004

countries in 2004, as well as the growth in real per capita income from 1990 to 2004, and infant mortality and life expectancy in 1990 and 2004. The table shows that the average per capita income of all developing economies and former communist countries was only $1,502 in 2004 ($620 and $1,500 for India and China, respectively) as compared with $32,112 in high-income developed economies. Worse still, the average growth of real per capita income was close to zero in sub-Saharan Africa (as a result of drought, wars, rapid population growth, the spread of HIV, and the general failure of development efforts), only 0.5 percent in Europe and Central Asia (because of economic restructuring after the collapse of communism), and 1.1 percent in the Middle East (because of wars, political turmoil, and the sharp decline in petroleum prices during the 1990s).

The average growth of real per capita income was also very low (only 1.1 percent) in Latin America and the Caribbean between 1990 and 2004 because of political turmoil and failure in the development effort. Only in East Asia and the Pacific economies (and in particular, in China) did the real per capita

income increase very rapidly from 1990 to 2004. In South Asia, the growth of real per capita income, while not as spectacular as in East Asia, was very respectable, largely fueled by the economic revitalization of India. The table also shows that infant mortality is much higher and life expectancy much lower in low-income developing countries, especially in sub-Saharan Africa, than in high-income developed countries, but major improvements were made in both measures throughout the world from 1990 to 2004 (except, again, in sub-Saharan Africa). But the wide disparities in per capita incomes between rich and poor countries, especially the poorest developing countries, can be regarded as one of the most serious global imbalances in the world economy today.

An international economic system that has spread the benefits from globalization so unevenly can hardly be said to be functioning properly   not to mention equitably. And a world where millions of people starve not only is unacceptable from an ethical point of view, but also can hardly be expected to be peaceful and tranquil. The huge difference in stan-

dards of living between rich countries and the poorest ones certainly represents one of the most serious global imbalances in the world economy today.

DOMINICK SALVATORE

■ global income inequality

Prevailing concerns about economic inequity in the world reflect many aspects of living standards and how they are distributed, and no single measure can hope to capture all those concerns. As conventionally measured, "inequality" and "poverty" are quite different aspects of income distribution, in that the former focuses on the (absolute or relative) disparities in income (or consumption), while the latter focuses on absolute levels of deprivation, which depend on the average levels of living in society as well as inequality.

Both poverty and inequality are closely related to a third concept, "social welfare," which aggregates welfare levels, which are taken to depend, at least in part, on income. (Differences in "income needs" may also play a role.) Poverty and social welfare are both sensitive to income changes at the bottom of the distribution: if everything else is held constant, as poverty rises, social welfare falls. They differ, however, in that standard measures of social welfare are also sensitive to changes at the top of the income ladder, whereas poverty measures typically are not. Inequality also relates to social welfare, since most social welfare functions have curvature properties that penalize higher inequality at any given mean income (Atkinson 1970).

Well-being itself has many dimensions, of course, and interpersonal aggregation is fraught with difficulties. Some people argue that the standard of living should be assessed in terms of capabilities   the set of "beings and doings" one is capable of enjoying rather than income or consumption (see, for example, Sen 1985). This can be interpreted as an issue of how best to deal with interpersonal heterogeneity in income "needs."

There is not enough room in this entry to do justice to all these issues. The focus here is on global consumption and income distribution, and how they are changing.

Concepts, Methods, and Data Conceptual and methodological differences lie at the root of the ongoing debates about global inequality. There are significant differences in four main areas: the welfare indicator ("inequality of what?"), the definition of the distribution, the choice of inequality measure, and the appropriate data sources. Without some understanding of these differences, it is impossible to take an informed position in this debate.

Inequality of What? Standard practice has been to rank households by consumption or income per person. The consumption or income numbers that can be formed from most nationally representative large household surveys are reasonably comprehensive, in that they span the commodity space or all income sources (with imputed value for income in kind from production for one's own use or consumption). But they can hardly be considered complete metrics of welfare; access to subsidized health care or schooling is generally excluded, for example. Hence it is important to also look separately at key "nonincome" dimensions of welfare that capture the missing components. We will return to this topic, but for now we focus on the standard consumption or income measures available from surveys.

The choice between consumption and income is not a minor one, since inequality is generally lower for consumption than for income, due to consumption smoothing (whereby savings or borrowing are used to assure that living standards do not vary as much over time as incomes do). The consensus in the development literature is that consumption is both the conceptually preferable measure   given some degree of smoothing in the presence of intertemporal income variability   and more accurately measured in surveys. (Against this view, however, some scholars have argued that income may better reflect opportunities for consumption.)

The near-universal normalization by household size is also questionable. For example, it does not allow for economies of size in consumption (whereby two people can live more cheaply together than apart), and doing so can affect inequality and poverty comparisons, such as the claims often heard that larger households are poorer (Lanjouw and Ravallion 1995).

Naturally, household surveys measure expenditures in local currencies, which then have to be converted to a single currency. The basic choice is between market exchange rates, which measure in-

ternational purchasing power in terms of traded goods, and purchasing power parity (PPP) exchange rates, which adjust for the fact that nontraded goods tend to be cheaper in poorer countries. Almost all researchers prefer PPPs, although there is more than one way to measure PPP exchange rates. The Geary-Khamis (GK) method used by the Penn World Tables (PWT) underestimates global inequality since the quantity weights used to compute the international price indexes give greater weight to consumption patterns in richer countries, which in turn results in an overestimate of expenditures in poorer countries. The Eltöte, Köves, and Szulc (EKS) method, which is the multilateral extension of the bilateral Fisher index, attempts to correct for this bias. (On the differences between the GK and EKS methods and implications for global poverty measures, see Ackland, Dowrick, and Freyens 2006. Since 2000, the World Bank's global poverty and inequality measures have been based on the Bank's PPPs, which use the EKS method.)

Although these are all difficult measurement issues, the main sources of the differences in existing numbers on the evolution of global poverty and inequality lie elsewhere.

What Distribution? There are three main — and very different — ways of defining the "world income distribution." The first is the distribution of country mean incomes, unweighted by population; we call this the "intercountry income distribution." This is of interest primarily to those who view the country, rather than the individual, as the main unit of interest. If gross domestic product (GDP) per capita is used as a measure of the country mean income, this concept corresponds closely to the macroeconomic literature on testing for international income convergence (see, e.g., Quah 1996; Pritchett 1997). The second distribution is that of country means, weighted by population — the "international income distribution." This places higher weight on more populous countries.

The third definition focuses on the distribution of *individual* incomes, across all people in the world. This is the "global income distribution," and for those concerned with the individual — rather than

the country — as the fundamental unit of analysis, this third concept is clearly preferable. If inequality between rich Chinese (or Americans) and poor Chinese (or Americans) is rising, why should this not be counted as part of world inequality? The earlier literature focused on intercountry and international inequalities largely for data availability reasons. It is only since about the mid-1980s that household survey data have become available for a sufficient number of countries so as to enable a computation of global inequality. (These three measures — intercountry, international, and global — correspond, respectively, to inequality concepts 1, 2, and 3, as defined by Milanovic 2005. For decomposable measures, international income inequality corresponds to the between-country component of global inequality.)

What measure? A key conceptual distinction too often ignored in applied work — is between *relative* and *absolute* measures of inequality. We consider relative measures first. One of the most popular inequality measures is the Gini index, which is constructed by summing income differences, expressed as a ratio to the mean, across all individuals in a population and then dividing it by the number of people. This measure has an intuitive interpretation: if two individuals are drawn at random, then the expected difference in their incomes, normalized by the mean, will be equal to twice the Gini index. The index can also be depicted graphically. If one orders the population from poorest to richest, and graphs the cumulative income share against the cumulative population share of each percentile (thereby obtaining the "Lorenz curve"), then the Gini index is twice the area between the Lorenz curve and the diagonal. There are many other inequality measures; a good overview can be found in Cowell (2000). Another popular measure is the mean log deviation, given by the average proportionate gap between mean income and actual income; this measure has some attractive properties, including decomposability into (population-weighted) between-group and within-group components (Bourguignon 1979).

These measures of inequality are designed to be *scale-invariant*, meaning that they do not change if

every income in the distribution is multiplied by a positive constant. The resulting measure then depends solely on income *ratios*, in contrast to absolute measures, which depend on the absolute *differences* in incomes. If every person becomes 10 percent richer, then a relative measure of inequality does not change, even though the (absolute) gains to the rich are many times larger than those to the poor.

Many commentators on globalization appear to focus on absolute income differences rather than relativities. Being sensitive to differences rather than ratios, an absolute inequality measure would increase in our hypothetical scenario of a 10 percent rise in everyone's incomes. Though not often used in practice, an absolute version of the Gini index can be constructed by dropping the normalization of income differences by the mean, so that the measure is one-half of the mean difference in incomes of pairs of individuals.

It may well be the case that much of the debate about what is happening to inequality in the world is actually a debate about whether one thinks about "inequality" in relative or absolute terms (Ravallion 2004). Yet the choice between absolute and relative inequality measures is not a matter of right or wrong. They correspond to different procedures for aggregating gaps between incomes, and thus to different normative concepts of inequality. (Ravallion 2004 discusses this issue further and the implications of other conceptual distinctions, such as between vertical and horizontal inequality, for one's assessment of the impact of globalization on inequality.)

Other observers in the globalization debate focus more on absolute levels of living of the poor, rather than the gaps (whether absolute or relative) between the rich and poor. The measures of poverty found in practice reflect the absolute consumption or income shortfalls from some agreed minimum standard, the poverty line, which aims to have the same real value over time and (when relevant) space. Suppose again that all incomes increase by 10 percent. Relative inequality will remain the same and absolute inequality will have risen. But the incidence of absolute poverty will have fallen, reflecting the higher living standards of the poor. Although this entry focuses

mainly on global inequality, this would give an incomplete picture if we did not also look at what has been happening to global poverty.

What data sources? One might have guessed that there was general agreement on data sources, but that is not the case, and the choices made do matter. There are essentially two approaches. The first relies on secondary data sources, from existing data compilations such as the World Bank's *World Development Indicators*, and the second relies more heavily on primary sources, including unit-record data from household surveys.

A number of studies have used quintile shares or inequality measures derived from various inequality data bases as estimates of inequality in each individual country (examples include Bhalla 2002; Sala-i-Martin 2006). These shares are often derived from already grouped data (rather than from microdata), and they refer to different welfare concepts (income or consumption) and different recipient units (households or individuals). In order to increase the data coverage, the quintiles are pooled together without due attention to their comparability.

Another data issue is the choice between using national accounts (NAS) versus household survey means as the appropriate mean for the distribution. While GDP per capita numbers computed from NAS were traditionally used to construct intercountry and international distributions, household surveys have been the traditional tool for measuring poverty and inequality. The aggregates from these sources generally do *not* agree, and that is hardly surprising when one probes the way the numbers are generated. It seems that over relatively long time periods the two data sources tend to converge to a common ratio in most countries, but the remaining difference in levels can be sizable, and there are some notable short-term divergences (as documented by Ravallion 2003 and Deaton 2005).

Whether using quintile estimates from secondary data or original microdata, some authors rescale individual incomes in each country so as to have a mean corresponding to GDP per capita (from the NAS). They often argue that surveys do not capture a number of determinants of welfare, such as publicly

provided goods. They also worry about income underreporting in these surveys.

There are problems with this rescaling method. On the one hand, it is not clear that the NAS data can provide a more accurate measure of mean *household* welfare than the survey data that were collected precisely for that purpose. On the other hand, even acknowledging the problems of income underreporting and selective survey compliance, there can be no presumption that the discrepancies with the NAS are distribution neutral; more plausibly, the main reasons why surveys underestimate consumption or income would also lead to an underestimation of inequality. For example, Banerjee and Piketty (2005) attribute up to 40 percent of the difference between the (higher) growth of GDP per capita and (lower) growth of mean household per capita consumption from household surveys in India to unreported increases in the incomes of the rich. Selective compliance with random samples could well be an equally important source of bias, although the sign is theoretically ambiguous; Korinek, Mistiaen, and Ravallion (2006) provide evidence on the impact of selective nonresponse for the United States.

Nor are the NAS always reliable. For instance, global inequality results depend crucially on China, but China's GDP per capita numbers are the subject of intense debate. Maddison (2003) and, to a lesser extent, Penn World Tables give significantly higher values for China's GDP per capita in the 1950s and 1960s than the official Chinese statistics. The differences have important implications for the estimation of global inequality.

For these reasons, there is a growing recognition that adjustment of household survey data by the NAS mean is probably undesirable (Deaton 2005; Bourguignon and Morrisson 2002; Anand and Segal 2008). The best current practices in measuring global inequality and poverty increasingly rely, to the maximum extent feasible, on nationally representative household survey data.

The Evolution of Global Inequality and Poverty Acknowledging these conceptual, data, and methodological caveats, what can be said about trends in the world distribution of income?

Bourguignon and Morrisson (2002) constructed a time series of world inequality estimates for the period from 1820 to 1992. For all but the last ten to twenty years of that series, disaggregated household survey data are not available for a large number of countries. Countries were grouped into 33 blocks, with block composition changing over time, depending on data availability (for details, see Bourguignon and Morrisson 2002). The distributions are constructed in such a manner that all the members of a block are assumed to have the same distribution as a country for which distribution data are available. The authors construct a distribution based on decile (and some ventile) shares, and on GDP per capita figures. Individuals are assumed to have the same incomes within tenths (or twentieths) of the distribution, where that income corresponds to the group's share of GDP per capita. This hybrid of the concepts discussed in the previous section was the compromise that allowed the authors to construct a long time series covering most of the 19th and 20th centuries. Given the long-run perspective of this exercise, however, it is likely that some of the problems discussed in the previous section were only moderately important. In particular, the estimated evolution of GDP per capita over such a long period is likely to be very strongly correlated with any measure of household welfare.

The main finding of the study is that world inequality rose almost continuously from the onset of the industrial revolution until the First World War. During that period, the Gini coefficient rose from 0.50 to 0.61. Although inequality was also rising within most countries for which data were available, the real driving force for this increase in global disparity was inequality *between* countries, that is, international inequality (see figure 1).

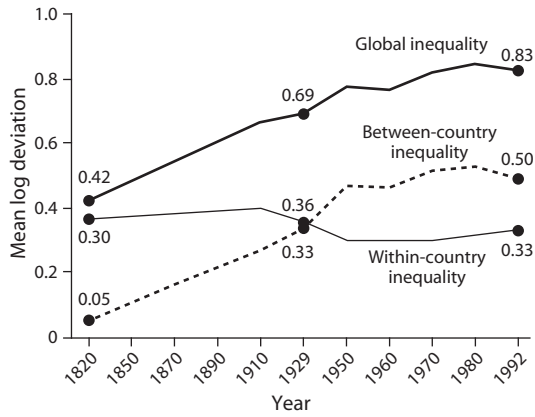
Between the two World Wars, and until around 1950, a decline in within-country inequality was observed, but the rise in inequality across countries continued apace and proved to be the dominant force. The world Gini coefficient rose further to 0.64. From the middle of the 20th century on, the rise of global inequality slowed, as Japan and parts of East Asia started growing faster than Europe and North


Figure 1

Inequality between and within countries. Source: Authors' manipulation of data from Bourguignon and Morrisson (2002).

America. This process became particularly pronounced after the takeoff of China in the 1980s. Broadly speaking, global inequality changes in the second half of the 20th century were much less significant than in the previous 130 years: there was certainly a reduction in the growth of inequality and, toward the end of the period, inequality may have started to decline.

When considering the last decades of the 20th century, however, better and more comprehensive data are available. Household survey data coverage, and the data's availability to researchers, increased dramatically in the 1980s and 1990s, and it became possible to construct not only intercountry and international inequality series based on a broader set of countries, but also real global income distributions, from the microdata.

Looking at the second half of the 20th century with these data, Milanovic (2005) and World Bank (2006) highlight two interesting regularities. First, even as (unweighted) intercountry inequality continued to grow between 1950 and 2000, international inequality began to fall. The disparate behavior in these two inequality concepts has been one of the reasons behind disagreements on globalization and inequality. The continuing rise in intercountry inequality (to which Pritchett 1997 refers as "divergence, big time") was due largely to slow growth in most poor (and small) countries, relative to some middle-income and richer countries. The decline in international inequality, which refers to a population-weighted distribution, was due fundamentally to rapid growth in two giant countries that started out very poor: China and, to a lesser extent, India. As figure 2 suggests, once China and India are excluded from the international distribution, the post-1980 trend in that inequality concept changes dramatically and becomes much closer to the rising trend in intercountry inequality.

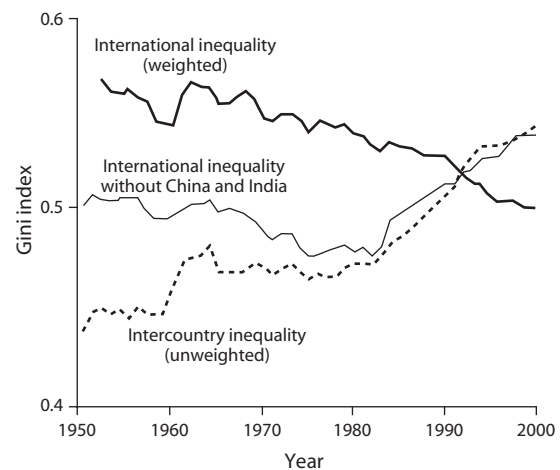
The second regularity is that the last two decades of the 20th century saw a resumption in the upward trajectory of within-country inequality, defined as the aggregate contribution of within-country inequality to total inequality. The rise in within-country inequality prevented the decline in international inequality (which began, slowly, around the 1960s) from translating immediately into a decline in global inequality. Recall that global inequality is the sum of (appropriately aggregated) within-country inequality and international inequality. Indeed, Milanovic (2002, 2005) finds that global income inequality between people was still rising between 1988 and 1993, but appears to have fallen between 1993 and 1998. This is confirmed by World Bank (2006), which extends Milanovic's data set by a couple of years.


Figure 2

Intercountry inequality and international inequality. Source: Milanovic (2005).

The foregoing discussion has been about relative inequality. What about the competing concept of absolute inequality, which depends on the absolute gaps in levels of living between the "rich" and the "poor"? As figure 3 shows, the two concepts give rise to completely different trends for international inequality: whereas all relative inequality measures shown fall from 1990 on, all absolute measures record substantial increases. The difference is practically as important when considering global inequality. It would slightly increase and plateau when defined in relative terms and increase drastically when defined in absolute terms.

Recall that none of these measures tell us directly about the absolute standard of living of poor people. Has rising inequality reflected falling living standards for the world's poor? Using the longest available period of time with consistent series — 1981–2004 — the World Bank's latest estimates (reported in Chen and Ravallion 2007) show that the poverty rate for the developing world as a whole fell from 40 percent in 1981 to 18 percent in 2001, judged by the $1/day standard at PPP (figure 4). Here too measurement methods matter. Using secondary sources on inequality and NAS data on mean income, Sala-i-Martin (2006) finds that the global poverty rate fell from 13 percent in 1980 to 7 percent in 1998. By both methods, the poverty rate was almost halved over 1980–2000, although the levels are quite dif-

Figure 4

Incidence of absolute poverty in the developing world. This figure gives the estimated percentage of the population of the developing world living below $32.74 per month ("$1 a day") and $65.48 per month ("$2 a day") at 1993 consumption PPP. The lines u + r give the corresponding percentages when one incorporates an allowance for the higher cost of living in urban areas. Source: Chen and Ravallion (2007).

ferent. However, GDP includes much more than household consumption, and it is not clear why one would use the same poverty line when switching from household consumption from surveys to GDP from national accounts. Sala-i-Martin's estimates based on a $2/day line — to allow for the non household consumption share of GDP — accord quite closely with the World Bank's estimates using $1/day.

While there is broad agreement that the world is making progress against absolute poverty, there are some important regional exceptions, notably much of sub-Saharan Africa over the 1980s and 1990s. It is also notable that a sizable share of the overall progress has been due to the success against poverty of just one country, China (Chen and Ravallion 2007).

Inequality in Other Dimensions Although this entry (and the broader debate) has focused on income inequality trends, there should be no presumption that it is the only inequality that matters. Indeed, from some perspectives, international disparities in health status and educational achievement may matter just as much (in addition to being instrumentally important in shaping income inequality and poverty). Since around 1930 there has

Figure 3

Absolute and relative inequality in the world. Source: Atkinson and Brandolini (2004).

been convergence in the intercountry and international distributions of life expectancy at birth (LEB). As mean world (weighted) LEB rose from 53.4 years in 1960 to 64.8 years in 2000, its distribution moved from bimodality to unimodality and the coefficient of variation fell from 0.233 to 0.194 (World Bank 2006). This heartening trend was partly reversed, however, during the 1990s, when LEB fell precipitously in some of the world's poorest countries, due largely to the spread of HIV/AIDS.

Educational inequality, measured by the distribution of years of schooling, has also fallen substantially since the 1960s. As mean years of schooling in the world rose from 3.4 in 1960 to 6.3 in 2000, the coefficient of variation fell from 0.739 to 0.461. (Note that inequality measures for variables like life expectancy or years of education have to be interpreted with care. Both variables are close to being bounded from above, and inequality tends to fall automatically when the mean increases.) This pattern of rising means and falling inequality in attainment was common to all regions of the world and, in addition, all regions also saw a reduction in gender disparities, as measured by the male to female schooling ratio (World Bank 2006).

Unfortunately, this reduction in *attainment* inequality has not always meant a reduction in the disparities in true educational *achievement*. Indeed, internationally comparable test score data suggest that these disparities remain strikingly large with, for example, the reading competence of the average Indonesian student in 2001 being equivalent to that of a student in the seventh percentile of the French distribution.

These changes in the distribution of health and education should be taken into account when assessing global inequality in a broad sense. While this entry provides only a very brief summary of the existing evidence along each dimension, a number of scholars have attempted to explore the correlations among the different dimensions. Because increases in longevity have been greater in poorer countries, for instance, Becker, Philipson, and Soares (2005) argue that inequality in measures of well-being that account for quantity, as well as quality, of life have been declining throughout the postwar period.

Another important aspect is the correlation of incomes over time, and the lack of mobility of countries in the international distribution. The persistence of poverty and income gaps across countries or individuals is not adequately represented by measures that are based on static snapshots of the global or international distribution of income. Relative income dynamics matter. Somehow, the severity of inequality, as observed at two different points of time, depends on whether individuals keep the same position or whether they switch. This is the reason for the attention given to the issue of convergence and the accompanying concept of intercountry inequality; for further discussion see Bourguignon, Levin, and Rosenblatt (2004), who analyze in some detail this issue of country mobility in the international distribution.

More work is needed to properly evaluate the extent of "global inequity" in all its dimensions and its evolution over time. Yet, despite the conceptual and methodological minefield inherent in measuring world income inequality and poverty, it is possible to reach agreement on some key stylized facts:

- Global income inequality was high in the early 19th century, but is even higher today.
- From the industrial revolution until roughly the middle of the 20th century, inequality rose in all three concepts of world income distribution: intercountry, international, and global.
- From around 1950 onward, although intercountry inequality continued to rise, (population-weighted) international inequality first stabilized and then declined. This reflects the catch-up of Asia with Europe and North America.
- Rising within-country inequality has attenuated the decline in global (interpersonal) inequality associated with growth in some of the poorest and largest countries, notably China and India. Nevertheless, global inequality appears to have fallen, or at least reached a high plateau, during the late 1990s.
- Although world inequality in the first few years of the 21st century has not yet been

properly analyzed, it seems likely that this trend has continued. Since 2002, the mean growth rate for low-income countries has been above the average rate for high-income countries, for the first time since the 1960s.

- Absolute income inequality in the world—the absolute gap between "rich" and "poor"—has been rising since at least 1970 and probably for a long time prior to that.
- Even so, the incidence of absolute poverty in the world as a whole has been falling since at least the early 1980s, though more rapidly in some periods and regions than others.
- Some large disparities in human development persist, although it is encouraging that global inequalities in health and education attainments have been falling overall. The scourge of HIV/AIDS has threatened this progress, with falling life expectancies in some of the poorest countries.

■ **global public goods**

Whether people live in industrial or developing countries, whether they are poor or rich, their well-being, in large measure, depends on the availability of

a well-tuned balance between private goods, like food or clothing, and public goods, like peace and security, rule of law, communicable disease control, or financial stability. Many public goods have assumed a global dimension. They are global in that their benefits (and, as the case may be, their costs) span national borders, making an impact on countries in several regions and affecting not only present but perhaps also future generations.

Definition of Public Goods and Global Public Goods The classification of goods as private or public is based on their consumption properties. Goods that are made or left excludable and for which clear property rights can thus be assigned are referred to as private goods. It is up to its owner to decide how and by whom a private good can be used or consumed.

In contrast, public goods are nonexclusive in consumption. They are in the public domain, available for all. The term *good* in this context has no value connotation. People's preferences for these goods may vary widely, due to socioeconomic, political, cultural, and geographic factors. Some may perceive a public good such as financial stability as a top priority; and others may accord greatest importance to exploring new, drought-resistant crop varieties. Yet all face the same public goods, at the same provision level. As a result, the question of which public goods to provide, at which quantity, in what form, and at what net cost or net benefit to whom is often highly contested.

Moreover, in many perhaps even most instances, "publicness" and "privateness" do not constitute an innate property of the good. Rather, a good may be in the public domain, available for all to consume, for various reasons, including the following:

- Infeasibility of exclusion for technical or economic reasons (as in the case of the moonlight);
- Deliberate policy choice (as in the case of norms and institutions such as the regime of property rights);
- Policy neglect (as in the case of HIV/AIDS in poorer countries, which was allowed to linger and develop into a pandemic);

- Lack of knowledge and information (as in the case of chlorofluorocarbons, whose detrimental effect on the ozone shield was not recognized for a long time).

The publicness of a good in many instances reflects a policy choice. And so does globalness, which can be seen as a special dimension of publicness. From a worldwide perspective the creation of sovereign states has aspects of privateness, and reducing at-the-border or within-country policy barriers to free cross-border movements of goods, services, capital, and people as has happened during recent decades as a result of often difficult and lengthy intergovernmental negotiations entails reestablishing enhanced publicness.

The Link between Global Public Goods and Globalization Some global public goods such as the ozone layer or the moonlight are global-public by nature. Others would be most appropriately described as globalized national public goods. The globalization of hitherto essentially national public goods may occur for two main reasons. One is deliberate, intended harmonization of national public policy approaches and outcomes aimed at creating enhanced openness and interoperability of national physical and institutional infrastructure. Examples are the international civil aviation regime and the multilateral trade regime.

As openness progresses, national public policy domains become more closely interlocked. And as a result, a second, often unintended and also unaccounted-for process of national-public-good globalization sets in. Public effects or externalities now also move more easily across national borders communicable diseases, contagion effects of financial crises, crime and violence, including terrorist threats.

Thus a growing group of globalized national public goods is joining the natural global commons and contributing to the increasing policy attention that global public goods are commanding today, nationally and internationally.

The Provision Path of Global Public Goods In order to understand the provision path of global public goods, it is useful, first, to examine how public

goods are provided within the national context — and how this process has changed in recent decades.

Public goods and externalities are usually listed among the conditions associated with market failure and that may thus potentially justify state intervention. Many textbooks of public economics and public finance, therefore, refer to public goods also as state-provided goods. And indeed, some decades ago the state provided many goods directly and in full. In recent years, however, national borders have become increasingly open, the roles of markets and states have been rebalanced, and public-private partnering has increased. Today, public goods are often provided by multiple groups of actors — including governments, private business, civil society organizations, and private households and individuals.

Certainly, the state still exercises a certain amount of coercion (via regulation and taxation) to overcome the collective-action (free-riding) problems that often beset public goods precisely because they are public — available for all to consume once they exist. But its interventions are now geared less toward doing by itself what private actors won't do without adequate incentives, that is, direct intervention in the economy, and more toward creating incentives for other, nonstate actors to contribute to the provision of public goods.

If the provision of national public goods appears to be complex, the provision of global public goods is an even more complex process. Besides public and private actors it often also involves several — perhaps even, all — countries, and initiatives at the national as well as the international level.

The reason for the multilevel approach is that in many instances global public goods emerge as a result of a summation process: national public goods being provided in a concerted, harmonized fashion. For example, polio eradication requires immunizing the entire population in all countries. Of course, in order to achieve such concerted action across borders it is often important to have an international organization that oversees the implementation of the agreement to act. Thus global public goods may call for international cooperation *behind* national borders — within countries — and they may call for international cooperation *beyond* national borders — at the international level. However, the bulk of the international cooperation required in order to support global public goods in many instances occurs at the national level.

In cases such as promoting the safety of air travel through airport security checks, the provision level of the good (air safety) depends on the contribution of the weakest link in the chain of providers. In these cases, it may, from a certain provision level onward, be more efficient for the other providers to find ways and means of encouraging the weakest-link actors to upgrade their contribution rather than improving provision levels at home. In such weak-link situations, corrective action at home may need to be complemented by interventions abroad. Yet, even in these cases, the bulk of international cooperation would most likely still consist of interventions within nations.

An exception arises in cases where the global public good follows a "best shot" production path. The invention of a vaccine is a case in point. Once the new vaccine technology has been found and formulated, it exists. To reinvent it would be inefficient. Yet, in order to release the new vaccine technology and permit its use, the inventors may want to be reimbursed for the research and development cost they incurred. If the vaccine in question is one that would primarily be of interest to the poor, the international foreign-aid community might decide to share the reimbursement costs and organize an international collective-action initiative for this purpose. In this case, international-level efforts may perhaps outweigh related national-level, private-sector initiatives.

Global challenges often need global responses. But "global" does not necessarily mean interventions only at the supranational level. Rather, it primarily means that governments in many countries have to act, individually as well as collectively, and in many instances also together with private and civil society actors — in concert, so that all the various inputs fit together and the global public good actually emerges.

At the national level, the state can intervene in a more or less direct, more or less coercive or incen-

tivizing role to orchestrate the many contributions from the myriad of private and public actors who are often involved in the provision of public goods. However, the institution of the state has no equivalent internationally. Intergovernmental cooperation has to happen voluntarily. Hence a critical difference exists between the provision path of ("pure") national public goods and global public goods (including globalized national public goods). In international venues national governments are quasi-private actors: They tend to pursue national, particular interests.

One could thus expect that global public goods are severely underprovided. Indeed, several are, and it sometimes seems that the world is facing a lengthening list of global crises due to such underprovision a crisis of global warming, intermittent financial instability, international terrorism, or new and resurgent communicable diseases. But then one also has to bear in mind that many global public goods are quite well provided, facilitating large streams of cross-border economic activity, sharing of information and knowledge, or the universalization of human rights and other norms such as those that help facilitate a good business climate.

The reason why quite a large number of global public goods are adequately provided despite the fact that intergovernmental cooperation has to happen voluntarily lies in the fact that different actors have different preferences for various public goods. Where their preference for a particular good is sufficiently strong, actors may in effect not free ride but reveal their preference and pay for the provision of the good, irrespective of whether others may also enjoy it or not. Thus private business has often nudged governments into fostering the integration of markets. And civil society organizations have put pressure on governments to take action on global environment or gender concerns.

In the case of public goods generally, but certainly when it comes to global public goods, government failure or hesitation to act on these issues is often corrected by nonstate actors either by way of private and voluntary provision of these goods (as the growing incidence of industry self-regulation signals) or by way of political advocacy and lobbying.

Policy Implications and Challenges The growing importance of global public goods has changed public policymaking in fundamental ways. It confronts policymakers with new tasks to be met under new, changed conditions. As a result of greater economic openness, exclusive policymaking sovereignty is, in most countries, giving way to what might be called "responsive policymaking sovereignty." National policymaking increasingly takes into account not only national policy preferences but also external expectations (e.g., concerning rule of law or fiscal discipline) and global exigencies (e.g., the risk of global climate change).

As a result, it also appears that the role of the state is undergoing a fundamental change. The conventional Westphalian-type state that exercises exclusive policymaking sovereignty within its territorial boundaries is progressively giving way to the intermediary state, the hallmark of which is the blending of external and domestic policy expectations. Through this blending approach, states foster the globalization of national public goods and contribute what is expected of them in terms of delivery of national building blocks to global public goods.

The blending function of the intermediary state is evident not only from changes in budgetary allocations that echo global concerns (e.g., more resources devoted to fighting HIV/AIDS) but also from the use of new policy instruments geared to promoting, on the one hand, even further economic openness (e.g., through new investment laws), or on the other hand, new forms of national closure (e.g., through the introduction of "green" taxes to discourage border-transgressing pollution like greenhouse gas emissions).

Global public goods have changed the national toolkit of policymakers as well as conventional foreign policy. International cooperation beyond national borders is also changing from an essentially intergovernmental process to a multiactor process of public-private partnering. Similar to the change in the role of the state nationally, intergovernmental organizations are increasingly sharing the operational tasks of international cooperation with nonstate actors. Global markets are taking on tasks formerly

performed by intergovernmental organizations. Examples are the emerging international carbon markets or also those for commodity-related futures and options markets. A variety of global public-private partnerships   established as either nonprofit or for-profit organizations   are today producing inputs into the provision of global public goods and making contributions to global equity concerns such as the development of poorer countries.

The Current Stage of the Debate on Global Public Goods Global public goods and their provision are a reality of growing importance. However, at present, this reality is frequently viewed through "old" conceptual lenses. International cooperation "practitioners" often view global public goods provision as foreign aid. The reason is that foreign aid or development assistance is a well-entrenched institution with existing policy and resource-mobilization channels. Thus when a global challenge like avian flu control requires financial support for a weak-link country that may lack requisite means for decisive and prompt corrective action, the richer industrial countries   the conventional aid donors   often use aid resources to provide such support. They do so, although this support is perhaps not being provided for ethical or moral reasons alone (i.e., because the recipient country is poor) but primarily in the "donors'" own, national self-interest   for efficiency rather than equity reasons.

Misperceptions occur not only on the practical-political side of global public goods provision but also on the academic, theoretical side. For the most part, mainstream public goods theory, and more broadly, public economics and finance theory are still based on the assumption of a closed, single economy. Thus current mainstream theory of public economics/finance may not always capture well the total provision path of global public goods. Its national-level focus may make it difficult for researchers to recognize that these goods call for a *concerted* provision of relevant national public goods and for limited yet critically important *complementary* international-level inputs like international agreements that often provide the framework for national-level policy harmonization.

A full understanding of how the provision of global public goods works at present and how it could work more effectively, efficiently, and equitably would require a broad perspective   a comprehensive examination of the overall provision path of these goods. It would involve rethinking a number of aspects of the current mainstream theory of public finance/economics. Much of this rethinking has so far been undertaken in respect to particular issues and is available in specialized journals and debates.

The time is now ripe for undertaking a synthesis of both the theoretical innovations and the lessons learned from various practical-political innovations that have been undertaken in order to respond to global challenges under the pressure of today's changed policy realities. An important question to explore in this context might also be whether an adequate understanding and management of the global economy would call for the creation of a new subfield within the domain of public finance/economics   the field of "global public finance."

The interested reader will find a comprehensive list of recently published contributions to the topic of global public goods, including academic studies, policy statements, and journalistic writings on the Knowledge Portal page. The Knowledge Portal classifies entries according to issue areas (e.g., climate stability, communicable disease control, or financial stability) and according to cross cutting themes (like the concept of public goods and global public goods or the politics and financing of global public goods provision).

INGE KAUL

■ globalization

Globalization refers to a multidimensional process whereby markets, firms, production, and national financial systems are integrated on a global scale. These processes can range across a wide variety of affairs, but all point to the internationalization of everyday life. While we could speak of purely political or cultural aspects of this "shrinking of the world," the economic dimensions of globalization attract the greatest attention. Economic globalization centers on the material mechanisms connecting different countries, which then have political, cultural, and social consequences within and between states.

Some specific definitions of globalization take an overarching view of the economic ties comprising the phenomenon. For instance, the Organisation for Economic Co-operation and Development defines globalization as a process "by which markets and production in different countries become increasingly interdependent due to dynamics of trade in goods and services and then flows of capital and technology" (Stocker 1998). Others try to focus on more limited aspects of the economic contact across borders. Some, such as Richard Rosecrance (1999), prioritize the ease and volume of international flows of the factors of production themselves. For simplicity's sake, we can limit the discussion to three factors of production: land, labor, and capital. Land

obviously is never mobile from one state to another, but the ability to move labor and capital over borders has fluctuated over time. Louis Pauly (1997) has observed that the opening up of financial markets since the early 1980s has focused scholarly attention on the fluidity of capital across borders. For many who study globalization, the integration of national financial systems, symbolized by the ease and speed at which capital can flow internationally, is the critical element of globalization.

Others emphasize the volume of goods in trade. Ronald Jones (2000), an economist, describes globalization in terms of rising interdependence thus emphasizing the nature of the goods involved in trade, not merely the volume. This sort of interdependence involves a high degree of specialization and may also entail a fairly high level of integration of production across borders. While we can imagine ways in which factor flows involve single episodes of capital or labor flowing from one location to another (leaving each state different from before, but without a lasting relationship), the emphasis on trade suggests an evolving, intertwining connection. Since trade involves altering the mix of goods produced locally, and production in turn shapes how people work, where they live, and what they can consume, trade should be considered an essential part of globalization.

Given the many different definitions of globalization, scholars have employed a wide variety of indicators to measure this phenomenon. Some people recommend using the value of exports plus imports as a percentage of gross national product (GNP) as a measure. Others note that the nature of the goods being traded must be changing, to reflect the interdependent nature of the trade itself; this would require a measure that captures the changes in types of goods exported and imported over time. The pattern of flows of goods or factors is also important for distinguishing globalization from other phenomena such as bilateral or regional integration. For those interested more in factor flows, we would turn to measures of economic migration (such as percentage of the population born abroad) or of capital flows (again perhaps contrasted against a measure of

domestic economic activity such as domestic savings or GNP).

Earlier Examples of Economic Globalization If we look at the evidence generated by any one of these indicators, we would discover that globalization is not a new phenomenon. The degree of the globalization of the world economy has fluctuated over time. For instance, during the decades between 1870 and 1914, national economies became much more tightly integrated than they had ever been before.

Economic globalization gained momentum in the late 19th century for several reasons. Technological advances in the early and middle part of the century reduced the cost of long-distance transportation. In particular, the harnessing of steam power made it possible to ship bulky commodities very far, very rapidly, at greatly reduced costs (O'Rourke 1997). Railroads penetrated deeply into the continents of North and South America, as well as Europe and Australia. Steamships shortened the time it took to cross oceans and also freed the ships to travel in directions other than the prevailing winds. The other important technological advance of this period involved communications. The development of the telegraph allowed people the first opportunity to send messages almost instantaneously over great distances. The ability to send information rapidly critically altered several aspects of the world economy. For instance, rapid communications helped individuals and firms select when and where to ship their goods. More important, better communications made it possible to integrate international production. Before the mid-19th century, the slow speed of communications made it difficult for producers to react to changes in distant markets or to seize new opportunities as they emerged.

Of course, policy decisions also determined why globalization accelerated in these years. The spread of liberal ideology in the middle of the 19th century led many states to lower their tariffs and to join the gold standard. By lowering their tariffs, they made it possible for firms and individuals to enter into international trade. These changes then triggered trade adjustment, as market forces pushed countries toward specializing in the types of goods they had a

comparative advantage in producing. The gold standard had attributes that also supported economic globalization. By stabilizing exchange rates, the gold standard reduced uncertainties in international transactions. It also committed states to open flows of capital. Considering the high levels of international migration that also occurred in these decades, it is no surprise that many people argue the world's economy was more globalized in this era than in any other capital and labor were both highly mobile across borders, as were all types of goods (i.e., both manufactured and agricultural products).

Economic globalization had risen and fallen in even earlier periods. In the 17th and 18th centuries, the expansion of the empires of European states caused the integration of their colonies' economies with those of the imperializing states. This economic integration was driven by mercantilism, however. Therefore, although parts of the world economy were linked together over vast distances, the type of integration was much more of the "hub and spoke" model than truly globalizing. In other words, we might observe the development of long-distance trade and the introduction of new commodities into international exchange (such as tobacco or chocolate), but the flow of goods often occurred within the political jurisdiction of a single authority rather than across the boundaries of states. Also, transportation and communication remained relatively slow.

Technological advances often triggered these earlier examples when globalization accelerated. The integration of the world's economy in the 16th and 17th centuries depended on earlier advances in navigation, the ability to construct more seaworthy ships, and map-making. These advances made it possible to introduce not only long-distance trade (as between Europe and Asia) in expensive items such as spices or precious metals but also to include bulky commodities such as timber or grain across shorter distances. While improvements in technology may permit globalization to proceed, by themselves improvements in technology cannot cause globalization. Some actor must seize the technology and utilize it; moreover, state policies must allow globalization to continue. Thus while technological ad-

vances create new opportunities for globalization, the impact of those opportunities is not felt evenly across the world.

Learning from These Earlier Eras of Globalization There are some important lessons to be learned from these earlier experiences with globalization. In the late 19th century, for instance, economic globalization triggered a greater integration of national economies, but various countries responded to this integration in quite different ways. Some countries grasped the economic opportunities present and used them to improve their economic welfare. In others, globalization sparked a political backlash.

As noted earlier, economic globalization initiates change. Some of these changes may appear fairly positive, but most involve reorganizing economic activity and consequently redistributing wealth within societies. Liberalizing trade is a perfect example. Liberalizing trade creates more wealth for society as a whole, but it also redistributes wealth within an economy. In the late 19th century, globalizing trade relations triggered both extreme efforts at adjusting production to exploit the opportunities present and also extreme efforts to shield national economies and societies from the pressures to transform themselves. Some states embraced liberalized trade, changed the goods they produced (and thus adopted new production techniques as well), and consequently reorganized the way people worked and lived. Countries such as Britain, Belgium, Sweden, and Denmark made great strides economically by industrializing and shifting to smaller-scale (but more capital-intensive) agricultural production. These changes were intimately tied not only to the creation and redistribution of additional wealth, but also to urbanization and dramatic changes in land-holding patterns in rural areas. These transformations in turn created new political dynamics in these countries. The economic improvements that came with globalization can be linked with additional pressures for democratization and the transformation of political institutions.

On the other hand, some states were politically dominated by groups that feared globalization. In

places such as Germany, the landed elite used their political advantages to defend their social and economic status. This meant separating the national economy from global ties. By blocking trade adjustment, the landed elite could continue to sell the goods they produced at prices above world market levels — but this undoubtedly proved a drag on other parts of the economy. The elites refused to share political power, since that would have led to a decline in their economic and social status as well. The elites' preference for protection led them to oppose democratization. Before leaping to the conclusion that protection and authoritarianism go hand in hand, however, one must consider other cases from the late 19th century. In France, the Third Republic's electoral rules gave great voice to the rural areas. Land reforms in the wake of the French Revolution had taken away land from large landholders and given it to peasants in small plots. Economic globalization proved more of a threat than an opportunity to these small farmers. Adjusting their production proved difficult, since they lacked the capital or technical skills to adopt new techniques. Their inability to compete in the global economy, coupled with their strong representation in the democratic institutions, led to overwhelming support for protectionism. In short, drawing on the experiences of a wide range of countries in the late-19th-century era of globalization, we can conclude that there is no simple relationship between the economic and political consequences of globalization. Depending on the economic and political context, globalization's impact varies.

Studying the Current Period of Globalization
The descriptions given earlier suggest that technological improvements may be a necessary (though not sufficient) cause for globalization to proceed. Different disciplines emphasize different dimensions of globalization but also pose quite varied questions about why it occurs or what its consequences are. This diversity can be observed by examining how separate disciplines address the issue.

For economists, the reasons for globalization often go unquestioned. Expansion of market relations makes perfect sense within standard economic frameworks. If markets are tools for generating greater utility for participants, then individuals and firms will seek to participate in ever wider markets. Economists may ask more questions about the consequences of this market integration — which is also their way to understand when and where opposition to globalizing forces arises. Depending on the aspects of economic globalization one selects, economists have developed models depicting how the increase in economic ties will affect domestic actors. While an expansion in the size and scale of the market generates growth and productivity gains, specialization triggers changes that redistribute wealth in important ways. Since most of these changes create both winners and losers, economists may therefore recommend that states participate in globalization and then adopt policies that compensate those who do not enjoy the benefits generated. Evidence also suggests that states that open themselves up to the world economy adopt higher levels of social policies to shield segments of the domestic economy from the buffeting caused by global economic forces (Rodrik 1997). On the whole, economists endorse globalization for the material gains it makes possible, although they recognize that it can also bring instability.

As the brief descriptions of previous examples when globalization accelerated make clear, globalization both is the result of policy choices shaped by politics and entails political consequences. Political scientists are interested in not only the consequences of globalization, but also why globalization has not proceeded in a clear, smooth trajectory over time. To understand why states choose to participate in economic globalization, political scientists begin with an economic model describing the likely economic gains and their distribution within the state, then use that information to inform their understanding of how interests align in political competition. Using models developed in political science to understand how institutions shape this competition over policy, political scientists can then explain why some states pursue the economic opportunities globalization offers (willingly making the domestic adjustments necessary) while other states forgo those economic opportunities.

Political scientists also question why globalization has proceeded in waves. While technological change may provide some insights into this pattern, political scientists also point to possible changes in the international political system. Markets require underpinnings to function effectively one need only think of the importance of an accepted medium of exchange as an example. Most national markets function well because these infrastructural underpinnings are provided by a legitimate political authority. Yet the international system lacks a similar political authority. Instead it is composed of numerous actors claiming to be sovereign. Thus political scientists would emphasize the importance of powerful or leading states (or perhaps of actors within powerful states) who could provide and manage international institutions that make economic globalization possible. Although the technological changes of the mid-19th century triggered a great expansion in the flow of goods and factors of production across national boundaries in the pre World War I period, that war disrupted many of those patterns. In the 1920s and 1930s, national policies undermined efforts to re-create a global economy but many parts of the infrastructural underpinnings were also lacking. The United States and its allies made a conscious effort to create institutions fostering economic globalization after World War II.

It should come as no surprise that political scientists and economists are interested in globalization's impact on individual state's policies. On the one hand, many fear that integration into larger markets increases the pressures to be competitive. Globalization has therefore been viewed as a threat to states' freedom of choice on many different fronts. If one assumes that intervention in markets leads to distortions that reduce the competitiveness of domestic firms or individuals, or if one believes that governments are largely parasitic (i.e., not necessary), then one might believe in the "race to the bottom" thesis: the claim that economic globalization pressures states to deregulate markets more and more. However, there is little evidence of such a general trend. Instead, data suggest that states have responded to economic globalization in a variety of ways, with some deregulating markets, but others introducing more government activity or services (Burgoon 2001). If the government can provide services that add to domestic actors' competitiveness, then globalization may trigger greater involvement in the economy, not less.

On the other hand, the pressures to compete also suggest ways in which government policies aimed at noneconomic goals may be adversely affected by globalization (Rudra 2002). Governments have increasingly sought to borrow funds to pay for their programs. Integration of national financial systems leads governments to borrow from foreign sources. Since their expenditures may target goals such as social or economic equality, without the aim of increased economic competitiveness, these states must be able to bear the weight of the debts they carry. Such pressures may be especially problematic for economically developing countries, since they may also wish to resist the global market's demands to specialize in nonindustrial production.

If we concentrate on international flows of the factors of production, the current period of globalization is striking for the speed and amount of short-term capital flows. Although high levels of capital were invested abroad in the late 19th century, this investment was largely long term (Williamson 1996). In the current period, the value of short-term speculative international investments now outweighs the value of goods in trade. Capital flows of this nature may deliver fewer benefits than the risks they also carry, especially for countries with few hard currency reserves. Therefore, many scholars have begun to question whether capital controls might be valuable suggesting that we have reached the limits of globalization. Labor, on the other hand, does not flow very freely and in the post September 11 world, flows of labor are not likely to be freed up anytime soon.

Globalization and Identity Globalization can describe more than economic relations, of course. Since other dimensions of globalization can refer to communications or media, globalization is often also related to cultural changes. These aspects may trigger political responses on their own or interact with the

politics sparked by economic globalization. Cultural issues may arise when we examine the nature of the goods crossing borders during globalization. If the goods include entertainment products (such as books, music, and films), these economic interactions can unleash strong forces on society.

This imagery was captured beautifully by the journalist Thomas Friedman in *The Lexus and the Olive Tree* (1999). Friedman's two images signify the pros and cons of globalization. The Lexus represents the greater wealth globalization makes possible. The olive tree represents culture the way domestic actors are rooted. In Friedman's view, domestic actors want both: they desire continuation of their culture (with minimal outside influence) but also greater wealth. Friedman's symbols capture very well the test globalization presents to societies: how can a state ensure that its engagement in the global economic system brings more benefits than costs?

Challenges Ahead in the Study of Globalization Globalization presents several challenges for social scientists, but the greatest is undoubtedly how to model the impact of the many dimensions of globalization together. This requires multidimensional modeling, since trade and factor flows can each have different impacts. On top of these effects, we would want to add different domestic policies that might moderate the impact of increased immigration, international capital flows, or trade adjustment. A broader model would also need to integrate the politics of identity triggered by globalization. Only when we bring together different theoretical approaches from international and domestic politics, and from micro- and macroeconomics, will we have a better grasp on the broad phenomenon we call globalization.

MARK R. BRAWLEY

■ gold standard, international

The international gold standard was a grand experiment in decentralized monetary unification. From approximately 1880 to the start of World War I, many countries in Europe, North America, and the Southern Hemisphere spontaneously joined the gold standard   a monetary system in which the value of money is defined in terms of a given quantity of gold   during a time of free capital and labor mobility and low levels of protectionism. These countries were diverse in income levels and stages of economic development, but shared the belief that the conservative handling of money would ensure price stability, and that central banks should enjoy a high degree of independence from government.

The international gold standard was a decentralized process but had its own rules (McKinnon 1993). To begin with, paper money had to be convertible into a fixed weight of gold at an official price. Convertibility could be suspended under exceptional circumstances, such as wars or banking and financial crises. After a temporary period, however, convertibility would have to be reestablished at the original parity. Second, the expansion of the national money stock was limited by the stock of monetary gold. Third, gold and capital were free to move from country to country. Finally, monetary authorities were not to hamper the economic adjustment that was implied by gold flows; on the contrary, they were to reinforce this adjustment with appropriate policy actions.

Bilateral exchange rate parities were determined by the relative money prices of gold. As an example, in 1879 the official price of an ounce of gold was £4.252 in Britain and $20.67 in the United States. Parity between the dollar and the pound was, therefore, $20.67/£4.252 or $4.856 = £1.0. The exchange rate fluctuated around parity but was constrained by a band, of which the upper and lower edges   called the gold points   were defined by the transaction costs of shipping gold from one country to another. In practice, the bilateral bands of fluctuations were rather narrow. For the dollar-pound exchange market, the upper edge was estimated at $4.890 and the lower edge at $4.827. If the actual exchange rate were to move beyond $4.890, gold would flow from the United States to the United Kingdom; if the exchange rate were to fall below $4.827, gold would move in the opposite direction. The band of exchange rate fluctuations was and is a typical feature of fixed exchange rates.

Basic Principles The gold standard rested on a decentralized organization in which participants retained their own monetary authorities, their own fiscal autonomy, and their own political sovereignty; in essence, participating countries enjoyed monetary integration without fiscal and political integration. If properly functioning, the system ensured a common

price level, the world price level, which was determined by the interaction of the global supply of and the global demand for money. The global supply of money was proportional to the stock of monetary gold; the global demand for money was the weighted sum of the national demands for money. The world price level would fall when real income rose relative to new flows of monetary gold. The latter would respond positively to the price of gold and productivity improvements in gold mining, and negatively to the world price level. As the price level rose, the stock of gold moved from monetary to industrial use. The decline in the stock of monetary gold reduced, in turn, the price level. For the world price level to be stable, the stock of monetary gold, inclusive of new flows, had to act as a buffer against the forces affecting the money market. But the stock of monetary gold, in fact, behaved too erratically to play this role (Cooper 1982, table 3), and prices, as we will see later, were not stable.

A country with a price level misaligned with respect to the world price level would face an adjustment process. The details of this process, known as the price-specie flow mechanism, were worked out by philosopher and economist David Hume in 1752. For example, a country experiencing a higher price level than the world price level would experience a balance-of-payments deficit. This deficit, in turn, would force a gold outflow and a proportional decline of the domestic monetary base. The money stock would decline in sympathy with the monetary base. With the economy running at capacity, the decline in the money stock would lower the domestic price level. The gold outflow in the deficit country would be directed toward countries with balance-of-payments surpluses and a lower price level than the world price level. In the surplus countries gold inflows would raise the monetary base and generate a process opposite to that in the deficit countries.

Under the assumption of fully utilized resources and price and wage flexibility, deficit and surplus countries would restore price level equilibrium symmetrically. To speed up adjustments, central banks were supposed to reinforce gold flows with appropriate policy actions. A gold outflow would have to be followed with a rise in the discount rate (the interest rate a central bank charges to commercial banks and other financial intermediaries for loans of reserve funds), which would attract capital inflows and contract at the same time the domestic component of the monetary base and bank credit; the opposite for a gold inflow. In essence, the rules of the game prescribed a positive correlation between the foreign and the domestic components of the monetary base.

Basic Facts The practice of the gold standard differed somewhat from the theory. The system actually evolved into a gold reserve standard, with "senior" and "junior" currencies and financial centers and a periphery. The British pound was the "senior" currency and London the biggest and most sophisticated money and financial center in the world. The French franc and the German mark were junior currencies; Paris and Berlin, junior centers. All other countries were periphery, although with different degrees of closeness to the senior and junior centers. Foreign exchange reserves   that is, short-lived assets denominated in the currencies of the centers   grew more rapidly than gold reserves. The amount of international liquidity held in the reserve centers by far exceeded the total gold reserves held by these countries, in particular British official gold. The senior center and the two junior centers were net capital exporters, reassuring reserve holders that the centers were financially solid. All in all, there was a clear tendency for the gold standard to evolve into a gold reserve standard, economizing on gold.

The adjustment mechanism was not as symmetric as the theory claimed. Instead, a hierarchical structure was in place: the same action imparted different effects on the system depending on where it was initiated. The senior center had the largest impact; the junior centers had less and the periphery even less. Hierarchy, or asymmetry, did not imply that the actor located at a higher level of the pyramid was fully insulated from the effects of the actions taken by actors located at a lower level of the pyramid. Capital flows were more sensitive to changes in British interest rates than to interest rates in other countries. Increases in the Bank of England bank rate (the equivalent of

the discount rate) tended to be followed by increases in the discount rates of other countries. Furthermore, if other countries were to match the British bank rate increase, capital would still flow to London.

To stem reserve outflows, and thus to prevent a convertibility crisis, other countries had to more than match the bank rate increase (Lindert 1969). Britain also reacted to interest rate changes initiated elsewhere, especially in the two junior centers. Some countries Argentina, Bulgaria, Chile, Italy, Mexico, and Portugal were so low in the hierarchy that were unable to compete in retaining reserves during rounds of bank rate increases and they had either to devalue their currencies or leave the standard altogether. The pressure on the periphery countries was especially intense during times of gold shortage, causing deflationary pressure and relatively high real interest rates.

The rule of reinforcing gold flows with appropriate changes in the discount rate was widely ignored. The typical pattern was an inverse correlation between the foreign and domestic component of the monetary base, evidence that central banks were sterilizing (compensating the effect of gold flows so as to leave the monetary base unaffected) gold flows to pursue domestic objectives (Nurkse 1944; Bloomfield 1959). The U.S. Federal Reserve system, as an example, sterilized gold movements for much of the 1920s. Even the Bank of England, at the center of the system, violated the rule, although less than other central banks. The sterilization of gold inflows by surplus countries, coupled with the pressure on deficit countries to raise interest rates and contract output, contributed to a deflationary bias in the system; see Keynes (1923, chap. 4).

The main achievement of the international gold standard was to stabilize the long-run inflation rate. For example, the average annual inflation rate in the United Kingdom from 1870 to 1913, measured with reference to wholesale prices, was 0.7 percent; in the United States, from 1879 to 1913, 0.1 percent (Bordo 1981, table 1). The money supply in the system was constrained by gold discoveries. Individual countries, on the whole, were committed to parity and were willing to undertake anti-infla-

tionary policies to restore that parity if they departed temporarily from it. The strategy of sticking to a course of action over time promised payoffs in terms of lower interest rates. In fact, countries that were stricter in the application of the standard enjoyed lower interest rates than countries with a sporadic commitment to convertibility.

The ex-post long-run stability of the price level did not mean, however, that price level uncertainty was low. The coefficient of variation of the inflation rate calculated as the ratio of the standard deviation of the inflation rate to its mean was approximately 3 times higher during the gold standard than in the interwar period and 12 to 14 times higher than post World War II.

These short-run variations must have created considerable difficulty in the private sector in distinguishing price level changes from relative price movements. Furthermore, high short-run variability of the price level was made worse by a high degree of unpredictability of the adjustment period required for the price level to return to equilibrium level (Phinney 1932 33). The swings of the price level lasted up to 50 years. While it is true that prices in 1910 were practically the same as prices in 1850, people living in 1870 or in 1895 would have faced considerable uncertainty in predicting when prices would have returned to the 1850 level. One arrives at a similar conclusion by looking at the wholesale price indexes of four countries: the United Kingdom, Germany, France, and the United States from 1816 to 1913 (see Cooper 1982, table 2). Prices fell and rose dramatically over extremely long swings. For example, in the United States prices fell 45 percent from 1816 to 1849, rose 67 percent from 1849 to 1873, fell 53 percent from 1873 to 1896, and rose 56 percent from 1896 to 1913. The swings were somewhat smaller in the United Kingdom, Germany, and France.

The Gold Standard in the Interwar Period World War I brought an end to the international gold standard. The Brussels Conference of 1920 and the Genoa Conference of 1922 tried to restore fiscal discipline, central bank independence, and the gold reserve standard. Despite the loss of its preeminent

position as the leading country of the international monetary system, the United Kingdom was a strong voice in the two conferences. On the other hand, the United States, anointed to replace the United Kingdom, decided not to participate at Genoa for reasons related in part to disputes over war debts and reparations (Eichengreen 1992, 11).

France strongly opposed the establishment of a gold reserve standard at the Genoa conference, seeing in this an attempt by Britain to reassert the dominance of the pound and London. What followed were a series of ad-hoc decisions without a common design. Germany returned to the gold standard in 1924 in the aftermath of its disastrous hyperinflation. Britain returned to the standard in 1925, and France in 1928. Prewar parities were set in Germany and Britain. The rules of the game dictated that, should a country leave the standard, it should reenter it at the old parity. This commitment was supposed to enforce credibility and prevent destabilizing speculation. In *A Tract on Monetary Reform*, John Maynard Keynes (1923) predicted that the return of Britain to prewar parity would be extremely deflationary: it overvalued the pound and created a deficit in the current account. Contrary to the hopes of the prewar parity advocates, the necessary downward price adjustment, especially of money wages, did not materialize; the adjustment fell primarily on production and employment.

France's new parity undervalued the French franc, causing a surplus in the current account. Furthermore, widespread speculation of a future appreciation of the French franc was responsible for large capital inflows. Consequently, international reserves exploded and the Banque de France sterilized the inflows of reserves with sales of domestic assets to prevent an appreciation of the franc. Saddled with large nongold reserves, the French were reluctant to give Britain the privilege of financing current account deficits with pound-denominated debt. The French opted to redeem reserves into gold, causing deflation in the "center" and easing the appreciation pressure on the franc. In terms of the implied rules of the game, France was no longer willing to accept the pre World War I hierarchical structure.

Other countries as well were unwilling to cooperate. National policies became less internationally oriented as the Great Depression of the 1930s affected much of the industrial world. National political systems had become increasingly reluctant to tolerate the large swings in unemployment and cyclical movements that accompanied the commitment to parity, and the international gold standard eventually lost its appeal.

MICHELE FRATIANNI

■ government procurement

Government procurement refers to state purchases of goods and services and to the leasing of capital equipment. The absence of any binding multilateral rules on government procurement practices is re garded as one of the most significant lacunae of the World Trade Organization (WTO) and its prede cessor, the General Agreement on Tariffs and Trade (GATT). A plurilateral agreement on government procurement exists, but its membership is confined principally to industrialized countries. Many free trade agreements (FTAs) contain provisions on government purchases, and a nonbinding United Nations Model Law on Procurement of Goods, Construction, and Services adds to the uneven patchwork of international disciplines on public procurement matters.

Typically the objectives of government procure ment policies are not just economic, such as obtaining "value for money." Often procurement policies seek to promote the well-being of certain societal groups, firms, regions, and industries. For example, small- and medium-size firms are the beneficiaries of such fa voritism in many jurisdictions, including in the Uni ted States. State purchasers have plenty of means to attain these ends. Procurement procedures can be broken down into three distinct stages: namely, ten dering procedures, evaluation of bids, and the notifi cation of contract awards and associated review pro cedures. It is important to bear in mind that discrimination in a government procurement proce dure can be both de jure (and, therefore, potentially transparent) and de facto (especially where state offi cials are given considerable discretion).

There is considerable uncertainty over the total value of government procurement of goods and services. The last attempt to compile a comparable cross-country dataset on state procurement expen ditures was based on 1998 data (OECD 2001). On average, state expenditures on goods and services accounted for 7.6 percent of the national income of Organisation for Economic Co-operation and De velopment (OECD) nations. The total amount of government spending on goods and services in the industrialized world amounted to $1.795 trillion. The comparable numbers for the developing coun tries included in this OECD study were 5.1 percent and $0.287 trillion, respectively. Information con cerning the ways in which governments discriminate against foreign bidders for state contracts is also hard to come by. However, the Trade Policy Reviews of the WTO do contain some useful information on the latter, yet no comprehensive database of procure ment-related barriers to international trade has ever been prepared. It is quite likely that paucity of data has held back research on this subject.

Data limitations have not deterred theoretical analyses of the effect of public procurement dis crimination on market outcomes and international trade. Although these analyses are almost always partial equilibrium in nature, in principle such dis crimination could have general equilibrium effects (see Evenett and Hoekman 2006 for a discussion of the latter). As far as procurement discrimination in markets is concerned, the modern literature was started by Baldwin (1970) and Baldwin and Rich ardson (1972). They demonstrated that in a perfectly competitive market a procurement ban on foreign

purchases by a state body will affect production levels, imports, and prices only if the quantity of goods demanded by that body exceeds total domestic supply at the moment the ban is imposed. If not, the procurement ban would merely induce a reshuffling of domestic and state purchasers between domestic and foreign suppliers. This finding, which other researchers have confirmed in alternative market structures, implies that not every discriminatory procurement policy reduces market access, so diminishing potential exporter interest in trade agreements that constrain such discrimination.

Many governments solicit bids for public contracts and consequently some analysts have examined the effect of discrimination against foreign bidders in an auction setting. McAfee and McMillan (1989) is the best known such analysis. They demonstrated that the introduction of a price preference, which inflates the foreign bids by a specified percentage before all of the qualifying bids are evaluated, can actually reduce the expected cost to the government of purchasing the good or service. The logic here is very similar to that of the terms-of-trade effects that can be induced by imposing a tariff on imports. Foreign firms partially absorb the price preference and so lower their (pre-preference-adjusted) bids. Domestic firms raise their bids but by less than the amount of the preference-adjusted foreign bids. If the distribution of foreign and domestic firms' costs is such that the probability of a foreign firm winning the contract is sufficiently high even after the price preference is imposed, then there are circumstances when the state's expected outlay falls. This result provides an efficiency-based rationale for the use of price preferences. Whether governments have the information necessary to optimally implement such price preferences is another matter. Moreover, retaliation by other trading partners may shift the calculus away from imposing price preferences.

From what is known about the international negotiations on public procurement matters at the WTO and the GATT it is not evident that these theoretical considerations have been given much weight. Instead the reluctance of some WTO members to develop multilateral disciplines on

public procurement matters has been attributed to concerns that the objectives of procurement policies (including industrial policy goals) may not be effectively met using alternative government policy instruments, to defensive steps taken by the recipients of the rents created by current procurement discrimination, to the suspicion that certain political parties or campaigns are directly or indirectly funded through public procurement policies, and to the concerns that multilateral disciplines would be too costly or burdensome to implement. In fact, in 2004 WTO members decided not to start negotiating new multilateral rules to enhance the transparency of government procurement practices. Consequently, the only prevailing WTO agreement on government procurement is a plurilateral one, the negotiation of which was concluded in 1994. This agreement has 38 signatories (27 of which are members of the European Union). Having said this, 19 WTO members are observers to this agreement, 8 of which are negotiating to join this plurilateral accord. In addition to requiring steps that promote the transparency of the signatories' public purchasing policies and practices and introducing faster procedures for losing firms to challenge state procurement decisions, this plurilateral accord also bans   for agreed sectors   the use of price preferences. The obligations of the 1994 plurilateral agreement are binding on its signatories, and disputes can be subject to the WTO Dispute Settlement Understanding. Many other forms of discrimination, including those that may prevent bids outright by foreign firms or raise their costs, were not banned in the 1994 Agreement suggesting that international disciplines in this area of government policymaking could be strengthened. The members of this plurilateral accord have sought its renegotiation, and in December 2006 a provisional agreement was reached (Anderson 2007).

It is important to appreciate that the WTO is not the only venue where international accords on public procurement matters have been developed. Binding obligations on these matters are frequently included in FTAs, in particular when an industrialized country is involved. In addition, the United Nations has developed a nonbinding Model Law on Procure-

ment, Goods, Construction, and Services. In the years to come researchers may want to examine whether the spread of FTAs with public procurement provisions alters WTO members' positions on the desirability of negotiating corresponding multilateral provisions. Moreover, attention could be given to the relative impact of these binding and nonbinding international initiatives on the reform of national procurement practices in both developing and industrialized countries.

■ gravity models

Gravity models utilize the gravitational force concept as an analogy to explain the volume of trade, capital flows, and migration among the countries of the world. For example, gravity models establish a baseline for trade-flow volumes as determined by gross domestic product (GDP), population, and distance. The effect of policies on trade flows can then be assessed by adding the policy variables to the equation and estimating deviations from the baseline flows. In many instances, gravity models have sig nificant explanatory power, leading Deardorff (1998) to refer to them as a "fact of life."

Alternative Specifications Gravity models begin with Newton's law for the gravitational force (GF_{ij}) between two objects i and j. In equation form, this is expressed as:

$$GF_{ij} = \frac{M_i M_j}{D_{ij}} \quad i \neq j \qquad (1)$$

In this equation, the gravitational force is directly proportional to the masses of the objects (M_i and M_j) and indirectly proportional to the distance between them (D_{ij}).

Gravity models are estimated in terms of natural logarithms, denoted "ln." In this form, what is multiplied in equation 1 becomes added, and what is divided becomes subtracted, translating equation 1 into a linear equation:

$$\ln GF_{ij} = \ln M_i + \ln M_j - \ln D_{ij} \quad i \neq j \qquad (2)$$

Gravity models of international trade implement equation 2 by using trade flows or exports from county i to country j (E_{ij}) in place of gravitational force, with arbitrarily small numbers sometimes being used in place of any zero values. Distance is often measured using "great circle" calculations. The handling of mass in equation 2 takes place via four alternatives. In the first alternative with the most solid theoretical foundations, mass in equation 2 is associated with the gross domestic product (GDP) of the countries. In this case, equation 2 becomes:

$$\ln E_{ij} = \alpha + \beta_1 \ln GDP_i + \beta_2 \ln GDP_j + \beta_3 \ln D_{ij} \quad (3)$$

In general, the expected signs here are $\beta_1, \beta_2 > 0$. However, the economics of equation 3 can lead to the interpretation of GDP as income, and when applied to agricultural goods, Engels's Law allows for GDP in the destination country to have a negative influence on demand for imports. Hence it is also possible that $\beta_2 < 0$.

In the second alternative, mass in equation 2 is associated with *both GDP and* population (POP). In this case, equation 2 becomes:

$$\ln E_{ij} = \varphi + \gamma_1 \ln GDP_i + \gamma_2 \ln POP_i + \gamma_3 \ln GDP_j + \gamma_4 POP_j + \gamma_5 \ln D_{ij} \quad (4)$$

With regard to the expected signs on the population variables, these are typically interpreted in terms or market size and are therefore positive ($\gamma_2, \gamma_4 > 0$). That said, however, there is the possibility of import substitution effects as well as market size effects. If the import substitution effects dominate, the expected sign is $\gamma_4 < 0$.

In the third and fourth alternatives, mass in equation 2 is associated with GDP per capita and with *both* gross domestic product *and GDP* per capita, respectively. In these cases, equation 2 becomes one of the following:

$$\ln E_{ij} = \tau + \delta_1 \ln (GDP_i/POP_i) + \delta_2 \ln (GDP_j/POP_j) + \delta_3 \ln D_{ij} \quad (5)$$

$$\ln E_{ij} = \mu + v_1 \ln GDP_i + v_2 \ln (GDP_i/POP_i) + v_3 \ln GDP_j + v_4 (GDP_j/POP_j) + v_5 \ln D_{ij} \quad (6)$$

Since they involve the same variables, the parameters of equations 4, 5, and 6 are transformations on one another: $\gamma_1 = \delta_1 = v_1 + v_2$; $\gamma_2 = -\delta_1 = -v_2$; $\gamma_3 = \delta_2 = v_3 + v_4$; and $\gamma_4 = -\delta_4 = -v_4$.

Theoretical Considerations After being introduced by Tinbergen (1962), the gravity model was considered to be a useful physical analogy with fortunate empirical validity. Subsequently, however, connections have been made to key elements of trade theory. The standard assumption of the Heckscher-Ohlin model that prices of traded goods are the same in each country has proved to be faulty due to the presence of what trade economists call "border effects." Properly accounting for these border effects requires prices of traded goods to differ among the countries of the world. Gravity models have been interpreted in these terms.

Anderson (1979) was the first to do this, employing the product differentiation by country-of-origin assumption, commonly known as the "Armington assumption" (Armington 1969). By specifying demand in these terms, Anderson helped to explain the presence of income variables in the gravity model, as well as their multiplicative (or log linear) form. This approach was also adopted by Bergstrand (1985), who more thoroughly specified the supply side of economies. The result was the insight that prices in the form of GDP deflators might be an important additional variable to include in the gravity equations described above. Price effects have also been captured using real exchange rates (e.g., Brun et al. 2005).

The monopolistic competition model of New Trade Theory has been another approach to providing theoretical foundations to the gravity model (Helpman 1987; Bergstrand 1989). Here, the product differentiation by country-of-origin approach is replaced by product differentiation among producing firms, and the empirical success of the gravity model is considered to be supportive of the monopolistic competition explanation of intraindustry trade. However, Deardorff (1998) and Feenstra (2004) have cast doubt on this interpretation, noting the compatibility of the gravity equation with some forms of the Heckscher-Ohlin model and, consequently,

the need for empirical evidence to distinguish among potential theoretical bases: product differentiation by country of origin; product differentiation by firm; and particular forms of Heckscher-Ohlin-based comparative advantage. In each of these cases, the common denominator is complete specialization by countries in a particular good. Without this feature, bilateral trade tends to become indeterminate.

Alternatively, there are other approaches to gravity-based explanations of bilateral trade that do not depend on compete specialization. As emphasized by Haveman and Hummels (2004), this involves accounting for trade frictions in the form of distance-based shipping costs or other trade costs, as well as policy-based trade barriers. Distance costs can also be augmented to account for infrastructure, oil price, and trade composition, as in Brun et al. (2005). The two approaches (complete versus incomplete specialization) can be empirically distinguished by category of good, namely differentiated versus homogeneous, as in Feenstra, Markusen, and Rose (2001).

Assessment Due to its log-linear structure, the coefficients of the gravity model are in terms of elasticities or ratios of percentage changes. These "unitless" measures are comparable across countries and goods and give us direct measures of the responsiveness of trade flows to the trade potential variables of equations 3 6. For GDP and distance, estimated elasticities tend to be close to 1.0 in value. For distance, comparison across groups of countries gives a measure of the degree of integration in the world economy. In addition to these standard variables, the coefficients of policy variables help us to understand the impacts of the represented policies on trade flows. It is also possible to obtain estimates of border effects independently of distance and other variables, as well as to investigate some issues in economic geography, as in Redding and Venables (2004). Despite some ambiguity regarding its theoretical foundations, then, the gravity model is an important empirical tool to help us understand trade and other economic flows in the world economy.

■ Group of Seven/Eight (G7/G8)

The Group of Seven/Eight (G7/G8) is an informal intergovernmental institution for the leaders of the world's most powerful countries to govern the global economy and promote the values of open democ racy, individual liberty, and social advancement. It emerged in 1973 when the finance ministers of the United States, France, Britain, and Germany, soon joined by Japan, met secretly as a Group of Five (G5) in the library of the White House to discuss a re placement for the international monetary regime of gold-linked, fixed exchange rates, which had been destroyed by unilateral American action on August 15, 1971. When the finance ministers of France and Germany became leaders, they invited their coun terparts in the G5 and Italy to Rambouillet, France, on November 15 17, 1975, to deal with the eco nomic stagflation and broader crisis of governability arising from the 1973 oil shock, the deadlocked Tokyo Round of trade negotiations, and security threats in the Middle East, Southern Europe, India, and Vietnam. They addressed economic growth, inflation and employment, international finance, trade, energy, and economic relations with the de veloping South and communist East.

At their subsequent summits, held for two or three days in late spring or summer every year, they added Canada in 1976, the European Community (later the European Union) in 1977, and the Russian Federation in 1998, to make it the G8. They have invited as partial participants the Soviet Union and then Russia since 1991; leading African and Middle Eastern democracies since 2001; China, India, Bra zil, Mexico, and South Africa since 2003; and the executive heads of multilateral organizations such as the United Nations, the International Monetary Fund, and the World Bank starting in 1996.

The G5 finance ministers continued to meet on their own and with their leaders at the summit. In 1986 Italy and Canada were added to the finance ministers to form the G7, which soon replaced the G5 and was separated from the now leaders-only summit in 1998. Usually meeting four times a year, the G5/G7 finance ministers have had some signifi cant achievements: the 1985 Plaza Accord, which produced a soft landing for the overvalued U.S. dollar, the 1987 Louvre Accord to manage the new exchange rate relationships, and action to contain the Asian-turned-global financial crisis that afflicted Thailand, Indonesia, South Korea, Russia, the Uni ted States, Brazil, Argentina, and Turkey from 1997 to 2001. Some see G7 finance performance as in herently harmful or declining during the globaliza tion of the 1990s. Others highlight its continuing importance as a source of new ideas.

Other G7/G8 ministerial bodies were created, including one for trade in 1982 and one for devel opment in 2002. In 1999, a broader Group of Twenty (G20) finance ministers and central bank governors of systemically important countries was created. At the official level, groups on energy pro liferated in the 1970s. Two on macroeconomics

arose in 1982. Many on financial crime, financial assistance to Russia, the Gulf States, development finance, Africa, terrorist finance, investment, and intellectual property have emerged since 1989.

The G7/G8 summit's economic agenda soon extended from macroeconomics into many specific microeconomic and social policy subjects. It also quickly embraced global issues such as migration, crime, drugs, and political-security subjects such as East-West relations, terrorism, proliferation of weapons of mass destruction, regional security, and the use of force. Its unique value has been in freely and flexibly addressing any and all issues, and integrating them in innovative ways. From its deliberations have flowed major new directions, such as redefining the relationship between inflation and unemployment. It has issued an expanding number of often ambitious collective commitments. Its members have generally complied at least partly with these commitments, especially in energy, trade, financial assistance to Russia, and debt relief for poor states.

The G7/G8 summit has made an effective contribution to global economic governance in several critical cases. In finance it mobilized the assistance necessary to sustain Russia's democratic revolution in the 1990s. In trade it provided a catalytic political push to launch multilateral trade negotiations in the Uruguay Round and Doha Development Agenda, and successfully conclude the overdue Tokyo and Uruguay Rounds. In energy it stopped the inflation and wealth redistributions brought by the second oil shock in 1979, although at the cost of a severe recession within the G7 and the default of several resource-rich developing states. In development, from the 1988 Toronto Summit to the 2005 Gleneagles Summit, it canceled the debt of the deserving poorest countries of the world and mobilized major new monies for development assistance. After the terrorist attack on the United States on September 11, 2001, it instituted an effective regime to control terrorist finance.

Some see G8 governance as propagating neoliberal values and perpetuating inequality between its rich Northern members and the poor developing South. Others regard it as an important source of political leadership and collective management, most clearly in its 1975 creation of a new monetary regime of managed floating exchange rates and its 1978 big package deal that integrated fiscal, monetary, trade, and energy concerns. Still others argue that it has emerged as the effective center of global governance in the post Cold War, rapidly globalizing world, where even the most powerful economies are vulnerable to shocks that require concerted action to address.

The G7/G8 is increasingly reaching out to incorporate the growing economic powers of China, India, Mexico, Brazil, and South Africa more fully in its annual summit and ministerial processes. It is reaching down to involve business and civil society in its work. Although it still lacks any formal charter or secretariat, its comprehensive reach, freedom, flexibility, direct connection with leaders, and increasing inclusiveness enhance its relevance in guiding the global economy in the 21st-century world.

■ growth in open economies, neoclassical models

The neoclassical growth model is a widely used framework to study economic growth. The main focus of neoclassical growth theory is on explaining economic growth via the accumulation of factors of production, namely physical capital.

When economies are closed to foreign exchange, a central prediction of the theory is that among similar countries (those converging to the same steady-state, determined by factors such as the quality of institutions, overall level of education, government policies, etc.), the poorest should grow faster than the richest. This notion of *conditional convergence* is important

because it suggests the existence of automatic forces that pull economies closer together. Several studies, relying on either cross-region or cross-country growth regressions, provide empirical support for conditional convergence. The assumption of closed economy is, however, very difficult to justify. A first problem is that, if conditional convergence holds among closed economies, the theory implies that foreign investors must be giving up extraordinary investment opportunities. Capital should actually be flowing across countries to arbitrage such return differences. A second problem is that many economies are in fact open. This includes South Korea, Taiwan, Hong Kong, and Singapore, the so-called East-Asian miracles that achieved very rapid and sustained postwar growth. Moreover, these are well-known examples of export-oriented growth. Open economy versions of the neoclassical growth model are able to deal successfully with both challenges.

Assumptions of the Theory Consider a typical economy, potentially open to trade with the rest of the world. The analysis rests on assumptions about the production technology and the preferences of individual consumers underlying saving behavior.

The economy produces a single homogeneous good, the model's counterpart to real gross domestic product (GDP) in the data. The technology available to produce this good is described by an aggregate production function the maximum output that is technologically feasible for the economy as a whole to produce given the available factors of production. A common specification is the Cobb-Douglas production function, $Y_t = A_t K_t^{\alpha} L_t^{1-\alpha}$, where Y_t is the output (real GDP) in the current period, and K_t and L_t are the inputs, aggregate physical capital (all the plants and equipment) and aggregate labor (total number of workers), respectively. Capital may be accumulated over time; however, for simplicity, we assume L_t is constant at L. The parameter $0 < \alpha < 1$ captures the relative importance of capital in production. A_t is the level of technology, that is, the general knowledge available to society on how to produce. It captures how efficient an economy is in combining the available production inputs. Its determinants are not just narrowly technological but

also more broadly institutions and government policies. Neoclassical theory is typically not explicit about these determinants; rather it assumes A_t grows at some constant rate common to all countries. For simplicity we assume here that A_t is constant at $A > 0$.

Since we are often interested in understanding the growth of real GDP per capita, rewrite the production function as $y_t = A k_t^\alpha$, where $y_t = Y_t/L$ and $k_t = K_t/L$. This production technology has two important properties. First, since $\alpha > 0$, increasing k_t always increases production. Second, since $\alpha < 1$, increasing k_t becomes less productive when the scale of production, as proxied by k_t, is already large — a key property called decreasing returns to scale. The idea behind decreasing returns to scale is that, as k_t increases, each worker needs to operate more units of capital, and so capital becomes less productive — for example, some machines become idle sometimes, because there are not enough workers to operate all of them simultaneously.

The economy's residents have a preference for current versus future consumption. In addition, government policy such as capital income taxation influences individual saving behavior. For simplicity, we assume preferences and policy lead to a simple aggregate saving rule: national saving is a constant fraction of national income, or real gross national product (GNP). Real GNP is the residents' total income irrespective of origin — GDP plus the net income generated abroad.

The simple saving rule determines the level of saving in each period. However, the economy also needs to decide how to invest each period's saving, either domestically or abroad. We assume investors choose the option with the highest rate of return.

When today's saving is invested domestically, it will increase the capital stock tomorrow — assuming it takes one period to install new capital. Let's say capital tomorrow increases by one unit. The gross return from this investment is the extra production generated tomorrow by the additional unit of capital — what economists call the marginal product of capital, which in the present case equals $\alpha A k_{t+1}^{\alpha-1}$. Because, due to wear and tear, capital depreciates physically during production, the net return will be lower. With a rate of physical depreciation every period of $0 < \delta < 1$, only a fraction of the initial unit of capital survives production. The net return from investing domestically becomes $r_{t+1} = \alpha A k_{t+1}^{\alpha-1} - \delta$. Importantly, because of decreasing returns to scale ($\alpha - 1 < 0$), a higher k_{t+1} lowers r_{t+1}: richer countries have a lower incentive to accumulate capital because they already have more of it.

Today's saving may instead be invested abroad. We assume there is a frictionless world credit market, where any economy can borrow or lend funds freely at the going world interest rate r_{t+1}^*. Suppose every economy is a small open economy, in the sense that their individual actions have a negligible effect on the world market. For simplicity, assume also that the world interest rate is constant at r^*. Picking the investment alternative yielding the highest return means comparing r^* with r_{t+1}.

So far, with a single homogeneous good being produced in every country, openness to trade only takes place in world credit markets. That is, all trade is intertemporal, involving only borrowing and lending — so far there is no scope for intratemporal trade in different commodities.

The Benchmark Case of a Closed Economy A closed economy has no access to world credit markets, so national saving is all invested domestically. Equivalently, domestic investment in physical capital must be financed through national saving.

Suppose the economy is relatively poor; in particular the current levels of capital and production are lower than their steady-state values. Because of decreasing returns to scale, r_{t+1} is high. With a high return, the saving rule generates enough investment to compensate for depreciated capital and still increase the capital stock tomorrow. Hence, the economy will be growing. However, the growth rate will diminish over time, since decreasing returns to scale reduce returns as capital grows. At some point, we reach a situation where the economy invests just the amount of resources needed to cover depreciation. At that point — the steady-state — capital and output per capita are constant over time, and the economy stops

growing. In the more general case in which the rate of technological progress is positive (A_t grows over time), then GDP per capita would grow at this same rate in the steady-state.

Convergence to the steady-state from the initial level of GDP is only gradual. Convergence is not faster because domestic saving is insufficient to generate all the investment necessary to close the gap between the current and the steady-state levels of capital per capita.

Neoclassical growth theory views cross-country differences in growth rates as stemming from countries gradually converging toward their steady-states, starting from different initial levels. Poor countries, induced by higher returns, grow faster. As Lucas (1990) pointed out, this poses a quantitative challenge to the closed economy assumption. Rewrite the (gross) domestic return as $r_{t+1} + \delta = \alpha A^{1/\alpha} y_{t+1}^{(\alpha-1)/\alpha}$, using the definition of y_t. Consider now the actual experiences of the United States and Kenya through the lens of neoclassical theory. If both countries shared the same technology and differed only in their current position as they transit to a common steady-state, then

$$\frac{r^{KEN} + \delta}{r^{US} + \delta} = \left(\frac{y^{KEN}}{y^{US}}\right)^{(\alpha-1)/\alpha}$$

In 2003, the United States was about 30 times richer than Kenya. With $\alpha = 1/3$, as suggested by the data, then investing in Kenya would have earned a gross return $30^2 = 900$ times higher than in the United States! Even if we attempted to factor in the technological differences that do exist between Kenya and the United States, the return gap would still come out too high. The incentive for capital to flow from the United States into Kenya would be enormous, making it impossible to sustain the closed economy assumption.

Openness to Capital Flows The small open economy has free access to the world capital market, at the constant interest rate r^*. This interest rate reflects the overall return on capital in the rest of the world. Consider a scenario in which the economy is initially in autarky, and suddenly gains free access to the world credit market. Assume the domestic economy is poorer than the rest of the world. Due to decreasing returns to scale, domestic returns under autarky are higher than the world interest rate, $r_{t+1} > r^*$.

Faced with this return gap, foreign investors have an incentive to invest in the domestic economy. There will be a massive instant inflow of funds, which fuels domestic investment. As the stock of capital increases, r_{t+1} declines. The inflow of funds only ceases when $r_{t+1} = r^*$. The domestic economy reaches the steady-state instantly, and GDP automatically attains the level of rich countries. The economy forever becomes a net debtor in world markets, with external debt being serviced via the permanent increase in real GDP.

Differently from the closed economy case, convergence to the steady-state is extremely rapid. Convergence can be fast now, since investing in domestic production may be in part financed with foreign funds, and it does not have to rely only on domestic saving.

Slow Convergence with International Capital Flows Infinite convergence speeds are clearly counterfactual. Realistic convergence speeds obtain if the basic model is extended as in Cohen and Sachs (1986). First, we may relax the assumption that the domestic economy has unrestricted access to foreign funds. In order to finance domestic investment, assume foreign investors require residents to use a certain fraction of their own resources along with foreign funds. This might occur if foreign investors fear residents might default on their debt in the future. Cohen and Sachs (1986) have introduced such credit constraint in the basic model. Barro, Mankiw, and Sala-i-Martin (1995) have introduced a similar type of constraint in an augmented version of the basic model, where not only physical capital but also human capital is an input to production. They assumed that while foreign investors impose no constraints when financing the accumulation of physical capital, they are unwilling to finance the accumulation of human capital — that is, investment in education. The idea is that while physical capital may be offered as collateral on foreign borrowing, human capital cannot be — on default, physical capital is more easily

repossessed by foreign investors than human capital. Since countries need to accumulate both physical and human capital in order to grow, a constraint on human capital accumulation is also a constraint on physical capital accumulation. Both types of constraint on borrowing generate realistic convergence speeds for credit-constrained economies.

Second, we may assume the existence of adjustment costs to investment in domestic capital. Suppose installing new capital entails costs that are higher than just the price of capital, and that these costs become much higher for very large investment rates. Then, the gap between r_{t+1} and r^* no longer determines by itself the incentives to invest: even if $r_{t+1} > r^*$, the effective return on domestic capital may well fall below r^* for large enough levels of investment. Economies will have to adjust slowly toward the steady-state, at realistic speeds.

Openness in Goods Markets To allow for trade in commodities, we need to extend the basic one-good model to multiple goods. Such a departure has been considered by Ventura (1997). Instead of the technology described previously, suppose real GDP is produced using two intermediate inputs call them traditional and modern. Both are produced using capital and labor, but the modern commodity is more capital intensive. A closed economy behaves exactly as the basic one-good neoclassical growth model described above the more general production technology leaves the convergence implications unaltered.

Suppose instead that both commodities are freely traded, while real GDP is nontraded, and capital and labor are immobile internationally. Due to free trade, commodity prices in the small open economy equal the corresponding world prices. With capital and labor perfectly mobile across the production of the two commodities, factor prices are also constant across countries sharing the same technology an instance of the factor-price-equalization theorem. That is, even in the absence of international factor movements, wages and the returns to capital are indirectly pinned down by trade in goods, namely we get $r_t = r^*$.

If saving rates are constant, like before, then not only rich and poor countries wish to invest at the same rate, now they also enjoy the same return r^*. Since trade removes the poor countries' edge in terms of high returns, they stay poor relative to rich countries. There is neither (conditional) convergence nor divergence in world incomes: two economies with identical production technologies will forever stay different if they start out the growth process different. This stands in sharp contrast with both the closed economy implications and those of the basic one-good model.

Whether GDP actually converges or diverges across countries depends on the behavior of saving rates over time. If saving rates increase with the level of GDP, then incomes diverge over time. For convergence still to take place with trade, saving rates must decrease as a country develops.

The East-Asian Miracles Trade in goods also helps us understand the extraordinary growth experience of the East-Asian miracles. The basic one-good model, as well as the multiple-good model without trade, has trouble explaining very high growth rates, sustained over long periods of time: it requires not only high but also increasing saving rates, capable of defying decreasing returns to scale. A much more plausible explanation is that, because of trade-induced return equalization, economies may sustain very high growth rates by avoiding decreasing returns altogether. The performance of the East-Asian miracles may then be understood by the success of these economies at raising saving rates in the early 1960s, and their heavy reliance on exporting industries. Instead of meeting decreasing returns, the fast rates of capital accumulation were channeled to the modern capital-intensive sector. This sector expanded at the expense of the traditional one, its increased production heavily exported in exchange for traditional good imports. In a nutshell, the East-Asian miracles were successful by having the rest of the world absorb their high capital accumulation rates through manufacturing exports.

■ growth in open economies, Schumpeterian models

Schumpeterian growth is a particular type of eco nomic growth generated by the endogenous intro duction of product and/or process innovations. The term *endogenous* refers to innovations that result from research and development (R&D) investments un dertaken by forward-looking, profit-seeking firms. The term *Schumpeterian growth* is named for Joseph Schumpeter, who described the evolution of capi talism through a process of "creative destruction." This process serves as the fundamental building block in models of Schumpeterian growth and cap tures the social costs and benefits that result from the endogenous destruction of old technologies by new ones: "Economic progress, in capitalist society, means turmoil. And . . . in this turmoil competition works in a manner completely different from the way it would work in a stationary process, however per fectly competitive. Possibilities for gains to be reaped by producing old things more cheaply are constantly materializing and calling for new investments. These new products and new methods compete with the old methods not on equal terms but at a decisive advantage that may mean death to the latter" (Schumpeter 1942, 42). Schumpeterian growth models are closer in spirit to Schumpeter's ideas than are other theoretical approaches to economic growth such as those that emphasize learning-by-doing, human capital accumulation, or physical capital ac cumulation as sources of economic growth.

The development of Schumpeterian growth the ory started in the early 1990s, motivated by the di vergence of national growth rates, Japan's challenge to the United States' technological leadership, and the inability of the neoclassical growth theory to ac count for the long-run causes of technological progress. The New Growth Theory has primarily

focused on causes and effects of long-run technological progress, which is the sole determinant of long-run growth of income per capita. One of the most important insights of the New Growth Theory is the relationship between the economics of ideas and economic growth. Two inherent features of ideas are that they are *nonrival*: an operations manual for organizing a retail store can be used by many stores without any significant replication costs other than photocopying the manual, whereas consumption of an apple by a consumer precludes its consumption by another consumer. Ideas are also partially *excludable* in the sense that the owner of an idea can charge a fee for its use because he/she can restrict access to other users. For instance, Coca-Cola can restrict access to its formula, at least temporarily, by locking the recipe in a safe or by acquiring a patent.

Nonrivalry and partial excludability imply that ideas, which fuel the generation of technology, need to be produced only once, and involve a fixed cost and negligible marginal production cost. Consequently, the economics of "ideas" is necessarily related to the presence of increasing returns to scale and imperfect competition. In a general-equilibrium framework, temporary monopoly profits are essential to finance the R&D cost that occurs before manufacturing of new products (based on new ideas) takes place. Therefore, monopoly profits are not necessarily bad for society but provide incentives for firms to engage in risky R&D investments to discover new products or better processes. The New Growth Theory shifts its focus from competition in product-markets to intertemporal competition in the market for innovations. The latter determines the rate of product development, which generates long-run Schumpeterian growth and limits the duration of monopoly power in product markets.

One variant of Schumpeterian (R&D-based) growth theory focuses on economic growth generated by the introduction of better-quality products. These dynamic general-equilibrium models capture the process of creative destruction as follows: first, sequential and stochastic R&D races are typically used to formalize the entrepreneurial risk, uncertainty, and fixed cost that are inherent in the innovation process; second, product obsolescence, which is based on the endogenous replacement of old, lower-quality goods by new, higher-quality ones, formalizes the Schumpeterian notion of creative destruction; and third, the assumption of patents granted to inventors of new goods formalizes the role of Schumpeterian temporary monopoly power that fuels technological change.

The presence of increasing returns and temporary monopoly power implies a divergence between the market and social optimum and leaves plenty of room for government intervention. In general, the welfare ranking between the social and market rates of Schumpeterian growth is ambiguous thanks to the presence of a few forces that create a divergence between social and private incentives to innovate. One force has been christened the *monopoly-distortion* effect. This force creates an incentive for overinvestment in R&D relative to the social optimum: firms are motivated by the instantaneous monopoly profit margin when engaged in R&D, which happens to exceed the increase in social value (measured by consumer surplus) generated by a typical innovation. Another countervailing force has been christened the *intertemporal-spillover* effect. This force creates a tendency for underinvestment in R&D relative to the social optimum: the social planner takes into account the fact that consumers benefit forever from an innovation. In contrast, being aware that their lives are finite (due to the process of creative destruction), private firms engaged in R&D discount the returns to innovation more than the social planner and invest less. This welfare ambiguity is present in both closed and open-economy Schumpeterian growth models.

First-generation models of Schumpeterian growth exhibit a counterfactual "scale-effects" property according to which more resources devoted to R&D are associated with a higher growth rate of total factor productivity (TFP), that is, output growth not accounted for by the growth in inputs, and the presence of a positive population growth rate must generate an unbounded (infinite) long-run growth rate of per capita income. In other words, according to these models, if R&D employment doubles, then the rate

of product creation and the economy's growth rate must also double. Since 1950, however, R&D employment in the United States and other advanced countries has more than doubled without generating any significant acceleration in TFP growth.

Since the mid-1990s, growth theorists have developed a second generation of scale-free, Schumpeterian growth models that fall into two distinct categories depending on the way of removing the scale effects property. Semi-endogenous Schumpeterian growth models incorporate diminishing returns to the stock of knowledge that affects the productivity of R&D resources by assuming that, as technology becomes more complex, sustained growth in R&D resources is needed to maintain a given rate of TFP growth. In other words, easier inventions are discovered first, and as the set of technological opportunities diminishes over time, it becomes more difficult to discover new products. Semi-endogenous growth theory predicts that the long-run growth rate of TFP depends only on the rate of population growth, and therefore it is not affected by policy-related parameters. In other words, semi-endogenous growth theory generates exogenous scale-free long-run Schumpeterian growth.

The second category of R&D-based growth theory consists of fully endogenous and scale-free Schumpeterian growth models. This approach to the removal of scale effects builds on the insight that aggregate R&D effort becomes less effective either because it is spread among more product lines (as new varieties are discovered), or because incumbents who face a risk of going out of business raise barriers to frustrate the R&D effort of challengers. Fully endogenous Schumpeterian growth models maintain the assumption of constant returns to the stock of knowledge of earlier endogenous growth models and generate endogenous long-run growth. In other words, with the exception that the size of an economy measured by its population level does not affect long-run growth, these models share the same properties as earlier endogenous growth models. Although the evidence against the empirical validity of earlier endogenous growth models is convincing, the ongoing debate on whether semi-endogenous or

fully endogenous Schumpeterian growth models are more empirically relevant is inconclusive. The terms *earlier*, *semi*, and *fully* endogenous growth models will be used to refer to first-generation, scale-free exogenous, and scale-free endogenous Schumpeterian growth models, respectively, to conserve space and to clarify the exposition.

Economic Openness and Growth Open-economy models of Schumpeterian growth constitute the backbone of dynamic trade theory and complement traditional trade theory by focusing on the analysis of the economic forces that determine the generation and international transfer of technology. They provide valuable theoretical insights into the patterns of growth and trade, global income distribution and poverty, and the effects of economic policies on the performance of the global economy.

Earlier Schumpeterian growth models analyzed the nexus between trade patterns and long-run growth using a variety of approaches. They generated product-cycle trade, which is based on the observation that many products are first discovered in advanced countries and then their production shifts to less advanced countries as their technology is imitated, within a context of a high-wage innovating North and a low-wage noninnovative South, or within the context of two Northern economies facing equal factor prices but differing in their factor endowments. They also identified the economic determinants of sustained comparative advantage in high-technology industries: countries with higher comparative labor productivity in R&D activities, or countries that are abundant in factors used intensively in R&D, such as human capital, will export high-tech products to the rest of the world.

Schumpeterian models have also analyzed the determinants of growth in open economies. Earlier endogenous growth models identified three broad channels through which economic openness affects long-run growth. First, trade, by increasing the size of the market, raises the profitability of R&D investment and increases the long-run rate of innovation and growth in all trading countries. Second, economic openness, by facilitating the international exchange of information, increases the scope of

knowledge spillovers, raises the productivity of researchers, and accelerates the rates of innovation and growth in the global economy. Third, trade openness, by reallocating economic resources across sectors and between R&D investment and manufacturing activities, affects the long-run rates of innovation and growth. This trade-induced "specialization" process, which is the major source of welfare gains in static models, has an ambiguous effect on long-run growth.

It should be noted, however, that the market-size-based effect of trade on growth can be traced to the scale-effects property of earlier endogenous growth models. Fully endogenous growth models predict more moderate effects of economic openness on growth. These effects operate through changes in relative prices and per capita reallocation of resources between R&D and manufacturing activities. For example, a reduction in international trade costs can accelerate the long-run rate of growth by increasing the flow of temporary monopoly profits and by shifting per capita resources from manufacturing production (that is, consumption) to R&D activities (that is, investment).

Globalization and Income Distribution Schumpeterian models of economic growth have provided valuable theoretical insights associated with the evolution of wage and income inequality within and across countries. The 1970s and 1980s witnessed an alarming rise in the demand for skilled labor and a decline in the demand for unskilled labor. These labor-market developments raised the relative wage of skilled workers in the United States and several developing countries and increased the unemployment rate of less-skilled workers in several advanced countries. Economic openness and skilled-biased technological change have been proposed as two competing explanations for the rise in the relative demand for skilled labor. In traditional trade theory, relative commodity prices represent the only channel that transmits the effects of trade openness on wages. The trade-based explanation for the rise in U.S. wage inequality has been rejected by evidence on U.S. relative prices, which have remained more or less constant during the period of rising wage inequality.

Unlike traditional trade theory, Schumpeterian growth theory views technological change as an endogenous process that could be affected by changes in the reward to innovation. The reward to innovation is proportional to the expected discounted profits associated with the discovery of new products. An increase in trade openness caused by a reduction in international trade costs can affect the profitability of R&D without necessarily causing any change in relative commodity prices. Under the reasonable assumption that R&D is a skilled-labor-intensive activity, Schumpeterian growth models predict that globalization increases the relative demand for skilled labor and accelerates the rate of technological progress. An increase in the relative demand for skilled labor can generate either a rise in the relative wage of skilled workers or a rise in the unemployment rate of less-skilled workers depending on the degree of labor-market flexibility. This novel mechanism has been formally established in the context of semi-endogenous and fully endogenous Schumpeterian models of economic growth.

The controversial issue of the dynamic effects of various components of globalization on the income gap between advanced (Northern) and poor (Southern) countries has drawn the attention of Schumpeterian growth theorists. An important strand of Schumpeterian models of North-South trade and growth has analyzed the income distributional effects of globalization-enhancing policies. The main insight of this literature is that any increase in the rate of imitation and/or decline in the rate of innovation reduces the North-South wage inequality measured by the Northern relative wage. In other words, faster international transfer of technology from North to South benefits Southern workers.

Government Interventions Schumpeterian models of economic growth have analyzed the long-run growth and welfare effects of a variety of government interventions. Policy instruments such as taxes and subsidies on R&D, production, and trade change relative product and factor prices and generate shifts in economic resources between consumption and R&D activities. In earlier and fully endogenous growth models, a policy-induced shift in per capita

resources toward R&D activities accelerates permanently the rates of innovation and growth. In semi-endogenous growth models this resource shift generates a temporary (as opposed to a permanent) increase in the rate of innovation. In the presence of asymmetric industries and countries, dynamic general equilibrium forces can reverse the well-intended effects of several policy interventions. For instance, R&D subsidies may cause a country to export fewer R&D-intensive goods and import more of them; and industrial policies that subsidize manufacturing activities in high-technology sectors may have detrimental effects on global long-run innovation and growth because they could raise the costs of R&D by shifting resources away from R&D activities.

Several North-South Schumpeterian growth models have analyzed the dynamic effects of stronger protection of intellectual property rights (IPR). Stronger IPR protection, modeled either as an increase in patent length or as a reduction in the rate of Southern imitation, reduces the rate of international technology transfer from innovating North to imitating South, raises the North-South wage gap, and has an ambiguous effect on the rate of innovation and global Schumpeterian growth. Even if stronger IPR protection increases the rate of Northern innovation in the short run, it could reduce the welfare of Southern consumers and could raise the welfare of Northern consumers by shifting production from low-price South to high-price North. Consequently, North-South models of Schumpeterian growth are well fitted to provide useful policy recommendations regarding the intense debate surrounding the Agreement on Trade-Related Intellectual Property Rights (TRIPS), which was ratified by the members of the World Trade Organization in 1995 and calls for stronger Southern IPR protection.

■ **Gulf Cooperation Council**

The Gulf Cooperation Council (GCC) was created in February 1981 by six Arab Gulf states: Bahrain, Kuwait, Qatar, Oman, Saudi Arabia, and the United Arab Emirates (UAE). The main motive for the creation of the GCC was to face the threat posed to the region's security by the Iran-Iraq war at that time. The aims of the GCC formation are to develop cooperation and integration among the member states on foreign and defense policies and to promote

common interest in economic, social, and cultural affairs. A customs union that allows no tariffs or other barriers to trade among members (as in free trade areas) and harmonizes trade policies (such as setting of common tariff rates) toward the rest of the world was created between GCC members in January 2004.

Members of the GCC share common features such as religion, language, historical background, and social life. The GCC economies depend on similar natural resources and have a comparable structural base. The GCC members also share the same sociopolitical system in which the states, ruled by kings and princes, own most of the natural resources and the large public sector dominates all aspects of the economy.

The GCC population as of 2005 was approximately 36 million. Saudi Arabia has the largest population base compared to the other five members. Approximately 38 percent of the total GCC population is composed of expatriates with no permanent residence. The proportion of nationals out of the total population varies from one country to another. This ratio is very small in Kuwait, Qatar, and the UAE (35, 27, and 22 percent, respectively), compared to Bahrain, Oman, and Saudi Arabia (62, 78, and 72 percent). Even though the GCC fertility rate is among the highest in the world, their economic dependence on foreign labor is not decreasing.

GCC social indicators depict a very positive human development profile. Life expectancy is well above 70 years, infant mortality is far below the world average, and the population per physician is very low. However, fertility rates in most GCC countries are among the highest in the world, reflecting generous family allowances provided by governments in order to increase the population base. Finally, education spending has contributed to declining illiteracy rates.

Expatriates constitute the largest percentage of the labor force in GCC countries. Table 1 shows that approximately one-third of the total labor force in GCC countries are citizens while two-thirds are expatriates. The percentage of citizen labor force in the states of Kuwait and the UAE is less than 20 percent. Only in Saudi Arabia is the percentage of citizens in the labor force slightly greater than 50 percent of the total labor force. The greatest majority of GCC employees are working in the public sector, and the average wages and salaries of GCC citizens are almost three times higher than those of expatriates.

GCC economies depend entirely on the production of oil, and all economic sectors revolve around revenues generated by oil exports. The exploration for oil began in the Gulf region in 1945. The Gulf oil has been important in the global energy market for many reasons. First, the oil reserves of the GCC are huge in comparison to the world's total reserves. The GCC oil reserves constitute around 50 percent of the world total. Second, the GCC plays a significant role in the supply of oil to the world market. The share of the GCC in total world production is approximately 25 percent. Third, geological factors such as the location of the onshore oil fields close to the deep Persian Gulf, the flow of the oil toward the sea, and the ease of drilling have helped the GCC's oil to be produced relatively more cheaply than the rest of

Table 1

Ministry of Planning in various GCC countries.

world's oil. Finally, the central geographical location of the Persian Gulf between the developed economies in the West and growing economies of East Asia has reduced transport costs and increased the significance of the GCC oil market.

Table 2 reveals that, at the end of 2005, oil reserves in GCC countries were approximately 470 billion barrels, oil products exceeded 15 million barrels per day, and oil revenue was approximately $187 billion. Saudi Arabia is the largest oil producer in the GCC countries, followed by Kuwait and the UAE. However, Qatar and Oman have much smaller oil reserves, and much less oil production and oil revenue, than these three members of the GCC. Bahrain seems to be losing its dependence on oil.

The petroleum and mining contribution to GDP in GCC countries constitutes 20 to 60 percent of total gross domestic product (GDP). This contribution is higher when oil prices rise. The contribution was the highest in Qatar (61 percent) and the lowest in Bahrain (22 percent) in 2005. The second most important economic activity is the services sector (wholesale and retail trade, transportation and communication, finance and insurance, real estate). The services sector contributes 20 to 30 percent of GDP. The contribution of the service sector in 2005 was 51 percent in Bahrain (which is no longer a major oil producer) and 15 percent in Qatar (which depends heavily on its production of oil and natural gas). The third most important sector is the government, which contributes 10 to 20 percent of GDP. The manufacturing sector plays a moderate

role in all members of the GCC. This sector contributes only 6 to 10 percent of GDP. The only exception is its contribution in the United Arab Emirates in 2005, which amounted to 14 percent. Contribution of the agricultural sector to GDP is negligible in most GCC countries and was only 4 percent in Saudi Arabia in 2005. The GCC members heavily subsidized the state-owned electricity, gas, and water sector.

The level of per capita income differs significantly among members of the GCC. Per capita income in the state of Qatar was the highest in 2005 ($39,101), while per capita income in Oman was the lowest ($9,939). Per capita income in all GCC members was approximately $14,346 in 2005.

The proportion of total expenditure on exports and imports constituted a significant proportion of GDP. Re-exporting is a major part of the Bahrain and UAE total exports (around 30 percent). The proportion of total expenditure on private consumption out of GDP is much lower than in countries with similar per capita income (around 35 percent) and is especially low in the state of Qatar (15 percent of GDP in 2005). Expenditure on public consumption was approximately 20 percent of GDP in the states of Kuwait, Oman, and Saudi Arabia in 2005.

The percentage of GDP devoted to gross fixed capital formation in the GCC countries varies from less than 15 percent in the case of Kuwait to 25 percent in the case of the UAE. The government carries out a large percentage of investment in these

countries. Public investment has been concentrated mainly in infrastructure and the oil sector, including petrochemical industries. Private fixed capital formation, on the other hand, was directed mainly to the construction sector and the (modest) manufacturing sector. Public investment is, to a great extent, autonomous of changes in demand and interest rates and is financed from government oil revenue. Private investment depends heavily on growth in private consumption, which is greatly affected by growth in government expenditure in the GCC countries. This suggests that total (public and private) investment in the GCC countries depends on lagged oil revenues.

The GCC countries depend heavily on the outside world for the supply of most of their needs (Metwally and Tamaschke 1980; Metwally and Daghistani 1987). This is because of the relatively weak productive capacity of these economies due to lack of resources, particularly labor, materials, and water. The downturn in oil prices after the end of 1982 resulted in a sharp reduction in GCC spending on imports (Metwally 1993). However, the proportion of GDP spent on imports of goods and services in 2005 (following the rise in oil prices) was approximately 40 percent. Moreover, available statistics suggest that the income elasticity of imports exceeds one in many GCC members (Metwally 2004a, b).

Many studies have developed econometric techniques and models to identify functional relationships in the GCC economies. Metwally (1987, 1993) attempted to examine the determinants of the external surplus or gap between exports and imports of the oil-producing members of the GCC. In spite of the sharp rise in oil prices during the 1970s, the GCC countries could not improve their external surplus per exported barrel. This indicated that the rise in oil prices was greatly matched by a larger increment in imports and by the fall in the volume of exports. Metwally tested the hypothesis that the external surplus balance varies inversely with GDP. In contrast to economic theory, the results showed that the external surplus is positively correlated with GDP in the case of GCC countries. The result was explained by the fact that total GDP in the GCC countries is dominated by oil revenues, which are owned by government and are not directly available for domestic expenditure. Thus an increase in oil exports would increase total GDP and add to the overall surplus. When non-oil income was used instead of total GDP, a significant negative correlation

was obtained between non-oil income and the external surplus. Metwally also tested the interaction between the economies of the GCC and the rest of the world. The oil exports of the GCC responded favorably to the increase in the share of the Organization of the Petroleum Exporting Countries (OPEC) in world oil supply and the increase in world oil consumption. Finally, the marginal propensity to import out of non-oil income was extremely high in all GCC countries. This resulted in an "import trap," i.e., a tendency to increase imports even when the value of exports is declining (Metwally 1993; Metwally and Rammadhan 2000; Metwally 2003).

Table 3 gives data on total trade and intra-trade of members of the GCC customs union during the period 1981 2005. It is clear that the rise in oil prices resulted in higher rates of growth of intra-imports and intra-exports of most members of the GCC (Metwally and Alsowaidi 2005). Also, most commodities produced in GCC countries are not substitutes for commodities imported from outside countries. A rise in oil prices results in an increase in intra-exports due to improvement of domestic productive capacity through use of advanced technology. The analysis of Kaul, Metwally, and Perera (2007) suggests that intra-trade of most GCC members is strongly influenced by oil prices. The results also suggest that intra-exports of Qatar, Saudi Arabia, and the UAE are positively related to their intra-imports. These results also indicate that there are very significant feedback effects in intra-trade of Qatar, Saudi Arabia, and the UAE. An increase in these members' intra-imports results in an increase in their importers' incomes. However, there are no significant feedback effects in intra-trade of Bahrain, Kuwait, and Oman. These members might benefit from giving more attention to dynamic benefits of their customs union.

■ health and globalization

Globalization interacts with health in several areas. Globalization directly affects economic outcomes, such as the level of income per capita, that may affect health outcomes, while health may affect the level or pattern of economic activities across countries. The dissemination of health-related know-how and internationally coordinated public health measures contribute to raising health standards globally. Increased movement of goods or people, however, also creates health risks arising from the dissemination of diseases or contaminated products.

Income, Inequality, and Health Higher income is associated with better health standards, both within and across countries. Cross-country studies find that aggregate health measures such as life expectancy are positively correlated with income per capita (see Pritchett and Summers 1996; Deaton 2004). The link between income and life expectancy appears to be strongest for low-income countries, but there also is more inequality in terms of health outcomes between these countries than among higher-income countries. Thus, although the potential health gains associated with higher incomes appear to be greatest in low-income countries, these countries are also where the impact of other factors on health outcomes is strongest, including (lack of) public health infrastructure or inefficiencies in the delivery of public health services, some of which, in turn, may also hold back improvements in income (Deaton 2004).

Rapid economic development is sometimes associated with an increase in income inequality, which may have implications for access to health services across income groups. Deaton (2003) points to the link between poverty and health outcomes, and finds little evidence for a role of inequality per se, however. Cross-country data on health care financing point to complex interactions between access to health care, poverty, and inequality. Financial sector development, and thus access to health insurance, is limited in many developing countries. Conversely, in developing countries the share of out-of-pocket expenditures in private health expenditure is higher, which implies that health risks are associated with higher risks to material living standards. For poor segments of the population, public health expenditure can compensate for the lack of health insurance, but the level of public health expenditures, their efficiency, and geographical access differ considerably across countries.

The correlation between increases in income and increases in life expectancy has motivated some studies trying to assess the contribution of each to improving living standards. Composite indexes, such as the Human Development Index of the United Nations Development Program, assign weights to measures of income, health, and possibly other indicators such as educational attainment. Some studies draw on microeconomic estimates of the valuation of mortality risks. Using this approach, Nordhaus (2002) suggests that the contribution of improved health to living standards has been of a magnitude similar to the contribution of improvements in gross domestic product (GDP) for the United States between 1900 and 1995, and Becker, Philipson, and Soares (2005) suggest that world

health inequality has been declining even if incomes have not converged.

Knowledge Flows and Health Technologies International knowledge flows have played an important role in falling mortality rates across countries. Deaton (2004) asserts that health improvements in developing countries in the 20th century "ultimately came from the globalization of knowledge, facilitated by local political, economic, and educational outcomes," including applications of the germ theory of disease, DDT spraying against malarial mosquitoes, the use of antibiotics against tuberculosis, and oral rehydration therapy.

The prominent role of knowledge flows points to the value of international cooperation to facilitate and speed up the dissemination of health technologies, and to assist in their implementation, which is one of the key mandates of the World Health Organization (WHO). Recent examples of internationally coordinated health programs include the Measles Initiative, which reportedly succeeded in reducing global deaths from measles by 60 percent (and by 75 percent in sub-Saharan Africa) between 1999 and 2005, largely through mass immunizations and improvements in care. Another major international health campaign was the WHO's 3 by 5 campaign and related efforts to reduce the incidence of HIV/AIDS and to improve access to antiretroviral treatment in low- and middle-income countries.

A key factor in the global dissemination of health technologies is the legal framework for the protection of intellectual property rights, including the Agreement on Trade-Related Aspects of Intellectual Property Rights (TRIPS), which requires all World Trade Organization member countries to meet certain minimum standards for the protection of intellectual property rights, including patents. Patents allow pharmaceutical companies to recoup the costs of drug development by charging prices that far exceed production costs. Although most essential medicines (according to the WHO definition) are no longer protected by patents, patent protection can complicate access to medicines for relatively new diseases, such as HIV/AIDS. The experience with antiretroviral drugs to treat HIV/AIDS also involved numerous ways of facilitating access to these drugs in low-income countries, however.

Apart from its effect on the dissemination of medical know-how and drugs, the legal environment also has implications for the direction of research. As most of the profits from new drugs arise from sales in high-income countries, pharmaceutical companies direct their research efforts toward drugs for these markets, rather than drugs addressing health issues that are more prevalent in low-income countries.

Health, Growth, and the Location of Economic Activity While higher income can buy better health, the state of health can also have implications for income levels and affect the location of economic activities. Most directly, healthier people are also more productive. Fogel (1993), discussing the effects of nutrition on increased labor supply in Britain between 1800 and 1980, argues that improved nutrition contributed to an increase in the labor force participation rate, and that a higher intake of calories increased workers' productivity. Together, Fogel estimates that these two effects account for 30 percent of economic growth in Britain over the 19th and 20th centuries.

Conceptually related are attempts to estimate the impact of health on productivity, using data on aggregate macroeconomic outcomes and health indicators. Among the wave of empirical studies on sources of growth starting in the early 1990s, numerous authors have included some measure of health, usually the level of life expectancy. For example, Bloom, Canning, and Sevilla (2001) find that one additional year of life expectancy raises GDP per capita by 4 percent; and Cole and Neumayer (2006) discuss the link between various measures of morbidity and total factor productivity. These studies, however, are usually not able to clearly distinguish between level of life expectancy and growth rate effects and — in light of the large range of proxies for health status used — offer few insights into the nature of the link between health and growth.

In addition to its effects on productivity, health may affect economic development through its impact on the rate of population growth. The logic of this is already present in the basic Solow growth

model, where higher population growth translates into a lower capital/labor ratio and thus lower output per capita. Along these lines, Acemoglu, Johnson, and Robinson (2006), studying the impact of declining mortality in the early 20th century, find that this has resulted in an increase in population growth and a slow-down in the rate of growth of per capita income. This effect has also played a role in explaining the limited impact of HIV/AIDS on economic growth in countries severely affected by the epidemic, as higher mortality translates to an increase in the capital/labor ratio; some studies, similarly, have illustrated the positive economic impact of health crises such as the Black Death and 1918 influenza epidemic on the incomes of survivors.

Another link between health and growth that has been intensively researched in recent years is the impact of health on institutional development. Acemoglu, Johnson, and Robinson (2003) highlight the role health conditions played in European colonial expansion. Where health conditions were hostile, Europeans set up extractive regimes with minimal investments of human resources and in institutional development, which tended to contribute little to the economic growth of the colonies. In environments more inviting to European settlers, European colonists were more likely to set up more egalitarian political and economic institutions that contributed more to the colonies' economic growth. The point of this institutional approach is that differences in health conditions have a persistent influence on economic outcomes through their impact on institutional development.

Although the evidence on the links between income and health suggests that health would improve with economic development, the link between globalization, development, and health may not be positive in all cases or for all regions or people involved. Specifically, health, environmental, and safety standards are generally less stringent in developing countries, which translates into a cost advantage for companies producing there. In a world of competitive markets, the stringency of health and other standards related to health may reflect legitimate societal preferences regarding the importance of achieving certain health outcomes compared to other development objectives such as raising incomes or reducing poverty. Thus a government may accept lower health and environmental standards to attract investment and pursue its broader development strategy, and employees may accept health risks in return for higher salaries.

The most compelling arguments against trade based on differences in health and environmental standards across countries rest on asymmetric-information, incomplete-market, or moral arguments. The correct pricing of health risks requires that both sides understand the risks involved, a condition that often does not hold in employment relations in developing countries. Similarly, the absence of effective regulations or weak contract enforcement means that companies are not held accountable for negative externalities associated with their activities. For example, in the case of disposal of toxic waste, part of the costs of such processes may be literally "dumped" on the local population, with little or no accountability for the originator. From a moral perspective, certain production methods (frequently quoted examples are child labor and exports of toxic waste) may be regarded as morally questionable, which could motivate legal provisions in the source countries of exports, or increasingly common public campaigns by nongovernmental organizations targeting consumer behavior.

Health Risks Associated with the Movements of Goods and People One of the defining characteristics of globalization is an increasing intensity of trade in goods, which also has some implications for global health risks. Contaminated food and other supplies can amplify the spread of diseases globally, especially if long incubation periods are involved or the disease is new and the associated risks are not well understood. For example, one important channel of transmission of HIV in the early stages of the epidemic was the trade in contaminated blood products.

Most commonly, however, trade-related health risks are associated with contaminated food or other products for human consumption. One example is a spate of deaths in Panama in 2006 linked to drugs containing contaminated ingredients imported from

China. More frequently, health hazards associated with imported food arise from contamination with pesticides or industrial waste (e.g., in seafood) or bacteria such as salmonella.

Globalization complicates the task of ensuring food safety standards. First, national efforts to attain certain standards in food production need to be complemented by measures to ensure the quality of imported products, which could involve inspections of imported products at the port of entry, harmonization of standards, or measures to ensure that certain standards are met in the source countries (e.g., EU beef import requirements). At the same time, mass production of and increased trade in food and other products means that such products are sold over large regions and across borders. Effectively responding to a health emergency thus also requires the ability to trace products back to their origin and possibly recall affected products.

Globalization has also expanded the trade in illicit drugs. The United Nations Office on Drugs and Crime estimates that the value of the global market in illicit drugs was U.S. $90 billion in 2003, and that about 200 million people (5 percent of the world's population) consumed illicit drugs at least annually, and 110 million at least monthly. By far the most widely used drug is cannabis. The largest consumer market for illicit drugs is North America, accounting for about 44 percent of the world market, while the most important producing regions are Latin America for cocaine, and various Middle Eastern and Asian countries for opiates.

Apart from trade in goods, a second element of globalization is the increased intensity of the movement of people, including a massive increase in global air travel. Between 1950 and 2005, the number of air travelers increased by a factor of 60 (from 31 million to 1.9 billion), and the number of passenger kilometers multiplied by a factor of 123 (from 28 million to 3.4 billion). As a consequence, it is increasingly difficult to contain an infectious disease locally or regionally, an issue that has gained increased attention internationally following the SARS outbreak and in light of the risks attributed to avian flu. Similarly, the global spread of an epidemic such as the 1918 influenza would, under current conditions, occur much faster, allowing less time for preventive measures or for preparation of a health response, and might lead to bottlenecks in the availability of essential medicines.

MARKUS HAACKER

■ Heckscher-Ohlin model

The Heckscher-Ohlin (H-O) model, which originated in Heckscher (1919) and Ohlin (1933) and was formalized and given narrower interpretation by Samuelson (1948), differs from the Ricardian theory of comparative advantage in two key respects. First, the Ricardian theory assumes only one factor of production, which robs it of any ability to address the internal income distribution effects of international trade. In contrast, the H-O theory allows for two factors of production, which opens the door to internal income distribution effects of trade. Second, whereas the Ricardian theory relies on the differences in technology across countries as the source of international trade, the H-O theory assumes the existence of the same technology everywhere and relies on the international differences in factor endowments as the basis of trade.

Because the H-O model allows economists to analyze the income distribution effects and plausibly gives a central role to intercountry differences in factor endowment rather than technology, which diffuses relatively rapidly internationally, it has come to serve as the main workhorse of trade theorists. The model leads to the conclusion that each country exports the goods that use its relatively abundant factor more intensively and such exports lead to a rise in the real and relative return to the latter. Symmetrically, the country imports products using its scarce factor more intensively, which lowers the real and relative return to the latter.

Recently, increased wage inequality in the rich countries as measured by skilled-to-unskilled wage has brought this model further to the center of the policy debate. Those favoring protection over free trade argue that just as the H-O model predicts, trade liberalization by skilled-labor-abundant rich countries has led to the rise in skilled-to-unskilled wage. Pro-free-trade economists argue, however, that the real culprit behind the phenomenon is technological advances in skilled-labor-intensive industries, which has led to a shift in demand in favor of skilled labor.

The Setting and Principal Results The following will largely focus on the strict two-factor, two-good, and two-country version of the H-O model, as formalized by Samuelson (1948). This version is narrower than originally conceived by Ohlin (1933) but is now widely used by trade economists. To formally outline the key assumptions and structure of the model, call the countries Home Country (HC) and Foreign Country (FC), products Corn (C) and Shirts (S), and factors Land (T) and Labor (L). Assume constant returns to scale in the production of each good. This means doubling the use of each factor in C doubles the output of C. The same holds true for S. Goods C and S require different technologies. Specifically, we assume that C is land intensive in the sense that at any given set of factor prices, the land-labor ratio in the production of C is higher than that in S: $T_C/L_C > T_S/L_S$. Here

T_C denotes the quantity of land employed in the production of C. A similar interpretation applies to L_C, T_S, and L_S. By implication, S is relatively labor intensive. Assuming both goods are produced in equilibrium and there is perfect competition in all markets, the H-O model leads to the following two theorems:

The Stolper-Samuelson (1941) theorem: An exogenous increase in the relative price of a good leads to an increase in the real and relative return to the factor used more intensively in that good and a decrease in the real and relative return to the other factor. For example, an increase in the price of C increases the real and relative return to land, which is used more intensively in the latter. It also leads to a decline in the real and relative return to labor, which is used more intensively in S.

The Rybczynski (1955) theorem: Holding the goods prices constant, an increase in the endowment of a factor leads to a proportionately larger increase in the output of the good using that factor more intensively and a decline in the output of the other good. For example, holding the goods prices constant, a 1 percent increase in the endowment of labor would raise the output of S, which uses labor more intensively, by more than 1 percent and lower the output of C.

Suppose we additionally assume that HC is land abundant relative to FC. Formally, using an asterisk to distinguish the variables associated with FC, $T/L > T^*/L^*$. The two countries have the same technology of production available. These two additional results follow:

The Heckscher-Ohlin theorem: The opening to trade leads each country to export the good using its abundant factor more intensively and to import the other good. For example, the land-abundant HC exports the land-intensive good C and imports the labor-intensive good S.

The Factor-Price Equalization theorem: Absent transportation costs, the opening to trade equalizes not only the goods prices but factor prices as well. That is to say, in a trading equilibrium, the HC ends up with the same real and relative wage and rental price of land as FC.

Deriving the Theorems Let us denote the wage by w and the rental price of land by r. The proportion of land to labor in C, T_C/L_C, depends on w/r. Specifically, as labor becomes more expensive relative to land, firms economize on the use of labor and employ land more liberally. In other words, as w/r rises, they raise the land-labor ratio. This relationship is shown by curve CC′ in figure 1.

We assume that C is land intensive relative to S. This means that at each wage-rental ratio, C uses more land per unit of labor than S. In terms of figure 1, the line showing the land-labor ratio in S at different wage-rental ratios, SS′, lies everywhere below CC′.

Represent the land-labor ratio of HC in figure 1 by T/L. We can then determine the range of possible wage-rental ratios in HC. At a sufficiently high relative price of C, the economy specializes completely in this product. In this case, the land-labor ratio in C coincides with the economy's land-labor endowment ratio, and the wage-rental ratio is given by $(w/r)_{min}$ in figure 1. At the other extreme, if the price of C is sufficiently low, the economy specializes completely in S, the land-labor ratio in S coincides with the economy's land-labor ratio, and the wage-rental ratio is given by $(w/r)_{max}$ in figure 1. At an intermediate price ratio, both goods are produced and the wage-rental ratio is between the two extremes.
Figure 1
Factor prices and factor intensities

As we move from $(w/r)_{min}$ toward $(w/r)_{max}$, we increase the output of S and reduce that of C. With the wage-rental ratio rising during this movement, both sectors raise the land-labor ratio, and thus allow the labor-intensive sector S to expand.

Figure 2 shows the output changes just described using the construction of the production possibilities frontier (PPF). Given technology and factor endowments, MN shows the PPF of HC. The absolute value of the slope of the PPF at any point gives the opportunity cost of the product on the horizontal axis (C) in terms of the product on the vertical axis (S). The PPF is bowed out, which means that the marginal opportunity cost of each product in terms of the other rises as we expand the output of that product. For example, as we move from M toward N, the absolute value of the slope rises, meaning that the opportunity cost of C in terms of S rises with the rising output of C. This rising cost is the result of the imperfect substitutability between land and labor. To expand the production of C, which is land intensive, we must lower the land-labor ratio in each product. The more we substitute labor for land, the lower the marginal return to such substitution and the higher the marginal cost of further expansion.

Under perfect competition, production takes place at a point where the marginal cost equals the price.

Therefore, letting $(P_C/P_S)^0$ represent the relative price, the economy would produce at a point such as Q^0 in figure 2 where the price line is tangent to the PPF. The tangency ensures that the relative price equals the marginal opportunity cost of production.

Starting at Q^0, suppose we consider a small increase in the relative price of C. This would lead to an increase in the output of C and decrease in the output of S. At the original factor prices, the expansion of C would require more land per worker than S releases. This creates an excess demand for land and excess supply of labor. The return to land rises and that to labor falls. That is to say, a rising price of C, which is land intensive, is associated with a declining w/r ratio.

Let us plot these relationships in figure 3. In the right-hand panel, curve RS shows increasing supply of C relative to S as a function of the relative price of C, P_C/P_S. In the left-hand panel, curve RR' shows an inverse relationship between wage-rental ratio and the relative price of C. This latter relationship partially represents the Stolper-Samuelson theorem: it connects the goods prices to the relative factor prices. The representation is only partial since the Stolper-Samuelson theorem also relates the price change to the real factor returns.

To elaborate on how the Stolper-Samuelson theorem works, consider a move from autarky to free trade by HC. Suppose that the world relative price of C exceeds its autarky price. This means HC would export C and import S under free trade. As already

Figure 2
The production equilibrium
Figure 3
The Heckscher Ohlin factor price equalization theorems

explained, the higher price of C brought about by trade would increase the output of C and lower the wage-rental ratio (see left-hand panel in figure 3). The income distribution within HC would move against workers and in favor of landowners. The critical question is whether the workers could still be better off in real terms due to the decline in the relative price of good S brought about by trade. The Stolper-Samuelson theorem answers this question in the negative: the wage declines not just in terms of good C whose price rises but also in terms of S whose price falls.

To see how this works, note that the firms employ workers up to the point where the wage equals the value of marginal product of labor. Denoting the marginal product of labor in C and S by MPL_C and MPL_S, respectively, we have

$$w = P_C . MPL_C = P_S . MPL_S \qquad (1)$$

Rearranging, this equation implies

$$w/P_C = MPL_C \text{ and } w/P_S = MPL_S \qquad (2)$$

That is to say, the purchasing power of the wage in terms of a commodity equals the marginal product of labor in that commodity. This purchasing power rises or falls as the marginal product of labor in the product rises or falls. A similar relationship applies to land: the purchasing power of rental income in terms of a good rises or falls as the marginal product of land in the production of that good rises or falls.

To determine what happens to the marginal product, recall that as C expands, the wage-rental rate falls, which leads to a decline in the land-labor ratio in each product. The decline in the land-labor ratio implies a decline in the marginal product of labor and a rise in the marginal product of land in terms of each product. It follows that the real return to labor falls and that to land rises in terms of each good. In effect, the decline in the wage is sharper than the decline in the price of good S, leaving the workers worse off even if they spend their entire wage income on that good.

Next, let us consider the effects of a change in the factor endowments at a given goods price ratio. To take a concrete example, let us increase the endowment of labor by 5 units. From curve RR′ in figure 3, we know that as long as we hold the goods price

constant, the relative factor prices remain constant as well. Figure 1 then tells us that the land-labor ratios in the two goods must also remain unchanged. The economy must absorb the additional labor supply without altering the land-labor ratios. This constraint immediately rules out a simple-minded division of the additional units of labor between the two sectors without reallocation of land since such allocation would necessarily change the land-labor ratio in each product.

To see what kind of reallocations would be compatible with full employment at unchanging land-labor ratios, begin by placing the entire additional labor supply in the labor-intensive good S. To maintain the original land-labor ratio, this requires drawing land from C to work with the additional five units of labor in S. But since C must also maintain its original land-labor ratio, it would not release land without releasing labor. This means that S must absorb not just the 5 new units of labor but also those released by C as it releases land.

For concreteness, suppose the land-labor ratio is 3 in C and 2 in S. Then each time C releases 3 units of land, it releases 1 unit of labor. But since the land-labor ratio in S is 2, it employs 1.5 units of labor for each 3 units of land. In other words, moving 3 units of land out of C allows S to absorb 1 unit of labor released by C plus a half unit out of the new 5 units. Therefore, if we move 30 units of land from C to S, the latter would absorb 15 units of labor that are exactly equal to the sum of the 10 units released by C and 5 new units. Full employment is achieved at unchanging land-labor ratios.

This example illustrates that a given expansion of the endowment of a factor leads to a proportionately larger expansion of the sector using that factor more intensively and a contraction of the other sector. We thus have the Rybczynski theorem, named after T. M. Rybczynski (1955), who first noted the result. The result is generalized in the sense that if both factors expand but the land-labor ratio declines, the output of the land-intensive good relative to the labor-intensive good falls as well.

The Rybczynski theorem is a key building block of the Heckscher-Ohlin theorem. Recall that we

have assumed FC to be relatively labor abundant: $L^*/T^* > L/T$. An immediate implication of the Rybczynski theorem is that at any given price ratio, FC produces less C relative to S than HC. Therefore, denoting by Q_i the quantity of output of good i (i = C, S), we have $Q_C^*/Q_S^* < Q_C/Q_S$ at each price ratio. This is shown by the relative supply curve RS* in figure 3.

Assuming the relative demand depends only on the relative price and the consumers in HC and FC are identical, we can represent the demand in the two countries by a common demand curve RD in figure 3. The autarky equilibriums in HC and FC are then given by A and A*. It is straightforward that under autarky the land-intensive good C is cheaper in the land-abundant country HC and the labor-intensive good S is cheaper in the labor-abundant country FC. Therefore, when the two countries open to trade, each country would export the good that uses its abundant factor more intensively, just as the Heckscher-Ohlin theorem predicts (see above).

Finally, observe that, as the left-hand panel of figure 3 shows, under autarky the wage-rental rate is higher in the labor-scarce HC than in the labor-abundant FC. The opening to trade leads to a rise in the relative price of C in HC. This leads to a fall in the wage-rental rate there. The opposite happens in FC: the relative price of C declines there, which leads to a rise in the wage-rental rate. Therefore, the factor prices converge between the two countries. Assuming no transport costs, trade would equalize the goods prices. But as goods prices equalize, the wage-rental rate would equalize as well.

Given the same wage-rental rates in the two countries at the free-trade equilibrium, figure 1 tells us that the land-labor ratios across countries would also equalize for each product. This would then lead to the equalization of the marginal products and hence real factor prices of each product. Free trade would lead to the equalization of the relative and real factor returns internationally, as predicted by the factor price equalization theorem (see above).

Trade and Wages In the contemporary policy literature, the Stolper-Samuelson and factor price equalization theorems have played a crucial role.

Between the late 1970s and early 1990s, the real and relative wages of unskilled workers in relation to skilled workers in the rich countries declined. The ratio of skilled-to-unskilled wages, a measure of wage inequality, rose almost 30 percent in the United States. This period also coincided with a rapid expansion of trade between developed and developing countries. This led many to link the changes in the wages to the opening to trade via the Stolper-Samuelson theorem. If we think of the two factors in the H-O model as skilled and unskilled workers, the developed countries are importers of unskilled-labor-intensive goods. The H-O theory then predicts that opening to trade with the developing countries would push down the real and relative wages of the unskilled. In the spirit of the factor price equalization theorem, some observers have gone so far as to suggest that the wages of the unskilled in the developed countries may be pushed down to the levels prevailing in the developing countries.

Trade economists disagree with this diagnosis and argue that trade with the poor countries cannot explain the bulk of the increase in the wage inequality. They cite four reasons in support of their position.

- Trade works to lower the unskilled wage by lowering the relative price of unskilled-labor-intensive goods. But a study by Lawrence and Slaughter (1993) pointed out that the relative price of unskilled-labor-intensive goods had actually risen since the late 1970s. By itself this point is not decisive, however. In principle, trade may have lowered the relative price of unskilled-labor-intensive products but other factors such as sharply declining costs of skilled-labor-intensive products may have reversed this decline. Lawrence and Slaughter only looked at the ex post change in the prices but did not decompose them according to the sources of the change. Therefore, their analysis remains incomplete.

- Extra imports from the developing countries during the relevant period account for less than 2 percent of the total expenditure

in the United States. This is the point made by Krugman (1995). He argues that such a small proportionate expansion of trade can simply not explain the large increase in wage inequality. This is a valid and important point.

- During this period, wage inequality rose in many developing countries as well. If the simple-minded Stolper-Samuelson theorem was driving the outcome, developing countries should have experienced a decrease in wage inequality. Given that they export unskilled-labor-intensive goods, the Stolper-Samuelson theorem should have driven their real and relative unskilled wages up. This did not happen.

- Technical change that shifted labor demand in favor of skilled labor and away from unskilled labor provides a far more compelling explanation for increased wage inequality in both rich and poor countries. Technological change has been concentrated in skilled-labor-intensive goods, and it has also moved progressively toward greater use of skilled labor. This change has shifted the demand in favor of skilled labor in both rich and poor countries and led to increased wage inequality in both regions.

The Heckscher-Ohlin model is the principal workhorse of trade economists. It shows that countries export goods that use their abundant factors more intensively and import goods that use their scarce factors more intensively. Given that imports bring goods that use the scarce factors more intensively, they lower the demand for and hence the returns to such factors locally. This conclusion has led to widespread claims that the imports of unskilled-labor-intensive goods from the poor countries have lowered real and relative wages of unskilled workers in the rich countries. Most trade economists disagree with this conclusion, arguing that a shift in technology in favor of skilled labor and away from unskilled labor is the true cause of the decline in the fortunes of unskilled workers.

■ hedge funds

Hedge funds are broadly defined as private invest ment pools that are not available to the general public. They are more lightly regulated and have wider investment flexibility than public investment companies such as mutual funds, which pool money from many investors and invest in stocks, bonds, and other securities. Hedge funds can buy and sell secu rities in many financial markets, representing long and short positions, respectively. In addition, they can use leverage and derivatives, which are financial instruments whose value derives from some under lying asset or price.

The first hedge fund was started in 1949 by Alfred Winslow Jones, a financial journalist, who believed that this new investment style could deliver good returns with more stability than investments in stock mutual funds. The hedge fund industry has grown from 600 funds in 1990 to more than 8,500 in 2005. During the same period, total assets in hedge funds have grown from $40 billion to more than $1 trillion. This growth has been driven by the stable investment performance of the industry, especially when com pared to the swings of the stock market. Because they pursue very active investment strategies, hedge funds are even more important than their asset size would suggest. As a result, hedge funds have become major players in international capital markets.

Types of Hedge Funds The hedge fund industry is much more heterogeneous than the mutual fund industry because of the greater latitude in investment style. Funds are typically classified into the following categories:

Global macro funds, which take positions in global markets (stocks, fixed-income in vestments, currencies, commodities);

Long/short equity funds, which buy and sell stocks;

Equity market neutral funds, where the long positions are exactly offset by short posi tions so as to create a zero, or neutral ex posure to the stock market;

Arbitrage funds, which take long and short positions in securities such as fixed-income and convertible bonds;

Event-driven funds (merger arbitrage and dis tressed debt), which take positions driven by corporate events such as mergers, takeovers, reorganizations, and bankruptcies.

Long/short equity funds represent the largest sector of the industry, with approximately one-third of the funds.

Investment Strategy Consider a typical hedge fund, which has both long and short positions in stocks. Say the initial capital is $100. This represents the equity, or net asset value. The fund buys $100 worth of stocks and sells $50 worth of other stocks. Short-selling is achieved by borrowing a stock and selling it in the hope that its price will fall later, at which time the stock can be bought back and trans ferred to the lender. In such case, the borrower keeps the difference between the (higher) earlier sales price for the stock and the (lower) later purchase price. In the event that the stock price goes up, however, the borrower loses the difference between the (lower) ear lier sales price and the (higher) later purchase price.

This type of investment strategy (short-selling) has two advantages relative to mutual funds, which typically are allowed to have long positions only. First, it allows the hedge fund manager the flexibility to buy assets that are viewed as undervalued, for ex ample, and sell assets that are overvalued. In contrast, the manager of a long-only fund cannot implement a view that an overvalued asset is going to fall in price, because the manager cannot short the asset.

Second, it has less exposure to the direction of the stock market (called *directional exposure*) than a long- only position. Indeed, to "hedge" a bet can be defined

as protecting against loss by taking a bet for a countervailing amount against the original bet. In hedge investing, the directional exposure to the market, also called *beta*, is reduced. As a result, the overall risk of loss is reduced as well. Hedge funds attempt to create risk-adjusted performance, also called *alpha*, without taking too much directional risk.

As an example, a manager could buy Google's stock because it is expected to go up by 25 percent, out of which 10 percent is due to the overall stock market and 15 percent to the company itself. The manager, however, is not confident about the direction of the stock market and is afraid the 10 percent expected profit on the market could turn into a loss. To hedge against a market fall, the purchase of Google is offset by a short position of the same size on the market. If the market falls by 10 percent, the transaction will create a profit of 15 percent minus 10 percent, for a 5 percent total gain on Google's stock, plus a gain of 10 percent on the stock market, for a total of 15 percent. Of course, if the market indeed goes up by 10 percent, the short position will lose 10 percent, leading to a net profit of 15 percent. Therefore, this hedge locks in a total profit of 15 percent irrespective of the market.

Another example of trading strategy that exploits inefficiencies in the market would be to identify two assets with similar characteristics, such as two long-term Treasury bonds with close maturities and similar interest rate risk. An *arbitrage* opportunity would arise if the bonds were to trade at sufficiently different prices. The hedge fund manager would then buy the cheap bond, say at $99, and sell the expensive one, say at $100. This position should create profits if the bond prices later converge. Even if successful, however, such strategy will produce only small profits, on the order of $1 per transaction (after taking into account the costs of making the transaction). To magnify profits, the hedge fund will typically use *leverage*. This involves the use of credit to increase the size of the position relative to the equity. For instance, the hedge fund with $100 in equity could be buying and selling $990 and $1,000 worth of bonds (using 10 percent equity and 90 percent credit), which will multiply the profit by a factor of 10.

This wider investment flexibility combined with hedging has proved successful. Hedge funds have generally performed well relative to other investments, especially when adjusting for risk. For fund managers, hedge funds provide greater remuneration than traditional investment funds. Typical investment management fees for mutual funds range from a fixed 0.5 percent to 2 percent of asset value. In contrast, hedge funds commonly charge a fixed 2 percent of assets plus 20 percent of positive returns.

Other categories of hedge funds include *multistrategy funds*, which invest across the categories listed earlier, and *funds of funds*, which invest in individual hedge funds.

Investment Issues Hedge funds take risks in the expectation of high profits. Because of the leverage inherent in most hedge funds, this naturally leads to failures. Leverage increases the profits, but also the risks. In our previous example, a leverage of 10 transforms a profit of $1 into $10. On the other hand, a loss of $1 now becomes $10. In the limit, a very large loss of $10 becomes $100, wiping out the $100 equity. Indeed, hedge funds have a high rate of disappearance, from 5 to 11 percent per year. In most cases, this reflects an investment or operational failure that leads to the closing down of the fund. Mutual funds also fail, but less frequently.

Hedge funds present some specific problems not shared by mutual funds. Because hedge funds often invest in assets that are not traded on organized exchanges such as the New York Stock Exchange, some positions can be difficult to value. Thus the proper *valuation* of assets is a major issue for hedge funds. Assets that are not traded often are called illiquid.

Illiquidity explains the common practice of imposing a lockup period, which is the minimum amount of time during which investor money is to be held in the fund, and a redemption notice period, which is the time required to notify the fund of an intended redemption. Lockup periods average 3 months, and can extend to 5 years; redemption notice periods average 30 days.

Another problem with hedge funds is the *lack of transparency*. Because hedge funds follow proprietary trading strategies, they are generally reluctant to re-

veal information about their trading ideas or positions. Having no information about positions has serious disadvantages for investors. It becomes difficult to monitor the risk of the fund, to aggregate the risk profile of the fund with the rest of the investor's portfolio, or even to detect fraud.

Regulatory Issues The rapid growth of hedge funds has led to regulatory concerns on several issues. One is the *protection of investors*. Investors can lose money in hedge funds. Direct investment in hedge funds, however, is restricted to professional investors, such as wealthy individuals, pension funds, endowment funds, and other institutional investors. The general presumption is that such investors are conscious of the investment risk they take and can therefore fend for themselves. Also, hedge fund managers generally have significant personal investments in the fund, which partially aligns their interest with that of other investors.

Fraud is another concern. Fraud occasionally occurs in all investment activities, and there is no evidence that hedge fund advisors engage disproportionately in fraudulent activities. Even so, there have been some high-profile cases of hedge fund fraud which, combined with the rapid growth of the industry, have led regulators to look more closely at hedge funds.

Another issue is *protecting market integrity*. Market participants should not attempt to dominate or manipulate markets. Like other large investors, hedge funds are subject to rules against market manipulation.

Regulators also worry about the potential for *systemic risk*. Systemic risk arises when default by one institution has a cascading effect on other financial institutions (the first institution's default being of such a magnitude as to cause the failure of its creditors, which in turn default on their obligations to other institutions, and so on), thus posing a threat to the stability of the entire financial system. Indeed, the spectacular failure of the hedge fund Long-Term Capital Management (LTCM) in 1998 is said to have endangered the world financial system. LTCM was a hedge fund founded in 1994 by John Meriwether, the former head of bond trading at Salomon Brothers. The fund lost $4.4 billion in 1998, forcing the Federal Reserve Bank to organize a private bailout to avoid disruptions in financial markets.

The primary mechanism for regulating hedge fund risk is the discipline provided by creditors, counterparties, and investors. The leverage of the hedge fund industry is provided by counterparties such as banks and brokerage firms. It is in these lenders' best interest to make sure that loans to hedge funds are controlled and have sufficient collateral. Holding collateral can provide effective protection against default. The LTCM crisis revealed lax lending standards. Since then, however, the Counterparty Risk Management Policy Group (2005) has reported a general improvement in counterparty risk management practices.

Role of Hedge Funds Hedge funds have become important conduits of capital in international financial markets. Like any other speculator trading in the expectation of making profits, hedge funds enhance market liquidity by generating more trading activity, leading to deeper and more liquid markets. In addition, many hedge funds use relative value strategies, which buy underpriced assets and sell overpriced ones. These actions should help to push prices faster to their equilibrium values, which enhance market efficiency.

■ hedging

Hedging refers to the reduction of an existent risk by the elimination of exposure to price movements in an asset. Hedging stabilizes markets since it removes potential shocks to balance sheets that can destabilize the financial system. Also, if hedging is complete at the aggregate level, long and short positions can be matched with less price volatility. Those taking a short position want to sell an asset because they be lieve its price is going to fall, while those going long want to buy it since they expect a rise in the asset price. Unhedged short-term foreign borrowing played a major role in escalating the East Asian crisis of 1997 98.

Currency risk is hedged through contracts that protect the home currency value of transactions de nominated in a foreign currency, removing the ex posure to exchange rate fluctuations. The currency risk is transferred to another party who wants to take an exposure in opposite direction.

The value of a derivative hedging contract is based on the underlying basic spot exchange rate. Stan dardized contracts are available, or customized (over-the-counter, or OTC) contracts can be designed. An Indian exporter, for example, can sell the dollars due to him in the future on the dollar-rupee forward market, through a forward contract or an agreement to sell the dollars at a certain future rate for a certain price reflecting current prices. Hedging can also be accomplished informally, for example, if an exporter takes a foreign loan. Then if the home currency de preciates he will gain in export income but lose as the home currency value of his debt rises, so that his net exposure is low.

Hedging versus Speculation If the exporter does not sell the future dollars forward, thus entering into only one leg of a foreign currency transaction, he is speculating on a belief the rupee is going to depre ciate. He may also take a short position on the rupee using derivative products. Speculation is the act of aiming to profit by betting on a predicted one-way price movement. Thus it is risk-taking, not risk-re ducing. It is sometimes argued that since speculators buy when prices are low and sell when prices are high, rational speculative activity stabilizes markets. But this does not always follow, since speculators buy when there is a high probability of price appreciation and sell when the probability is low, and thus can cause cumulative movements.

Buying and selling currency in the spot market requires an initial cash payment. Forward contracts require no such initial payment, but can lead to a gain or a loss in the future transaction depending on changes in the exchange rate. Therefore, forward markets provide extra leverage to a speculator in comparison to spot markets. Options, another type of derivative, increase the leverage further since they confer a right but not an obligation to make a transaction. The option has an initial cost but then does not require buying or selling currency either in spot or in the forward market. Therefore it provides even higher leverage, at a price.

Incentives to Hedge Hedging does not neces sarily rise with the availability of more market in struments, since the same derivative can be used for hedging or for speculation leveraging initial capital many times. Incentives to induce hedging are more important. Markets, instruments, and opportunities,

with some restrictions on currency derivatives, existed in East Asia prior to the crisis, yet hedging was inadequate (Burnside et al. 2001).

Speculation dominates if there are aspects of the financial structure that encourage taking too much risk, such as lowering liability for promoters or managers; or if policy, such as one-way movement of exchange rates, creates opportunities for speculation. A firm's cost of borrowing is minimized if it is fully hedged so that bankruptcy does not occur. Since creditors normally set interest rates to cover expected default under bankruptcy, the risk-free interest rate is lower. So a fully hedged firm should get loans at lower rates. But if government guarantees the loan repayments and covers bankruptcy costs the incentive to hedge risks disappears (Burnside et al. 2001). Results are similar if laws make it difficult for creditors to recover loans.

If domestic interest rates are high, the high borrowing costs raise the opportunity costs of buying hedging instruments. Even if an importer holds a dollar deposit as an informal hedge, he sacrifices potential high domestic interest earnings. Similar considerations affect the hedging activities of banks.

Regulatory authorities sometimes put restrictions on derivative products that could facilitate hedging, in order to curb speculation. But with modern technology and regulation it is possible to distinguish between hedging and speculative foreign exchange market activities. Hedging transactions are charged lower margins on modern exchanges and their tax treatment also differs. If it is possible to monitor the use of derivatives it is not necessary to ban them.

Psychological factors also undermine rational hedging decisions. People prefer a sure gain, but they prefer an uncertain outcome with a small probability of a gain to a sure loss. Hedging involves a small sure loss or cost, and without it there is a small probability of a gain. Thus they are willing to forgo hedging and undertake more risk than is rational. But proper "framing" sensitive to psychological attitudes can reduce risk-taking behavior. An understanding that concentration on core business makes them more competitive and reduces volatility of profits may make firms more willing hedgers.

■ HIV/AIDS

HIV/AIDS refers to the human immunodeficiency virus and the associated acquired immunodeficiency syndrome, which were first recognized as a global health issue in the early 1980s. In 2006, about 40 million people globally were living with HIV/AIDS, including 25 million in sub-Saharan Africa, and the epidemic claimed almost 3 million lives in that year. The international response has involved a rapid scaling-up of aid and an expansion of prevention and treatment programs, as well as the establishment of two specialized international agencies to deal with the epidemic the Joint United Nations Program on HIV/AIDS (UNAIDS) and the Global Fund to Fight HIV/AIDS, Tuberculosis, and Malaria (GFATM).

Epidemiology and Demographics The most important modes of transmission of HIV are sexual contact with an infected person, sharing needles for injected drug use, mother-to-child transmission before or during birth or through breast-feeding, and transfusions of infected blood or blood clotting factors. HIV/AIDS is largely asymptomatic during the

first years after infection. Over time, HIV/AIDS progressively damages the immune system, resulting in increased susceptibility to opportunistic infections (e.g., pneumonia, tuberculosis, and certain types of cancer) and, eventually, death. Antiretroviral treatment suppresses the virus and slows down the progression of the disease.

The region most affected by HIV/AIDS is sub-Saharan Africa; however, the high HIV prevalence rate of about 6 percent for the region masks very substantial differences in HIV prevalence across countries, ranging from less than 1 percent (e.g., in Senegal) to more than 20 percent in Botswana, Lesotho, Swaziland, and Zimbabwe (all data on HIV prevalence relate to the population ages 15 49, at end-2005). Although HIV prevalence appears to have stabilized in sub-Saharan Africa since around 2001, it has been spreading rapidly in Eastern Europe and Central Asia. Outside Africa, the country with the largest population of people living with HIV/AIDS is India.

Development Impact From an economic development perspective, the most direct impact of HIV/AIDS is the increase in mortality and consequent decline in life expectancy associated with it. For some of the most affected countries, it is estimated that HIV/AIDS has reduced life expectancy by more than 20 years. Development indexes such as the United Nations Development Program's Human Development Index, which combines measures of income, education, and health, suggest that HIV/AIDS has been the most significant single factor to adversely affect development in recent decades. Another consequence of the increase in mortality among young adults associated with HIV/AIDS is an increase in orphan rates, which are estimated to have reached 20 percent of the young population in some of the countries most affected by the epidemic.

The evidence regarding the macroeconomic impacts of HIV/AIDS is less clear. In light of the slowdown of the growth of the working-age population, there is a consensus that growth of gross domestic product (GDP) also slows as a consequence of HIV/AIDS. Studies applying a neoclassical growth model typically find that HIV/AIDS reduces GDP per capita through declining productivity and a fall in capital per worker that occurs as health-related spending lowers the national saving and investment rates. These effects are at least partly offset by the impact of increased mortality on the capital/labor ratio (mortality decreases the denominator, causing an increase in the overall ratio). The latter effect, however, partly dissipates if investment flows are sensitive to changes in the rate of return to capital.

On the microeconomic level, HIV/AIDS is associated with income losses (as household members become too sick to work and as working time is devoted to caregiving) and with increased health-related expenditures. Microeconomic data, largely from sub-Saharan Africa, therefore suggest an adverse impact of HIV/AIDS on incomes, consumption, and wealth of affected households. This is most pronounced during illness or around the time of death; households appear to partly recover later on. To understand the impact of HIV/AIDS on poverty or inequality, it is necessary to take a broader perspective, also covering households that may gain financially as they benefit from income opportunities associated with deaths in other households, most obviously when household members fill HIV/AIDS-related vacancies. Overall, the sparse evidence suggests that an increased volatility in incomes associated with higher mortality translates into an increase in poverty.

International Response On a global level, recognition of the health, humanitarian, and development challenges posed by HIV/AIDS has translated into an unprecedented effort to contain the epidemic and expand access to treatment. Important steps of the international response were the establishment of UNAIDS and the GFATM, and the United Nations General Assembly Special Session on HIV/AIDS (2004). In financial terms, the scale of the international response to HIV/AIDS has expanded very rapidly. Consistent estimates for HIV/AIDS-related spending are available for low- and middle-income countries only; for these, spending has increased from about U.S. $300 million in 1996 to about U.S. $9 billion in 2006, of which about U.S. $6 billion

was financed by external aid. The most important funding agencies are the GFATM and the U.S. President's Emergency Plan for AIDS Relief.

National responses to HIV/AIDS depend on the state of the epidemic in a country. To various extents programs emphasize public prevention measures in schools and work places, prevention and awareness measures targeted at high-risk groups, strengthening the health care system, improvements in care for people living with HIV/AIDS, measures to mitigate the social impacts (including support for orphans), and programs to expand access to treatment.

The most effective prevention measures are those targeted at groups at high risk of contracting and passing on the virus, including promotion of condom use among sex workers and provision of sterile needles to injecting drug users. Those measures, together with the perceived impact of the epidemic, have been credited with increasing awareness and reducing risky behavior. Social attitudes, particularly toward men who have sex with men, or the illegal nature of some of the risky behavior such as injecting drug use, can complicate the implementation of prevention programs, however.

In the most affected countries in Southern Africa, the epidemic is generalized, and prevention efforts are geared toward raising awareness and reducing risk behavior across the population, especially among young adults, through the education system, media and advertising campaigns, and public endorsements by leading politicians. Although HIV prevalence has risen to double-digit levels in numerous countries in spite of these efforts, in 2005 6 many of the most affected countries reported increasing HIV awareness and somewhat falling prevalence rates among young adults.

The most significant development in the early years of the 21st century regarding the response to HIV/AIDS was the decline in the costs of antiretroviral treatment. In many developing countries, certain forms of antiretroviral treatment were available in 2007 at costs of around U.S. $300 annually, down from about U.S. $10,000 in 2000. This development reflected voluntary agreements with drug companies, often under the threat of compulsory

licensing to a local producer, and the fact that only a certain range of antiretroviral drugs was available at these low prices, which allowed for some market segmentation between industrialized and developing countries.

Falling prices of drugs and strong international financial support have contributed to a rapid expansion in access to treatment. UNAIDS reports that the number of people receiving antiretroviral treatment in low- and middle-income countries increased from 400,000 to 1.3 million between 2003 and 2005 (corresponding to a coverage rate of about 20 percent), with sub-Saharan Africa accounting for the bulk of the increase.

Continued spread of the disease and the longer survival of those already infected make the management of an increasing number of people requiring treatment the principal challenge in addressing the epidemic in the near future. Additional challenges include extending the gains made to countries with weaker public health systems, where progress in expanding access to treatment has been less pronounced so far, and managing the fiscal challenges and long-term commitments associated with the expansion in these health programs.

UNAIDS and the Global Fund The perception of HIV/AIDS as a threat to global health, beyond the capacity and expertise of any single international organization, resulted in the establishment of a unique institution, UNAIDS, in 1994. UNAIDS coordinates the HIV/AIDS-related activities of its cosponsoring organizations, which are 10 (initially 6) organizations under the UN system. Although a relatively small organization on an international scale (its annual operational budget amounted to about U.S. $58 million in 2006 7), it is also financing part of the activities of its cosponsors on HIV/AIDS, as well as interagency activities (U.S. $42 million annually in 2006 7). Moreover, cosponsors include all of their HIV/AIDS-related activities in UNAIDS's Unified Workplan, which brings the total of HIV/AIDS-related spending coordinated by UNAIDS to about U.S. $1.3 billion annually for 2006 7, about one-sixth of global spending on HIV/AIDS. Additionally, UNAIDS is a key provider of public

information on the epidemic, including the annual Report on the Global AIDS Epidemic, which is the most important regular publication on HIV/AIDS.

The GFATM is primarily a funding agency. It receives about 95 percent of its funding from government sources. Grants typically underwrite comprehensive country programs, which are coordinated nationally, for several years. Between 2002 and end-2006, the GFATM disbursed U.S. $3.3 billion, of which U.S. $1.35 billion was disbursed in 2006. Of the accumulated grant portfolio, HIV/AIDS accounts for the lion's share (56 percent), followed by malaria (27 percent) and tuberculosis (15 percent). Although public institutions play the most important role as implementing agencies (accounting for about half of GFATM-supported funding), many of the national responses are implemented by nongovernmental organizations (about a quarter of funding) or by faith-based and academic organizations. Reflecting the burden of HIV/AIDS in the region, sub-Saharan Africa accounts for more than half of GFATM funding.

■ home country bias

Home country bias, or simply *home bias*, usually refers to a situation in which the proportion of foreign equities held by domestic investors in their portfolios is too small relative to the predictions of standard portfolio theory. The extent to which equity portfolios are concentrated in equities of the investor's domestic market is a notable feature of international portfolio investment and has remained an important yet unresolved empirical puzzle in financial economics since the 1970s (Levy and Sarnat 1970). Since portfolio theory is the foundation of asset pricing theory, the empirical evidence that investors may not optimize along objective risk-return trade-offs as portfolio theory predicts has important implications for our understanding of the way security prices are set.

Standard models of optimal international portfolio diversification imply that equity investors have not diversified internationally nearly as much as they should. If investors only care about the mean and the variance of the real return of their portfolio, one would expect investors, as a first approximation, to hold the world market portfolio of stocks. In empirical finance literature, home bias is essentially measured by the underweighting of foreign securities in portfolio allocation relative to market-capitaliza-

tion weights. For example, by the end of 1989, Americans held roughly 94 percent of their equity portfolio in the U.S. stock market, even though the U.S. equity market comprises less than 48 percent of the global equity market (French and Poterba 1991). By the mid-1990s only about 10 percent of U.S. equity wealth was invested abroad, still much less than what it would have been had the U.S. investors held the world market portfolio (Tesar and Werner 1998). This phenomenon exists in other countries as well. A study based on worldwide equity fund holdings data in 1999 and 2000 documents the existence of home bias in every single country in its sample of 48 countries across the globe (Chan, Covrig, and Ng 2005). The literature has also shown that home bias exists not only among individual investors but also among institutional investors.

At the country level, the benchmark for measuring home bias is the share of equity of that country in the world market portfolio. For example, U.S. equity market capitalization accounts for about 50 percent of the world, and therefore the benchmark for U.S. portfolio diversification is 50 percent. At the individual level, the specific optimal mix depends on an individual's utility function, which should include factors such as risk aversion and investment horizon. Foreign holdings of all U.S. based mutual funds (who are institutional investors) that invest in international stocks are considered foreign investment in the literature.

Possible Explanations of Home Country Bias
International financial markets offer a means for diversification across markets. Most investors do not fully exploit this risk-sharing opportunity, however, but instead hold large shares of their portfolios in domestic equities. Earlier studies in the literature mainly provide theoretical explanations for the home bias. One major explanation is that there are barriers to international investment such as governmental restrictions on foreign and domestic capital flows, foreign taxes, and high transaction costs associated with international investments (Errunza and Losq 1985). Many financial economists, however, have found that even though the barriers to international investment have fallen dramatically, foreign owner-

ship of shares is still extremely limited and much smaller than one would expect in the absence of these barriers. Home bias is prevalent even among investors with relatively low costs of transacting in financial markets such as institutional investors. Other explanations include investors' desire to hedge against inflation risk, deviations from purchasing power parity (Adler and Dumas 1983; Cooper and Kaplanis 1994), and the price uncertainty of human capital or other nontraded assets (Eldor, Pines, and Schwartz 1988; Stockman and Dellas 1989). By holding sufficient amounts of domestic assets, risk-averse investors may hedge against price uncertainty of the goods they consume, since the average return on the portfolio is high (low) when consumption becomes expensive (inexpensive). None of these factors, however, can fully explain the observed reluctance of investors to diversify their holdings internationally.

An alternative view attributes home bias to empirical mismeasurement of the home bias. Some researchers find that, after incorporating empirical uncertainty into the analysis, there may be no home bias because foreign diversification does not lead to a statistically significant improvement in portfolio performance, though the general validity of this thesis remains in doubt (Bekaert and Urias 1996; Pastor 2000).

As investor behavioral factors have been proposed to explain various anomalies in finance since the 1990s, familiarity has become the most dominant explanation of the home country bias puzzle. Familiarity is associated with a general sense of comfort with the known and discomfort with, or even fear of, the alien and distant, which adds a nonpecuniary dimension to the traditional risk-return trade-off emphasized by portfolio theory. Huberman (2001) finds that familiarity breeds investment, and paucity of international diversification is only one of the implications of this tendency to invest in the familiar. Familiarity can feed into the home bias puzzle through two channels: "pure" familiarity effect due to geographic proximity (such as language, culture, and distance) and, more important, information asymmetries caused by distance, which include low

visibility of foreign firms, an inability to monitor the firms, and low credibility of financial information (Kang and Stulz 1997). Separating out pure familiarity effect from informational asymmetries, however, remains a challenge for the empirical literature. Some studies document that even within their foreign portfolios   however small these foreign holdings may be   investors prefer the stocks of foreign countries that are closer (Portes and Rey 2005) and whose equity markets are more, not less, correlated with their own (Chan, Covrig, and Ng 2005). Other studies find that familiarity-caused home bias is not only international, but also regional. For instance, U.S. investment managers exhibit a strong preference for locally headquartered firms in their domestic portfolios, where local investments reflect a true informational advantage (Coval and Moskowitz 1999). In addition, in Finland, there is evidence that investors are more likely to hold and trade stocks of Finnish firms that are located close to them, that communicate in their native language, and that have chief executives of the same cultural background (Grinblatt and Keloharju 2001).

Although the various factors just mentioned have been shown in the literature to explain the home bias to some extent, no single explanation seems to fully account for the extent of home bias. Nevertheless, attempts to explain home bias have helped raise questions to guide further studies on the issue.

Home Country Bias in Macroeconomics The home country bias also applies to real, not just financial, investments. Indeed, the oft-documented high positive correlation between a country's long-term savings rate and its investment rate suggests that money saved in a country is invested in that country rather than in the (possibly foreign) country that offers the best return. A closely related phenomenon is the so-called consumption home bias in macroeconomics, which refers to the lack of risk sharing observed in consumption co-movements across countries. Intuitively, the equity home bias puzzle and consumption home bias puzzle may be linked, yet home bias in equities is neither sufficient nor necessary for home bias in consumption (Lewis 1999). On the other hand, home bias in portfolio holdings and home bias in consumption may have some common causes such as various costs of international transactions (Obstfeld and Rogoff 2001). Further, understanding about the potential link between the two puzzles may rely on a better unified understanding of consumption and equity prices.

■ **host country**

See location theory

■ **hot money and sudden stops**

Hot money, also known as *mobile capital*, refers to short-term private capital that flows across borders into different markets in search of higher returns and can be easily reversed. Hot money consequently makes a country susceptible to "sudden stops." The sudden stop problem, first emphasized by Calvo (1998), refers to an abrupt cessation in foreign capital inflows and/or a sharp capital outflow concurrent with a currency/balance-of-payment crisis. Notable episodes of sudden stop crises are the financial crises that hit Mexico in 1994, Thailand and Korea in 1997, Indonesia, Malaysia, and Russia in 1998, and Argentina in 2001.

There is a growing body of literature that attempts to define and measure sudden stops. One definition of a sudden stop is any episode in which two con ditions are met: (1) there is a significant reversal of capital inflows (a decrease in the financial account of at least 2 standard deviations below the country-specific sample mean), and (2) the current account deficit is reduced in either year t or in $t+1$ (Calvo, Izquierdo, and Talvi 2006). Another definition of a sudden stop is an event in which a currency crisis and a current account reversal (an increase in the current account surplus of more than 3 percent of GDP) occur simultaneously (Hutchison and Noy 2006).

What leads to a sudden stop? Even after ac counting for all macroeconomic fundamentals that may cause a capital outflow, a large unexplained component remains, which has been linked to herding behavior (Chari and Kehoe 2003).

Sudden Stops and Output Contractions Re gardless of the exact definition, sudden stops lead to a large, though short-lived, negative impact on output growth that is substantially greater than the impact associated with a currency or financial crisis without a sudden stop. This abrupt reversal in foreign credit inflows, in conjunction with a realignment of the exchange rate, typically causes a sharp drop in do mestic investment, domestic production, and em ployment. The recovery from these types of crises seems to be rapid, though it is usually not accom panied by full resurgence in capital inflows or by a recovery of domestic investment. There is evidence that sudden stops generally have a larger adverse impact on output in countries relatively closed to trade and with greater exchange rate fixity (Edwards 2004).

The question that follows is: What are the exact mechanics by which mobile capital leads to a finan cial crisis? The crisis-inducing nature of bank loans/ debts is based on an open economy version of the bank panic model (Diamond and Dybvig 1983). Following some negative shock, depositors, con cerned about the safety of their savings, attempt to

withdraw en masse (which occurs because, given the "first-come-first-served" rule of deposit withdrawals, depositors all rush to withdraw their money before the banks fail). Since the banks' liquid asset/reserves (cash available for withdrawals) are often less than their potential obligations (demand deposits), they are forced into the premature liquidation of long-term investments. Given the partial irreversibility of investments, they obtain a lower return on liquidation. In the open economy, if the foreign currency revenues obtainable in the short term are less than the corresponding short-term potential foreign currency obligations, the banks are "internationally illiquid" (Chang and Velasco 1999), while creditors, such as foreign banks, are unwilling to roll over short-term interbank loans, especially for emerging markets. The sudden termination of bank finance that follows forces the abandonment of potentially solvent investment projects. This consequent decline in capital formation indeed, capital destruction leads to a sudden output/economic collapse.

The maturity mismatch story leading to a possible bad equilibrium in the event of a bank panic is well known, but there are many other possible channels of output contraction as well. Another prominent explanation relies on a "Fisherian" debt-deflation channel (Fisher 1933). In these models, deflation, triggered by an endogenous occurrence of a sudden stop when credit constraints become binding in high-debt states, leads to lower marginal returns to factors of production; this leads, through a debt-deflation amplification process, to a large decline in economic activity. The debt-deflation multiplier can be even more severe: firm bankruptcies may cause banks to become ever more cautious, reducing lending to other firms, and thus inducing a further fall in credit (Mendoza 2006).

Adverse balance sheet effects an increase in liabilities that is not matched by a corresponding increase in assets, due to a combination of currency depreciation following a reversal in hot money and unhedged (uninsured) borrowing in foreign currency are another channel through which sudden stops could adversely affect the real economy (Rajan and Shen 2006).

Importance of Financing via Foreign Direct Investment Economies that finance their current account deficits mainly through foreign direct investment (FDI) generally are less susceptible to sudden stops than are economies that experience high levels of hot money inflows. Thus, Hausmann and Fernández-Arias (2000) refer to short-term debt as "bad cholesterol" as it is motivated by "speculative considerations" such as exchange rate expectations. This type of financing is the first to exit in times of trouble. The resulting boom-bust cycle of capital flows in the 1990s inflicted great damage on many emerging economies.

Of course, short-term debt is not the only form of liquid liability. An alternative and more complete measure of illiquidity is mobile capital, or international capital markets, which refers to short-term bank loans plus portfolio investment in the form of equity and bond issues in offshore markets. Equity investment at least shares in the risk of falling market values, while long-term bond issues are less liquid. But FDI is seen as "good cholesterol" because it is bolted down and is relatively irreversible in the short run. It flows in because it is attracted by long-term prospects; it enhances the productive capacity of the country and produces the revenue streams necessary to cover future capital outflows (if they occur) without increasing the overall indebtedness of the economy.

Available summary statistics of private capital flows to developing economies suggest, consistent with conventional wisdom, that FDI has been the most resilient form of external financing (for instance, see Chuhan et al. 1996; Sarno and Taylor 1999). Empirical analysis suggests that emerging economies most prone to currency crashes tend to have a relatively smaller share of FDI in total capital inflows and a relatively higher share of short-term external debt (Frankel and Rose 1996). Other studies have confirmed that short-term indebtedness is a robust predictor of financial crises (Rodrik and Velasco 1999).

A potential criticism of the conventional view regarding differing degrees of stability of various capital flows is that complex interactions between

FDI and other flows are not taken into account. Therefore examining each flow individually, particularly during short periods of time (such as year-to-year variations) may not be a reliable indicator of the degree of risk of various classes of flows at best and could be highly misleading at worst (see Bird and Rajan 2002, and references cited there).

Contrary to popular belief, FDI itself, which is a form of external finance, is not "bolted down," though the physical assets it finances are. Foreign investors could use the physical assets as collateral to obtain a loan from banks and place the funds abroad. In other words, the foreign direct investor may hedge the firm's FDI exposure by borrowing domestically and taking short-term capital out of the country. Hence a firm may be doing one thing with its assets and a completely different thing with the manner in which it finances them. This appears consistent with the Malaysian capital flows data during the crisis where, as noted, portfolio outflows in 1997 sharply outweighed the cumulative inflows between 1980 and 1996. Apparently the portfolio outflows must have entered from some other account (such as FDI or bank loans) (Bird and Rajan 2002). Indeed, the distinction between portfolio and FDI flows in the balance of payments can be somewhat arbitrary, and the proportion of FDI flows in aggregate capital flows may be overstated. Small differences in equity ownership are unlikely to represent substantially different investment horizons.

All of this suggests that the casual presumption that the switch from hot money to FDI alone will automatically safeguard a country against sudden stops and output contractions should be viewed with a degree of caution.

**ASHIMA GOYAL, ILAN NOY,
AND RAMKISHEN S. RAJAN**

■ illegal drugs trade

Despite the lack of reliable estimates on other illegal markets, the trade in prohibited narcotics and other psychoactive drugs is generally considered to be the illegal activity with the largest turnover worldwide. The *2005 World Drug Report* of the United Nations Office on Drugs and Crime (UNODC) includes a systematic effort to produce a comprehensive set of estimates. For illicit drugs as a whole, the UNODC estimates a total of almost $322 billion in retail sales in 2003; $94 billion in wholesale revenues; and $13 billion in producer sales (UNODC 2005).

The largest market, according to the UN calculations, is cannabis herb (normally called marijuana), which has a retail market size of $113 billion. Marijuana is followed by cocaine ($71 billion), the opiates ($65 billion), and cannabis resin (popularly called hashish, with $29 billion). The markets for synthetic drugs (properly called amphetamine-type stimulants and including methamphetamine, amphetamine, and ecstasy) total about $44 billion. Though derived from an economic model, these figures are in reality guesstimates and have to be treated with great caution. The basis inputs that are needed for such calculations data on production, prices, and quantities exported, imported, and consumed are themselves often estimates and frequently based on deficient data.

If compared to global licit exports or global gross domestic product (GDP) (respectively, $7,503 billion and $35,765 billion in 2003), the estimated size of the global illicit drug market may not appear to be very large. Total retail drug expenditures correspond to 0.9 percent of global GDP and drug wholesale revenues represent only 1.3 percent of global exports measures. The size of the global illicit drug market is not insubstantial, however. Illicit drug wholesale revenues account for 14 percent of global agricultural products and are much higher than the export value of most licit agricultural commodities (UNODC 2005).

The global drug market also involves a considerable number of people. According to the 2006 UNODC estimates, about 200 million people currently use illicit drugs at least once a year (about 5 percent of the world population age 15 64). Cannabis is by far the most popular and widespread illegal drug: out of the 200 million total, 162 million are cannabis users. Cannabis is followed by synthetic drugs (some 35 million people), which include amphetamines (used by 35 million people) and ecstasy (almost 10 million people). The number of opiate users is estimated at some 16 million people, of which 11 million are heroin users. Some 13 million people use cocaine at least once a year. A large proportion of drug users can be found in Asia. More than 60 percent of the world's amphetamine users and more than half of opiate users reside there (UNODC 2006; Paoli, Greenfield, and Reuter 2008). Asia accounts only for a small portion of total retail expenditures, however: $35 billion or 11 percent. With $142 billion (or 44 percent) and $106 billion (or 33 percent), respectively, North America and Europe account for the bulk of total retail expenditure

estimates (UNODC 2005), simply because retail drug prices are much higher there than in developing nations.

Drugs and Source Countries The two most dangerous plant-based drugs, heroin and cocaine, are produced in a small number of poor countries, which are often thousands of miles away from many end-users. Virtually all the cultivation of the coca bush (from which cocaine is made) is concentrated in three Andean countries: Colombia, Peru, and Bolivia, accounting for 63, 25, and 11 percent respectively of world production in 2005. Most cocaine hydrochloride is processed in Colombia and from there is exported into the United States and Europe (UNODC 2006).

From the late 1980s on, Afghanistan and Burma effectively "owned" world opium production, with a fringe of second- and third-tier producers contributing only modestly. Together, Afghanistan and Burma (or Myanmar, as it was renamed by the military dictatorship in 1989) accounted for more than 95 percent of world production in 2005. After 2001, however, the two-country dominance began shifting to one-country dominance, with Afghanistan accounting for an increasing share of world production Afghanistan's share of the total was more than 88 percent in 2005. Although it accounted in 2005 for less than 1 percent of world's heroin production, Colombia has since the mid-1990s become one of the major suppliers of the U.S. market. With slightly higher figures (1.5 percent of total production), Mexico is also an important source of heroin for the U.S. market (UNODC 2006; Paoli, Greenfield, and Reuter 2008).

The cultivation of cannabis is much more decentralized than that of opium and coca so much so that in 2006 the UNODC identified 176 countries or territories where cannabis is produced. This spread is primarily due to the great adaptability of the cannabis plant, which grows well in virtually every inhabited region of the world and can be cultivated with little maintenance in small plots or even indoors. In addition, unlike most other illicit drugs, cannabis products can be consumed with little processing after harvesting. Thanks to these two char-

acteristics, users can feasibly cultivate their own supply even in countries that rigorously apply the world prohibition regime. The U.S. authorities, for example, report that about two-thirds of the cannabis consumed in the country, predominantly in the form of marijuana, is domestically produced. The main foreign supplier of marijuana in the United States is Mexico. Hashish, the cannabis resin that is particularly popular in Europe, predominantly comes from Morocco (UNODC 2006).

Even more than cannabis, synthetic drugs are rarely trafficked across long distances because they can be easily manufactured in small and mobile laboratories in, or close to, areas of consumption. Hence, for example, the majority of the ecstasy pills consumed in Europe is produced in the Netherlands and, to a much lesser extent, in Belgium and some Eastern European countries. Likewise, the U.S. demand for methamphetamine is traditionally supplied by clandestine laboratories in California, several Midwestern states, and Mexico. Reflecting Asia's lion's share of the synthetic drug market, Burma is the world largest producer of methamphetamine (UNODC 2006).

Evolution of Drug Markets and Variable Characteristics of Suppliers Notwithstanding the large number of illegal drug users worldwide and the magnitude of the world drug economy, the illegal drug trade is a relatively new phenomenon. In fact, only in the last three decades of the 20th century did it assume mass proportions. Until about the beginning of the 20th century, all psychoactive drugs could be freely produced and consumed not only in Asia and Latin America, but also in Western countries. The production, trade, and consumption of opium, coca, and their derivatives began to be severely regulated and then largely prohibited (except for limited medical purposes) only after the first International Opium Convention was concluded in The Hague in 1912. The new international drug control regime, whose enforcement was entrusted after World War I to the League of Nations and after World War II to the United Nations, seemed quite successful at first. During the 1920s, 1930s, and 1940s the consumption of all prohibited substances rapidly declined in

the United States, Europe, and many Asian nations (scholars debate the extent to which the interwar decline is attributable to increasing prohibition rather than other factors, above all, changing medical and public attitudes toward drugs; see Courtwright 2001; Berridge 1999). Under pressure from the United States, cannabis trade and possession were also increasingly restricted and, finally, subjected to the international drug control regime in the early 1960s.

From the 1960s onward, the demand for heroin, cocaine, and cannabis rose again, first in the United States and then in Western Europe. At the end of the 20th century, it also grew in the second (former communist) and third-world countries. The postwar expansion of illicit drug use was caused by contingent events such as the Vietnam War, which brought thousands of young American soldiers into contact with heroin and macrosocial changes. Among the latter, two are most important: (1) the rise of a youth mass subculture, which resorted to illegal psychoactive substances to distinguish itself from the mainstream culture, and (2) technological progress, which made communication, travel, and trade in both legal and illegal commodities easier and faster.

From the 1960s onward, the rising demand for illicit drugs fostered the development of drug distribution systems able to transfer drugs from producers to consumers. In the beginning, illegal drugs were imported by the consumers themselves, who used some of them and sold the rest within a close circle of friends. It was a sort of "ants trafficking." Soon, however, in both the United States and Western Europe the professional role of the drug dealer began to consolidate. In a few years, the development of a large-scale drug market fostered the progressive entry of professional criminals into the drug business.

In source countries, where the state authorities are often unable or unwilling to enforce the international prohibition regime, large organizations have sometimes emerged to coordinate opium poppy and coca cultivation and to process heroin and cocaine. In northern Burma, for example, the refinement and export of heroin were first organized by the nationalist Chinese Kuomintang Army and, more recently,

by several armies representing local ethnic minorities. Much of the coca cultivation in Colombia also takes place in the inland areas controlled by guerrilla and paramilitary movements, particularly the FARC (Fuerzas Armadas Revolucionarias de Colombia).

In developed countries, the constraints deriving from the illegal status of the drugs have so far prevented the consolidation of large-scale, hierarchically organized drug-trafficking enterprises. These constraints arise from two facts: all illegal market actors particularly drug traffickers and dealers are obliged to operate (1) without the state and (2) against the state.

Since the goods and services they provide are prohibited, illegal market suppliers operate without the state; they cannot resort to state institutions to enforce contracts and have the violations of contracts prosecuted. As a result, property rights are poorly protected, employment contracts can hardly be formalized, and the development of large, formally organized, enduring companies is strongly discouraged.

All suppliers of illegal commodities specifically drugs are also required to operate against the state, that is, under the constant threat of being arrested and having their assets confiscated by law enforcement institutions. They therefore try to organize their activities to assure that the risk of police detection is minimized. Incorporating drug transactions into kinship and friendship networks and reducing the number of customers and employees are two of the strategies that drug entrepreneurs most often employ to reduce their vulnerability to law enforcement efforts (Reuter 1985).

Empirical research confirms these insights. In Europe and North America, the great majority of drug deals, even those involving large quantities, are carried out by numerous, relatively small, and often ephemeral enterprises. Especially at the intermediate and lower levels, many dealers work alone, either to finance their own drug habits or, more rarely, to earn fast money. Many drug distributors are members of ethnic minorities who either exploit direct connections to source countries or are pushed into dealing by lack of rewarding alternatives in the legitimate

economy. At the retail level and in closed settings, drugs are also often distributed by inconspicuous persons who have no contact with the underworld.

For the same reasons, the relationships among illegal drug enterprises generally involve competition rather than collusion. The best evidence against control is simply the ease with which new sellers enter and the speed with which dealers depart. There may be rents for various capacities, but certainly no power to exclude. Throughout Europe and North America, moreover, drug-dealing firms are price-takers rather than price-givers: that is, none of them is able to influence the commodity's price appreciably by varying the quantity of the output it sells. The continuing decline of prices during the 20-year period 1985 2005 at all levels of the market in heroin and most other drugs suggests that, if markets power ever existed, it has by now been dissipated.

The danger that the contemporary illegal drugs industry represents for the world economy is not limited to its turnover and the number of people it involves as producers, traffickers, and users. Two further aspects need to be considered. The industry is a major source of corruption, violence, and instability in a number of drug-producing and transit countries its collateral effects being occasionally reinforced by the war on drugs itself. Moreover, the international routes and networks that have been developed for the transportation of illegal drugs from source countries to the final consumer nations (and for bringing back the money the other way round) can be used for a plurality of other illicit goals, ranging from human smuggling and trafficking to terrorism financing.

■ import substitution industrialization

Import substitution industrialization (ISI) is a trade and economic policy based on the premise that a developing country should attempt to substitute products it imports with domestically produced substitutes. The policy has three major tenets: (1) an active industrial policy to promote a domestic industrial base producing strategic substitutes, often involving strong public sector investment in infrastructure and in "strategic" sectors, and the establishment of development banks to support these ac-

tivities; (2) protective barriers to trade (namely, tariffs and quotas to protect new or infant industries) and changes in the internal terms of trade against traditional primary exports; and (3) a monetary policy that rations foreign exchange, with multiple exchange rates to channel it preferentially to the imports of noncompetitive intermediate and capital goods. Generally, a distinction is made between a first "easy" phase of ISI, during which mostly nondurable goods are produced, and later more "mature" phases in which import substitution deepens, producing nondurable consumer as well as intermediate and capital goods, and (in some cases) more emphasis is given to export promotion (by the imposition of export incentives on old layers of import protection).

Historical Origins The first experiments with ISI were launched and sustained by the industrializing countries of Europe, North America, and Russia in the 19th century in order to overcome their relative economic (and political) backwardness vis-à-vis the industrial leader, then the United Kingdom (Gerschenkron 1962; Chang 2002). Early theoretical justifications for ISI include List (1841) and Manoïlesco (1928). The most coherent post World War II formulations of and justifications for ISI appear in Prebisch (1950), Nurkse (1959), and Gerschenkron (1962). Important reviews of the evolution of ideas about ISI are Bruton (1998) and Waterbury (1999).

The Rationale for ISI Import substitution policies were adopted by many low-income developing nations during the early 1950s as a means to escape from the primary commodity specialization trap and to promote industrial diversification. Specialization in labor-intensive primary commodities was considered undesirable because of declining world markets for primary products, the limited scope for technological progress in primary production, and the long-term deteriorating terms of trade of primary commodities, which caused low-income countries to have to pay relatively more for manufactured goods imported from industrialized countries. Further motivation for ISI was provided by the lack of adequate external financing, in combination with a reluctance to devalue the exchange rate (for fear of its inflationary effects), and the high levels of (agricultural) protection in the industrialized countries.

Industrialization of the developing world was considered imperative: only by the transformation of productive structures toward manufacturing could average labor productivity be raised so as to generate a higher standard of living (through increased real wages) and to reduce the incidence of poverty and destitution. Crucial to the generation of increased (manufacturing) productivity growth was the development of substantial technological capabilities, including technical knowledge, quality control practices, entrepreneurial and managerial skills, and work habits (Amsden 2001). The buildup of such technological capabilities is a path-dependent process in which accumulated experience plays the crucial role; it involves learning by doing, adaptation, and induced technological change as well as the development of manufacturing entrepreneurial and working classes. ISI was regarded as essential in kick-starting the development of such technological capabilities. While the initial costs of industrial production are higher than former import prices, the economic rationale for ISI is that, given time, (1) the industry will eventually be able to reap the benefits of large-scale production, technological learning, manufacturing experience (learning by doing), and lower production costs (the so-called infant industry argument for tariff protection), and (2) the balance of payments will be improved as fewer manufactured goods are imported.

ISI Policy Instruments The typical strategy is first to erect tariff barriers or quotas on the importation of strategic commodities and then to try to set up a domestic industry to produce the goods imported; often, this involves cooperation with foreign companies encouraged to set up their plants behind the wall of tariff protection and given various tax and investment incentives. Tariff protection is supplemented by numerous quantitative and direct controls on the availability of foreign exchange. The other major policy instrument is the exchange rate, which is generally overvalued (relative to a free trade situation) in order to keep the domestic price of

capital goods low. Often, *multiple* exchange rate systems are used instead of trade policy to implicitly tax competitive imports and traditional exports and subsidize complementary imports. Domestically, ISI policies include strong public-sector investment in infrastructure and in strategic sectors, including energy and irrigation, the establishment of development banks to support these activities, industrial policy regulating domestic investment, and price and fiscal policies to change the domestic terms of trade against agriculture and traditional primary exports (Bruton 1998; Amsden 2001).

The Logic behind ISI In theory, there is no presumption that ISI will unambiguously reduce or accelerate economic growth in relation to openness in trade. The main complications are twofold.

First, in traditional (static) trade theory, assuming that no market imperfections and other imposed distortions exist, the effect of import protection (as under ISI) is to reduce the level of real gross domestic product (GDP) at world prices; however, simple Harberger triangles from a competitive model rarely identify welfare losses from trade restrictions larger than 1.5–2 percent of GDP, which is far too small to produce significant changes in growth (Ocampo and Taylor 1998; Winters 2004). But in the presence of market failures (such as positive production externalities in import-competing sectors), traditional trade theory shows that real GDP can be higher under protection than under free trade (Bhagwati 1958).

Second, in models of endogenous growth, generated by nondiminishing returns to reproducible factors of production or by learning by doing and other variants of technological progress, the forces of comparative advantage may push an economy's resources in the direction of dynamic activities that generate long-run growth (via externalities in research and development, expanding product variety, learning by doing, increasing returns to scale, agglomeration effects, the creation of forward and backward linkages, and so on) *or divert* them from such activities into traditional, nondynamic ones. Free trade can thus be detrimental to a country's economic growth prospects, especially when it lacks

adequate technological capabilities and (given its initial factor endowments) has a comparative advantage in nondynamic sectors. Import protection may lead to higher long-run growth of real GDP if the trade restrictions promote technologically more dynamic sectors over others (Ocampo and Taylor 1998; Rodríguez and Rodrik 2001).

Experience with ISI The voluminous empirical literature evaluating the benefits and costs of ISI can be classified into two categories: cross-country regression-based studies investigating the impact of import protection (often under ISI) on economic growth (Rodríguez and Rodrik 2001; Srinivasan and Bhagwati 2001; Winters 2004), and in-depth (comparative) analyses of historical country experiences (Little et al. 1970; Balassa et al. 1971; Bhagwati 1978; Krueger 1978; Cardénas et al. 2000; Amsden 2001; Wade 2004). From these two strands of literature, no general, unambiguous conclusion about the *net* impact of ISI policies on growth (and economic performance in general) emerges, but only *contingent* conclusions pointing to a large number of country-specific, often political-economy, and external characteristics.

Cross-Country Regression Studies Surveys of cross-national econometric studies of the relationship between trade policy regimes (including ISI trade policy regimes) and growth, including Edwards (1993), Rodríguez and Rodrik (2001), and Winters (2004), conclude that much of the cross-country (linear) regression studies have been plagued by conceptual and empirical shortcomings, lack of relevant control variables, problems of causality and endogeneity, multicollinearity, lack of appropriate control variables, and measurement errors. As a result, no robust systematic conclusions about the impact on growth of ISI trade policies can be drawn from this literature (Srinivasan and Bhagwati 2001).

Comparative Country Studies The effects of ISI have been analyzed in a number of influential studies under the auspices of the Organisation for Economic Co-operation and Development, the National Bureau of Economic Research, and the World Bank (e.g., Little et al. 1970; Balassa et al. 1971; Bhagwati 1978; Krueger 1978). These identified substantial

macroeconomic costs of ISI. First, ISI led to inefficiencies in resource allocation, because through an overvalued exchange rate it introduced a bias against exports and in favor of (capital-intensive sectors in) the home market, thus leading to underutilization of capital stock (in capital-scarce economies), declining capital productivity, and a failure of high investment rates to significantly reduce widespread unemployment and underemployment (Bruton 1998). In addition, ISI generally gave rise to a wide and nontransparent dispersion of effective exchange rates, which served to make the protectionist regime more complex, distorting the structure of incentives that ISI itself required. Second, imports generally rose faster than expected due to the demand for capital goods and intermediate goods to support the new industries; as a result, balance of payments problems were widespread the more so because (agricultural) exports were penalized by the broad strategy of ISI (Little et al. 1970; Balassa et al. 1971). Rather than reducing dependence on imported inputs (energy) and technology, the strategy may have significantly increased it. Third, IS regimes have been argued to induce directly unproductive profit-seeking (DUP) activities (Bhagwati 1982), diverting resources from productive use into unproductive but profitable lobbying to change or evade policies or to seek the revenues they generate; this, in turn, reduced investment and productivity growth and hence long-term growth (Winters 2004). Fourth, in countries where the home market is relatively small, ISI created less competitive markets, which in some cases reduced aggregate efficiency, productivity growth, and innovativeness. Taken together, these tendencies suggest that the trade and exchange rate policies of ISI became self-defeating in terms of its objectives: to increase capital accumulation and generate a more diversified productive structure of production.

During the 1990s, however, the impact of ISI on economic performance was reconsidered (Bruton 1998; Rodrik 1999) particularly within the context of the rapidly growing East Asian economies (Storm and Naastepad 2005). According to this "revisionist" literature, ISI worked well during the period 1950 73, bringing unprecedented economic growth to many developing countries in Latin America (Cárdenas et al. 2000; Rodrik 1998) and (East) Asia (Amsden 1989, 2001; Wade 2004). Along with GDP growth came labor productivity increases (through rapid capital accumulation), which translated into higher real wages of those employed, rising standards of living, and the development of substantial technological capabilities in manufacturing. The "revisionists" argue that ISI preceded exporting in almost all industries in almost all late-industrializing countries and in fact was a prerequisite for export-led growth, because it would not have been possible without the technological capabilities accumulated during the ISI effort that preceded it. The revisionist account emphasizes that countries pursued radically different strategies during the "mature" stage of ISI. One group of countries, including many Latin American ones, began to deepen import substitution in intermediate and capital goods. In conjunction with inappropriate monetary and fiscal policies (which led to frequent periods of high domestic inflation), this contributed to significant exchange rate instability, with large adverse effects on nontraditional exports growth and export diversification. The result was unsustainable external balances, growing international indebtedness, and collapse in response to negative external shocks (Cárdenas et al. 2000). The other group of countries, including most East Asian newly industrializing economies (NIEs), began to place substantially more emphasis on export promotion, tying incentives to export performance, while continuing with ISI. This "mixed" model of ISI became a success, unlike the "deepened" model, because NIEs' governments (1) were able to discipline private-sector firms by means of monitorable performance standards (e.g., export targets) in exchange for subsidies to make private manufacturing activities profitable (Amsden 2001); (2) avoided external imbalances by promoting exports and maintaining competitive exchange rates; and (3) succeeded in designing protection and export-promotion measures that induced indigenous technological learning and knowledge accumulation (Bruton 1998). From the revisionist literature follow important, still unresolved political-economy ques-

tions related to the nature of government, the main one of which is how NIEs' governments could induce the technological learning in private-sector firms that is usually assumed to be the consequence of market competition.

■ impossible trinity

The impossible trinity describes an apparently inescapable constraint faced by policymakers, namely the impossibility of simultaneously fixing an exchange rate, permitting full capital mobility, and implementing a monetary policy with only domestic goals in mind. A fixed exchange rate implies, by the law of purchasing power parity (PPP), an inexorable link between domestic and foreign price levels. A less restrictive interpretation of PPP implies that domestic inflation is completely determined by foreign inflation. Clearly, if this is the case then a monetary policy geared toward purely domestic objectives cannot succeed. Similarly, a fixed exchange rate that operates in a world where capital is perfectly mobile must lead to a loss of control over domestic monetary policy.

Imagine an exchange rate that is undervalued that is, the domestic price of the foreign currency (i.e., the exchange rate) is above what is perceived to be the equilibrium exchange rate. If interest rates happen to be the same in the two countries then, other things being equal, foreign investors will find domestic investments more attractive since, assuming the present situation does not persist, and the exchange rate returns to equilibrium, in the future

foreign investors will be able to buy more of the foreign currency when their investment matures. As a result, the mere fixing of an exchange rate out of equilibrium creates forces that influence domestic interest rates. The important point is that a fixed exchange rate and full capital mobility can be incompatible with an independently determined domestic monetary policy (Obstfeld and Rogoff 1995).

Some economists have argued that the unwillingness to accept the existence of this trinity led many emerging economies (middle-income countries with some access to global financial markets) to adopt "soft" pegs instead of the "hard" peg assumed in the foregoing description of the impossible trinity phenomenon (Calvo and Reinhart 2002). Essentially, a hard peg establishes a rigidly fixed exchange rate that leaves relatively little room for change in the event of some unexpected event. In contrast, a soft peg is a fixed exchange rate system where the policy authorities, either explicitly or implicitly, leave room for adjustments or changes in the exchange rate as circumstances warrant. Others have pointed out that the existence of an impossible trinity is confirmed by the failure of the so-called soft pegs as demonstrated by the currency crises in emerging markets, such as Mexico in 1994; Thailand, Indonesia, and Korea in 1997; Russia and Brazil in 1998; and Argentina and Turkey in 2000 (Fischer 2001). The consequence is that exchange rate systems throughout the world have become bipolar in nature: they gravitate toward fixed or floating exchange rates. Intermediate exchange rate regimes are, therefore, a vanishing breed.

Not all interested observers agree with the notion that the impossible trinity is an immutable economic force. An understanding of these different positions requires an exploration of the proposition of the so-called vanishing middle.

The Vanishing Middle? The vanishing middle phenomenon is a corollary of the impossible trinity. Since it not possible to simultaneously fix an exchange rate, permit full capital mobility, and implement a monetary policy with only domestic goals in mind, economies will either gravitate toward a pegged exchange rate or permit their exchange rate to freely float. In order to understand the significance of

the impossible trinity it is necessary to briefly examine how exchange rate classifications are made. Until approximately 2000, the long-standing practice of the International Monetary Fund (IMF) was to report exchange rate regimes according to each member country's own view of how its exchange rate is set. As such, the resulting classification can be likened to a type of de jure classification.

By 2000, the IMF was confronting the fact that de jure and de facto definitions of the exchange rate need not be the same. Several academics (e.g., Levy-Yeyati and Sturzenegger 2005) were beginning to modify official classifications. They were dissatisfied with how governments interpreted the type of exchange rate regime they had in place when they reported their view to the IMF. However, the classification used by the economist Fischer (2001) in making the case for the impossible trinity continued to distinguish among pegged rates in a horizontal band, a crawling peg, and managed floating regimes with no preannounced exchange rate path. This suggests that a managed float differs from certain types of pegged exchange rate regimes only because the desired exchange rate is not preannounced. However, if one were also to classify exchange rate regimes based on their credibility, transparency, or durability, then it is difficult to see what sets these types of exchange rate regimes apart from one another. The soft versus hard peg classification permits a more subtle distinction between types of pegged exchange rate regimes though again, based on the historical record, or using the metric of central bank transparency, the distinction is more a matter of convenience than one with meaningful economic implications. In general, whether central banks manage international reserves owned by the government, or own them outright, they are almost always responsible for initiating intervention.

The economists Reinhart and Rogoff (2004) take a different approach to setting up an exchange rate regime classification scheme according to five categories: pegged, limited flexibility, managed float, freely floating, and freely falling. The authors conclude that far fewer countries than previously thought actually chose either one of the corner so-

lutions of the peg and the free float. More important is their finding that floating regimes deliver relatively lower inflation, but possibly at the cost of a lower average per capita economic growth rate than less flexible exchange rate regimes. The point is that the difficulty of defining a true peg suggests, as noted earlier, that a variety of managed floating regimes exists. Nevertheless, classifications still rely on whether the central bank and/or the government have a particular exchange rate regime in mind and how much variability is permitted in the exchange rate. No consideration is given to the possibility that an exchange rate regime in which intervention is used to influence uncertainty in exchange rate movements is, in some sense, also a type of managed regime.

Also absent from the discussion so far is whether it makes any difference whether the economies in question are advanced, emerging, or developing. It could be argued that one's interpretation of whether in fact exchange rate regimes are evolving to one corner of the exchange rate regime type spectrum or the other, namely, whether countries are increasingly adopting either fixed or floating regimes, is strongly related to restrictions placed on capital movements (Eichengreen and Razo-Garcia 2006). More advanced countries are much more likely to permit the free movement of capital than developing countries and, therefore, are more likely to adopt a floating exchange rate regime.

Can a Country Escape the Impossible Trinity?
The concept of a trinity immediately brings to mind the notion of an inescapable constraint in the menu of policies available to sovereign nations. Of course, the arguments are expressed in purely economic terms. However, when political dimensions are considered the policy choice dilemma facing the authorities can become even more complicated. After all, governments typically choose the exchange rate regime while the monetary policy strategy, at least in short run, is often the responsibility of the central bank. Rodrik (2000) refers to a "political trilemma," which is a variant on the impossible trinity concept. The trilemma seeks to reconcile the influence of economic integration on the nation-state. The latter

is arguably less "independent" the greater the influence of globalization. Whereas globalization involves the internationalization of economic forces, international agreements such as the Bretton Woods arrangement after World War II link nation-states through formal international political structures. Finally, at the other end of the trilemma are attempts to create a global form of federalism wherein nation-states relax the divisions created by national borders for some greater political or economic goal. The European Union immediately comes to mind.

Perhaps the best way to summarize the state of the debate is to quote from Cooper (1999, 16 17):

What is less obvious is that floating rates, independent monetary policy and freedom of capital movement may also be incompatible, at least for countries with small and poorly developed capital markets, i.e., for most countries. That would leave a more limited menu of choice for such countries: between floating rates with capital account restrictions and some monetary autonomy, or fixed rates free of capital restrictions but with loss of monetary autonomy. Put bluntly, two prescriptions regularly extended to developing countries by the international community, including the IMF and the US Treasury, namely to move toward greater exchange rate flexibility and to liberalize international capital movements, may be in deep tension, even deep contradiction.

■ infant industry argument

The infant industry argument suggests that an industry may be developed under the umbrella of the government's temporary protection. Such a policy must weigh the future cost savings of an industry in which dynamic economies of scale are present with the current consumers' foregone rents due to higher domestic prices as well as higher imported prices of similar products. By establishing an import tariff that is somewhat related to the efficiency level of the domestic industry relative to the foreign one, the government articulates a rent redistribution mechanism, from domestic consumers to local producers, that may help the local industry to overcome the initial cost disadvantage and thus survive in the long run.

The argument that local industry can develop only if given a chance to reduce costs has been around for a long time. During the first Washington administration (1788 92), the first U.S. secretary of the treasury, Alexander Hamilton, favored the temporary protection of the American industry to facilitate its full and fast development as an effective way for the United States to become less dependent on English manufactures. Import substitution can certainly be welfare enhancing if learning is fast enough so that near-future cost savings overcome current consumer losses. It should be pointed out that an import duty not only makes imports more expensive. It also allows domestic producers of similar products to charge higher prices, thus softening domestic competition. This is perhaps the reason why Thomas Jefferson, then secretary of state of the Washington administration and representative of the rural South, bitterly opposed Hamilton's protection plan. Import duties immediately made consumption of all products more expensive for southerners while the North reaped the gains through an increase in jobs and industrial capability. Hamilton's policy as later Friedrich List's proposals for Germany was intended to be temporary but it was still around more than a half century after it was first implemented, and the issue of protection was second only to slavery in the contentious relations between the North and the South in the period leading up to the Civil War.

The academic debate surrounding the infant industry argument focuses on whether this policy can be effective and on analyzing whether the future gains

offset current costs. But this is a debate that is not alien to the influence of political ideology. Left-leaning parties traditionally favor the involvement of governments in economic activity and as a consequence they traditionally favor a protectionist policy based on the infant industry or any other argument. Conservative parties favor promarket policies, lately favor free-trade agreements, and commonly have denounced the infant industry argument based on failed experiences or have pointed out how easily a projected temporary protection can become permanent.

Infant industry tariff protection was successfully implemented in Japan after World War II, establishing the principle that has inspired the import-substitution policy of many Latin American and Asian countries for many decades with varying degrees of success. Despite many promises of an imminent opening to trade, successive governments repeatedly renewed tariff protection. Japan succeeded in developing its industry and some other countries later moved toward a policy of export promotion in order to ensure fast learning and the development of the domestic industry. The Latin American experience was less positive. Domestic industries failed to take off despite repeated renewals of protection, while locals felt impoverished as imports and related domestic products became more expensive. Furthermore, as domestic producers felt that their respective governments would renew protection, they had little interest in innovating and becoming more efficient. If the dynamic gains of protection are never realized because domestic producers do not believe that protection is temporary, the effects of the infant-industry protection can be analyzed within a static setup with a domestic industry with market power. In the case of Latin America a well-intended but poorly designed policy led to a massive transfer of rents from consumers to producers, who saw their market power significantly increased and the incentives to innovate reduced.

As noted earlier, an import duty does more than just increase the price of imports. Local producers of similar products can charge higher markups as foreign competitors lose at least part of their cost advantage. These are not the only costs of protection. In addition, protection induces a loss of competitiveness of industries that use the output of the infant industry as inputs. These "collateral costs" of protection are ignored in the partial equilibrium analysis commonly used to evaluate the welfare implications of the infant industry argument. However, since governments commonly fail to lift protection, these additional costs of establishing a "temporary" import duty confirm the current negative opinion that the overwhelming majority of economists share regarding any tariff protection based on potential learning effects.

The temporal trade-off of cost and benefits motivates the research question surrounding the infant industry argument. Could the infant industry have been developed without protection? If so, what is the cost of this development? Will the infant industry ever be able to compete with developed foreign firms? In welfare terms, can protection lead to a higher total surplus than simply allowing imports at competitive prices? And last, will protection ever end or is the infant industry argument just another excuse to prolong protection indefinitely?

Perhaps the most important criticism of the infant industry argument is that governments lack any incentive to lift such protection in the future. If that is the case, any incentive that protection may introduce for firms to invest and take advantage of this temporary protection will disappear, and thus the country will end up, as many undeveloped economies nowadays, with high import duties but without dynamic industrial development.

The practical implementation of the infant industry argument is certainly difficult. Governments must be able to accurately predict the learning dynamics of each particular industry to be protected as well as the cost that such protection generates to domestic consumers and firms. From a theoretical point of view, the question is a different one: Is infant industry tariff protection "logically" time-inconsistent? Should we oppose such protection on the basis of a theoretical result or just because from a practical perspective we believe that its effectiveness is quite implausible?

A majority of economists have argued against infant industry protection mostly from ideological premises rather than based on an appropriate theoretical model. Thus the infant industry argument is frequently dismissed by pointing out that free trade is Pareto dominant, that is, it would be mutually beneficial to all countries involved. Neither Hamilton nor the protectionists ever claimed such a global viewpoint. The infant industry argument therefore needs to be addressed within the partial equilibrium framework of a small country and evaluated on the basis of whether a temporary protection policy can effectively help develop a domestic infant industry that otherwise would never have taken off.

The academic debate on infant industry protection has recently focused on precisely the issue of whether tariff protection will ever end after successfully helping the domestic industry to develop. To summarize the results described in the rest of this entry: infant industry protection may be effective and temporary when the level of protection is linked to the efficiency level of the domestic industry. However, it will commonly fail if it sets a future liberalization date that is independent of the degree of development of the domestic industry, or if cost reduction requires specific investments that are not directly linked to the production decisions of domestic firms.

A Framework for the Analysis of Infant Industry Protection Consider a small country where an early industry suffers from such cost disadvantage relative to foreign producers that it will have to shut down in the event that the domestic government enforces a free trade policy. The domestic and foreign industries produce similar, but not necessarily identical products. The foreign industry is assumed to behave competitively and to have exhausted all its dynamic economies of scale. A single infant monopolist is assumed to produce all domestic production. This firm enjoys significant learning by doing and marginal cost will fall as production takes place. The demand for differentiated domestic and imported products depends on the decision variables of the two players: government chooses the import tariff to maximize the discounted sum of consumer surplus, profits, and tax revenues while the monopolist chooses the relative price of the domestic good that maximizes the net present value of future profits. Marginal cost reduces at a certain rate with current production and experience depreciates as a fraction of the current level of marginal cost. Therefore, learning is a reversible process that requires some positive output to induce cost savings while at the stationary equilibrium, once learning is exhausted, current production only impedes marginal cost from increasing.

The monopolist and the government engage in a dynamic game where the former chooses the price and the latter the tariff level. Both players discount the future at a common rate. The game is dynamic because each player's action affects the state of the game, that is, the level of marginal cost through the direct or indirect effect on the domestic production and accumulation of experience. This setup is essentially a capital accumulation game World such as the one studied by Reynolds (1987). If we further restrict our attention to a system of linear demands for domestic products and imports, this dynamic model becomes a linear-quadratic differential game that allows us to obtain a closed-form solution and thus easily characterize the features of the equilibrium strategies.

Alternative Assumptions The foregoing description is based on Miravete (2003). Melitz (2005) departs from this framework in two main aspects: the domestic industry is assumed to be competitive and the government behaves as a social planner.

The earlier framework could be easily generalized to an *n*-firm symmetric oligopoly industry without changing qualitative results other than learning would now be slower as each firm would only count for one *n*th of accumulated experience. Thus the more firms in the domestic industry, the faster learning needs to be in order to achieve higher welfare than the default scenario where domestic firms just shut down and consumers only purchase from foreign firms. An additional issue that may arise when

several firms compete in the domestic market is the existence of learning spillovers. As Stokey (1986) shows, this introduces additional reasons to protect an industry.

By assuming the existence of a social planner rather than a noncooperative solution, Melitz eliminates the dynamic interaction between government and firms. This corresponds to a situation in the above framework when the government and the monopolist collude in choosing the tariff and price strategies, which may be important for state-owned industries or when the industry in question has significant political influence. In a dynamic strategic environment firms would charge higher prices and the government lower rates than in Melitz's case.

This framework presents another important advantage: an infinite horizon game rules out the possibility of any other future rent after the formal end of the game, and the equilibrium strategies are thus robust to the existence of any other unaccounted rent. This is not the case of Leahy and Neary (1999), Miyagiwa and Ohno (1999), and most explicitly Tornell (1991), who considers the possibility of a third period where wages are renegotiated when the initial protection of the industry was planned only for two periods. Considering extraneous elements after the planning horizon of the game as formally ended turns protection, by definition, into a time-inconsistent policy.

Markov versus Non-Markov Strategies The basic criticism to the infant industry argument is that governments lack the ability to commit to taking particular policy actions in the future. In particular, a government cannot commit to reducing protection if the protected industry fails to make the anticipated productivity gains. Although this may be true in practice, it cannot be defended with models that by construction make reneging from the announced policy the dominant government's strategy. A more interesting distinction is the use of strategies that are linked to the level of efficiency of the domestic industry. The effect of learning is reducing the marginal cost of production simply by means of producing in the past. A protection strategy linked to this marginal cost (or alternatively to the related level of output or price) of the domestic industry is called a Markov strategy.

A way to help governments renege from announced liberalization is by using non-Markov strategies such as in the case of Staiger and Tabellini (1987) or Matsuyama (1990). Protection eases domestic production, and thus, through learning, marginal costs get reduced. In these models, however, cost reduction depends on investments that are not linked to the state of the game, that is, the level of marginal cost. Therefore there is no source of commitment for the government either. In the framework described earlier such policies can indeed be computed when both the government and the domestic producer can commit to a sequence of tariffs and prices over time. But most generally, a Markov perfect equilibrium can be constructed when both tariffs and prices are made contingent on the evolving level of marginal cost. The interesting added result of taking this approach is that if such strategies are employed, the best response of the government to the pricing of firms is to reduce tariff protection as the level of marginal cost decreases. Thus there is no need to renege and time-consistent equilibrium strategies lead to future trade liberalization. The government simply allows the domestic firm to earn the minimum markup to induce them to reduce costs beyond the static equilibrium. As this process takes place, marginal cost gets reduced, and the required level of protection needed is also lower. But this result also confirms Hamilton's intuition, that protection based on the infant industry argument would be only temporary despite sometimes surviving for a long time.

EUGENIO J. MIRAVETE

■ inflation targeting

Since the early 1990s, inflation targeting has become the predominant monetary policy choice for central banks in industrial and developing economies alike. New Zealand, the United Kingdom, Canada, Australia, Norway, Sweden, and Israel were among the first countries to adopt this policy. Since then, many emerging market economies have also adopted it, including Chile, Brazil, South Africa, Korea, Indonesia, Thailand, and the Philippines. Inflation targeting is currently regarded as best practice monetary policy for countries operating flexible exchange rate regimes.

At its core, inflation targeting is a monetary policy system that manipulates a policy instrument (usually a short-term nominal interest rate, but sometimes the nominal effective exchange rate) according to available information with the objective of controlling inflation. The rate of inflation is the primary objective of this regime but is not the sole objective; the system permits the pursuit of secondary objectives such as smoothing changes in output, interest rates, or even the exchange rate.

The successful implementation of inflation targeting depends on a checklist of features:

1. A binding commitment to price stability as the primary policy objective. This is normally presented in a central bank act or similar piece of legislation that sets the objectives and operational rules for the functioning of a central bank.
2. Transparency. This takes the form of announced inflation targets, published minutes of meetings of the monetary policy committee, and the publication of periodic inflation reports.
3. An independent and accountable central bank.
4. A floating exchange rate. In a world of high capital mobility, having an exchange rate target compromises the efficacy of inflation targeting. Nonetheless, central banks in emerging markets often have a strong desire to manage exchange rate movements while maintaining an inflation targeting regime.

5. A monetary policy rule (MPR). The MPR is a policy rule that guides the instrument of the inflation targeting policy. If the nominal interest rate is the policy instrument, the MPR states how it should react to key economic variables such that the policy objective is attained (see Taylor 2001).

Inflation targeting has several advantages. First, it enables policymakers to focus on domestic policy considerations and to respond to those shocks affecting the domestic economy. Second, inflation targeting does not require a stable relationship between the money supply and inflation but uses all available information deemed useful in achieving the target. Third, inflation targeting is transparent and easily understood by the public (Mishkin 2000). Inflation targeting also has two notable disadvantages. The first is that, owing to the long and variable lags between the time a policy is instigated and point it begins to take effect, inflation is inherently difficult to control. The second, which is pertinent to emerging market economies, is that the exchange rate flexibility associated with inflation targeting may lead to financial instability.

A strict inflation target provides that inflation is the *sole* objective of monetary policy. In other words the only variable the central bank cares about is inflation. Flexible inflation targeting essentially targets inflation but allows for a secondary objective. The usual secondary objective is output, where the central bank seeks to minimize the gap between the current growth rate of output and some steady-state value. Other secondary objectives may include dampening the growth of asset prices, reducing the volatility of the exchange rate, or minimizing potential disruptions in domestic financial markets caused by sharp changes in interest rates. It is commonly held and demonstrated in simulation studies (see Svensson 1997) that output variability is lower under flexible inflation targeting and that the inflation target is attained more quickly under strict inflation targeting. Central banks are often under pressure to take output conditions into account, however, and in this situation, flexible inflation targeting is a viable option.

There are several other analytical and operational dimensions to inflation targeting that are significant in its construction. These include the central bank's selection of a strict versus flexible inflation target, whether it should target domestic inflation (inflation in the price of those goods produced and consumed domestically) or consumer price index inflation (domestic inflation plus inflation in the price of tradable goods), whether the central bank should target current inflation or an inflation forecast, and the extent to which the central bank should respond to the exchange rate and asset prices.

■ information and communications technology

Information and communications technology (ICT) refers to all technologies and devices used in managing and processing information systems. In contrast to the manufacturing industries such as shipbuilding, steel, automobiles, and textiles, which create value directly, ICT in the form of computers, software, the Internet, multimedia, and management of information services creates value indirectly. ICT includes data for business use, voice communication, images, multimedia, and many types of technologies for the purpose of development and exchange of information. The definition of the ICT sector differs among industrialized countries. The U.S. and Organisation for Economic Co-operation and Development (OECD) definitions are presented in table 1.

The introduction of increased processing power of hardware along with complementary software and telecommunications infrastructure have enhanced the ability to store, retrieve, analyze, and communicate data and information within and between organizations and their partners and suppliers, and ultimately to the consumer. In particular, ICT deals with the use of electronics, computers, and computer software to convert, store, protect, process, transmit, and retrieve information. For that reason, computer professionals are often called information technology (IT) specialists or business process consultants, and the division of a company or university that deals with software technology is often called the IT department. Other names for the latter are information services, management information services, or managed service providers.

As a general rule, capital and labor as important elements in the growth of an economy lead to decreasing returns to scale. Therefore, even though these factor inputs of production may increase, the growth of an economy over a certain level cannot be expected. Information may produce increasing returns to scale and become an important factor for sustainable growth, however. Thus, in recent years, ICT has been considered an input in the production of goods and services and a factor affecting total factor productivity growth at both the micro- and the macro levels (see Shiu and Heshmati 2006).

Review of the ICT Literature ICT is considered one of the three major technological breakthroughs of the modern era (see Edquist and Henrekson 2007), the others being steam power and electricity. ICT includes some of the wider information technology innovations and applications, and their commercialization and transfer have been quite rapid. These enhance the communication of more accurate and value-added information to workers, managers, and consumers, thus reducing uncertainty and time use in conducting many types of businesses.

There has been great interest among researchers in investigating how some countries were able to take advantage of ICT to accelerate their rates of growth and productivity. In these studies one examines the contribution of IT investment to economic growth and finds that the returns on IT investment are significantly positive. In the transitional countries of Central and Eastern Europe (CEE), one observes a chronic underinvestment in telecommunications infrastructure. The result suggests that improving investment may ultimately improve the channel between aggregate investment and growth economywide (see also Zhu 1996; Madden and Savage 1998).

Return on IT differs by the country's development level. Results from intercountry studies relating IT and non-IT inputs to gross domestic product (GDP) over time suggest that for developed countries, returns from IT capital investments are positive, while returns from non-IT capital investments are not commensurate with relative factor shares. The situation is reversed for developing countries, where

returns from non-IT capital are quite substantial, but those from IT capital investments are not statistically significant. The impacts of IT investment on economic growth in a cross section of countries shows that the relative contribution of IT to GDP growth in developing counties between 1980 and 1995 was less than 2 percent, compared to more than 10 percent in developed countries (see Dewan and Kraemer 2000; Pohjola 2001).

Investment in ICT and Its Diffusion Evidence on the role of ICT investment is primarily available at the macroeconomic level. It has been observed that ICT has been a very dynamic area of investment, due to the steep decline in ICT prices, which has

encouraged investment in ICT and expansion of production at the same time shifting investment away from other assets. The capital deepening that results from investment in ICT is considered an important driver of economic growth. It establishes the infrastructure for the use of ICT networks and provides productive equipment and software to businesses. Measures of ICT investment are therefore of considerable interest in examining growth performance in many countries. Investment is usually estimated by using business surveys. These surveys usually allow the total investment to be disaggregated into a number of well-defined asset groups, including ICT. There is a broad understanding in the statistical community about the definition of ICT products. The pace of investment differs widely by country. The lowest levels of the share of investment in ICT are found in low-income nations, while the highest are in high-income nations.

Generally, network products, including telephone, e-mail, Internet, computer hardware, and software, have distinct features such as network effect, critical mass, lock-in, and path dependency, which affect late takeoff in their diffusion. A positive direct network effect means a positive utility gain for consumers when the number of users operating the same system increases. For example, the first e-mail message was sent in 1969, but the adoption did not take off until 1990. Since then, Internet traffic has been doubling every year. This example raises an important question, which is when to expect a new technology to diffuse and what should be the minimum number of users (the critical mass) needed for inducing potential consumers to adopt it.

At the global level, the diffusion of key ICTs such as the Internet, mobile phones, and personal computers in accordance with the World Bank's classifications are shown in figures 1, 2, and 3. To judge from these graphs, which are based on data published in OECD (2000; 2004), United Nations Conference on Trade and Development (2003), U.S. Department of Commerce (2003), and World Bank (2006), we observed that high-income countries show a high level of diffusion. In addition, in the case of the diffusion of the Internet and personal com-
Figure 1

The diffusion of the Internet
Figure 2

The diffusion of mobile phones
Figure 3

The diffusion of personal computers

puters, the gap between high-income and low-income countries measured in Internet users per 1,000 people increases over time.

The "digital divide" is the socioeconomic difference between communities with access to computers and the Internet and those without such access. At the microlevel, it refers to the gap between individuals, households, businesses, and geographical areas with regard to their opportunities and abilities to access and to use IT services for a wide variety of activities. The gap is due to differing literacy and technical skills, and the gap in availability of useful digital content. The digital divide at the aggregate level is often discussed in conjunction with the gap between rich and poor, and developed and underdeveloped nations concerning access to and use of digital communication. In an international context, the divide indicates that developed countries are far better equipped than developing countries to use the advantages of rapidly expanding Internet technology. The more rapidly the rate at which Internet technology is developed and spread, the more the quality-of-life differences between developed and underdeveloped countries become evident. Despite the productivity, connectivity, and many other recognized and measurable positive effects associated with Internet use, the international digital divide is widening.

Given the gradually decreasing number of fixed (land-line) telephone subscribers per 1,000 people in contrast to mobile subscribers, it is highly probable that the traditional fixed phone is being supplanted by the mobile phone as telecommunications services develop. Consumers show increasing preference for data-based communication instead of voice-based, and new communications services such as voice-over-Internet protocol have entered the market through the development of Internet technology. Given the Internet's high rate of growth and the emergence of broadband services, the difference between Internet telephony and traditional voice telephony has begun to erode. Such changes are dynamically transforming the traditional communications industry structure. The diffusion into the marketplace of telephone, mobile phone, and Internet services has

progressed differently in different places, determined mainly by local and regional economic conditions.

The Effects of ICT on Economic Growth Much attention has been given to how much IT affects the growth of an economy (see Jorgenson 2001). As is well known, IT can transform our economic system by increasing productivity and stimulating economic growth. At the firm level, there are four mechanisms or channels through which IT investment affects the growth of an economy. The first channel is that the IT industry itself grows dramatically, and the nations where the IT industry occupies a leading position may have more than one leading growth sector. In the decade between 1995 and 2005, many nations' portion of revenue derived from the IT sector in their total GDP increased. For example, even in the case of China achieving an 8 percent annual growth rate during that decade, the growth of the IT sectors was faster than the overall economic growth. Accordingly, the expansion of IT sectors affects the growth of the economy positively. By the second channel, IT can facilitate the catch-up process by activating the diffusion process of technologies. According to Antonelli (1990), developing countries can take advantage of the opportunity of catch-up by overcoming asymmetry and disequilibrium of information through the diffusion of IT. The third relation between IT and economic growth is that developed IT affects the integration and efficiency of markets and it stimulates economic growth. This is called the market integration effect. In the final mechanism, IT improves the management and decision-making processes of companies. Additionally, ICT helps firms gain market share, raise overall productivity, expand their product range, customize the services offered, respond better to client demand, and reduce inefficiency.

Economies that successfully implement new ICT may be able to overcome barriers that have long held them back in their contribution to the global trade. The rapid spread of the Internet has opened up previously unavailable commercial and political information. In particular, ICT has reduced many of the transaction costs of participating in subcontracting through business-to-business interaction, and it

facilitates the operations of low-cost suppliers of IT services based in developing countries. In other words, IT can increase total output eventually through reduced transaction costs. Enough constructed IT infrastructure decreases the cost of information, and in the long run it makes the market more effective. Less-developed countries face a higher cost to obtain information because their information market is less efficient than in developed countries.

IT investments have specific features. A decreased telecommunications cost can be used to decrease costs associated with decisions to distribute resources between cities and rural communities. The decreased telecommunications costs make the use of a larger quantity of information possible, which contributes to better decision making. It increases the opportunity for arbitrage and makes the financial market more efficient. Finally, decreased cost can provide more information about market prices. Even if ICT spread in similar ways in different places, one would not expect similar economic benefits from it. Only with a regulatory environment, the availability of appropriate skills, the ability to change organizational setups, and the strength of accompanying innovations in ICT applications can the benefits of IT be maximized. The magnitude of complementary policies for IT investment must be expanded. Such policies aim to enhance the conditions for developing the economy, through provision of infrastructure, prohibition of monopoly in the telecommunications market, allowing for new entrants, enacting efficient laws and regulations, and providing a high-quality education system.

Edquist and Henrekson (2007) examined productivity growth following the three major technological breakthroughs: the steam power revolution, electrification, and the ICT revolution. The authors distinguish between sectors producing and sectors using the new technology and find a long lag from the time of the original invention until a substantial increase in the rate of productivity growth can be observed, as well as strong evidence of rapid product price decreases over time. The highest productivity growth rates are found in the ICT-producing industries, which may be explained by the ICTs' more rapid rate of technological development compared with previous breakthroughs.

New Economy and the Productivity Paradox
The extraordinary performance of the U.S. economy in the late 1990s and the associated economic growth were referred to as the "new economy." The computing power of microchips, which underlies the rapid progress in productivity of ICT, has doubled every 18 24 months since 1965, as Moore's Law predicted. Contrary to mainstream economists' theoretical models, inflation and unemployment were low at the same time, particularly following 1992, and the economy experienced sustained growth and the stock market boomed throughout the 1990s.

The new economy phenomenon happened because of a number of factors. First, increased efficiency in firms' management though ICT adoption affected productivity growth at the firm level and connected productivity growth in each industry through spillover effects. As a consequence, productivity in the total economy increased. In other words, since the middle of the 1980s, more intensive competition between companies contributed to high investment in IT and the introduction of innovative management, which in turn affected productivity gains.

Second, productivity gains led to a low inflation rate. When productivity continues to grow, the inflation rate becomes lower because inflation is offset by productivity increases. Furthermore, low inflation coexists with low interest rates, and it increases the investment rate. Finally, it can link productivity growth and sustained economic growth in an interconnected cycle of investment, productivity, and economic growth.

Third, the wide-ranging diffusion of IT and Internet use made it possible for the new economy to evolve. The spread of IT and the Internet due to price reductions stimulated the network effect, and it induced sustained economic growth by creating increasing returns to scale in the whole economy. Furthermore, continuous strong productivity growth since the 2001 recession made it likely that some of the gains of the late 1990s may endure.

In disagreement with the widespread view about productivity gains through ICT adoption, Robert Solow commented in 1987 on the IT productivity paradox that the productivity of the workforce had not risen as IT had extended through Western industry. It was widely believed that office automation was boosting labor or total factor productivity, but the growth accounts did not seem to confirm this, because the "computer era" from the early 1970s to the time that Solow spoke about the paradox included a massive slow-down in growth as the machines were becoming ubiquitous.

The causes of the productivity paradox are the following. First, a portion of the benefit from ICT is not included in productivity statistics. Productivity statistics of service sectors with a high rate of investment in ICT correspond to this case. For example, the increased benefit of financial services such as ATMs (automated teller machines) is not included in productivity statistics. Insurance, business services, and health services show the same phenomenon of the benefits of ICT not being fully reflected in productivity statistics.

Second, there may be a lag in productivity improvements. The lag is because computers did not enhance productivity until things such as software, the Internet, and handhelds became prevalent. It takes a long time for a new technology to become popular and companies to adopt it. Given that ICT increases multifactor productivity through networks, and building a network requires a long time, productivity growth will lag behind the initial introduction of new technology. Productivity growth originating from IT may already be occurring, but a flaw in the measurement tools available may be hiding it.

Third, previously much research aimed at identifying the effect of ICT at the company level was based on small samples. If the early impact of ICT is trivial, research in the early stage will not capture the contribution of ICT. In addition, some research shows that the ICT impact differs by industrial sector. These days, there are more detailed data on ICT investment available to measure the impacts of ICT.

In the search for explanations of the productivity paradox, Oliner and Sichel (2000) deny the significance of the IT sector by arguing that IT accounted for no more than 2 percent of the capital stock in any country in the world. Other economists have made more controversial statements about the utility of computers: that they pale into insignificance as a source of productivity advantage when compared to the first industrial revolution or the adoption of motorcars.

The Role of ICT in the World Economy The OECD (2004) report on the impact of ICT provides two important messages. First, ICT continued to have a strong impact on performance. Productivity growth in the United States, the main example of ICT-led growth and productivity improvements, continued to be strong. ICT networks had spread throughout much of the OECD business sector and would spread further to enhance business performance. The release of increasingly powerful microprocessors was projected to continue for the foreseeable future. These factors were expected to encourage ICT investment and support further productivity growth.

Second, the impact of ICT differed markedly across OECD economies. Many OECD countries lagged in the diffusion of ICT and had scope for greater uptake. It was expected that the largest economic benefits of ICT would be observed in countries with high levels of ICT diffusion. Having the equipment or network is not sufficient to derive economic benefits, however. Other factors, such as the regulatory environment, skills, ability to change organizational setups, and the strength of innovations in ICT applications all affect the ability of firms to seize the benefits of ICT. Consequently, the impact of ICT on economic growth and performance of countries with equal ICT diffusion will not be the same.

IT makes a positive although small contribution to economic growth, but its impact is positively related to the level of development. Studies of the relationships between IT and economic performance suggest that the impact of IT diffusion can differ even among developed countries with similar level of

development. The limited existing empirical evidence shows that developing counties that did not adopt complementary policies have gained little benefit from IT investment. In general, for developing countries it is rather difficult to catch any systematic evidence about such relationships. While the evidence suggests that IT contributes to the growth of developed countries, this relationship is less clear in the case of developing countries.

A long time period is required to link IT investment to economic growth and establish a causal relationship between the two. For IT to be effective, its spread needs to reach a critical threshold. To obtain high returns from IT investment, developing countries must adopt complementary policies that fulfill conditions for economic development such as building up the basic infrastructure, creating a non-monopoly telecommunications market, opening the market, enacting effective laws and regulations, and building a high-quality educational system. For developing countries, diffusion and application of IT can play an important role in the growth of the economy, but for IT to have a full impact, more fundamental complementary investments are essential.

■ infrastructure and foreign direct investment

Foreign direct investment (FDI), acquiring a controlling share of a foreign firm, is more likely to occur in countries with good physical infrastructure such as bridges, ports, and highways. Therefore, especially for countries with poor infrastructure, investing in improvements in infrastructure may be important for attracting FDI. Nonetheless, some countries with poor infrastructure may be unattractive hosts for FDI for a variety of other reasons, and even substantial investments in infrastructure might not bring FDI pouring in. But all else being equal, a country with better infrastructure would be expected to attract more FDI (as well as more domestic investment).

The positive effect of infrastructure on FDI has been found to be quite robust to time periods and countries considered, other control variables included, the measure of infrastructure used, and the like. Examining the determinants of FDI into U.S. states for 1981 83, Coughlin, Terza, and Arromdee (1991) find that more extensive transportation infrastructures were associated with increased FDI.

Wheeler and Mody (1992) find that infrastructure quality is an important variable for developing countries seeking to attract FDI from the United States, but is less important for developed countries that already have high-quality infrastructures.

Using a self-reinforcing model of FDI, Cheng and Kwan (2000) find support for good infrastructure (density of roads) as a determinant of FDI into 29 Chinese regions from 1985 to 1995. The quality of the roads, however, did not seem to matter much: high-grade paved roads did not perform any better than all roads in determining which regions hosted the most FDI.

Infrastructure Broadly Defined Fung et al. (2005) examine whether hard infrastructure, in the form of more highways and railroads, or soft infrastructure, in the form of more transparent institutions and deeper reforms, leads to more FDI. Their analysis controls for other determinants of FDI such as regional market sizes, human capital, and tax policies. Their data are on FDI from the United States, Japan, Korea, Hong Kong, and Taiwan to regions of China. They find that soft infrastructure is a more important determinant of FDI than hard infrastructure.

Government infrastructure is used to refer to a country's political, institutional, and legal environment. It captures aspects of legislation, regulation, and legal systems that condition freedom of transacting, security of property rights, and transparency of government and legal processes (Globerman and Shapiro 2003). Government infrastructure is an important determinant of both inflows and outflows of FDI. Not only does government infrastructure attract FDI, but the proper conditions can also stimulate the creation of home-grown multinational enterprises (MNEs) that invest abroad. The biggest gains from improving government infrastructure appear to arise for small developing countries the benefits of further enhancements may be less for countries already enjoying good governance.

Globerman and Shapiro (2003) examine the effect of government infrastructure on both the probability that a country receives FDI and on the amount of FDI received (for countries receiving any FDI). They find that countries failing to achieve a mini-

mum threshold of effective governance are unlikely to receive any U.S. FDI. Thus ineffective governments that fail to promote transparent markets and whose legal systems are not rooted in English law are apt to be excluded from FDI. Globerman and Shapiro's second analysis examines the determinants of the amount of FDI, for those countries receiving FDI. They find government infrastructure, including aspects of the legal system, to be an important determinant of the amount of FDI received, for countries that do receive FDI.

As richer data become available, the influence of more types of institutions can be examined and for a wider range of countries. Given the likelihood that the impact of institutions on FDI drops off once a certain level has been achieved, most interest has focused on examining the role of institutions on FDI into developing countries. Most estimates suggest that institutions are very important. Improving institutional quality from a low level to a high level could have as much of an impact on FDI as if suddenly the country shared a border with the investing country a big change. It may be important to properly control for the correlation between per capita gross domestic product and FDI and for potential endogeneity of institutions (that FDI creates pressure for better institutions). In addition to institutions affecting FDI, some researchers have argued that FDI affects institutions, as will be discussed for the case of corruption in the next section.

Corruption Corruption is the misuse of public power or authority for private gain. Corruption tends to arise when governments control access to markets, so naturally corruption can matter for FDI. Wei (2000) established corruption's deterrent effect on FDI. Using data on bilateral investment from 12 source countries to 45 host countries, Wei finds that an increase in the corruption level in the host country leads to a reduction in inward FDI. An increase in the corruption level from that of Singapore to that of Mexico is estimated to have the same effect of deterring inward FDI as raising the tax rate by 50 percent. Additionally Wei finds that

U.S. investors are no more averse to corruption than average for investors from member countries of the Organisation for Economic Co-operation and Development (OECD).

Not just the level of corruption in a host country, but the degree to which it differs from the level in the source country, may matter for FDI. Habib and Zurawicki (2002) provide support for the negative impact on FDI of both the level of corruption in the host country and the absolute difference in the corruption level between the host and the source country. MNEs from a country with high degrees of corruption may be better able to deal with high levels of corruption in a host country than firms from a country with little corruption. The former firms are experienced in dealing with corruption, whereas the latter are accustomed to transparency. Of course, corruption may take many forms, and thus experience from one country may not fully translate to another. On the other hand, firms accustomed to dealing with bribery might be able to operate well in less corrupt environments, but even they may undergo some adjustment to the different environment. Especially when there is still some corruption, it may be hard for foreign firms to learn just where bribes are needed and where rules must be followed.

While many papers operate on the notion that corruption deters FDI, the opposite can be argued as well. In fast-growing countries with substantial bureaucracies, the ability of corruption to "grease the wheel" may be more important than the amount of the bribe required. In such situations, the bribe may be considered a small price to pay for cutting through many layers of red tape and speeding up approval. When weighing costs versus benefits, how big a bribe is required must be compared to how much improvement in speed or likelihood of approval is gained. The terms "helping hand" versus "grabbing hand" corruption have been used to distinguish corruption that positively affects FDI from that which negatively affects FDI (see Egger and Winner 2006). The fact that corruption on the whole seems to deter FDI suggests that corruption does more grabbing than helping.

In addition to the question of how corruption affects FDI there is also the question of how FDI might affect corruption. Under the U.S. Foreign Corrupt Practices Act of 1977, U.S. firms are not allowed to bribe (or give gifts to) foreign governments to gain favor in contracts, so FDI from the United States might be expected to push toward less corruption. Kwok and Tadesse (2006) propose three avenues through which MNEs may affect institutions in host countries. First, the regulatory pressure effect describes implications of the fact that foreign firms may be constrained to not pay bribes. Bribes may be against company norms, rules set by the source government, or conventions set by the global business community. Second, the demonstration effect is based on the notion that, like productivity, the tendency of MNEs to avoid corruption may spill over to other firms. When local firms deal with MNEs or hire some of their former workers, they can observe how business decisions are made in MNEs. The presence of MNEs should counter existing norms by demonstrating an alternative method of conducting business that can be more efficient. Finally, the professionalization effect relates to the likelihood that leaders (or future leaders) of host firms will acquire training in professional business practices (which discourage corrupt practices) and that these new practices will become socialized in younger generations.

One should recognize that the effect of corruption may be difficult to separate from other aspects of government infrastructure such as bureaucracy, as corruption and bureaucracy tend to be linked (corruption arises to cut through the bureaucracy). In addition to affecting whether a country receives FDI and how much FDI it receives, corruption could also affect the value foreign (or even domestic) firms are willing to pay when acquiring local firms. In general, corruption may be one of many dimensions a country may seek to improve in the hope of becoming a more attractive location for FDI.

Remaining Questions More work needs to be done on how firms adapt to environments plagued by corruption. Some evidence suggests that more firms may opt for joint ventures in the face of corruption. A local partner may be more experienced at dealing with corruption and the host government in general. What other strategies do (or should) firms use when operating in a corrupt environment? Similar to joint ventures, are firms more likely to opt for acquiring a local firm over greenfield investment (building a new plant) in corrupt environments? Is there evidence that firms adopt an expansion strategy in which experience in moderately corrupt countries helps prepare them to begin operations in more severely corrupt regimes? Do firms hire a larger proportion of local workers in more corrupt environments?

More work should also be done to address the variation in types of corruption. All corruption is not created equal. Are some forms of corruption more damaging to FDI than others? Some forms of corruption may act more like fixed costs, such as a bribe for approval to enter the market. Such corruption could be less distorting (as long as it is not prohibitive) than a bribe that is set in relation to number of employees, production, or profits. What evidence is there that bigger or more profitable firms are expected to pay larger bribes? In which situations are foreign firms especially exposed to corruption, and when are domestic firms just as bad off?

Kellenberg (2007) compares a policy of public input provision to a policy of subsidy incentives for attracting FDI. More analysis of this kind is needed, such as comparing a reduction in corruption or an improvement in government infrastructure to use of subsidies. One might like to know, due to corruption (alone), how much of a subsidy would Mexico have to pay to make it as attractive to FDI as Singapore? The next decade of research should bring us answers to such questions, and many more.

AMY JOCELYN GLASS

■ intangible assets

The integration of the world economy has under lined the need for firms to exploit their intangible assets on a global scale. Firms' intangible assets in clude their stock of knowledge, which is related to ideas, research and development (R&D), patent and blueprints, scientific and technical workers, and management techniques. In addition, intangible as sets consist of their stock of goodwill, which is asso ciated with product quality reputation, trademarks, and brand names.

The empirical evidence shows that the growth in intangible assets has been a recent phenomenon. As emphasized by Griliches (1994), the source of eco nomic growth and wealth lies no longer in the in vestment of physical, tangible assets but in the crea tion and use of intangible assets. The contribution of the latter is hard to measure due to lack of data and uniform definition concerning its measurement. There is, however, substantial anecdotal evidence that enterprises have increased their relative invest ment in intangible assets. The pace of intangible investment by U.S. private firms has risen sharply in recent decades. By the late 1990s, their investments in intangible assets were around 1 trillion dollars a year, which was about the same as expenditure on tangible assets (Nakamura 2001).

The traditional explanation of multinational en terprises (MNEs) rests on the existence of firm-spe cific intangible assets. These assets give MNEs off setting advantages over foreign producers because

they have the property of *joint inputs*. Relative to physical tangible assets, intangible assets are easier and cheaper to transfer to foreign subsidiaries. For instance, blueprints and patents are very costly to produce but once they are created, they can be supplied to any foreign subsidiaries without reducing their value or productivity. Investing in tangible assets typically involves fixed costs at the plant level, whereas investing in intangible assets involves fixed costs at the level of the firm.

The empirical evidence confirms that MNEs have a larger value of intangible assets relative to their market value (compared to other firms). Industries with a high proportion of multinational firms tend to be characterized by high levels of intangible assets (evidenced as substantial R&D and advertising expenditures relative to sales), new or sophisticated products, and high shares of skilled employment (Markusen 1995). Since the early 1990s, for instance, the stock of business services has risen ninefold, to reach 26 percent of total inward foreign direct investment (FDI) stock in services in 2002 (UNCTAD 2004).

Understanding the importance of intangible assets for FDI requires investigating their transferability to local firms and their impact on host economies.

Transferability of Knowledge-Based Assets Transferring knowledge-based assets to local firms is quite different from transferring other intermediate inputs. Knowledge is not necessarily easily transferred, especially across firms. The reason is that knowledge-based assets are usually deeply embedded in the institutional and organizational contexts of their origins. Moreover, knowledge-based assets have a tacit component that is not codified and therefore is imperfectly transferable to local firms. For instance, production processes requiring highly specialized workers are usually transferred to subsidiaries rather than to other firms since licensing would entail costly training of local employees (Teece 1986).

The transmission of knowledge-based assets is subject to market failures such as the dilution of property rights. Product reengineering, for example, may allow the local firm to discover the tacit knowledge embedded in the new product and to start

a rival firm. In addition, the MNE might break the terms of the license and transfer the knowledge-based asset to a different local firm. The problem for the MNE is to design an optimal contract that preserves the value of its knowledge-based assets. This contract usually includes rent sharing with the local firm. If defection cannot be avoided, the MNE will prefer to internalize its assets in spite of higher setup costs.

The empirical evidence presented by Smith (2001) on U.S. firms' foreign operations shows that licensing is a more likely entry mode in markets characterized by stronger protection of intellectual property rights.

Transferability of Goodwill Assets The stock of knowledge is not the only intangible asset that is difficult to transfer to local firms. The transfer of goodwill assets such as reputation for quality can face severe problems if the local firm does not fully appropriate the returns from maintaining the MNE's brand reputation. Examples of industries where reputation is important include hotels and restaurants, consulting, and financial services. The reputation problem faced by MNEs is as follows. Consumers value quality and are willing to pay more if they believe that the firm is supplying high-quality products or services. The local firm may be tempted to compromise on products' quality to reduce costs. This strategy leads to higher short-term profit, but once consumers become disappointed with their purchases, the MNE may retaliate and purchase products from other suppliers.

The fact that foreign parties do not fully appropriate the returns from maintaining the MNE's reputation gives rise to FDI. The local firm does not internalize the costs to the global reputation of the MNE when it provides low-quality goods. This problem is why the MNE should design contracts that specify much more than prices. In practice, the usual method to achieve such a result is a franchise contract in which the local firm agrees on a complete business concept. The contract needs to ensure that the local firm provides a level of quality sufficient to maintain the reputation of the MNE. However, the franchising agreement will still not be sufficient to

solve the reputation problem when efforts to maintain the quality of products and/or services are not fully verifiable. In this case, the MNE may prefer to set up its own subsidiary, which allows more effective incentive and control systems.

Intangible Assets and Spillovers to Foreign Economies Researchers have attempted to identify and empirically measure spillovers from MNEs' transfer of intangible assets to local firms. These spillovers may be positive or negative. On the one hand, MNEs may enable local firms to upgrade their technology, to the extent that they bring better business practices, technology, or management. On the other hand, MNEs may increase competition by attracting demand away from local firms. If economies of scale are important, the loss of demand will reduce the productivity of local firms by reducing the scale of their production.

Positive or negative spillovers may be direct, from firm to firm, through imitation of technology, managerial and organizational innovations, or competition. They can also be indirect through the labor market when specialized skilled workers from the MNE are complementary to workers in the local firm or when they move to rival firms. In either case, the ability of local firms to assimilate or value new knowledge, the so-called *absorptive capacity*, is crucial for obtaining significant benefits from FDI.

There is weak evidence for spillovers from MNEs. Positive spillovers from multinational firms are supported by casual evidence from many countries, but their existence and magnitude are difficult to establish empirically (UNCTAD 2001). Several studies have emphasized the role of local firms' absorptive capacity in explaining the lack of spillovers from multinational activities. This reasoning suggests that spillovers may not affect firms equally but may benefit only firms with high levels of absorptive capacity. The lack of strong empirical evidence for spillovers suggests also that multinational firms have succeeded in protecting their intangible assets.

In sum, intangible assets are vital to the incentives for MNEs to form and vital to the ability of MNEs to continue to prosper. Successful MNEs have valuable intangible assets, transfer the benefits of these intangibles to subsidiaries producing abroad, and protect their intangible assets by limiting the degree that the benefits spill over to rival firms.

■ **intellectual property rights**
Intellectual property rights are legal devices designed to protect intellectual property, which can be broadly defined as a recognized ownership over the ideas, designs, inventions, or concepts created by a person or organization. Intellectual property rights are therefore instruments intended to ensure that the originators of intellectual property have control over its use.

Intellectual property rights relate to two broad categories of intellectual property: industrial property, and literary and artistic property. Industrial property can be protected by patents, utility models, industrial designs, trademarks, and geographical indications. Literary and artistic property protection may be provided by copyrights. Intellectual property rights may also be granted in the form of sui generis protection. Additionally, trade secrets offer an alternative way of providing protection to intellectual property.

Types of Intellectual Property Rights *Patents* allow an inventor to exclude all others from commercially exploiting his or her invention for a fixed period of time, usually 20 years. They apply both to novel products (such as new drugs) and to novel processes (such as a new method of producing an existing drug).

Utility models are also used to protect inventions in certain countries but are usually sought for less technically complex devices. The requirements for achieving protection under utility models are less stringent than the ones for achieving protection under patents, and the length of protection is also shorter for utility models.

Industrial designs protect the ornamental or aesthetic features (shape, pattern, color) of a useful article that is reproduced by industrial means.

Trademarks and service marks are used to protect a distinctive mark or name that identifies a product, service, or company.

Geographical indications are signs used on goods that originate from a particular geographical location and possess qualities or a reputation that are due to that location.

Copyrights protect the rights of creators of literary and artistic works (such as books, poems, music, paintings and sculptures, films) to communicate, display, perform, and make or sell copies of those works. The length of protection is usually the lifetime of the creator plus 50 to 70 years. Copyrights may also apply to technology-based works such as computer programs, electronic databases, and multimedia productions.

Sui generis protection refers to new categories of intellectual property rights that apply to forms of creative activities resulting from recent technology advances that do not fit into the standard categories of intellectual property. Computer software, layout design of integrated circuits, plant breeder's rights, and electronic transmission of databases or broadcasts are some examples.

Trade secrets are not intellectual property rights in the traditional sense. They provide protection to industrial property through legislation that deems it illegal to disclose or use proprietary information about production practices and processes that is considered commercially valuable for a company (ranging from a list of secret ingredients to customer lists). Trade secrets have no statutory time limit but the protection they offer may expire through learning by fair means, such as reverse engineering or reading public documents.

National and International Dimensions of Intellectual Property Rights Intellectual property rights are national in scope: legislation regarding intellectual property rights is enacted at the national level and is part of a country's legal system. Countries face a fundamental trade-off when designing a system of intellectual property rights. On the one hand, intellectual property rights should generate a sufficient incentive for invention and creation to occur by providing an effective means of protection to the rights of the originators of intellectual property. On the other hand, intellectual property rights should ensure proper diffusion and access to intellectual

property, so that society as a whole benefits from public access to new ideas. For instance, by offering intellectual property protection through a patent, society has opted to create a temporary monopoly (or exclusive market) for the product protected under that patent. The presence of such monopoly imposes societal costs in terms of high prices and lower efficiency, but it also generates the incentives for invention to occur by guaranteeing higher profits to patent holders. Once a patent is granted, however, all technical information pertaining to that new product (or process) becomes publicly available for others to use in their own research activities. In this sense, intellectual property rights restrict the use of proprietary ideas in production, but patenting may foster their use by others in research. Therefore, the societal benefits derived from having access to this information may outweigh the costs imposed on society by the presence of a monopoly.

Economists explain this basic trade-off by thinking about intellectual property rights in terms of the provision of a public good. First, intellectual property is nonrivalrous, that is, one person's use of it does not reduce another person's use. Therefore the marginal cost of providing access to the information embodied in intellectual property to another user is very small and has the potential to generate benefits to society as a whole. For example, the patenting of a plasma display panel can generate positive benefits (or externalities) through technological spillovers, since all the technical details pertaining to such invention can now be accessed by other researchers at a negligible cost. Second, intellectual property may be nonexcludable by private means. That is, it may be impossible to preclude others from using the information without authorization. This generates what economists refer to as a free-rider problem: without protection of intellectual property, no one will wish to bear the costs of generating it.

Most legal systems try to balance these two goals of providing financial incentives for innovation and providing society with access to new ideas and inventions, which is a challenging task. If intellectual property rights were too weak, plasma display

panels might have never been created. If intellectual property rights were too strong, the spillover benefits associated with such an invention might never sufficiently spread across society. Note that this basic trade-off presents static and dynamic considerations. By bearing the static costs of protecting intellectual property today, society may enjoy the dynamic gains of faster innovation and growth in the future.

Each form of intellectual property right is designed with these goals in mind. When patents are granted, society gains full access to the technical information regarding a new product or process, and the fixed length of protection minimizes the costs of providing access to this product or process at prices higher than marginal costs. Copyright protection allows exceptions under the "fair use doctrine," which defines activities that can make use of protected works in the interests of educational, scientific, and technical advances. It is less clear how trade secrets can provide net benefits to society since they generate market power without divulging information. Economists have started to recognize, however, that protecting trade secrets may also generate important incentives for innovation, for example, by reducing incentives for research and development patent races or by facilitating reverse engineering.

Additional considerations about designing a system of intellectual property protection are relevant to the case of an open economy. For countries that are net exporters of intellectual property, large losses can occur from the imitation and use of their innovations in foreign countries with weak intellectual property rights. For countries that are net importers of products subject to intellectual property protection, the decision to provide or even strengthen intellectual property rights generates static costs such as higher prices for imported goods or technology, transfer of monopoly rents to foreign firms or foreign countries, and loss of employment in local firms whose production is imitative in nature. And to the extent that imitative activities may generate technological spillovers and affect a country's growth rate, intellectual property protection may impose dynamic costs in

terms of reduced access to international technologies and slower growth in the long run.

Stronger intellectual property rights may also result in dynamic welfare gains. For instance, the transfer of monopoly rents to foreign firms may result in innovation that is better suited to domestic needs than to foreign needs. Additionally, stronger intellectual property rights can facilitate technological diffusion, innovation, and growth by generating incentives for trade in knowledge-intensive goods, foreign direct investment (FDI), and licensing agreements. A key issue in evaluating the net impact of these trade-offs for an open economy is a country's overall technical potential. If the local economy does not possess the infrastructure and know-how to reproduce new technologies through imitation or reverse engineering, weaker intellectual property protection would not generate the positive effects of technological diffusion. In this case, stronger intellectual property rights might be more desirable since they provide better opportunities for formal technology transfer through access to knowledge-intensive goods, foreign patents, joint ventures, and licensing agreements. Another important consideration is market size; foreign firms may not have enough incentives to engage in production targeted to domestic needs if the size of the local market is relatively small.

Since intellectual property rights are national in scope, the level of protection provided by such instruments (and the level of enforcement of such protection) can vary widely across countries, with the largest variations occurring between developed and developing countries. These discrepancies exist not only with respect to the de jure level of protection, but also with respect to the de facto enforcement of the existing legislation. This issue becomes especially important and controversial as owners of intellectual property seek to exploit international markets. The debate is relevant not only for individuals or organizations that possess ownership of intellectual property but also for national policy, since a country's level of intellectual property rights may affect its volumes of international trade and FDI flows and its levels of innovation and economic growth.

The International Debate Regarding Intellectual Property Rights The need to protect industrial property at the international level was first recognized in the Paris Convention for the Protection of Industrial Property in 1883, and later extended to literary and artistic property in the Berne Convention for the Protection of Literary and Artistic Works in 1886. These treaties, which constitute the core foundation of the World Intellectual Property Organization (WIPO), established a system in which inventors or artists could seek protection for their work in other countries on terms no less favorable than the terms available to the nationals of those countries. Note that this would imply that a U.S. patent holder, seeking to extend protection of her intellectual property to other countries, would still need to apply for a patent in each country separately. The treaties, however, guaranteed that she would be treated just like any other citizen of that country. Since then, the international legislation regarding intellectual property rights has undergone several changes primarily driven by two important forces: technological progress and globalization. First, technological progress has required the adaptation of intellectual property rights instruments in key areas such as integrated circuits, computer software, and biotechnology inventions. Second, the globalization process has facilitated the diffusion of intellectual property across international borders, increasing the controversy over discrepancies in intellectual property rights across countries.

The current system of global intellectual property rights encompasses various intergovernmental treaties administered by the WIPO, as well as intellectual property rights legislation that is part of bilateral, regional, or international trade agreements. The most important and controversial of such agreements is the Agreement on Trade-Related Aspects of Intellectual Property Rights (TRIPS), which came into effect in 1995 under the auspices of the World Trade Organization. In contrast to the Paris Convention, the TRIPS agreement imposes minimum standards of protection, which are either in line with or exceed the practices of most industrialized countries, and

establishes a dispute settlement mechanism to enforce these minimum standards.

As intellectual property rights become a standard feature in many international trade agreements, the need for a better understanding of how these rules will affect countries becomes a pressing issue in economic research. Recent theoretical and empirical research has focused on trying to better understand the specific channels through which intellectual property rights might affect innovation and economic growth, such as international trade flows, FDI, and licensing.

Economic theory suggests an ambiguous relationship between intellectual property rights and international trade flows. On the one hand, stronger intellectual property rights raises demand for the protected goods and could lead to increased sales. On the other hand, stronger intellectual property protection also augments the market power of foreign patent holders, allowing them to charge higher prices, which could generate reduced sales. Empirical studies in this area are therefore needed to settle this question.

Research undertaken so far suggests that stronger intellectual property rights have a positive impact on overall trade volumes, but are not relevant to trade in high-technology goods. Several explanations have been offered for this puzzle. It is possible that high-technology trade flows are less responsive to intellectual property rights because those products are simply harder to imitate than low-tech products. It is also conceivable that intellectual property rights matter the most to middle-income large developing countries, which are more likely to possess the technical capabilities to undertake reverse engineering. Finally, high-technology firms may decide to serve foreign markets through FDI and licensing.

The theoretical ambiguity with respect to the impact of intellectual property rights also extends to FDI and licensing. Empirical studies suggest that intellectual property rights are less important in attracting FDI than other factors, such as a country's infrastructure or overall business climate. Stronger intellectual property rights, however, are important in stimulating formal transfers of technology, espe-cially in the case of large developing countries with strong abilities to absorb technology. This result also holds for international licensing flows, since stronger intellectual property rights reduce the costs of establishing and monitoring licensing contracts.

Economic research in all these areas relies on national rankings of intellectual property rights, mainly the Ginarte and Park (1997) index. This is a time-varying index of intellectual property rights protection based on five categories of patent law: extent of coverage, membership in international patent agreements, provisions for loss of protection, de jure enforcement mechanisms, and the duration of protection. The index provides extensive coverage in terms of countries and years; however, one of its main drawbacks is the fact that it does not account for the de facto enforcement of the legislation.

Other Controversial Issues The debate over intellectual property rights is further complicated by ongoing deliberations regarding such critical issues as parallel imports, compulsory licensing, and traditional knowledge.

Parallel Imports Parallel imports occur when price differences between countries, generated by disparities in intellectual property protection, allow international arbitrage to take place. Consider a situation in which legitimate goods (as opposed to knock-offs) are placed in circulation in a certain market under legislation that protects intellectual property. If the wholesale price of such goods is low enough and transportation costs are not prohibitive, it may be possible for an independent trader to profit by selling those goods in other markets in which intellectual property rights are weaker. Parallel imports are not prohibited under international legislation (TRIPS), and their legality depends on whether or not national laws confine protection to the country in which the protected goods are first sold. If protection is exhausted at the international level, firms fully lose control over a product's distribution once the product has been put for sale in any location. In that case, markets are open to parallel imports from foreign countries. Economists have shown that the effects of limiting parallel imports on a country's

welfare are theoretically ambiguous and depend on the underlying motivations to pursue parallel trading in the first place.

Compulsory Licensing Compulsory licensing refers to a situation in which the government of the importing country has the legal authority to force the foreign holder of a patent to license production to a local firm as a condition of patent protection. This practice is allowed by international legislation (TRIPS) only under extreme circumstances, such as public health emergencies.

The regulation of parallel imports and the use of compulsory licensing have been critical issues in various international forums on providing access to medicines in developing countries.

Traditional Knowledge Most research in economics has focused on patents and copyrights, ignoring questions related to traditional knowledge. Traditional knowledge generally refers to the wisdom, knowledge, and teachings that are long-standing traditions of certain regional, indigenous, or local communities. These traditions can be expressed through various means, such as stories, folklore, rituals, and songs. The controversy over the protection of traditional knowledge has its roots in the 1992 Convention on Biological Diversity, which recognized the value of traditional knowledge in protecting species, ecosystems, and landscapes in language that contradicts international intellectual property agreements, especially the TRIPS agreement. Protecting traditional knowledge requires a sui generis type of protection and is a particularly important issue in developing countries, which have objected, for example, to patenting of traditional uses of medicinal plants.

Future Concerns The scope and pace of globalization, as well as technological progress, will ensure that intellectual property rights continue to play an important role in negotiations regarding international trade agreements. Intellectual property rights will also remain an important issue in designing domestic policies, especially in developing countries, since they have the potential to affect important macroeconomic variables such as a country's growth rate, volume of international trade, or FDI and licensing flows. Economists' efforts to better understand the precise mechanisms through which intellectual property rights affect these variables are therefore essential in facilitating the resolution of international disputes over intellectual property protection. But this research effort should also try to improve existing measures of cross-country comparisons involving intellectual property rights, and focus on less explored issues, such as whether and how to provide intellectual property protection to traditional knowledge.

PATRICIA HIGINO SCHNEIDER

■ intellectual property rights and foreign direct investment

The impact of intellectual property rights (IPRs) on foreign direct investment (FDI) plays a central role in the debate between developed and developing countries over intellectual property rights protection. Many developing countries have begun to reform their IPR regimes in response to the Agreement on Trade-Related Aspects of Intellectual Property Rights (TRIPS) and pressure from developed countries. As multinational enterprises (MNEs) strive to make use of their knowledge assets beyond national borders, they have made IPRs an issue of multilateral negotiations. Governments of developing countries also believe that agreeing to TRIPS ultimately would allow them wider access to agricultural and textile markets in developed countries. In addition, business interests within many developing countries have encouraged their governments to adopt stronger IPR protection in order to protect their own innovations tailored to the domestic market. Some observers also argue that stronger IPRs protection can encourage imports, inward FDI, and technology licensing, all of which can lead to an increase in technology transfer.

Effect of IPRs on Technology Transfer and Innovation Technology is fundamental to economic development, and its importance for raising productivity and living standards has long been recognized. Innovation and technological progress can raise productivity through the introduction of new goods, the improvement of existing goods, and reduction in the costs of production. Resources for innovations tend to be highly concentrated in a small number of advanced countries, however. For developing countries whose firms are not at the technological frontier, international technology transfer is important for promoting development. Some transfers occur between willing partners in formal trans-actions, but much comes through informal non-market transactions or spillovers. One of the transfer channels is trade in goods and services, with imports of goods having the potential to transfer knowledge through reverse engineering and cross-border learning of production methods and product design. Another channel is FDI, particularly inward FDI, where MNEs deploy advanced technology to their subsidiaries that may be diffused to host-country firms. Licensing, which involves the purchase of production and distribution rights for a product and the knowledge required to make effective use of these rights, is another channel for technology diffusion. Joint ventures combine many of the properties of FDI and licensing, and hence will also involve technology transfer. Informal channels of technology diffusion include imitation, movement of personnel from one firm to another taking with them specific knowledge of their original firm's technologies, data in patent applications, and the migration of people. There is no formal compensation to the original owner of the technology transferred. In this case, IPRs clearly play a role.

Intellectual properties have the characteristic of a public good: they are available on a nonexclusive basis. It is not possible to prevent others from applying knowledge even without the authorization of its creator. They are also nonrivalrous in use (additional parties can benefit from them at zero additional cost). Once an innovation has been created, its nonrival character suggests that benefits will be maximized if its use is free to all at marginal cost. Although a policy of free access might yield benefits in the short run, it will damage the incentive for further innovation. When the new technology is imitated, it reduces the potential profits of the original inventor and potentially removes the incentive to engage in innovative activities. Since imitation has lower costs than innovation, imitators have the advantage over innovators unless the latter can restrict access to their innovation. This characteristic provides the argument for strong IPRs protection. In the absence of IPRs, the market for intellectual properties would fail or yield an inefficient supply of output. As to the connection to FDI and trade, many pro-

ducers of intellectual output are engaged in both domestic and foreign markets. Risks of unauthorized copying and imitation exist both at home and abroad. Thus in regions where IPRs are weak, incentives to market via trade or FDI might be weak since the innovating firm's ability to appropriate rents is threatened. Moreover, an infringement of IPRs may adversely affect incentives to innovate and produce and thereby affect the potential to export and invest abroad.

Effect of IPRs on Imports, FDI, and Licensing
In determining the impact of IPRs on FDI, it is useful to rely on the widely accepted ownership-location-internalization (OLI) framework by Dunning (1993). When selling its products abroad, a firm is at least initially disadvantaged relative to local producers. Thus, to compete effectively with indigenous firms, a foreign producer must possess some advantages. Ownership advantage explains that MNEs must have assets that are unique to the firms, which usually take the form of new technologies, know-how, reputation for quality, or brand name. Ownership advantages assure a firm's ability to enter the host country's market. Location advantages are needed for firms to locate business abroad. This could be in the form of lower transportation cost, avoiding tariffs, lower input prices, lower standards and regulations, and access to the distribution markets. Internalization advantage gives the incentive to the MNEs to retain full control over the production process rather than to license their knowledge assets to local firms in a foreign country. This advantage covers the costs from license contract breaching, as well as control over the quality and reputation of the MNEs' products.

As mentioned earlier, MNEs have several options to exploit their knowledge assets. Apart from FDI, international trade and cross-border licensing represent the most important channels to transfer technology to the host countries. Hence, according to the OLI framework, IPRs protection should have an impact on the relative attractiveness of the three modes. Weak IPRs protection increases the probability of imitation, which erodes a firm's ownership advantages and makes a host country a less attractive location for foreign investors. An inadequate IPRs regime, therefore, deters FDI and encourages exporting. At the same time, a weak IPRs system increases the benefits of internalization since it is associated with a greater risk of the licensee's breaching the contract and acting in direct competition with the seller; this improves the attractiveness of FDI while discouraging licensing. Thus the overall relationship between the level of IPRs protection and FDI can be ambiguous.

Other theories conclude that the impact of IPRs protection on FDI varies by industries. MNEs are more likely to undertake FDI rather than licensing when they have a complex technology and highly differentiated products and when the costs of transferring technology through licensing are high (Horstmann and Markusen 1987). In such circumstances stronger IPRs, by reducing the risks of technology leakage, may increase the extent of licensing (Yang and Maskus 2001), thus reducing the need for FDI. For industries where technologies are relatively easy to imitate, however, we would expect more attention to be paid to the strength of IPRs protection. As such, the IPRs regime is likely to be important for sectors such as drugs, cosmetics, and health care products; chemicals; machinery, and equipment; and electrical equipment (Smarzynska 2004).

The concern about the IPRs regime also depends on the purpose of an investment project, being the highest in the case of R&D facilities and the lowest for projects focusing exclusively on sales and distribution (Mansfield 1994). This difference is expected given the nature and function of IPRs, which center on the ability to appropriate. In industries where firms have alternative means to appropriate the returns to their investments, the firms may forgo seeking IPRs and rely on other forms of protection. Other methods of protecting their knowledge assets include: (1) education and incubation of local innovators: for example, Microsoft is helping China develop its local software industry; (2) R&D strategies: firms increase their R&D to increase their lead time, sales, and services because litigation is slow, costly, and uncertain (some of them add anticounterfeiting features to prevent imitation); (3) other

business strategies: working with the imitators, lower prices on products in developing countries, and bundling products with services. These possibilities might explain why FDI in certain industries is found to be insignificantly affected by IPRs.

Empirical evidence on the relationship between IPRs protection and FDI is mixed. Lee and Mansfield (1996) find positive relationship between the two in 14 developing host countries, while Primo Braga and Fink (1998) do not obtain statistically significant results. When considering the simultaneous effects of IPRs on three entry modes (export, FDI, and licensing), Smith (2001) found that strong IPRs promote licensing more than FDI but have no impact on exports, while Maskus, Saggi, and Puttitanun (2005) found that strong IPRs result in a higher probability of FDI relative to licensing.

The inconsistency of empirical results might be due to the crude measure of IPRs protection. The measurement problems are common in proxy for the IPRs protection such as national patent indexes of Rapp and Rozek (1990) or Ginarte and Park (1997). While it might be relatively easy to classify relevant laws and regulations on the books (such as coverage and patent length), actual enforcement is very difficult to judge objectively. Moreover these measures capture only overall countrywide variations in the protection of intellectual property in a single national index, ignoring the cross-industry differences in effective protection.

Conflicts between Developed and Developing Countries over IPRs Strengthening the IPRs regime has been pushed aggressively by the United States and other major industrialized countries. These developed countries tend to opt for relatively strong IPRs systems, with the aim of encouraging creative activities and innovations that are seen as an important source of long-run economic growth.

Developing countries, on the other hand, argue that stronger IPRs could limit the local imitation of new technologies, reduce the supplies of products, and increase the prices of new goods. Hence the majority of developing countries have opted for weak IPRs protection, if any, as a way of allowing the rapid diffusion of knowledge through imitation as a sig-

nificant source of technological development. Providing stronger IPRs protection is seen as shifting profits from domestic imitative firms to foreign firms and reducing outputs of new technologies to the monopoly level, and hence increasing prices in the domestic economy rather than encouraging domestic innovative activity.

The counterargument is that stronger IPRs protection can help reward creativity and risk-taking even in developing economies, while weak IPRs protection can keep developing countries dependent on dynamically inefficient firms that rely on counterfeiting and imitation. It is also argued that the lack of technology transfers to the developing countries via FDI is due to the inadequacy of the IPRs protection and that such protection would promote FDI.

Nevertheless, economics studies showed that the net welfare effect of the host country depends on the host country's characteristics. In a small country where production and innovation capabilities are limited, higher IPRs standard likely will improve welfare through higher access to products that would not be available otherwise. If a country has greater production and imitation capability, but limited innovative capacity, higher standards of protection will hurt local producers and result in lower welfare for the economy. However, as innovative capacity improves, a country will gain from higher IPRs standard (Chen and Puttitanun 2006). In sum, strengthening IPRs protection has different welfare implication depending on the characteristics of each country.

■ **interest parity conditions**
Interest parity conditions are no-arbitrage profit conditions for financial capital. When such condi tions hold, it is infeasible for investors to obtain higher returns by borrowing or lending. Hence, in principle, interest parity conditions define theoretical linkages between interest rates and exchange rates between countries.

The easiest way to understand parity conditions is to consider how a typical investor can save in dif ferent locations. Suppose the home currency is a dollar, and the foreign currency is a euro. Further assume that a forward market exists. A forward

contract allows an investor to enter into an agreement this period to exchange currencies k periods hence at a forward rate F known today. Then the investor can either save at home, receiving interest rate i, or save abroad, converting by the exchange rate S, receiving the foreign interest rate i^*, and then converting back to home currency by the forward rate F obtaining at time t for a trade at time $t+1$.

$$(1+i) \qquad versus \qquad (1+i_t^*) \times \frac{F_{t,t+1}}{S_t}$$

If the gross return on the left is greater than that on the right, then investors will place their capital in the home country; if it is less, then investors will place their capital abroad. With infinite amounts of capital moving in search of the highest return (and in this example, there is no risk in nominal terms), these returns will be equalized.

$$(1+i) = (1+i_t^*) \times \frac{F_{t,t+1}}{S_t} \qquad (1)$$

After manipulation,

$$\frac{(i-i^*)}{(1+i_t^*)} = \frac{F_{t,t+1} - S_t}{S_t} \qquad (2)$$

This condition is called "covered interest rate parity," reflecting the fact that investors are "covered" against nominal uncertainty by way of the forward market.

If the forward rate is equal to the future spot rate, such that $F_{t,t+1} = S_{t,t+1}^e$, then (2) becomes:

$$\frac{(i-i^*)}{(1+i_t^*)} = \frac{S_{t,t+1}^e - S_t}{S_t} \qquad (3)$$

where the e superscript denotes "expected." Equation (3) is termed *uncovered interest rate parity*. This expression holds when investors do not require compensation for the uncertainty associated with trading currencies in the future. It states that *expected* nominal returns are equalized across borders in common currency terms.

When interest rates are low, the following log approximations are often used for equations (2) and (3).

$$(i_t - i_t^*) = f_{t,t+1} - s_t \qquad (2')$$
$$(i_t - i_t^*) = s_{t,t+1}^e - s_t \qquad (3')$$

where f and s are the logs of the forward and spot rates, respectively.

Frankel (1991) has labeled condition (2) holding as characterizing perfect capital mobility, while condition (3) is associated with perfect capital substitutability. These terms arise from the view that if (2) does not hold, there must be some sort of impediment capital controls or the threat thereof to the free flow of financial capital. But even if capital is free to move, investors may still respond to risk; that response to risk might drive a wedge between the expected spot and forward rates. When investors are risk-neutral in nominal terms, then investors will treat capital (say debt instruments issued in different currencies) as perfectly substitutable.

The conditions just discussed pertain to financial capital. In order to consider the mobility of physical capital, one has to bring into play the prices of commodities. Integration of goods markets are often defined as relative purchasing power parity (PPP) holding. Ex ante relative PPP can be written as:

$$s_{t,t+1}^e - s_t = (p_{t,t+1}^e - p_t) - (p_{t,t+1}^{*e} - p_t^*) \quad (4)$$

where p is the log price level. Equation 4 states that expected depreciation equals the expected inflation differential. Combining (4) with the uncovered interest rate parity condition (3′) leads to real interest parity.

$$i_t - (p_{t,t+1}^e - p_t) = i_t^* - (p_{t,t+1}^{*e} - p_t^*) \quad (5)$$

This says that the expected rate of return on capital, expressed in physical units, is equalized across borders. To the extent that in neoclassical models the marginal product of capital equals the real interest rate, this condition is equivalent to the equalization of marginal product of capital equalized across borders.

Covered Interest Parity Assessed For developed economies since the dismantling of capital controls, covered interest parity holds fairly well. It should be noted that most tests are conducted using offshore rates, in which case (2) is sometimes termed *closed interest parity*, although the term *covered interest parity* is often used to encompass this concept.

Early tests were conducted by Frenkel and Levich (1975). They found that, after accounting for transactions costs, covered interest parity held for

three-month horizons. Offshore rates sometimes diverge from onshore rates, so that the findings of covered interest parity are somewhat weaker.

The question of whether covered interest parity holds for longer horizons is an open one. Popper (1993) concludes that covered interest differentials at long maturities are not appreciably greater than those for short (up to one year) maturities. This is a surprising result given that there are likely a number of regulatory impediments that would tend to introduce frictions into the arbitrage process.

Prior to the dismantling of capital controls, and in many emerging markets today, covered interest parity is unlikely to hold. In other words, covered interest differentials could be interpreted as political risk, associated with the possibility of governmental authorities placing restrictions on deposits located in different jurisdictions (clearly this is not relevant when all the deposits are offshore). Aliber (1973) is credited with this interpretation, while Dooley and Isard (1980) provided empirical estimates for the deutsche mark/dollar rate.

The Empirical Evidence for Uncovered Interest Parity Uncovered interest parity (UIP) is a more difficult condition to test, essentially because expected exchange rate changes are unobservable. In the literature, most tests of UIP are actually joint tests of UIP and the rational expectations hypothesis, that is, that ex post realizations of the exchange rate are an unbiased measure of the ex ante exchange rate, namely, $s_{t,t+1}^e = E(s_{t+1}|I_t)$. This assumption combined with equation (2′) yields this standard regression equation, sometimes called the Fama equation (Fama 1984):

$$s_{t+1} - s = \beta_0 + \beta_1(f_{t,t+1} - s_t) + v_{t+1} \qquad (6)$$

Or by virtue of covered interest parity holding,

$$s_{t+1} - s = \beta_0 + \beta_1(i_t - i_t^*) + v_{t+1} \qquad (7)$$

where under the joint null hypothesis v_{t+1} is a mean zero error unpredictable using past information, and $\beta_1 = 1$.

The evidence in favor of this joint hypothesis of UIP and rational expectations is quite weak. The regression of the ex post change of the spot exchange rate on either the forward discount (in equation 6) or the interest differential (in equation 7) typically

yields a slope coefficient estimate that is not only different from unity, but in fact negative and different from zero at conventional levels of statistical significance. This is true for reserve currencies (the U.S. dollar, the yen, the Swiss franc, the deutsche-mark, the franc, or the euro) at horizons up to a year. It is also true for some emerging market currencies (see Frankel and Poonawala 2006). One interesting characteristic of these regressions is that, although the coefficients are typically different from zero in a statistical sense, the proportion of total variation explained is typically very small.

At longer horizons (3, 5, and 10 years) the evidence is more supportive of the combined UIP rational expectations hypothesis. Chinn and Meredith (2004) document that estimates of the β_1 coefficient are usually not significantly different from the posited value of unity at 5- and 10-year horizons. The finding that the joint hypothesis of UIP and rational expectations holds better at long horizons than at short appears to be robust. Nonetheless, some caution is necessary here. Consider regressions involving 10-year interest differentials; by 2003, there would be only three nonoverlapping observations available per currency. Interestingly, Chaboud and Wright (2005) find that UIP also holds at extremely short horizons of a few minutes.

Other interesting results pertain to periods of extreme market turmoil. Flood and Rose (2002), following their 1996 work, find that UIP holds better in recent times when the sample encompasses successful attacks on currency pegs. Nonetheless, they still find lots of heterogeneity in experiences with UIP.

A different perspective on UIP is provided by dropping the rational expectations hypothesis.

A new area of research involves an investigation of whether UIP holds for emerging markets. Bansal and Dahlquist (2000) found that there was a basic asymmetry in whether UIP holds. In particular, they find that when the U.S. interest rate is lower than foreign country rates, UIP holds, while UIP fails to hold when the U.S. rate is higher. They also find that idiosyncratic factors, such as the gross domestic product per capita of the foreign country, are

important in determining the degree of failure of UIP to hold.

Using the forward discount instead of interest differentials, Frankel and Poonawala (2006) find that there is substantial heterogeneity in the results. What matters importantly is the exchange rate regime: highly managed exchange rate regimes are associated with currencies that exhibit greater deviations from UIP.

Real Interest Parity Measured If UIP does not seem to hold at short horizons, it seems unlikely that real interest parity, described as exact equalization of real interest rates, would hold. One could, however, still test the weaker condition that movements in real rates in one country would be met by one-for-one real movements in other countries.

The key difficulty with testing this condition, like that with testing UIP, is that market expectations are not directly observable. Hence, one can conduct only joint tests for real interest parity. In Fujii and Chinn (2001), real interest rates are calculated using a variety of proxy measures of expected inflation: ex post inflation, and inflation predicted using lagged values of inflation models. Both approaches are consistent with rational expectations. They find that the real interest parity holds with different strength at different horizons. As in numerous previous studies (Cumby and Obstfeld 1984; Mark 1985), the real interest parity (RIP) hypothesis is decisively rejected with short horizon data. At 5- to 10-year horizons, however, the empirical evidence becomes far more supportive and in some cases the RIP hypothesis is not rejected. In general, RIP, *up to a constant*, holds better at long horizons than at short horizons. These results are robust to alternative ways of modeling expected inflation rates.

In recent years, several countries, including the United Kingdom, the United States, France, and Canada, have begun issuing inflation-indexed debt securities. These are marketable securities whose principal is adjusted by changes in the price level (usually the consumer price index). The principal increases with the inflation rate so that the real return can be directly observed. A cursory investigation re-

veals that there is no evidence of equalization. Moreover, although there is some covariation, it is not anywhere near one for one. The thinness of the markets and the differences in the maturities of the relevant debt instruments, however, make strong conclusions in either direction difficult.

■ internalization theory

Internalization refers to the decision by a multinational firm producing abroad whether to own a foreign production facility or to license or contract with a foreign firm to produce a good or service on behalf of the multinational. Specifically, internalization refers to production internal to the ownership boundaries of the firm. This topic has a long history in the international business literature, but has more recently emerged under the converse name of outsourcing. This is merely a change in name: the firm must decide whether to internalize or outsource. Other terms used to refer to this decision include *mode choice* and *boundaries of the firm.*

This entry focuses on relatively recent papers that offer alternative formal models of the internalization decision. Nevertheless, it is important for researchers in this field to acknowledge the substantial contributions of earlier writers in the international business tradition, including John Dunning, Mark Casson, Alan Rugman, Oliver Williamson, and others. An excellent review of this literature is provided in Caves (2007) and in a somewhat more circumscribed fashion in Markusen (2002).

Firms make mode choices, such as among exports, subsidiary production, and outsourcing, in response

to the conditions and constraints they experience. A typical starting point in the theory of the multinational is that the firm possesses proprietary assets that give it a motive for expanding abroad in the first place. These assets could include product or process technology, a brand name or trademark, or a reputation for product quality. But in moving or using these assets abroad, the firm runs certain risks of asset dissipation or holdup through opportunistic behavior of foreign licensees, contractors, or even by the firm's own managers in the case of an owned subsidiary. Asset dissipation is therefore a motive for internalization. But this must be balanced against other competing forces, such as giving the local manager or licensee strong incentives to engage in efficient investment and effort levels. Internalization theory explores the tension among these alternative factors and derives the optimal mode choice for firms subject to various assumptions about contracting and other constraints.

The Internalization Decision and Opportunistic Behavior Some of the first formal models of the internalization decision were published in the late 1980s and 1990s and draw their empirical motivation from the strong association of multinationality with knowledge-based assets such as those described in the previous paragraph (again, see Caves 2007 and Markusen 2002). On the one hand, these assets (or the services thereof) are easily transferred overseas, such as providing a blueprint, chemical formula, or procedure to a foreign plant. On the other hand, the same characteristics that make it easy to transfer these assets make them easily learned by foreign managers, agents, or licensees. Once the agent sees the blueprint or license he or she could defect to produce the product in a new firm.

Horstmann and Markusen (1987) have a model in which the intangible or knowledge-based asset is a reputation for product quality. This quality can only be observed by a consumer after purchase and use of the product. The difficulty is that, if the firm extracts all of the rents from a local licensee, that licensee has an incentive to product a cheap, low-quality substitute and earn positive profits for one period before being fired. The multinational risks asset dissipation

through agent opportunism, a theme that occurs repeatedly in subsequent papers.

The Horstmann-Markusen (1987) paper tends to focus on a firm's decision to export versus produce abroad. It is less well suited to explicitly considering the decision to create an owned subsidiary versus using a foreign licensee; after all, the local manager has much the same incentives as a licensee. Two 1996 papers made some further progress on this issue. Ethier and Markusen (1996) have a model in which a firm introduces a new product every second period. During the first period of a product's life, the local agent or manager absorbs all relevant aspects of the technology and is capable of producing the product on his or her own in the second period. At the end of the second period, the product is obsolete and the manager's knowledge is of no further use.

Under certain parameterizations of this model, the multinational can extract all rents with a single-product licensing contract, and so this is of course optimal. For other parameterizations, this cannot be done. The alternative is for the multinational to offer a contract that shares some rents with the local manager, and this can be credible and incentive-compatible for both parties over the long term in which the contract and rent sharing is repeated with every new product. This long-term incentive-compatible sharing arrangement is thought of as a subsidiary relationship, not limited to one product but continuing indefinitely into the future.

Horstmann and Markusen (1996) have quite a different approach, introducing asymmetric information along with moral hazard. The potential local agent or manager possesses local information on market demand or costs that is not known to the multinational. The market could actually be large, but the agent has an incentive to pretend it is small and shirk on effort so that sales are consistent with high effort in a small market. The best feasible licensing contract forces the multinational to share rents, termed information rents, with the agent. The alternative is for the firm to establish an owned subsidiary from the beginning, which is more costly, but the firm learns the true state of demand or costs without having to share rents to extract this infor-

mation. In the vernacular, an owned subsidiary gives the multinational a larger share of a smaller pie, another theme that occurs repeatedly in the internalization/outsourcing literature.

Three later papers followed in the tradition of the Ethier and Markusen (1996) model: Fosfuri, Motta, and Rønde (2001); Glass and Saggi (2002); and Markusen (2001). All share the idea that knowledge is absorbed by workers in the course of production, and they are then at least potentially able to defect and start rival firms after some period of time. The Fosfuri, Motta, and Rønde model has a richer technological structure than the original Ethier and Markusen model. In particular, the managers or licensees who absorb the knowledge from the multinational may later enter into a complementary relationship with their former employer rather than a competitive one, supplying goods or services to the multinational. This is a valuable development insofar as there are many examples of former employees, in Taiwan, for example, becoming contractors in a cooperative relationship with their old firms.

Glass and Saggi (2002) focus on workers in general and not managers or licensees specifically. Workers absorb knowledge and can be hired away by local firms. The multinational has two options to prevent the dissipation of its technology, termed a transfer of technology (i.e., the term *technology transfer* in this model refers to transfer from the multinational to the host-country firm, not to whether or not the multinational uses or "transfers" its technology to the host-country plant). The firm can pay its workers a wage premium, or it can choose an alternative, more costly location (e.g., export to the host country). Glass and Saggi solve for parameters under which the multinational prevents technology transfer by paying sufficiently high wages and under which the multinational's best option is to pay minimal wages and accommodate the technology transfer through worker mobility. The welfare consequences of these alternatives are analyzed. There is no explicit modeling of a licensing or outsourcing alternative to establishing a subsidiary.

Markusen (2001) follows in the Ethier-Markusen tradition as just noted. He extends this model to in-

clude an explicit analysis of intellectual properties rights and provides a welfare analysis. Tighter intellectual property protection and contract enforcement raise the costs to the local manager of defecting, but also raise the costs to the multinational of firing and replacing the manager after one period. Tighter enforcement means that the incentive-compatible contract allows the multinational to share fewer rents with the local manager or licensee. This presents a trade-off for the host country in setting policy. Tighter enforcement means that the multinational may now enter the country whereas before the optimal policy was to export, and this is welfare improving for the host. On the other hand, for a firm that is entering anyway, tighter enforcement transfers rents from the local manager to the firm and hence is welfare reducing.

Property Rights Approach and the Holdup Problem About the same time as this last set of papers, an important advancement to the internalization question was being developed by Antrás, Grossman, and Helpman (Antrás 2003, 2005; Antrás and Helpman 2004; Grossman and Helpman 2004). All of these authors substitute the term *outsourcing* for the term *internalization*. Their approach is sometimes termed the "property-rights" approach to the firm after contributions by Grossman and Hart (1986) and Hart and Moore (1990), following earlier contributions of Williamson (1985) and others in the international business literature.

The new literature combines a number of separate elements that together produce a coherent model that offers clear empirical predictions. The first element (in no particular order) is the assumption that production requires "relation-specific investments," meaning that a multinational and a foreign individual or firm must incur sunk investments prior to production that have no outside value if the relationship breaks down. The second element is the assumption of incomplete contracting: certain things are simply not contractible or alternatively any contract on these items is not enforceable. The papers just mentioned focus on the idea of noncontractibility, in particular they assume that certain things either cannot be observed and/or are not verifiable by third parties rather than focusing on institutional failures such that contracts cannot be en-

forced. These two elements of the newer theory are shared with the older literature reviewed above.

The assumptions of sunk investments and non-contractibility lead to a third problem, which is ex-post "holdup." What happens after production occurs cannot be contracted ex ante, and so each party has some ability to negotiate ex post and to prevent the other party from fully utilizing the output. As is generally assumed in this approach to the firm, the Antrás-Grossman-Helpman papers assume that the multinational and the local manager or firm engage in ex post Nash bargaining over the surplus. The final element of this approach is the notion of ownership, necessary in order to distinguish an owned subsidiary from an arm's-length supplier. The property rights approach defines the owner of the foreign production facility as the party that has residual rights of control; that is, the party that owns any output or other assets of the firm in the event that bargaining breaks down.

The difficulty for the multinational is that the choice between an owned subsidiary and an arm's-length licensee both entail some inefficiency again due to incomplete contracting. Antrás (2003), in an elegant model and exposition, assumes that the multinational chooses the quantity of capital to be used in production and the local manager or licensee chooses the quantity of labor. In the Nash bargaining phase, the problem is that each party will receive only a fraction of the marginal return to its ex ante investment, and thus there will be investment in both capital and labor (in Antrás's model) in equilibrium. Ownership of the local supplier entitles the multinational to residual rights of control and thus improves the ex post bargaining position, but reduces the local manager's incentive to make an efficient ex ante investment.

Antrás assumes that there are many potential host-country licensees or managers and that the multinational can impose an up-front fee and so competition among suppliers will lead the up-front fee to adjust so that the local supplier will just break even. Let X be the output that is produced. Because X is assumed to be a component that is specific to the multinational firm, it also follows that the local manager/licensee has no ability to use X outside the relationship even if he or she

has residual ownership rights, and so the manager/licensee's outside option is zero under either the subsidiary or licensing relationship. But the multinational's outside option is higher with residual rights of control. The firm can use at least part of the X when the multinational is the owner, but neither party can use X in the licensing relationship when bargaining breaks down. Thus the multinational will capture a larger share of the surplus in ex post bargaining under a subsidiary arrangement.

The consequence when combining these various elements is that, while both a subsidiary and a licensing relationship suffer from underinvestment, the subsidiary relationship suffers more from an underinvestment in labor relative to capital: the licensee has less incentive to invest due to a smaller marginal share. The licensing arrangement suffers more from an underinvestment in capital, since the multinational receives a smaller share in the ex post bargaining outcome. The next step becomes straightforward: the subsidiary is the more profitable option for a capital-intensive industry while the arm's-length contract is more profitable for a labor-intensive industry. This clear prediction is successfully taken to the data.

A conceptually related model is found in Antrás (2005). A product-cycle model is developed, in which a high-tech input that can be produced only in the North is combined with a low-tech input that can be produced either in the North or South. As time passes, the technology shifts so that the high-tech input is less important. The theory predicts that, as time passes, production first shifts to the South within firm boundaries and only later to independent foreign firms.

Various extensions and refinements of this approach are found in other Antrás-Grossman-Helpman papers noted above. These are an advance on the earlier literature discussed above, insofar as the difference between an owned subsidiary and an arm's-length relationship is sharper and better defined. Empirical predictions are similarly sharper and then have so far stood up under empirical investigation such as in Feenstra and Hanson (2005) in addition to Antrás's own results.

Chen, Horstmann, and Markusen (2007) have produced a new model in which there is both knowl-

edge capital and physical capital. As in the earlier literature, the knowledge capital is absorbed by the workers over the first period and hence there is no clear ownership issue: knowledge is nonexcludable. The physical capital is fully excludable as in the newer property-rights papers and belongs to the residual claimant, the owner of the production facility. They obtain the prediction that the owned subsidiary is more likely to be chosen in an industry in which the ratio of knowledge capital to physical capital is high. They suggest that this could be proxied by a Tobin's Q statistic in subsequent empirical analysis. The results seem consistent with the extensive empirical analysis surveyed in Caves (2007).

Areas Needing More Research All of these models are helpful in understanding the internalization versus outsourcing decision, and they seem to be standing up well to empirical analysis as noted. They are, however, very specific models. The international business literature, while less formal and analytic, identifies a far broader range of factors influencing a firm's entry mode choice in serving a foreign market. Judging by the references contained in most of the papers surveyed here, the international business literature under the term *internalization* is generally being ignored in the literature under the name *outsourcing*. This is surely a mistake, and researchers in the more formal economics tradition are missing out on the richness of detail, ideas, and empirical evidence found in the international business literature. Again, Caves (2007) is an excellent background for any scholar interested in this field.

We can conclude then with a brief listing of some of the other factors that seem important and which are ripe pickings for more formal analysis. Complex tax systems influence firms' mode choices. Formal barriers to majority-owned affiliates, often indirect and hard to measure, corrupt observations from developing countries and suggest more joint ventures and arm's-length arrangements than would actually be observed in less-regulated markets. A broad range of institutions including legal systems, contract enforcement, corrupt practices, host government holdup, and intellectual property protection influence the relative attractiveness of owned affiliates versus licensing and other hybrid mode forms.

Some disconnect with empirical evidence is also evident. While many of the newer formal models surveyed here assume the foreign partner is providing an intermediate for the multinational, empirical evidence consistently shows that the major motive for foreign direct investments is to serve local markets, with production for regional third countries coming in second. Production for export back to the parent country amounts to only about 10 percent of sales for foreign affiliates of U.S. manufacturing multinationals and even then, much of this small amount is final goods assembled in labor-intensive factories abroad. Examinations of lengthy, complex outsourcing contracts apparently cast some doubt on convenient assumptions that a whole range of things are noncontractible since they appear very explicitly in these real-world contracts, but there is little published evidence on this point.

Other even more intangible but no doubt very real considerations are often mentioned in the international business literature. Dissimilar corporate cultures and conflicts between the global objectives of the multinational and the more circumscribed and short-run objectives of the potential local contracting firm are just two of many examples. Multinationals are not trying to maximize local profits, and the task of inducing a local affiliate, much less a licensee, to respond to the firm's global strategy is a difficult contracting complication. All of these factors suggest that there is still much to be done.

JAMES R. MARKUSEN

■ international financial architecture

The international financial architecture is the set of institutions and norms both international and domestic that shape the international financial system. The institutional relations among industrial economies are clearly part of the international financial architecture. The policy debate that followed the currency crises in Asia and other emerging market crises in the late 1990s focused on reforms that could help make the integration of emerging economies into the international financial system less disruptive.

The resulting debate rested on two assumptions. First, private capital should normally flow from advanced economies to emerging economies at least to those with sound economic fundamentals and solid policy frameworks. Second, the integration of emerging economies into global financial markets a process that was catalyzed by the 1989 90 Brady plan, which transformed bad loans left over from the 1980s debt crisis into bonds had not proceeded as smoothly as many had hoped. The "architects" consequently sought to create an institutional structure that would sustain private financial flows to emerging economies while reducing the risk that sudden interruptions in these flows would lead to painful crises and also increasing the international community's ability to manage crises that could not be avoided.

Background U.S. treasury secretary Robert Rubin first used the term *international financial architecture* in a speech in April 1998. The resulting debate culminated in the Cologne communiqué in 1999. It emphasized the need for a higher standard of transparency, stronger financial systems in emerging economies, changes in financial regulation in industrial economies to help make capital flows less cyclical, "corner" exchange rate regimes, and greater efforts to involve private creditors in the provision of crisis financing. This agenda informed much of the work of the International Monetary Fund (IMF) over the next few years.

It would be a mistake, however, to limit analysis of the architecture reforms solely to the specific proposals that followed from Rubin's speech: the debate over the need to reform the international financial architecture started well before Rubin coined the term *architecture* and did not end when the term disappeared from the official sector's formal lexicon in 2001. After Mexico's crisis of 1994 95, the Group of Seven (G7) called for the development of new facilities designed to allow the IMF to lend larger sums, but for shorter periods and at higher rates, as well an expansion of the IMF's lending capacity. These reforms were implemented in 1997 and 1998 with the creation of the Supplemental Reserve Facility and congressional approval of an IMF quota increase. The substantive debate over many key issues continued through 2003, when Mexico's decision to introduce collective action clauses (CACs) provisions that allowed a supermajority of bondholders to amend a bond's financial terms ended the debate over IMF's proposal for a new international sovereign bankruptcy regime. The intensity of the debate over the right scale of IMF lending waned in the absence of any major crises. New topics, notably a surge in the U.S. current account deficit largely financed by a rise in the current account surplus of the emerging world, moved to the top of the international economic and financial policy agenda.

During the peak of the debate over financial crises in emerging economies, many complained that talk of architecture was too grand and that "plumbing" would be a more appropriate metaphor. Such arguments came from two directions: those who thought better plumbing was all that the international financial system needed, and those who thought the G7 was making a mistake by just fiddling with the plumbing when a truly new architecture was needed.

Ambitious Proposals The Asian crisis certainly generated a host of ambitious proposals. The IMF's first deputy managing director Anne Krueger proposed radically changing the institutions for debt restructuring by amending the IMF's Articles of Agreement to provide sovereign governments in default with bankruptcy-style protections (the sovereign debt restructuring mechanism, or SDRM). The economist Joseph Stiglitz suggested a "super" Chapter 11 regime to facilitate an across-the-board restructuring of private borrowers' debts in the event of macroeconomic shocks.

Anne Krueger's predecessor, Stanley Fischer, focused more on the institutional structure for crisis lending than on the institutional structure for debt restructuring. Fischer argued that the IMF should be transformed into a lender of last resort, able to lend in quantities that would be sure to end cross-border runs. The International Financial Institutions Advisory Committee (2000), more commonly called the Meltzer Commission, suggested that the IMF get out of the business of lending to countries that promise to deliver sound macroeconomic policies only when they are close to default and instead lend large sums to countries that qualified in advance for extra protection by maintaining good policies. The International Financial Institutions Advisory Committee (IFIAC) specifically recommended that the IMF lend large sums for short-term loans   120 days with only one possible rollover   to countries that prequalified for support. The IFIAC also suggested that the strength of a country's banking system be the key criterion for determining eligibility. Others have proposed less draconian forms of prequalification.

Proposed changes in governance of the major international financial institutions were equally dramatic, with proposals tabled to merge the IMF and the World Bank, to eliminate both institutions, and to create a new global financial regulator.

More Modest Results In the end, calls for major reforms generally were rejected in favor of more incremental changes. The IMF toyed with a facility based on prequalification (the contingent credit line, or CCL) but never gave up its traditional crisis lending. A new forum that brought regulators together with finance ministries, central banks, and the IMF (the Financial Stability Forum) and the development of new international codes and standards substituted for the creation of an international superregulator. No major reforms were made to the IMF's voting structure after the Asian crisis   though in 2006, the IMF did increase the quota of four underrepresented emerging economies: China, Korea, Mexico, and Turkey. The membership of informal clubs such as the G7 that often influenced IMF policy did not change, but a new forum, the G20, was created to bring the G7 together with major emerging markets.

Modest Reforms In the end, though, the architects did more than just clean up the plumbing. Some of the most consequential changes were adopted early on. After the crisis in Mexico, the United States decided to strengthen multilateral institutions for crisis financing. This led, in time, to important changes in the architecture. A bigger IMF was combined with facilities designed to allow the IMF to put more money on the table faster. In principle, exceptional IMF financing came with an expectation that those funds could be repaid more quickly than a typical IMF loan. In practice, the IMF's major shareholders did lend large sums to some countries that did not have a realistic chance of repaying the fund quickly; the large short-term loans provided to Turkey, Brazil, and Argentina in 2001 and 2002 all had to be refinanced. Large-scale crisis financing from the IMF effectively became the norm   despite claims by the G7 to the contrary   when major emerging economies encountered financial difficulties.

The institutions for debt restructuring evolved organically. The large international banks generally stopped providing medium- to long-term syndicated loans to the governments of emerging economies after the debt crisis of the 1980s, instead lending for shorter terms to private banks (some of which then lent to their local government) or private firms. Nonetheless, the architecture for coordinating the major international banks that was inherited from the sovereign debt crisis of the 1980s was adapted in Korea to help coordinate a rescheduling of interbank credit lines. New institutions for bond restructuring emerged, though not without some birth pangs. Negotiations between a distressed sovereign borrower and a coordinating committee of banks gave way to exchange offers. Distressed debtors, often advised by a major international bank, offered to exchange old bonds for new bonds with different payment terms. The success of these exchanges   participation was high and litigation proved less troublesome than initially anticipated   eliminated much of the pressure for more dramatic changes to the institutions for debt restructuring.

Arguably of most importance, the policies of most of the world's emerging economies changed dramatically. Emerging market economies embraced central bank independence and inflation targeting. Indeed, their inflation rates began to converge with those of the advanced countries. Local currency bond markets took off. Emerging economies concluded that they needed to hold far more reserves than they had held in the past; most now hold reserves well in excess of their short-term external debts. Many emerging economies began to allow their exchange rate to float, though most still intervene far more heavily than advanced economies. Transparency increased dramatically   at least for those emerging economies that felt compelled to live up to the IMF's revised standards.

Compared to the changes made in emerging markets, the changes in regulatory structure in industrial economies were quite modest. Concerns that capital flows from the industrial world to emerging economies were procyclical, with too much money flowing into emerging economies in good times and too much flowing out in bad times, did not prompt major policy changes. A revised set of Basel capital standards was in the process of being implemented as of 2007. Although hedge funds and the regulators of the banks that provide hedge funds with leverage were temporarily chastened by the 1998 implosion of a major U.S. hedge fund, Long-term Capital Management, the formal regulatory structure changed little. After a brief down period, hedge funds entered a new phase of phenomenal growth.

The debate on architecture ended with a broad consensus on the steps emerging economies needed to take to reduce the probability of crises, but with few tools that could force an emerging economy to follow these recommendations. A comparable consensus on the core issue of crisis resolution never truly emerged. The G7 was comfortable with an IMF that had the capacity to make big loans, and policy statements that claimed   without much credibility   that this capacity would not be used in the future. The G7   and for that matter the world's major emerging economies   never could define

when a debt restructuring should be an integral part of efforts to resolve a crisis.

Changes in the global economy, though, gradually shifted the focus of policy markets away from emerging market crises and reduced the pressure to find real consensus on difficult issues. Worries about too much demand for IMF lending gave way to concerns that the IMF might earn too little from its lending to cover its expenses. Concerns that the IMF was too reluctant to criticize emerging economies that clung too tenaciously to exchange rate pegs in the face of current account deficits gave way to concerns that the IMF was too reluctant to criticize emerging economies that intervened heavily to maintain undervalued exchange rates. Concerns that emerging economies had too few reserves gave way to concerns that they held too many   and were adding even more every year.

By 2005, private capital flows to emerging economies matched their pre Asian crisis peak. Eastern Europe, in part because of its institutional tie to the rest of Europe, relied on these capital inflows to cover significant current account deficits. But most other emerging economies used this surge in private capital flows, along with the windfall from rising commodity prices, to add to their reserves. In aggregate, the emerging world ran a large current account surplus, financing deficits in many of the world's advanced economies. This system, which has been labeled a new Bretton Woods system, represented a real change in the international financial architecture, even if it did not emerge from the debate that occupied policymakers in the 1990s, let alone a new Bretton Woods conference.

The debate over the architecture for managing financial crises in emerging economies has been superseded by a different architecture debate focused on finding new ways to facilitate macroeconomic policy coordination between the world's new creditor countries and its major debtor countries to help reduce global imbalances. This debate covers a very different set of topics than the previous debate from the optimal use of emerging economies' vast reserves to strengthening the IMF's surveillance of surplus countries in the emerging world and deficit

countries in the G7. One topic, though, has stayed constant: the continuing need to adapt the international financial world's governing institutions, both formal and informal, to better reflect the growing role emerging economies play in the international financial system.

■ international financial centers

International financial centers (IFCs) are global hubs for banking, insurance, capital, money, and foreign exchange transactions. A large share of global trade and management of financial wealth and debt instruments is conducted in these centers. By virtue of the volume of transactions and the depth of their markets, they are leaders in setting the price of financial instruments. Such instruments are used to channel (intermediate) capital between savers and borrowers and to transfer financial risk.

The predominant IFCs are London and New York. Other key centers include Tokyo and Frankfurt. A number of financial centers are important in a regional context, including Singapore and Hong Kong. Offshore financial centers are important domiciles for international financial transactions with the pricing and trading of the financial instruments keyed off the markets in the major IFCs. The term *international financial center* is also used as a signal by some centers that a preferential tax and/or flexible regulatory regime will apply to financial entities/transactions domiciled there. Competition among the financial centers is intense, and successful centers offer comparative advantage for market participants.

Growth and Evolution of IFCs The major IFCs have evolved in response to underlying economic circumstances. The initial importance of both London and New York can be traced to their geographical and historical locations as centers of trade and commerce and to the use, respectively, of British pounds and U.S. dollars for the denomination of international trade and investment transactions. Through a series of financial innovations, London has remained a dominant IFC notwithstanding the post World War II decline in the importance of sterling and the UK economy. Since the 1960s, for example, London has been the principal host of an international market in money, credit, and debt instruments denominated in U.S. dollars (the so-called Eurodollar market). Other innovations include deregulation of its stock market in the mid-1980s, elimination of exchange controls, and a market-friendly approach to regulation. The volume of international transactions in London is now several times that of domestic transactions. A similar balance of transactions can be found in centers such as Hong Kong, Singapore, Luxembourg, Ireland, and Switzerland, for example. By contrast, domestic transactions still dominate in centers such as New York and Tokyo, reflecting the size of their domestic economies.

Several factors have promoted the development of IFCs. The growth of international trade and investment in the period following World War II was accompanied by a rapidly expanding volume of international capital flows. The global increase in capital movements has responded to and helped finance the emergence of substantial imbalances between countries with surpluses and those with deficits in their balance of payments. A significant part of these international capital flows has been intermediated by the institutions and markets in the IFCs as they adapted their financial institutions and instruments to the global financing needs. Large deficits in the U.S. current accounts have been matched by increases in purchases of U.S. dollar assets, primarily through the major IFCs.

During the 1970s, a succession of increases in oil prices resulted in significant balance of payment surpluses among oil-producing countries. These surpluses were "recycled" through the IFCs, initially largely through the placement of surplus funds in bank deposits in those centers. At the same time, a number of advanced, developing, and emerging market economies looked to the international financial markets to finance their foreign-exchange reserve positions or their programs of economic growth and development. The facilities and instruments to mobilize the capital transfers, such as syndicated loans and international bonds, were provided by institutions based in the IFCs. Large corporations also tapped the international markets to finance investment.

A theoretical explanation of why certain financial centers have become dominant can be found in the literature on central place theory, which is used to explain why cities tend to be of unequal size. The underlying idea is that there is a trade-off between economies of scale that lead to concentration of activities, spurring centers of activity to grow, and the costs of accessing these centers of activity, which places a limit on the size of the center and allows other centers to grow. In the case of financial transactions, potentially significant benefits of concentration include the pooling of expertise and the bringing together of a large number of buyers and sellers of financial instruments. The ability to trade with a financial center can also be limited, for example, by the time zone where the financial center is located. The central-place theory has limitations when it comes to financial centers, which are in intense competition. No center can remain dominant as an IFC relying solely on its location. In the first decade of the 21th century New York started falling behind, losing traditional businesses to London, while new centers sprang up, as in Dubai, for example, which captured business from Europe, Asia, and the Middle East.

IFCs are characterized by mature financial markets that are deep (have a capacity to handle a range of transactions of different tenor and in large volumes), liquid (have a capacity to trade in and out of positions with reasonable certainty about the prices at which the trades will take place), and relatively efficient

(have pricing that reflects current market information). The legal foundation for financial contracts is well developed, providing reasonable legal certainty in the execution of the transactions, combined with sufficient flexibility to accommodate rapid innovation in financial instruments. The technical and institutional infrastructures for the financial markets are advanced and include a highly skilled and specialized labor force, ease of communications, efficient and low-cost trading platforms, and payments systems that help to mitigate financial systems risks. These systems are supported by regulatory structures and supervisory systems directed to customer protection, the prevention/mitigation of market and institution failures, and the prevention of financial abuse. The concentration of financial activity in the major centers places a significant responsibility on the host countries to ensure that the financial markets and institutions meet the highest regulatory standards, not least to protect their reputations, and regulators and central banks have proved quite adept at intervening at critical moments to maintain the stability and reputation of their centers.

The importance of the major business lines varies among the different financial centers, and they have also been evolving rapidly under intense competition and financial innovation. These business lines include (1) international banking (intermediating between international borrowers and depositors), investment banking (e.g., underwriting of equities and fixed-income investments, underwriting and brokering securitized streams of payments obligations [e.g., from credit cards, mortgages] and advisory services in mergers and acquisitions), and private banking (investment and advisory services for private wealth management); (2) foreign-exchange trading in spot, forward, and swap markets covering all the major currencies as well as nondeliverable forward markets in less convertible currencies; (3) insurance activities of various forms (e.g., life, marine, property, and casualty) and reinsurance; (4) securities dealing in equities, primarily through organized exchanges, and bonds in domestic and international currencies; (5) fund and asset management and administration such as mutual funds, pension funds, and hedge funds; (6) derivatives trading (e.g., swaps, options, interest rate equities, commodities, and credit contracts) both in over-the-counter markets and on organized exchanges; and (7) commodities trading (e.g., precious and other metals, agricultural and energy products) in spot, futures, and options transactions.

Consequences of Growth of IFCs IFCs are important both to the economies where they are located and internationally. They have direct importance to the local economies as sources of employment, contributors to foreign earnings and the balance of payments, and to gross domestic product. Internationally their importance derives from the provision of a range of financial services more efficiently than would be possible in local financial markets, reflecting the volume of transactions and the sophistication of the supporting infrastructure. The major banking and financial groups, which have a large international presence, are also headquartered in these centers. The management of a large share of global financial activity is therefore directed through these centers. The institutions in the IFCs have traditionally been at the forefront of innovations in financial instruments and techniques, adapting rapidly to changes in the global financial environment.

The global consequences of IFCs have not been without controversy. The growth of the Eurocurrency market was associated with concerns that it would undermine monetary policy and result in an uncontrolled expansion in global credit. These concerns abated as the authorities moved from monetary control that relied on direct instruments (such as credit ceiling and high, non-interest-bearing reserve requirements) which were not applied to transactions through the euro markets to indirect monetary instruments that relied on the market's adjustment of interest rates. The latter has a global impact, including in the euro markets. From time to time there are concerns that competition in the IFCs leads to an underpricing of risk, threatening the stability of financial institutions, and the global financial system. Credit spreads have tended to follow patterns of decline associated with financial innovation, only to

face sudden reversals when the assumptions and instruments on which the declines were based are tested by worsening economic conditions. Examples include the decline in spreads in the 1970s and 1980s on credits to developing countries with the growth of the market in syndicated credits that preceded the first international debt crisis; and the expansion of securitization to a broader range of debt payment flows, including subprime mortgages that preceded a sharp loss of confidence in the international credit markets in 2007. Rapid innovation in financial centers has posed, and continues to pose, a major challenge for financial regulators as they seek to understand and mitigate potential and emerging risks. As the underlying transactions have become less transparent, the rating agencies have grown to play an increasingly important role in the pricing of credits and the functioning of markets. The IFCs have provided global benefits, but they are not without risk, and history has shown that the markets and their regulators will be tested.

■ international income convergence

Observers of the world economy often ask whether poorer countries are catching up with the rich countries. Put differently, are average living standards converging? This fundamental question has been much studied, especially since the development of new models and data in the mid-1980s. The answers help to shed light on the effects of globalization and development policies and provide a way of thinking about long-run predictions for the world economy. In principle, they also help to discriminate between models of the growth process. For all these reasons, the convergence question is central to the study of growth and development and also plays a role in international economics.

In popular commentary, it is common to hear claims such as "the rich countries are getting richer and the poor are getting poorer." It is well known that, after the mid-19th century, income levels diverged as some countries grew faster than others, but whether the poor countries became even poorer is open to debate. For more recent decades, the pattern is more complicated. Some poor countries have grown rapidly, notably many of those in East and Southeast Asia. Others have not, and some of the worst performers, predominantly in sub-Saharan Africa, have seen their gross domestic product (GDP) per capita decline even in absolute terms.

The diversity of experience implies that detailed studies of convergence may have an informative role to play. These studies are usually based on comparisons in relative terms, using ratios (rather than absolute gaps) to assess inequality in living standards or labor productivity at different points in time. Measurement should allow for differences in price levels across countries, and this can be achieved using version 6.2 of the Penn World Table developed by Heston, Summers, and Aten (2006). Using the standard deviation of the logarithm of output per capita to measure inequality, and excluding countries with populations below 250,000 in 1960, reveals a modest but steady increase in dispersion between 1960 and 2003 for a sample of 93 countries. The standard deviation rose by around 25 percent over the period as a whole.

The pattern is more complicated if we concentrate on the developed countries. For the countries above the 80th percentile of output per capita in 1960, there is some convergence until the late 1970s, but divergence later. There is clearer evidence for convergence if we restrict the sample to the Western European economies. In summary, there is no general tendency for convergence, unless we consider subgroups of similar economies, such as those of Western Europe. These findings will be one theme of what follows.

Convergence and the Solow Model Our understanding of convergence and divergence needs to be guided by theoretical models. Much of the literature, especially in its empirical guise, starts from the one-sector neoclassical growth model of Solow (1956). An aggregate production function is used to relate a country's output to a set of inputs, which would typically include capital equipment and labor. In this view of the world, international differences in labor productivity arise from differences in inputs per worker, or from differences in how efficiently inputs are combined. Convergence then requires stocks of inputs per worker, or efficiency levels, to move closer together. If GDP per capita is the yardstick, rather than output per worker hour, we should also consider changes in labor force participation rates and average working hours.

Models of this kind embody a view of living standards that is very different from the accounts found in popular commentary. In those accounts, development is often seen as a competitive process, in which wealth in one country is said to require poverty elsewhere. In contrast, in many theoretical models, productivity is determined independently of the productivity levels of other countries. If countries abroad are growing rapidly, this does not undermine domestic living standards.

In exploring the other predictions of growth models, the literature has distinguished between two different ways in which countries might be said to converge. *Absolute convergence* is the form that most commentators have in mind, namely whether inequality across countries in average living standards is tending to diminish. As we have seen, the overall tendency in recent decades has been one of gradual divergence.

We can learn more about this using a second idea, that of *conditional convergence*. The central hypothesis is that convergence is only to be expected within groups of economies that share similar structural characteristics. Within such groups, we should expect the countries that are initially poorer to grow more quickly, but this tendency is still compatible with divergence overall, given that there may be important differences across groups.

For this idea to be more than a truism, we need to be specific about the characteristics that are similar within groups. Consider a simple version of the Solow model, in which technical efficiency grows at the same rate in all countries. In this case, countries will converge to parallel equilibrium growth paths. Along these paths, capital and output will grow at the same rate, which is the equilibrium outcome, or steady-state, implied by the model. We can now consider what the model predicts about relative levels of output per worker in the long-run equilibrium   in other words, the extent of dispersion of the equilibrium paths. The highest levels of output per worker will be associated with countries that have high rates of investment, high levels of efficiency, and low rates of population growth. If two countries are alike in these various respects, the country that is initially poorer will grow relatively quickly, and living standards in the two countries will converge. But this convergence is only conditional, because it relies on the two countries looking alike in terms of the variables that influence the level of the steady-state growth path. This can explain why we might observe absolute convergence only within subgroups of countries, such as those of Western Europe, that are likely to share similar steady-state paths.

Even when conditional convergence is a good description of the data, whether or not countries converge in the absolute sense will depend on a range of factors. These include not only the dispersion of the equilibrium growth paths, but also the starting point of each country relative to its own equilibrium path. A further complication is that variables such as investment rates or population growth rates may be changing over time. In this case, the equilibrium paths of the different countries will move gradually apart or closer together, and this too will influence the observed extent of convergence.

The same basic analysis can easily be extended in other directions. For example, the quality of a country's institutions may be an important determinant of the level of the steady-state growth path. Other candidates include the education and skills of a country's workforce and the extent of government-provided infrastructure. The explicit specification

of steady-state determinants is central to the Solow model's empirical content and the testing of its predictions.

Convergence predictions become more complicated in models where there is more than one equilibrium outcome. For example, the Solow model can be adapted to make the population growth rate a declining function of the level of income per capita. In that case, there may be one equilibrium with high living standards and slow population growth, and another equilibrium with low living standards and faster population growth. Although models with more than one equilibrium outcome are inherently difficult to test, they support the idea that income dispersion is not the only relevant issue. We might also be interested in whether there is any mobility within the distribution of living standards and whether the distribution changes shape over time. The work of Quah (for example, 1996) represents the major contribution along these lines.

There are several other limitations to the analysis sketched above. One is that we have assumed that the rate of technical progress is the same across countries, so that all countries grow at the same rate in the long run. This assumption is unrealistic, but less so than it first appears. Imagine that, other things equal, countries with a low initial level of efficiency are more likely to show rapid improvements in efficiency, perhaps because there is greater scope for easily adopting existing technologies from abroad. In that case, there may still be an equilibrium in which all countries grow at the same rate in the long run. In this long-run equilibrium, differences in the speed of adoption will be reflected in equilibrium "technology gaps" between leading and following countries, so that countries differ in relative income levels rather than long-run growth rates.

Convergence among Interdependent Economies The simplicity of the Solow model can be useful, not least in developing some intuition about where and when convergence should be expected. It is clear that absolute convergence is far from inevitable and that, even in a simple model, a wide range of outcomes is possible. The model is also a useful corrective to the view that economic development is

essentially a competitive process and helps to explain why that view is less popular with economists than with noneconomists. Nevertheless, it is obvious that much of interest has been omitted. In practice, countries exchange goods and services; capital and labor sometimes move between countries; and ideas and technologies may spread beyond national borders in complex ways. These interactions are worth considering in more detail.

Many observers see the international trade of goods and services as central to the convergence process. It is true that, in principle, trade can lead to convergence in factor prices such as real wages and the returns to capital. In this case, differences in living standards will arise only when inputs per capita differ. If capital and labor are the only inputs used in production, factor price equalization implies that differences in living standards are driven entirely by differences in capital-labor ratios.

There are two problems with this story. First, it is false even at the level of casual observation, because real wages are readily seen to vary widely across countries. Second, the theoretical conditions under which factor price equalization occurs are extremely strict. Typically, production technologies are required to be the same across countries, but recent empirical work usually concludes that levels of technical efficiency vary widely. In this case, trade may still equalize factor prices, but only once we adjust them for international differences in the productivity of the different factors. The required adjustment makes this more general prediction harder to test.

Even in the absence of factor price equalization, trade in goods and services may still contribute to the convergence process. One view is that trade helps to encourage the transfer of technology across countries. These "dynamic" gains from trade are less well understood than the static gains of conventional trade theory. Their possible importance is highlighted by countries that have grown rapidly while becoming more integrated with the world economy. Separating this process of integration and growth into cause and effect is not straightforward, and empirical researchers seem to be divided on the

extent to which trade flows promote technology diffusion and convergence. It is also worth noting that introducing dynamic considerations can overturn some of the predictions of textbook models of trade. For example, firms and countries may become more productive as they gain experience in producing a particular good or service. If this process of "learning-by-doing" has an important role in productivity improvement, then sometimes trade can even lead to divergence (see Helpman 2004 for more discussion).

Since the relationship between trade and convergence is potentially ambiguous, empirical evidence becomes especially important. One of the best-known studies is that by Sachs and Warner (1995). They classify most of the world's economies as either closed or open to trade. Over the period 1970 89, they find evidence for convergence within the group of open economies, but not within the group of closed economies. Open economies are also found to grow more quickly on average. The results are hardly conclusive, however. A high proportion of the open economies in the sample are members of the Organisation for Economic Co-operation and Development, and perhaps these countries converged because they are alike in other ways. Moreover, when Sachs and Warner distinguish between closed and open economies, their criteria can be interpreted as reflecting several broader dimensions of economic policy, and not simply trade policy.

Another approach asks whether specific episodes of trade liberalization have been followed by convergence among the liberalizing countries. Slaughter (1997) provides a summary and critique of some of this work. An ever-present constraint is the small number of countries available to empirical researchers, which makes it difficult to establish whether trade liberalization promotes convergence in practice.

If the effects of trade on convergence are uncertain, those of international capital flows are even more so. As is well known, these flows increased over the 1980s and 1990s, as many countries dismantled capital controls. The move to open capital accounts means that domestic investment is no longer constrained by domestic saving, and capital will tend to move to wherever the return is highest. Countries that are initially poor, with low saving rates, could be among those to benefit from this process. In textbook models, the marginal product of capital will be especially high in these countries, and capital will flow into them until the returns are driven down to the level available elsewhere in the world. Output and wages have the potential to increase rapidly. Although profits associated with the new investment will be returned to the foreign owners of capital, national income will also increase over time.

This mechanism only works, however, if foreign investors are not deterred by high risks. Moreover, countries that receive large-scale capital flows have the potential to be destabilized by, for example, changes in investor sentiment. This argument gained increased prominence with the East Asian financial crisis of 1997 98. To the extent that capital flows are destabilizing, their effects on convergence must be regarded as ambiguous.

Such problems may be less serious for long-term capital flows, notably foreign direct investment (FDI). It is often suggested that FDI encourages the international diffusion of technology, promoting convergence. The effects of FDI on productivity in recipient countries, and the extent of spillover benefits for domestic firms, have been a focus of recent empirical research.

This introduction only skims the surface of the theory and evidence on convergence. In this respect, one final point is worth making. In popular commentary on issues such as globalization, or development policies, the outcomes are sometimes assessed primarily in terms of inequality between countries. This is not without its associated dangers. In principle, it is conceivable for some events or policies to raise incomes everywhere, while leading to overall divergence in living standards, if some countries benefit more than others. This suggests that the analysis of convergence development in relative terms should often be supplemented with consideration of the level of development in absolute terms. It is the latter that is likely to have more influence on the everyday lives of the world's poor.

■ **international institutional transfer**

There is by now a substantial literature on the im portance of institutions to economic development. Institutions are formal or informal rules that con strain individual choice and reduce transaction costs, thereby facilitating collective action (North 1990). Governments that can credibly commit to the en forcement of property rights and a rule of law that can adjudicate conflicting property rights claims are seen as particularly important in facilitating long term investment and therefore growth (de Soto 1989). In addition, political institutions that miti gate social conflict and provide public goods are also critical. There is substantial empirical evidence that institutions are strongly correlated with growth (see Knack and Keefer 1995; Easterly and Levine 2002); there is a debate, however, as to whether institutions are endogenous or exogenous to the economic system (see Sachs 2005).

Colonialism One of the most common exoge nous sources of institutions are foreign actors, in the form of colonial powers, occupation authorities, industrialized great powers, multilateral organiza tions such as the World Bank or the International

Monetary Fund, or other international donors. There is considerably less empirical understanding of possibilities for institutional transfer across international boundaries than there is for the endogenous creation of institutions within a single society.

One important source of information concerning institutional transfer comes from the history of colonialism, where mostly European great powers exercised formal sovereignty over territories in what is now the developing world. There is, unfortunately, a relatively small comparative literature that systematically analyzes the long-term institutional impact of different colonial regimes. This is, of course, a morally fraught subject, since most colonial relationships were exploitative and destructive of indigenous institutions and cultures. It is clear that there is a huge variance in colonial experiences, even within individual empires. The British, for example, left relatively durable institutions in the Indian subcontinent and in their settler colonies in southern Africa, but in other places such as West Africa they relied largely on local elites and left behind considerably weaker institutions. The Japanese were relatively more successful in creating durable economic institutions in their Korean, Taiwanese, and Manchurian colonies (Woo 1991) than the Americans were in the Philippines. Acemoglu, Robinson, and Johnson (2001) suggest that European colonialists left strong institutions in territories where environmental conditions (particularly disease burdens) allowed them to settle, such as North America and South Africa. In other places, such as Latin America and West Africa, they created extractive regimes that were not conducive to securing property rights or rule of law. In a similar vein, Engerman and Sokoloff (2002) have suggested that initial factor endowments the nature of cash crops, mineral resources, and labor predisposed institutions in North and South America and the Caribbean to greater or lesser degrees of inequality, differences that have persisted over time.

The Governance Agenda in International Development Decolonization and the emergence of the developing world in the 1950s, 1960s, and 1970s created new conditions for institutional transfer. In the late 20th and early 21st centuries, foreign powers usually did not have sovereign authority over the territories to which they sought to transfer institutions but had to use indirect methods such as foreign assistance, technical advice, and conditionality in lending for structural adjustment and other purposes. There continued to be instances of direct rule by international actors, however, under postconflict conditions in places such as Haiti, Somalia, Bosnia, Kosovo, Timor-Leste, Afghanistan, and Iraq (see Chesterman 2004). Over the years, the international donor community has been increasingly concerned with improving the governance and institutional performance of developing countries, to the point where a substantial proportion of lending by multilateral institutions such as the World Bank and the Inter-American Development Bank are linked to public sector reform (World Bank 1997, 2000, 2002).

It is difficult to assess the overall impact of these external interventions designed to strengthen institutions and governance. In certain regions of the world such as Latin America, there has been a clear improvement in public sector performance, particularly in the area of macroeconomic policy management (Lora 2007). On the other hand, there has been much less progress in strengthening judicial systems, fighting corruption, or improving the performance of social sector institutions in education and health. In either case, it is not clear the extent to which existing institutional reform has been the product of external advice, help, and pressure, or internally driven reform processes. The World Bank's program to improve financial management in Highly Indebted Poor Countries has yielded very ambiguous results (Levy and Kpundeh, 2004). In Timor-Leste, the United Nations Transitional Authority for East Timor undertook the direct rule of a new nation between 1999 and 2002; while this was initially regarded as a big success for international state-building, Timor-Leste's army and police collapsed in internal fighting in 2006. The American experience in trying to create liberal democracies in Afghanistan and Iraq has been, to say the least, disappointing.

Theorizing Governance Recent efforts to improve governance have been conceptualized under a principal-agent framework. Governments are understood to be hierarchies in which principals (in a democracy, the sovereign people) direct agents to perform certain activities. The agents, however, have their own interests, which are not always aligned with the interests of the principals. Improving governance is therefore understood to be a matter of aligning agent incentives with those of their principals, largely by creating systems of monitoring and accountability.

Public sector services can be characterized along two dimensions: transaction volume and specificity. *Transaction volume* refers to the number of decisions or other outputs that a particular public sector agency has to make; they can range from small, in the case of a central bank or finance ministry, to large, in the case of a judicial system or public education system. *Specificity* refers to the degree to which the quality of the output of a public sector agency can be externally monitored. Macroeconomic policy institutions such as central banks and finance ministries have much lower transaction volume and higher specificity than institutions providing public education or legal services; their performance can therefore be much more easily monitored and brought under a principal-agent framework. This explains why most improvement in institutional performance in recent years has come in low-transaction-volume, high-specificity parts of the public sector.

This framework indicates why legal systems protecting property rights are particularly hard to transfer. Legal systems involve high transaction volumes, and their output is very difficult to measure. Property rights can be and often are selectively enforced, leading to rent-distribution systems with highly variable effects on economic growth (Khan and Jomo 2000).

Why Institutions Are Difficult to Transfer More broadly, there are four reasons why institutions are generically difficult to transfer across national boundaries. The first is that there are often large problems of fit between desired institutions and the nature of the underlying society. The models for well-functioning states in the minds of Western donors are often idealized versions of their own political institutions, which in turn are based on some vision of a Weberian rational-bureaucratic state. These embed certain clear value choices and moral perspectives: that exchange should be impersonal, that obligations to the society as a whole should trump narrower communal attachments, that hiring and advancement should not be based on kinship but on merit, and so on. These values do not come naturally to any human society and emerged in the West and in parts of East Asia only after a prolonged historical process. It is therefore not surprising that there is a poor fit in virtually all developing countries between the existing normative order and social structure and the kinds of institutions that donors prefer. Many donors believe that the burden falls on the developing country to adjust to this idealized model. The adjustment, however, must be mutual. There are no "optimal" forms of institutions; among developed liberal democracies, there is a wide variance in the ways institutions are implemented that make them "fit" their societies better.

The second obstacle to institutional reform concerns the problem of transmission mechanisms and ownership. The objectives of service delivery and capacity-building are often at odds; because public sector services are weak or nonexistent, donors are often tempted to provide them directly, which then weakens the capacity of the reforming country's government to provide them over the long term. Most successful state-building projects, such as those of the East Asian fast developers, have been driven by domestic elites; the latter may have gotten help in the form of resources or technical assistance from outside allies or donors, but themselves created demand for reform. In the absence of such internal demand, donors are often tempted to stimulate it artificially, either through conditionality in lending to mechanisms like the European Union's accession criteria. America's Millennium Challenge Account seeks to provide similar incentives for governance reform. Alternatively, donors can seek to promote independent civil society and independent media, which, it is hoped, will unlock a latent demand for change by

putting pressure on corrupt or incompetent governments. Although breakthroughs such as Ukraine's Orange Revolution occasionally occur, externally stimulated demand for reform is seldom sufficient to produce decisive results.

The third obstacle is that state-building is at base a political process and not a technical one, one that involves access to power and resources and is therefore highly contested. Most dysfunctional public bureaucracies can trace their poor performance directly to the intervention of politicians who want to use the administrative machinery for their own purposes or prevent it from interfering in their activities. This, of course, presents a major obstacle for external donors, whose influence on local politics is either prohibited by statute, as in the case of the World Bank, or else is limited by past historical colonial relationships. Administrative reform pursued as a technical assistance project can get only so far if political will is lacking, and donors often do not have the patience to wait for the emergence of the right political conditions.

The fourth obstacle has to do with the need for nation-building in addition to state-building. It is common for those involved in postconflict reconstruction to concentrate on improving the capacity of public sector institutions and to shy away from attempts to help formulate or strengthen national identity, common culture, or shared values within the client country's society. Yet the latter is critical for the success of the former in the long run. If bureaucrats in a public agency, for example, do not identify the public good with that of the nation as a whole, but rather see their purpose as helping one particular ethnic or kin group advance relative to others, then that agency's purposes will be corrupted from the start. Outsiders usually have limited means of fostering national identity. Although it has been done in the past (for example, by the British in India), building a national identity is a very slow process and does not suit the timetables of most donors.

Future Directions The difficulty of transferring institutions has led to suggestions that institutions need to be, in effect, outsourced. Krasner (2004) has suggested the need for a system of "shared sovereignty" in which certain state functions are performed by international organizations or other external actors. Other writers have suggested that it is often well-meaning interventions on the part of the international community that create state weakness in the first place, and that states may be better off being left alone to generate institutions endogenously (Weinstein 2005). It is clear, however, that the realities of globalization mean that institutional development in many parts of the world will be inescapably linked to external actors, ideas, resources, and influences. To an increasing degree, it is impossible to separate the exogenous and endogenous, internal and external, sources of growth and decay of institutions.

FRANCIS FUKUYAMA

■ international investment agreements

Investment provisions in bilateral investment treaties and reciprocal preferential trade agreements (PTAs) are intended to promote investment flows by grant ing investors greater predictability of the policies regulating foreign investment. These agreements typically provide for transparency, national treat ment, nondiscrimination among foreign investors, and guarantees against expropriation. Some agree ments may include disciplines preventing trade-re lated investment measures (TRIMS), such as local content requirements and local hiring requirements. Finally, nearly all provide some sort of dispute set tlement provisions.

The Rise of Bilateral Investment Treaties (BITs)
BITs are the primary vehicle for international co operation on the regulation of investment flows.

They customarily provide a definition of investment coverage, include rules of origin to determine the nationality of investors, and specify the treatment of inward investment and investors, either once established and/or preestablishment. Most BITs do not deal with market access restrictions per se — such as restrictions on sectoral entry or equity ownership limitations — although some do impose disciplines on performance requirements and similar TRIMs. They generally guarantee most favored nation (MFN) and national treatment (banning discrimination among investors from signatory countries and guaranteeing treatment of foreign investors on the same footing as domestic investors, respectively). Often the treatment that is guaranteed foreign investors is actually better than that accorded to domestic investors, for example, in terms of access to foreign exchange or ability to transfer capital outside of the country, or in terms of investor protection/rights.

A major function of BITs is to provide investor protections such as against expropriation, stipulating that there be due process, transparency and compensation for any expropriation of foreign investments. They also provide for a dispute resolution mechanism to enforce these provisions. Dispute settlement provisions vary, but usually include arbitration procedures, often based in recent BITs on international standards, such those of the World Bank Group's International Center for Settlement of Investment Disputes (ICSID) or the UN Commission on International Trade Law. BITs involving the United States generally allow private investors to bring cases against host-country governments, thereby removing any foreign policy–driven uncertainty regarding the willingness of their home country governments to defend their rights.

BITs have proliferated sharply since the 1980s. The total number of BITs in force has risen from 355 in 1990 to 1,891 by the end of 2005; another 604 had been signed but not yet entered into force (UNCTAD 2006a). The pace of new annual signings decreased — from more than 200 in the mid-1990s to 70 in 2005 — as the pool of countries willing to enter into agreements began to reach full coverage. Although the majority of agreements are North-South arrangements, recent signings feature agreements among developing countries. South-South agreements now constitute 29 percent of the total. The top 10 signatories of BITs included seven from Europe (Germany, France, the United Kingdom, Italy, Belgium, the Netherlands, and Switzerland). China, Egypt, and Romania round out the top 10.

BITs now cover a substantial share of foreign direct investment (FDI) flows from members of the Organisation for Economic Co-operation and Development (OECD) to developing countries. In 1990, roughly 9 percent of investment flows were covered (though data in the early years are somewhat understated). By 2004, 43 percent of investment was covered.

Preferential Trade Agreements (PTAs) PTAs, like BITs, have multiplied in the years since 1990. The United Nations Conference on Trade and Development (UNCTAD) reports that 232 PTAs were in force at the end of 2005, 86 of which were purely South-South arrangements. Many of these agreements, particularly the North-South agreements, now cover investment. PTAs involving the United States and the European Union (EU) have been important drivers. By 2006, the United States had in force free trade agreements with investment provisions involving 14 countries, including Mexico, Chile, and Singapore, with three signed and before the U.S. Congress, and three more under negotiation. The EU engagement in PTAs is even more extensive, with more than 100 PTAs as of 2003, and investment is more frequently covered. Thus, for example, investment policies are being discussed as part of the Economic Partnership Agreement negotiations with African, Caribbean, and Pacific countries and the recent agreements with southern Mediterranean countries.

U.S. Free Trade Agreements (FTAs) Recent U.S. FTAs include preestablishment rights of market access. These provisions imply opening services markets to competition from foreign suppliers — or locking in prior autonomous liberalization — except in those sectors excluded (through a negative list). This therefore may expand on the coverage of com-

mitments in the General Agreement on Trade in Services (GATS), where a positive list is used and greatly enhances the transparency of prevailing policies. Since most of the countries with which the United States has concluded bilateral PTAs are already open in most sectors, the agreements lock in prevailing openness and generally effect changes in only a few still-restricted activities. Common provisions range from inclusion of insurance, financial advisory services, and selected telecommunications services to arguably relatively inconsequential changes to already open regimes, such as the commitment by Singapore to cease cross-subsidies in express mail delivery or the commitment of Chile in insurance services and a few other sectors. Moreover, notable for their absence is the exclusion of labor services, except provisional visas for professionals associated with investing firms.

All U.S. FTAs provide for national and MFN treatment. For many of the initial FTA countries, these had long been included in national legislation and/or have been incorporated into bilateral investment treaties on a postestablishment basis.

The U.S. FTAs have subsumed preexisting BITs and provided new measures covering investment. Agreements, especially those signed after the North American Free Trade Agreement (NAFTA), include broad definitions of investment, including not only FDI but also portfolio flows, private debt and even sovereign debt issues as well as intellectual property. Such broad definitions of investment policies can expose countries to dispute settlement across a wide range of assets.

The inclusion of intellectual property rights in the definition of assets covered by the investment provisions creates a potential liability for signatory governments. Not only are the intellectual property rights far more extensive under the recent PTAs than under the WTO's Agreement on Trade-Related Aspects of Intellectual Property Rights (TRIPS) (see Fink and Reichenmiller 2005), the dispute settlement provisions are more powerful. For example, if a government decides to issue a compulsory license to control drug prices and the patent owner disputes this action under the terms of the U.S. PTA, the patent holder can take the claim to commercial arbitration under the PTA's investment provisions. This instrument is considerably more powerful for intellectual property rights enforcement than the state-to-state provisions under the TRIPS Agreement (see World Bank 2003).

Another area of disciplines concerns trade-related investment measures (TRIMs) government policies that require foreign companies to export in a certain portion of their sales or balance trade, using local inputs to achieve value-added objectives. All of the bilateral U.S. PTAs ban TRIMs. The U.S. bilateral agreements have in effect established a "WTO TRIMs Plus" set of obligations that include outright bans on certain performance requirements, including management restrictions and export, minimum domestic content, domestic sourcing, trade balancing, and technology transfer requirements. Government procurement, environmental standards, and requirements for local research and development are generally not covered.

A key feature of U.S. agreements is the use of negative lists excluding sectors or industries from coverage. This feature implies that all other sectors not mentioned including new economic activities are included; this is distinct from the positive list approach typically found in EU agreements and most South-South agreements. Ratchet provisions, also a feature of U.S. agreements, bind liberalizing policies enacted subsequent to the agreement's entrance into force, thus locking the policy framework progressively in ever greater openness and certainty.

Finally, with the exception of the Australian FTA, all the U.S. agreements contain an investor-state dispute resolution provision that permits investors to take foreign governments to dispute resolution for violation of the treaty's national treatment, nondiscrimination, or expropriation provisions, among others.

European Union Agreements Because investment is the competence of the EU member states, not the European Commission, EU PTAs have treated investment only generally or indirectly. The earliest (and least comprehensive) are the Euro-Mediterranean Partnership agreements (starting in 1995) and

the South African agreement (1999), which contained virtually no investment provisions. Thus the market access provisions were general, directed mainly at services, and contain only the promise of potential liberalization after discussions to transpire some 5 years after the entry into force of the agreement. In the EU-Mexico PTA, several general provisions were included, many ratifying GATS arrangements, as well as specific liberalization commitments in the financial sector. The EU-Chile agreement goes further by additionally locking in some liberalization of telecommunications and maritime services.

The EU agreements with Mexico and Chile, though more comprehensive than earlier agreements, do not have the same strength of disciplines as the U.S. agreements. The trade provisions use a positive list and implicitly exclude new products. The treatment of investment and capital flows in both agreements were not extensive. For example, the EU-Mexico agreement simply states that the existing restrictions on investment will be progressively eliminated and no new restrictions adopted, without specifying particular sectors or setting a timeline for liberalization. The language in the EU-Chile agreement is even more general, calling for "free movement of capital relating to direct investments made in accordance with the laws of the host country." Both agreements allow for use of safeguards in the event of monetary or exchange rate difficulties, and although the time limit is set at 6 months for Mexico and 12 months for Chile, allow for continuation of the safeguard after the time limit through its formal reintroduction.

The treatment of dispute settlement involves state-to-state mechanisms rather than the investor-state provisions in U.S. agreements that allow private companies to initiate arbitration cases against governments. The EU provisions pertaining to investment are subsumed in the general dispute settlement provisions for all matters in the PTA. State-to-state dispute settlement is first attempted through consultations with a Joint Committee (Association Committee in the case of Chile and Mediterranean countries) within 30 days of a party's request. If this step of "dispute avoidance" proves unsuccessful, in the case of Chile, the concerned party can forward its request to an arbitration panel comprising representatives of both parties. The arbitration panel's decisions are binding, and the panel can also rule on the conformity of any measures undertaken as a result of its decision with the original ruling. Both agreements provide extensive detail on the process of appointing members to the arbitration panel, timelines for the panel's ruling, and compliance with the panel's decisions. Still, companies in member states that have their own BITs with recipient countries can activate investor state arbitration through BIT mechanisms.

Multilateral Initiatives Since 1948 when the Havana Charter was created, governments in high-income countries have sought to weave investment provisions into international trade law. While selected investment issues were addressed with the creation of the UN Center on Transnationals and the OECD Guidelines for Multinationals, it was not until the OECD launched the Multilateral Agreement on Investment in 1995 that a full-scale effort was resumed. This effort eventually foundered in the face of resistance from labor and environmental groups as well as developing countries that were largely excluded; when France withdrew from the negotiations in 1998 over the failure to protect its media and cultural interests, the negotiations collapsed.

With the launching of the Doha Development Agenda in the Ministerial Meeting of the WTO in November 2001, it seemed that investment would once again be taken up as part of the negotiating mandate for the so-called Singapore issues. Discussions in the 20 subsequent months before the next Ministerial meeting in Cancun, Mexico, in 2003, focused on the definition of investment to be covered, whether to adopt positive or negative lists, and the type of dispute resolution to be adopted. In each of these areas, the contentious negotiations tended to gravitate toward outcomes favoring the lowest common denominator: narrowly focused definitions of investment, positive lists with abundant room for exclusions, and state-to-state dispute resolution.

However, progress in the Doha Round was painfully slow in the run-up to the Cancun meeting, and disagreement on the Singapore issues was only one symptom. The inclusion of investment in the negotiations encountered vehement opposition from a coalition of developing countries, including most notably India and Malaysia. Negotiations were stymied over other major issues in agriculture and nonagricultural products, and many developing countries considered the heated discussions on the Singapore issues a distraction and of little value to their development.

Finally, in an ill-fated effort to move the discussions off dead center, the EU, the principal *demandeur* of Singapore issues, at the last minute offered to abandon investment and competition and even cease future WTO activity in the Working Group. The Cancun Ministerial nonetheless broke down in acrimony. Only later when India offered to accept one of the four Singapore issues, trade facilitation, did this later become the accepted position in subsequent negotiations. Investment was officially dead as an issue for negotiation in the WTO's Doha Round.

Effects on Investment A main objective of a BIT is to increase the flow of investment to signatory countries. Does the signing of bilateral investment treaties in fact increase the flow of FDI? Hallward-Driemeier (2003), in one of the first systematic statistical analyses, considered bilateral flows from OECD members to 31 developing countries over two decades. Her analysis found that, controlling for a time trend and country-specific effects, BITs had virtually no independent effect in increasing the share of FDI to a signatory country from a home country. Countries signing a BIT were no more likely to receive additional FDI than countries without such a pact. Even comparing flows in the three years after a BIT was signed to the three years prior, there was no significant increase in FDI. Rose-Ackerman and Tobin (2005) analyzed the flows to 63 countries with data averaged over a five-year period and found that only with countries at very low levels of risk was there any increase of investment from the signatory home country; in a detailed analysis of U.S. FDI behavior,

they failed to find any statistically significant effects on U.S. FDI to 54 countries, irrespective of political risk.

In contrast to these findings, Neumayer and Spess (2005), using a larger sample over a longer period and considering simply the number of BITs signed, found robust and positive effects of the total number of BITs on total inflows of FDI. This finding relies heavily on the notion that signing a BIT signals to all would-be investors that the environment is more welcoming. In this model, the signal is more important than the specific investor protections. These contradictory findings at minimum suggest that the jury is still out and that it cannot be accepted axiomatically that BITs increase investment flows.

Assessing the evidence of investment provisions in PTAs is more difficult. The reason is that it is difficult to distinguish the effects on investment flows of creating a larger, single market from the effects of investor protections and other investment provisions in the trade agreement. Empirical studies generally consider the combined effects of PTAs trade and investment provisions together.

Available evidence suggests mild positive effects on overall investment. The Global Economic Prospects 2005 (World Bank 2004) examined the effects of PTA membership and other variables on FDI inflows for a panel of 152 countries during the 1980 2002 period. The study found that PTAs that result in larger markets do attract greater FDI. The interaction of signing a PTA and expanded market size associated with the integrated markets is significant and positively related to FDI. On average, a 10 percent increase in market size associated with a PTA produces an increase in FDI of 5 percent.

One example is NAFTA, which is a comprehensive arrangement that includes significant investor protections in combination with broad-based tariff reductions and border liberalizations. Chapter 11 of the NAFTA agreement allows investors to sue the government in the event of regulatory or other actions that might diminish the value of a foreign investment. In their study, Lederman, Maloney, and Serven (2003) find that, in addition to positive forces

in the global economy that propelled investment into Mexico and other emerging markets after 1994, the trade opening and NAFTA accession also played a role in Mexico's FDI rise.

Neither this study nor others attempt to distinguish the role of enhanced investor protections from access to the Mexican market and its other resources in increasing the flow of FDI. It may be that simply liberalizing the investment law in 1993 and making it easier to take advantage of productivity-adjusted wage differentials in the NAFTA countries was sufficient to explain the difference. However, it is possible that investor protections in chapter 11 played an important independent role because Mexico's legal framework was seen as less reliable than other investment destinations. In an analysis of shareholder rights, creditor rights, efficiency of judiciary, rule of law, and absence of corruption, Mexico scores below the Latin American average in four of five measures (as cited in Lederman, Maloney, and Serven 2003). To the extent that chapter 11 provided investors with additional comfort over and above the existing investment climate, its protections would have offset these disadvantages. In any case, Lederman et al. (2003) conclude that Mexico's entry into NAFTA led to an increase in annual FDI by around 40 percent.

Dispute Settlement: Rising Case Load and Rising Awards The costs of resolving investor disputes can be large. The number of cases brought under the various bilateral investment treaties and PTAs has risen dramatically. Though the absence of reporting data from all the dispute tribunals prevents full analysis, the International Center for Settlement of Investment Disputes (ICSID) at the World Bank reports a steady increase in the number of cases from an annual average of 1.5 cases in 1972 95 to 29 in 2003 4, after which a tapering off is evident. However, UNCTAD has established a database that includes other sources, and its main report (UNCTAD 2005) and subsequent update (UNCTAD 2006b) point to a continued upward trend through 2005. Some 48 known cases were brought in 2005 (UNCTAD 2006b).

In fact, the dispute settlement process is cloaked in opaqueness. The ICSID registry contains only minimal information about the dispute it is not known whether the dispute arises from a BIT provision, a FTA provision, or some other state contract. Information often becomes available only when one of the parties to an arbitration makes it public. Many of the disputes outside of the ICSID tribunal are never made public, and even less is known about their resolution.

United States FTAs do provide for somewhat greater transparency. In NAFTA, for example, as of July 2004, there were 31 cases brought under chapter 11 (including 14 against Mexico, 9 against Canada, and 8 against the United States). Six cases have been decided in favor of the investor, but the amount awarded has been small compared to initial (undoubtedly inflated) claims. Tribunal awards have totaled $35 million compared to claims of $1.0 billion.

At least 61 governments 47 from the developing world (including transition countries) have faced investment treaty arbitration. Forty-two cases were lodged against the Argentine government after its devaluation of the peso in 2001. Causes have varied from changes in tax policy perceived as adverse by investors to expropriations following conflict or coups, irregularities in bidding processes, and others (Peterson 2003a, 2003b).

Awards can be hefty. In February 2005, the Slovak Republic agreed to comply with an ICSID arbitral award of $830 million to CSOB, a Czech bank. This award surpassed that of a tribunal in Stockholm, which required the government of the Czech Republic to pay one company, Central European Media (CME), $350 million for violation of a BIT that deprived CME of a stake in an English-language TV station in Prague. This amount was ten times higher than previously known awards under arbitration cases and about equal to the entire public sector deficit of the Czech Republic (Peterson 2003a, 2003b). But the biggest case has been filed against the Russian Federation, involving a claim for $28 billion for the alleged expropriation of Group Menatep's

majority shareholding in the Yukos oil firm under the 1994 Energy Charter Treaty (as yet unratified). In one of a series of decisions that have gone against the government of Argentina, in February 2007 Siemens was awarded $217 million for violation of a Germany-Argentina bilateral investment treaty (Peterson 2007). To these awards must be added legal fees and tribunal costs. Governments may have to pay costs that can range from $1 million to $2 million (UNCTAD 2005).

Flaws in the System of Property Rights Enforcement Theodore Moran (2006) discusses weaknesses in the dispute settlement procedures through the lens of prominent NAFTA cases. Perhaps the most detailed case study of investment dispute resolution and its consequences is the Wells and Ahmed (2007) study of Indonesia in the wake of the 1998 East Asia crisis. In an illuminating history of the collapse of private power contractual arrangements and subsequent dispute resolution, Wells and Ahmed conclude that the arbitration process "served the host countries poorly" and that companies found the promised protections were "largely illusory." Wells and Ahmed point to five weaknesses:

1. The system of contracts and enforcement is overly rigid, failing to take into account changed circumstances, excessively large claims, the role of corruption, and reasonable expectations from public policy.

2. The system produces inconsistent outcomes, as "tribunal shopping" has led to wildly different outcomes based on differing standards of evaluation using the same contracts.

3. The investor-state arbitration system is inherently asymmetric, according investors a superior position in the resolution process, in relation to both governments (that cannot initiate a case against an underperforming investor) and to domestic investors (who cannot avail themselves of the system).

4. The system creates a "moral hazard" that effectively discourages companies, based on rigidly interpreted rights, from seeking res-

olution through renegotiating contractual arrangements.

5. The system, by focusing only on awarding damages, foregoes the opportunity to encourage mutually beneficial contractual restructuring, policy changes, or negotiated settlements.

Many of these conclusions also emerge from the study of Cosbey, Mann, Peterson, and Von Molke (2004) who examine investment agreements from a cross-country perspective. They underscore the lack of transparency, potential conflicts of interests in the selection of arbitrators, inconsistency across multiple tribunals reviewing the same case, and lack of accountability of the system. Moran (2006) detects a lessening of salience of treaty-driven investor protections as experience tends to caution investors against overrelying on these instruments and moderate expectations of developing countries about higher investment flows.

In conclusion, international investment agreements are on the rise, even though their ability to promote investment remains unclear. Several questions merit additional exploration: What recourse do investors have legally if a government refuses to pay claims awarded against it, and does recourse provide sufficient incentive for full payment? Because the costs of enforcing payment of an award are usually high, governments could negotiate down the final settlement. What has been the experience of investors after being awarded large claims; have they collected full amounts, and if not, what was the negotiating process that led to final settlement?

Further, how can the arbitration process be made more transparent, fairer, and more open? Is there a synergy between investor protections and free trade provisions that would encourage FDI? Do countries with negative list provisions in their BITs and FTAs attract more investment than countries with positive list provisions?

If the objective is to increase the inflows of FDI, countries should begin with improvements in the domestic investment climate sound macroeconomic policies, stable property rights for all investors,

and sound regulatory policies and treat investment treaty provisions as a complement rather than a substitute for an attractive policy framework.

RICHARD NEWFARMER

International Labor Organization

The International Labor Organization (ILO) was created in the wake of World War I and the communist takeover of Russia with the narrow goal of improving working conditions around the world. The underlying objectives, however, were to avoid political instability by addressing issues of social justice and concerns that global competition could undermine countries' efforts to improve working conditions at home. The first wave of globalization had already crashed on the shoals of World War I by the time the ILO had come into being. But a century later, a new wave of globalization triggered similar concerns and the ILO once again found itself at the center of debates over how to address economic insecurity and inequality.

The ILO is the only League of Nations institution to survive World War II and is also the only international organization that is not purely intergovernmental in its governance structure. Union and employer group representatives are part of each country's delegation and have the same right to vote as government representatives at policymaking meetings. As of 2006, the ILO had adopted 187 conventions determining international standards for various aspects of work and employment. Some of the standards dealt with fundamental rights of workers, but most are narrow and technical, on issues of importance only to labor, management, or regulators in specific sectors, for instance, shipping or communications.

In 1998, the ILO approved a "Declaration on Fundamental Principles and Rights at Work," which provided a consensus definition of four core labor standards that became the centerpiece of the global standards movement. In the face of accelerating globalization, the ILO has also focused more attention on employment, adjustment, and migration issues. In 2002, it established a World Commission on the Social Dimensions of Globalization to explore ways to make economic globalization more inclusive and to spread its benefits more broadly.

The Organization of the ILO The ILO is a tripartite organization with 179 member states and 716 voting delegates, with each member having two government representatives and one each representing employers and workers. In theory, worker and employer delegates are not bound by their government's position and vote independently. Delegates gather annually at the International Labor Conference, where new conventions may be adopted, implementation of existing conventions is reviewed, and the budget is approved. The Governing Body, except for ten permanent members, is elected by the conference and is the executive body of the organization, responsible for developing policy, electing the director-general, and overseeing the organization's work program.

The International Labor Office, headed by the director-general, is the secretariat of the organization with headquarters in Geneva and branch offices around the world. The office provides advisory services and technical assistance, for example on how to create or reform laws for social protection, and carries out research projects, such as studying the implications of the end of the Multifiber Arrangement for workers in clothing factories around the world. The activities of the office are organized around the theme of "decent work" and four strategic objectives: rights at work, employment, social protection, and social dialogue.

The ILO's Tools In addition to standards-setting, the ILO has three main tools for improving working conditions. It supervises compliance with global labor conventions and publicizes violations of standards to shame countries into improving. It gives technical assistance to labor ministries and other agencies, unions, and employer groups to address employment-related issues and to improve the implementation of labor standards. And it can punish

countries that do not comply with their commitments, though complaints have rarely led to formal enforcement measures.

Supervising and Publicizing Country Performance
The ILO has extensive mechanisms for supervising the application of conventions, including routine reporting by countries on implementation of conventions they have ratified, why they have not ratified others, and what they are doing to achieve the goals of those conventions. These reports are reviewed by independent experts who identify areas both of progress and of special concern, which may be taken up by the Conference Committee on the Application of Standards at the annual conference.

The most important innovation in ILO monitoring came with the 1998 Declaration on Fundamental Rights and Principles at Work, which defined four core labor standards:

- freedom of association and the right to organize and bargain collectively;
- freedom from forced labor;
- the eventual abolition of child labor;
- nondiscrimination in employment.

The follow-up mechanism for implementing the declaration requires member countries that have not ratified one or more of the eight conventions associated with these principles to report annually on what they are doing to promote the conventions and encourages employer and worker groups to comment on the national submissions. In addition, the conference requires the director-general to prepare a global report summarizing how each core standard is being implemented around the world and identifying key obstacles to compliance.

Technical Assistance Ministries of Labor and other organizations seeking to raise standards and improve the operation of labor markets are often weak bureaucracies with inadequate resources and limited support from political leaders. In such situations, even modest ILO technical assistance can be helpful. The ILO also conducts extensive research and outreach on issues related to employment and underemployment in developing countries, as well as the obstacles to standards compliance posed by extensive employment in the informal sector in many countries.

For decades ILO technical assistance programs received only modest funding from wealthier member states and the agency had a limited presence in developing countries. In the 1990s, however, many countries, including the United States, responded to demands that the world community do more to improve labor standards by increasing their funding for ILO programs. As a result, technical cooperation spending increased from an average of just over $90 million per year in 1998 2000 to nearly $140 million in 2004. Virtually all of the increase went to programs to eliminate child labor, which accounted for nearly 40 percent of total technical assistance in 2004.

Enforcement of Conventions and Standards In addition to routine reporting and review, the ILO has two ad hoc mechanisms for promoting compliance with labor standards, though critics charge that the organization is toothless. Article 24 of the ILO Constitution allows any worker or employer organization in the world to file a complaint alleging that a member government is not complying with a convention it has ratified or that a country has violated freedom of association (regardless of whether it ratified the relevant conventions). If such complaints are not resolved through informal consultation, the Governing Body can refer them to the Committee on Freedom of Association or appoint an ad hoc committee to analyze the situation, ask the government to respond, and make recommendations on what the government can do to comply. If the problem remains unresolved, official ILO delegates can file an article 26 complaint.

The ILO Governing Body will again try to resolve the problem informally through consultations. But if that leads nowhere, it can appoint a Commission of Inquiry to formally investigate the charges and recommend how to correct the problem. The target of the complaint can appeal the commission's finding to the International Court of Justice. If the commission's findings are upheld and a satisfactory resolution is still not forthcoming, article 33 of the ILO

Constitution provides that "the Governing Body may recommend that the Conference take such action as it may deem wise and expedient to secure compliance therewith."

Between 1919 and 1960, there was only one article 26 complaint. From 1961 to 2000, there was an average of six complaints per decade. In its history, the ILO has appointed only nine Commissions of Inquiry, usually regarding alleged violations of one of the four fundamental rights. The ILO did not take the next step of invoking article 33 until 2000, when the conference approved a resolution calling on member states "to review their relationship with the Government of Myanmar (Burma) and to take appropriate measures to ensure that Myanmar 'cannot take advantage of such relations to perpetuate or extend the system of forced or compulsory labour.'" Raising questions about the ILO's effectiveness in difficult situations, however, the annual conference asked the Governing Body to consider what additional steps might be taken if the government in Myanmar remained uncooperative.

In sum, the ILO aims to improve living conditions for people around the world by increasing employment opportunities, making work safer and more productive, and in recent years, ensuring that workers share in the benefits of globalization. It does this by promoting social dialogue and basic rights that allow workers to bargain over wages and working conditions; by promulgating, monitoring, and enforcing other standards; and by providing technical assistance to employers associations, unions, and governments in pursuit of these objectives. The ILO also conducts research on a variety of employment-related issues and is the major source for what data exists on labor markets.

KIMBERLY ANN ELLIOTT

■ international liquidity

International liquidity refers to the availability of internationally accepted means of settling international debts relative to the demand or potential demand for such financial assets. The availability or supply of international liquidity depends on the stock of total reserve assets owned by world central banks or national monetary authorities, as well as the ability of these institutions to borrow from the International Monetary Fund (IMF), the Eurocurrency market, and other financial institutions. The adequacy of international liquidity also depends on the demand for, or the expectation of, having to make such payments.

International reserve assets comprise reserve currencies, Special Drawing Rights (SDRs), and gold owned by nations' central banks or monetary authorities, as well member nations' reserve

position in the IMF. Reserve currencies are foreign currencies held by central banks or monetary authorities that can be used (i.e., are accepted) for the settlement of intergovernmental claims. Reserve currencies represent almost 90 percent of total international reserve assets and the U.S. dollar accounts for about 65 percent of the total stock of reserve currencies. The second most important reserve currency is the euro. Other reserve currencies are the Japanese yen, the British pound, and the Swiss franc.

Special Drawing Rights (SDRs) are accounting entries on the books of the IMF introduced in 1967 to supplement international reserves. SDRs are used only among central banks to settle balance-of-payments deficits or surpluses; they cannot be used in private commercial dealings. At the 1967 IMF meeting it was agreed to create SDRs in the amount of $9.5 billion to be distributed to member nations according to their quotas in the IMF in three installments in January 1970, 1971, and 1972. Further allocations of SDRs made in the 1979 81 period brought their total to about $19 billion. The value of one SDR was originally set equal to one U.S. dollar, but rose above $1 as a result of the devaluations of the dollar in 1971 and 1973.

Starting in 1974, the value of SDRs was tied to a basket of currencies.

Gold was the international reserve asset par excellence during the gold standard period (1870 1914). Under the Bretton Woods system of fixed exchange rates (1947 71), gold was one of several types of international reserve asset held by national central banks or monetary authorities and the United States used gold as backing for the dollar reserves held by foreigners. In 1971, the United States suspended the dollar convertibility into gold at the fixed price of $35 per ounce. The price of gold then increased on the world market, but monetary gold (the amount held by nations' central banks or monetary authorities) continued to be valued at $35 per ounce in official transactions. Today, gold has lost a great deal of its importance as an international reserve asset and the IMF is moving toward demonetizing it, so that in the future gold would be used only for commercial purposes.

Member countries' reserve position in the IMF also constitutes a part of international reserves. This is equal to the amount of international reserves (originally, gold and reserve currencies but now only reserve currencies) that nations pay into the fund (based on their quota into the fund) on becoming

Table 1
International reserves, 1950 2005 (billions of SDRs, at year end)

International reserve asset	1950	1960	1970	1980	1990	2000	2005
Foreign exchange	13.3	18.5	45.1	292.6	611.3	1,490.2	2,918.2
SDRs			3.1	11.8	20.4	18.5	20.1
Reserve position in the fund	1.7	3.6	7.7	16.8	23.7	47.4	28.6
Total reserves minus gold	15.0	22.1	56.2	321.3	655.4	1,556.1	2,966.8
Gold at SDR 35/ounce	32.2	37.9	37.0	33.5	32.9	33.3	30.9
Total with gold at SDR 35/ounce	48.2	60.0	93.2	354.7	688.3	1,589.4	2,997.7
Gold at SDR market price	33.0	38.6	39.6	455.4	253.1	200.6	316.6
Total with gold at market price in SDR	48.0	60.7	95.8	776.6	908.3	1,756.7	3,283.4
U.S. dollar per SDR	1.0000	1.000	1.000	1.2754	1.4227	1.3029	1.4293

Source: IMF, *International Financial Statistics Yearbook,* various issues.

members, and which nations can automatically borrow from the fund without any restrictions or questions asked.

The amount of the various international reserve assets available to nations from 1950 to 2005 (at ten-year intervals) is given in table 1, with and without the inclusion of gold reserves, and with gold at the official price of SDR 35/ounce and at market price. Note that the amounts of the various international reserve assets are given in SDRs by the IMF, but their dollar value can be obtained by multiplying them by the dollar value per SDR shown in the last row of the table. For example, the foreign exchange reserves of SDR 2.9185 trillion at the end of 2005 was equal to $4.171 trillion (SDR 2,918.2 billion times the dollar value of the SDR of $1.4293/SDR in 2005).

The adequacy of international liquidity depends not only on the supply or availability of liquidity but also on the demand for liquidity. Under the Bretton Woods system, nations needed international reserves to pay for temporary balance-of-payments deficits, without the need to restrict imports directly or indirectly through slower domestic growth. During this period, most of the increase in world liquidity resulted from the increase in official holdings of foreign exchange reserves, mostly dollars, to finance U.S. balance-of-payments deficits. The problem was that the more U.S. deficits persisted and the more dollars accumulated in foreign hands, the less willing foreigners were to hold additional dollars and the less confidence they had in the dollar (i.e., that the dollar would retain its international value and that the United States would be able to honor its commitment to redeem dollars in gold at the fixed price of gold of $35 per ounce, in the face of dwindling U.S. gold reserves). Indeed, it was precisely to avoid this confidence problem that the IMF decided to create SDRs in 1967. But this was not enough to prevent the collapse of the Bretton Woods system in 1971, when some central banks demanded conversion of some of their dollar reserves into gold, thus triggering the collapse of the system.

After the collapse of the Bretton Woods system, most developed nations and many developing nations moved to a system of managed exchange rate flexibility, which persists to this day. Under such a system, a nation with an actual or potential balance of payments deficit would experience a depreciation of its currency, which would correct the deficit by stimulating the nation's exports and discouraging its imports. Since the adjustment takes time, however, nations continue to need international reserves or liquidity. Nations also use international reserves or liquidity to intervene in foreign exchange markets to smooth out excessive exchange rate volatility or when attempting to influence the underlying value of the exchange rate of their currencies. Central banks could also increase their interest rate to attract international capital flows to cover balance of payments deficits or borrow additional reserves from the IMF or in the Eurocurrency market at a charge. In the case of currency crises (such as those that afflicted several emerging markets economies from 1994 to 2002), liquidity could be mobilized on an international scale under IMF leadership.

■ International Monetary Fund (IMF)

The International Monetary Fund (IMF) is an
intergovernmental organization that seeks to ad-
vance global financial stability. The IMF's respon-
sibilities, as set out in its Articles of Agreement,
include promoting international monetary coop-
eration and exchange stability, facilitating the ex-
pansion and growth of international trade, and
making its resources available to members experi-
encing balance of payments difficulties. There are
185 member nations, and the headquarters is in
Washington, DC.

The IMF was established in 1944 at the Bretton
Woods Conference in New Hampshire. The repre-
sentatives of 44 nations also created the International
Bank for Reconstruction and Development (World
Bank) for the purpose of postwar reconstruction; its
mandate was later expanded to encompass economic
development. The chief architects of the new inter-
national monetary system were Harry Dexter White
of the U.S. Department of the Treasury and the
noted British economist John Maynard Keynes.
They sought to design a system that would prevent
repetition of the chaos of the interwar period, when
countries abandoned the gold standard and depre-
ciated the values of their currencies in attempts to use
exports to bolster their economies.

In the Bretton Woods system, central banks
maintained fixed rates for their currencies in relation
to the U.S. dollar. They held their foreign currency
reserves in the form of dollars, which they could ex-
change for gold from the United States. The IMF
served as a monitor of the system to ensure that
governments fulfilled their obligations. The IMF also
provided credit to members with balance of pay-
ments deficits in order to provide time for their
governments to implement policies to restore equi-
librium.

The Bretton Woods system collapsed in the early
1970s, in part because foreign central banks feared
the inflationary consequences of the flow of dollars
from the United States. However, the IMF acquired
new roles by dealing with the debt crisis of the 1980s
and then the emergence of the transition economies
at the end of that decade. In the 1990s it coped with
international financial crises, such as those that oc-
curred in 1994 in Mexico and in East Asia in 1997,
while promoting growth in its poorest members.

Governance The IMF is under the jurisdiction of
its Board of Governors, which includes one member
and one alternative member appointed by each
country, and meets once a year. The Board of Gov-
ernors delegates the responsibility for supervising the
daily operations of the IMF to the Board of Direc-
tors. A country's position and voting power on the
Board of Directors is based on the size of its quota. A
country's quota is determined by its economic size
and the value of its international transactions. The
United States currently has the largest quota share,
17.09 percent, while Palau has the smallest relative
quota, .001 percent. Since major decisions require a
special majority of 85 percent of the votes cast, the
United States has an effective veto.

There are 24 executive directors representing the
IMF's members. The five countries with the largest
quotas appoint executive directors to represent
their interests on the board, while smaller members
form constituencies and elect a joint director. The
members with the largest quotas and their own
directors are the United States, Japan, Germany,
France, and the United Kingdom; Saudi Arabia, a
major creditor to the fund, China, and Russia form

single member constituencies and also name their own directors.

The Board of Governors conducts quota reviews at regular intervals, usually every five years. The Twelfth General Review took place in 2003, without any change in the quotas, and the Thirteenth General Review was scheduled to be completed by 2008. In the period between the 2003 and 2008 reviews, many members believed that the relative allocation of quotas was skewed in favor of some European nations at the expense of Asian economies and contended that there should be a reallocation of quota shares.

A country's quota also determines the amount of money it contributes to the IMF, called its subscription, and the limits on its access to financing. When it joins the IMF, a member makes a payment equal to its quota; one quarter of this subscription must consist of widely accepted currencies, such as the U.S. dollar or the euro. Increases in quotas require increases in the subscriptions paid in by the member nations. The quota payments provide the IMF the financial resources for its lending operations. In 2006 the IMF had $175 billion available for loans over the next one-year period.

The executive directors appoint a managing director to administer the fund's activities. The managing directors have always been Europeans, and Dominique Strauss-Kahn of France became the IMF's tenth managing director in 2007. There are three deputy directors to assist the managing director, and approximately 2,700 staff members, of whom about two-thirds are economists. The IMF has five area departments (African, Asia and Pacific, European, Middle East and Central Asia, and Western Hemisphere), eight functional departments (Finance, Fiscal Affairs, IMF Institute, Legal, Monetary and Capital Markets, Policy Development and Review, Research, and Statistics), and several information and support services departments. There is also an Independent Evaluation Office, which reports to the Executive Board.

Special Drawing Rights Special Drawing Rights (SDRs) are a unit of account used by the IMF. In the 1960s, central bankers outside the United States became concerned about the use of U.S. dollars as international reserves. The IMF's Board of Governors amended the original Articles of Agreement in 1969 to allow the introduction of the SDR by the IMF as a supplementary reserve asset. The first general distribution of SDRs was made in 1970 72. However, the need for new reserves diminished with the collapse of the Bretton Woods system and the development of private capital markets. The IMF continues to use SDRs as a monetary measurement. The value of the SDR is based on the foreign exchange value of the dollar, the euro, the yen and the British pound, and is posted on the fund's Web site (www.imf.org) daily.

Surveillance The IMF engages in surveillance activities to monitor and guide the economic policies of its members. The fund conducts bilateral surveillance of its individual members, as authorized under Article IV of the Articles of Agreement. A group of its economists, known as a staff mission, travel to a member's capital to consult with government officials about the member's exchange rate and monetary and fiscal policies. In recent years the talks have broadened to include the financial sector and assessments of vulnerability to capital flows, as well as structural issues such as fiscal reforms.

The IMF's economists submit a report of their findings to the fund's Executive Board, which uses it as the focus of its discussion of the country. Approximately nine out of ten of the IMF's members allow summaries of the staff's and board's views to be made public in the form of Public Information Notices, which are available at the IMF's Web site. Many countries also allow publication of the staff's report.

The IMF engages in multilateral surveillance to assess regional conditions and the world economy. The results of this work are published in the IMF's *World Economic Outlook* and its *Global Financial Stability Report*, each of which appears twice a year. The IMF has initiated a process of multilateral consultations with members in areas where there is a need for collective action, such as resolving global payments imbalances. However, the IMF can only operate through persuasion in these circumstances because it has no power over sovereign governments.

Technical Assistance The IMF provides technical assistance to its members, particularly lower-income members, on macroeconomic policies, financial sector regulation, and the collection and maintenance of databases. This assistance is financed by the IMF itself and the contributions of members as well as multilateral donors. The IMF integrates technical assistance with its surveillance and lending activities whenever possible. The IMF makes its assistance available through different mechanisms. It may send a team of economists to a country for a short-term project, or a resident advisor for a longer period. It also offers courses and training programs at the IMF Institute at its Washington, DC, headquarters and its six regional technical assistance centers and seven regional training institutes and programs in Africa, Asia, the Caribbean, Europe, the Pacific Islands, and South America.

Lending The IMF offers credit to countries with balance of payments imbalances; the institutional arrangements targeted for special circumstances are known as "facilities." The most commonly used mechanism is the Stand-By Arrangement (SBA), which is designed to assist countries with short-term problems, and usually lasts for 12 to 18 months. The Extended Fund Facility (EFF) was established to assist countries with longer-term problems and operates for up to three years. The Supplemental Reserve Facility (SRF) was introduced in 1997 to provide large amounts of funds to countries which experience sudden capital outflows, and these programs operate for two to three years. The Compensatory Financing Facility provides credit to countries subject to a shortfall in their export earnings or an increase in the cost of cereal imports. The fund also provides emergency assistance in special circumstances, such as natural disasters. The amount of money that a country can borrow from the fund its access limit depends on the type of program and the size of the country's quota. However, the IMF's lending can exceed this limit if a SRF is activated. All of these loans carry a market-based rate of charge, and large loans carry a surcharge.

The IMF also makes credit available to its poorest members through special facilities. The Poverty Re-

duction and Growth Facility (PRGF) is the successor to the Enhanced Structural Adjustment Facility (ESAF), which in turn followed the Structural Adjustment Facility (SAF). The new name was chosen to emphasize the twin goals of poverty reduction and growth.

A government that seeks external funding consults with the IMF about its needs and then signs a Letter of Intent (LOI), which is presented to the Executive Board for approval. A country can borrow up to 25 percent of its quota on liberal terms; larger amounts require activation of a lending arrangement. The LOI specifies the amount of available credit and also the policy conditions that the borrowing government agrees to implement. Once the LOI is signed, the IMF releases the credit in phased installments, which are tied to the adoption of the policies enumerated in the LOI. This practice is known as conditionality.

These conditions traditionally dealt with monetary and fiscal policies and a country's exchange rate. However, as upper-income countries turned to the private international capital markets in the 1980s, developing economies and subsequently the transition countries became the IMF's borrowers. The scope of conditionality expanded to include policies that were designed to improve the efficiency of these economies and promote growth. Structural policies included the liberalization of foreign trade, the restructuring of the financial sector, and privatization of state enterprises. Many of these conditions were consistent with the set of market-oriented policies that became known as the Washington consensus. By the 1990s, structural conditions appeared in virtually all of the IMF's programs.

The use of structural conditions, however, was widely criticized. The effectiveness of these conditions in promoting growth was questioned by critics, who pointed to counterexamples of successful development. China and India, for example, opened up their economies, but their governments played a role in the allocation of resources among firms and sectors. In addition, the record of implementation of structural conditions was mixed, in part because of domestic opposition.

The IMF reviewed its conditionality practices in 2002 and issued new guidelines. The Executive Board announced that the focus of structural conditionality in the future would be streamlined and limited to achieving the macroeconomic goals of the program. Moreover, the IMF acknowledged that programs were successful only when the borrowing government was committed to the process of reform a concept known as country ownership. Ownership required the full participation of the government in developing the program with a regard for the country's circumstances.

Criticisms The IMF has been the subject of criticisms from both wings of the political spectrum. As noted above, structural conditionality was often viewed as inappropriate and misguided. Some critics charged that it had unduly harsh impacts on the poor because of cutbacks in government spending on social policies. A number of nongovernmental organizations (NGOs) have protested the fund's use of conditions, and the IMF's Annual Meetings have been the subject of picketing and demonstrations.

The fund's macroeconomic conditionality was also criticized in the wake of the 1997 98 East Asian crisis, when Thailand, Indonesia, and Korea turned to the IMF for assistance. The IMF initially called for contractionary fiscal and monetary policies, consistent with its traditional view of a crisis as the consequence of expansionary domestic policies. However, these crises were driven by capital outflows that in some cases were prompted by contagion from neighboring countries, and the countries were already undergoing contraction as domestic private expenditures collapsed. The increases in interest rates recommended by the IMF for the purpose of supporting exchange rates also deepened the decline in output. The IMF subsequently revised these programs to allow fiscal deficits, but defended its call for higher interest rates as necessary to arrest further depreciations and inflation.

The IMF has also been charged with indirectly contributing to the emergence of these crises through its lending, an example of the phenomenon of moral hazard. Critics assert that foreign lenders have been willing to make risky loans because they believed that the IMF would provide financial support in the event of a crisis. Some of these critics have called for the abolition of the IMF, which they claim no longer serves the purpose for which it was created.

However, many observers believe that in a world of global capital flows and recurring financial crises, there is a need for an organization to deal with breakdowns in international monetary flows. Many of these collapses require collective action to resolve, and an institution like the IMF has the capability to coordinate the private and official responses.

However, in recent years the number of new lending arrangements has fallen sharply. Part of this decline is due to economic growth in developing countries and increased holdings of foreign exchange reserves by central banks. But many of the emerging markets can now obtain credit in the private capital markets and therefore do not borrow from the IMF except in crisis conditions. The IMF needs to redefine its role in a world of global financial markets if it wants to retain its relevancy.

JOSEPH P. JOYCE

■ International Monetary Fund conditionality

The International Monetary Fund (IMF) lends to its member nations with balance of payments problems in order to promote international financial stability. The government of a country that borrows from the IMF agrees to implement economic policies to rec tify the situation, and the IMF disburses the credit as these policies are implemented. This monitoring mechanism is known as conditionality. The IMF uses conditionality to ensure that the borrowing country is resolving its problems and that the IMF's financial resources will be available to other mem bers. The nature of conditionality has evolved over time in response to changes in the role of the IMF in the international economy and with its members.

Lending Procedures A country can borrow an amount equal to 25 percent of its quota with the IMF on liberal terms; larger amounts require the estab lishment of a policy program. The IMF uses a number of administrative programs to make credit available to its members. The most commonly used are the Stand-By Arrangement (SBA), which is de signed to assist countries with short-term (1 to 2 years) problems, and the Extended Fund Facility (EFF) for countries with longer-term (typically 3 years) problems. Both programs carry a market-related interest rate. Between 1953 and 2007, there were 835 SBAs approved and 76 EFFs.

The IMF also lends to its poorest members at a below-market rate through the Poverty Reduc tion and Growth Facility (PRGF), which is the successor to the Structural Adjustment Facility (SAF) and Enhanced Structural Adjustment Facility (ESAF). The interest rate on a PRGF loan is 0.5 percent, and the lending typically takes place over a 3-year period. There are approximately 75 mem bers of the IMF are eligible for the PRGF. There were 199 SAF/ESAF/PRGFs approved between 1953 and 2007.

After consultation with the IMF, a government that seeks credit signs a Letter of Intent, which spe cifies the amount of credit to be made available and the policy conditions that the government agrees to implement. A country applying for a PRGF must submit a Poverty Reduction Strategy Paper, which describes the steps that its government will undertake to foster growth and reduce poverty. Once the ar rangement is approved by the IMF's Executive Board, the IMF releases the credit in phased install ments, which are tied to the adoption of the enu merated policies.

The IMF monitors compliance with the policy conditions through a variety of institutional mecha nisms. Prior actions are prerequisites that a country undertakes before the program actually begins. Per formance criteria are specific conditions that a country must meet before it receives a disbursement of credit. Quantitative performance criteria include macroeconomic policy targets, such as monetary aggregates and fiscal balances. Structural perfor mance criteria deal with an economy's efficient use of its resources and include measures such as deregula tion. There may also be structural benchmarks that provide additional information about a country's program implementation.

The IMF will suspend a program if its conditions are not met. Waivers can be granted, however, when implementation has been delayed due to circumstances outside a government's control, such as lower than expected tax revenues or insufficient external financing. The IMF's Executive Board can perform a program review in situations where the original program requires revision due to new developments.

Analytical Tools The IMF draws on analytical frameworks in formulating the policies it recommends to borrowing countries. Among these is financial programming, which was developed at the IMF in the 1950s. This model links balance of payments deficits under fixed exchange rates to domestic monetary policy. It is based on two behavioral equations (the demand for money and import demand), two identities (the base money supply and the balance of payments), and an equilibrium condition (money market equilibrium). Private capital flows were considered to be fixed, as they often were in the Bretton Woods era. Financial programming is based on data that are usually available to policymakers, and the model's simplicity was an asset in the postwar era when data limitations were more common.

In the model, a rise in a central bank's holdings of domestic credit leads to an increase in national income and consequently imports. The immediate result is a current account deficit and a loss of reserves. In the long run, the initial change in domestic credit is completely offset by the change in foreign reserves. The solution to a balance of payments deficit lies in curbing the growth of domestic credit. This adjustment in monetary policy can be linked to the government's fiscal position, since in many developing countries a fiscal deficit is financed by the central bank.

The other model developed at the IMF is the absorption model, which relates the state of the current account to domestic expenditures and output. In this model, the current account reflects the difference between domestic output and absorption, which is the domestic demand for goods and services. A surplus is recorded when national output is higher than absorption, and a deficit in the opposite situation. Contractionary spending policies are required to lower or eliminate the deficit.

The policies in IMF-supported programs have been based on these models. Fund programs usually call for a tightening of monetary and fiscal policies in order to reduce total expenditures, and the IMF's performance criteria often include limits on domestic credit expansion and government expenditures and increases in tax revenues. In addition, the IMF in some cases has recommended a depreciation of the exchange rate in order to switch expenditures to domestically produced goods and stimulate exports.

There have been a number of criticisms of these models. The demand for money is often not stable and predictable, and changes in velocity affect the transmission of monetary changes within the economy. Moreover, the liberalization of the capital account and the increase in private international capital flows have introduced new sources of volatility into the financial sector.

The IMF's macroeconomic policy conditionality came under sharp criticism during the 1997–98 East Asian financial crisis. The cause of the crisis was a rapid outflow of capital, not expansionary government policies. Critics claimed, however, that the IMF misjudged the nature of the crisis and promoted contractionary policies at a time when output in the crisis countries was already falling. As the crisis progressed, the IMF realized that the emerging fiscal deficits reflected the crisis-induced declines in output and relaxed its call for fiscal consolidation. The IMF defended the use of higher interest rates, however, as necessary to prevent further depreciation of the exchange rates and an outbreak of inflation.

The IMF developed new tools in response to the emergence of capital account crises, such as those that occurred in East Asia and in Mexico in 1994–95. The balance sheet approach specifies the assets and liabilities of the different sectors of the economy, including the financial liabilities that are denominated in a foreign currency. These represent a source of vulnerability if foreign creditors lose confidence in domestic borrowers' ability to fulfill their obligations and decide to withdraw their funds. Economists at the IMF have also sought to develop indicators of

impending currency crises that would serve as early warning systems and give the IMF and the country at risk time to prevent the crisis.

Structural Conditionality During the 1980s, the IMF's lending focused on developing economies drawn into the debt crisis. In the following decade, the transition economies that emerged after the dissolution of the Soviet Union also became fund borrowers. The governments of these countries were concerned about economic growth as well as external stability and sought to enact policies that would accelerate growth. In response, the IMF and its sister institution the World Bank devised structural adjustment policies to improve the efficiency of an economy and promote growth. These policies originally were included in the IMF's concessionary lending programs for the poorest members, but over time appeared in the SBAs and EFFs as well.

Structural adjustment policies can include fiscal reform, the privatization of government-owned enterprises, and the reorganization of the financial sector. These measures are intended to replace government allocation of resources with those of the market. Some of these reforms appeared in the set of market-oriented policies known as the Washington consensus, which encapsulated the state of thinking among many policymakers and advisors in the late 1980s and early 1990s regarding the steps needed to advance growth in developing countries.

Over time the scope and number of conditions rose. The specification of conditions became more detailed because implementation of structural policies is more difficult to assess than the traditional macroeconomic conditions. The IMF (2001b) reported that more slippage took place in the implementation of structural conditions than occurred with conditions in the traditional area of macroeconomic policies.

Structural conditionality became a focus of criticism. First, many of these policy areas were outside the IMF's expertise in macroeconomics. Second, there was limited evidence connecting many of the structural conditions to increased growth. Countries that had established strong records of growth in the past, such as Taiwan and Korea, had allowed domestic firms to develop before opening up their economies. Third, in many cases there was limited domestic political support for structural conditions, which were viewed as an infringement of national sovereignty.

The criticisms of structural conditionality peaked after the East Asian crisis. Goldstein (2003) reported that the number of structural conditions totaled about 140 in the case of Indonesia, 90 in Korea, and 70 in Thailand. In the case of Indonesia, many of these conditions dealt with issues that had only tangential relevance to the goal of balance of payments equilibrium. Moreover, critics charged that the IMF itself had indirectly precipitated the crisis through its earlier promotion of financial liberalization.

The IMF undertook a review of its conditionality practices in response to the criticisms and issued new guidelines in 2002, which were reviewed in 2005. These guidelines emphasize the need for national ownership of the policies contained in a lending program. The IMF has subsequently sought to deepen government involvement in the formulation of programs. The Poverty Reduction Strategy Papers for the PRGF programs, for example, are prepared by governments in consultation with civil society and other participants. The new guidelines also called for the streamlining of conditions to those areas that were seen as essential to reestablishing a sustainable balance of payments.

Compliance and Recurring Usage Other aspects of IMF conditionality that have received scrutiny and discussion are the implementation and the recurring use of the IMF's resources. In some cases governments do not implement all the conditions contained in their Letter of Intent, and in response the IMF suspends its disbursement of funds. Countries with interrupted programs do not establish strong records of economic performance. Empirical analyses of these situations reveal that domestic political economy factors, such as a lack of cohesion within a government, can impede the progress of a program.

Governments that do not complete one program may adopt another. A study by the IMF's Independent Evaluation Office (2002) found that when prolonged usage is defined as the adoption of

IMF programs for 7 or more years in a 10-year period, then 44 countries were prolonged users between 1971 and 2000. The report also found that prolonged usage expanded consistently since the 1970s, and the authors attributed this development in part to the expansion of the goals of the IMF's lending programs. Studies of frequent usage find that these recurring borrowers do not achieve a stage of economic performance in which they can dispense with the IMF's assistance. Incomplete implementation and frequent usage detract from the effectiveness of fund programs and may delay the establishment of national policies and institutions to resolve continuing deficits.

■ International Monetary Fund surveillance

Surveillance, as practiced by the International Monetary Fund (IMF), is the process of overseeing the functioning of the international monetary system and certain economic and financial policies of IMF member states. The legal mandate for this activity is Article IV of the IMF Articles of Agreement, which was rewritten after the 1973 collapse of the Bretton Woods system, when exchange rates were no longer

anchored by gold, and currency values of most of the major industrial countries floated. Section 1 of the new Article IV (adopted in 1978) requires "each member . . . to collaborate with the Fund and other members to assure orderly exchange arrangements and to promote a stable system of exchange rates." Section 3 requires the IMF to "oversee the international monetary system in order to ensure its effective operation, and [to] oversee the compliance of each member with its obligations under Section 1 of this Article." To that end, the fund is required to exercise "firm surveillance" over member countries' exchange rate policies, and those members are required to consult with the fund on their policies.

Practice The two main methods of surveillance are periodic (usually annual) consultations between the fund and each member and the preparation by the fund of periodic reports on global economic and financial conditions. The first method   the Article IV consultation   is known as bilateral surveillance, and the second as multilateral surveillance. Since 2006, the second form has been expanded to include multilateral consultations, in which the IMF convenes discussions involving several members and covering issues of mutual interest and systemic consequence.

An Article IV consultation is primarily a confidential discussion between the fund and the country's monetary authorities (the finance ministry and the central bank). Increasingly in recent years, these consultations have also provided a means for the IMF to convey its views to the general public and to financial markets. Each consultation begins with a visit to the country by a team of IMF staff, referred to as a staff mission. The mission meets with officials in the finance ministry, the central bank, other official agencies as needed, and usually with representatives of the business community, labor, and civil society. At the conclusion of these talks, the mission chief presents a preliminary report to the government setting out the fund staff's assessment of economic and financial conditions in the country and its advice on exchange rate and related policies. With the government's permission, he or she may also hold a

press conference to make the mission's findings known more widely.

After returning to the IMF headquarters in Washington, DC, the mission prepares a more detailed report, which the IMF Executive Board discusses. The board chairman then issues a summary of the discussion that sets out the fund's policy advice in final form. With the government's consent, the fund may then issue a public information notice (PIN) based on the summing up. Each PIN is published on the IMF's Web site, often together with the staff report.

The core of multilateral surveillance is the *World Economic Outlook* (WEO) exercise, which is normally conducted semiannually. The staff prepares a set of studies on world and regional economic developments, including forecasts and medium-term scenarios under specified assumptions and detailed analyses of key policy issues. The WEO reports have been published since 1980 and have become the flagship publication of the IMF. The other major component of multilateral surveillance is the preparation of the semiannual *Global Financial Stability Report*, which includes an analysis of developments in financial markets, incorporating both official and private capital flows.

Limitations Although the IMF considers surveillance to be its core activity and responsibility, critics argue that bilateral surveillance is an ineffective way to influence and discipline countries' policies. In broad terms, the success of surveillance depends on the quality of the fund's analysis and policy advice, the effectiveness of the dialogue and the communication of the fund's views to the authorities and to the public, and the willingness of members to accept the fund's advice. Although specific criticisms can always be leveled at specific aspects of the dialogue and the conclusions regarding a country's economic and financial policies, the central difficulty in bilateral surveillance is in persuading the authorities to act on the basis of advice from the IMF. In many cases, governments may have shorter-term domestic objectives or domestic political constraints that conflict with the longer-term and more international objec-

tives promoted by the IMF. In other cases, there may be genuine differences of economic philosophy between the fund and the authorities.

The voluntary nature of the response to IMF surveillance contrasts with the position of countries that borrow from the IMF. For the latter, because the fund's lending is generally conditional on the borrower's adherence to an agreed program of policy improvements, a country that needs the fund's financial support faces practical constraints in its choice of policies. Advanced economies with ready access to private capital markets and developing countries that have accumulated foreign exchange reserves by running external payments surpluses are thus freer to accept or reject policy advice from the IMF than are countries with more limited financial means. These differences, of course, reflect disparities in the world economic order, not an institutional weakness in surveillance.

History When the IMF began operations in 1946, it conducted consultations only with countries that availed themselves of the temporary provisions of Article XIV of the Articles of Agreement. Under the terms of that article, these countries were still imposing exchange restrictions on foreign trade and other current account flows, and were obligated to consult with the IMF on their plans to eliminate those restrictions when practicable. At the beginning, most members maintained such restrictions, and the number fell only gradually. By 1960, only 10 of the fund's 68 members had accepted the obligations of Article VIII prohibiting further recourse to current-account restrictions. In 1961, however, the number of Article VIII countries more than doubled, in response to the restoration of current account currency convertibility across much of Europe. Thus the need for Article XIV consultations began to fall.

In that same year, 1961, the United States   the IMF's largest member country and the first to accept the obligations of Article VIII in 1946   agreed voluntarily to hold annual consultations with the fund "as a means of exchanging views on monetary and financial developments." From that point on, an increasing number of countries volunteered to hold these "Article VIII" consultations. None of this activity was yet called "surveillance," but it did lay the groundwork for the more formal and obligatory system of consultations that would come later.

IMF surveillance, in the sense that the term is used today, began with the collapse of talks by a committee of the IMF's governing board in 1974. For two years, this Committee of Twenty tried to devise a new system of stable exchange rates to replace the Bretton Woods par-value system that had been abandoned in 1973 after the United States terminated the gold convertibility of the dollar. When it finally became clear that the United States and some other major countries were not prepared to peg their exchange rates again, the committee fell back on the subtle distinction of promoting a "stable system of exchange rates" rather than a "system of stable exchange rates."

In order to achieve stability while exchange rates were floating, the Committee of Twenty reasoned that the IMF could play a key role by overseeing the international financial system and the macroeconomic policies that underpinned it. The fund's charter was then amended in 1978 to let countries choose their own exchange arrangements   pegged to another currency or a basket of currencies, freely floating, or managed more or less flexibly   subject to a requirement to consult regularly with the IMF on how they were implementing their policies. As noted above, the IMF was given a mandate to exercise "firm surveillance" over the conduct of members' exchange rate policies and to oversee the functioning of the system. Hence, modern surveillance was born.

A tug-of-war quickly emerged between the desirability of focusing on key issues and problem cases, on the one hand, and trying to be comprehensive and even-handed with all member countries, on the other. If the IMF conducted annual consultations with all members covering all policies and conditions with significant effects on exchange rates and international payments balances, staff resources would be stretched thin and the process would become routine. If it was more selective, it risked missing some brewing problems and violating the requirement that

the fund treat all of its members in an even-handed manner. In either case, surveillance would fall into disrepute and again become ineffective. Attempts were made to hold ad hoc special consultations with countries that were suspected of manipulating their exchange rates for competitive advantage, but resistance to such procedures proved to be strong. Regularly scheduled bilateral consultations continued to be the primary means of communicating the fund's advice to members.

In two respects, the effectiveness of surveillance was enhanced during the 1990s. First, the Interim Committee (the successor to the Committee of Twenty) agreed in general terms on standards for the conduct of macroeconomic policies, most notably through the declaration of the Partnership for Sustainable Global Growth in 1996. Those standards, which the IMF managing director dubbed the "Eleven Commandments," enabled the fund to give more pointed advice to countries whose policies appeared to be out of line. Second, the fund adopted new procedures to open up the dialogue to wider participation and to allow the publication of staff reports and PINs. This new transparency facilitated public scrutiny and international comparisons of countries' policies and made it more difficult for governments to ignore the fund's recommendations.

By the late 1990s, two other problems with the effectiveness of surveillance had become clear. First, the quality and timeliness of financial data published (or even provided privately to the fund) by monetary authorities were not uniformly high. In a few cases, countries that had been particularly reluctant to reveal the state of their official reserve position were hit by severe financial crises. In response, the IMF embarked on a major effort to encourage members to improve financial reporting, including the establishment of standards for data dissemination and a system for disseminating data electronically to the public. Second, the fund's traditional emphasis on dialogue with members' monetary authorities occasionally left it with insufficient information about developments in financial markets. This problem was particularly acute in so-called emerging market countries, where bank loans and other private capital

flows were major sources of external financing. After a wave of financial crises hit emerging market countries in the late 1990s, the IMF responded by greatly expanding its contacts with and analysis of capital markets and strengthening its capacity to assess countries' vulnerability to crises.

In 2006, when the world economy was growing rapidly but was at risk because of large and growing imbalances among the large economies, it again appeared that the tools of IMF surveillance needed to be further strengthened. That led to the inauguration of multilateral consultations, the first of which was aimed at enhancing the dialogue among the countries with the largest surpluses and deficits and seeking a commonly acceptable solution.

■ international policy coordination

The coordination of economic policies among countries is a means to promote economic and financial stability and a way to orchestrate growth, particularly in periods of depression, without the costs of additional inflation. At first it was viewed in terms of coordinating monetary policies to reduce the tendency for interest rates to rise and fluctuate as countries attempted to emerge from recession (the Bonn Summit, 1978), or to eliminate the need for competitive devaluations as economies attempted to expand in a world of increasing trade flows and capital links (European Monetary System, 1979). Later, as inflation performance came into line with the targets set for it, the focus shifted to fiscal coordination (the Plaza Agreement, 1985), joint exchange rate targeting (Louvre Accord, 1987), and to institutional coordination within an economy or group of economies. In the early 21st century, policy coordination is mostly implicit: often discussed, but seldom in the form of explicit rules or agreements. What survives is the staff work behind the annual Group of Eight (G8) summits of the world's largest economies.

Rationale for Coordination The rationale for coordinating the policies of interdependent, but politically sovereign, policymakers is usually efficiency. Formal game theory models show that policy bargains can always be found that will leave some countries better off without others being worse off in terms of their own policy objectives. By cooperating to improve the performance of domestic policy targets and to account properly for the consequences of the spillover effects of their own policies on others, each country may achieve its own objectives, relative to what could be obtained by adopting the alternative strategy of determining its policies independently. This argument is well established in theory and has been demonstrated formally in a range of analytic and empirical models (Hamada 1976; Canzoneri and Gray 1985; Hughes Hallett 1986).

It is sometimes useful to think in terms of absolute and relative coordination. Absolute coordination focuses on the overall stance of policy to ensure that countries do not, in pursuing their own interests, adopt policies that are too tight or too loose for the world as a whole. This has to do with efficiency, or comparative advantage in getting better outcomes for all. Relative coordination, meanwhile, is concerned with adverse spillovers, redistribution, and the relative positions of countries. It therefore tends to focus on exchange rates, trade imbalances, or fiscal imbalances. Policymakers usually appear to be more interested in relative coordination (for example, the current trade imbalances), but turn to issues of absolute coordination in periods of widespread recession or inflation. Given that, the academic literature has been concerned with the following issues:

1. How large are the gains from policy coordination in practice, and how will they be distributed among participating economies?

2. What are the key determinants of the size and distribution of the payoffs?

3. Are the policies of a coordinated policy bargain stable? The problem is that once a country is persuaded to adopt policies different from those that are optimal in a noncooperative context, the other countries have an incentive to reoptimize once again on the basis that their partners are now committed to particular policy paths.

4. What are the obstacles to coordination? There may be political and institutional

reasons why it is more difficult to secure an agreement on certain policy variables, but easier on others.

5. To what extent are coordinated policies sensitive to errors, or to disagreements among policymakers about the assumed policy responses in the economy or what the appropriate policy priorities might be?

Levels of Policy Cooperation and Coordination
The potential benefits and costs of policy coordination will depend on the degree of cooperation among policymakers. There is a natural hierarchy here:

Information exchanges. Countries freely exchange information about their targets, priorities, information sets, and how they think those targets would respond to domestic or foreign policy changes. But given that information, national policymakers would continue to make decisions in a decentralized, autonomous way. By pooling their information, countries could make gains by eliminating incomplete or faulty information over objectives, expectations, and assumed policy responses.

Crisis management. Coordination would respond to episodes of particular difficulty in the international economy, involving policy changes that are particular to that episode. It might involve ad hoc policy adjustments for difficult periods, when imbalances and current policies have interacted to yield a crisis.

Avoiding conflicts over shared targets. Shared targets arise where countries actually target the same variable (for example, a mutual exchange rate), or where they target variables that are linked by an identity that cannot be relaxed via policy (for example, the "n 1 problem" in a set of current accounts, which will be discussed later). In this case, coordination could generate gains by means of agreements that prevent countries from setting incompatible targets for the same variable, or by preventing countries from attempting competitive policy changes that cannot all be achieved simultaneously.

Intermediate targeting. A limited degree of coordination may be achieved when countries jointly control the variables that form the main monetary, fiscal, or financial links between their economies. In that case, the linked variables are treated as intermediate targets, being instrumental in obtaining better results for the other targets but without significance in themselves. Intermediate targets may or may not be shared targets, although the scope for fruitless competition over shared targets makes them the most obvious candidates.

Partial coordination. Countries cooperate in achieving certain targets but may aim at other targets uncooperatively or according to some preassigned (national) rules. It is often suggested that countries should coordinate their monetary policy, leaving fiscal policy (which is hard to manipulate in the short term) for domestic targets as happens in the European Monetary Union. Fiscal policy needs to be sustainable, however, so a minimal degree of fiscal coordination may be required to permit effective monetary coordination.

Full coordination. Countries adopt a certain bargain across all targets and fiscal, monetary, or exchange rate instruments. They would aim to maximize the gains over the noncooperative policy settings, subject to an acceptable distribution of those gains among participants or countries.

The Gains from Coordination Studies designed to evaluate the gains from policy coordination empirically have found the benefits to be valuable but small. The gains for industrial countries from cooperating are generally thought to be in the range of 0.5 1.5 percent of gross national product (GNP) to each country, over the best available noncooperative outcomes (Oudiz and Sachs 1984; Hughes Hallett 1986). Nevertheless, these gains turn out to increase significantly with the size and persistence of external shocks and the reputations (for consistency) of the governments concerned (Currie, Levine, and Vidalis 1987). It can be debated whether one-half of 1 percent of GNP is only a "small" gain. It would represent a significant amount of extra productive capacity if fully invested. But it is not large compared to annual growth rates. Moreover, if the expected gains are small relative to the imprecision with which policies can be implemented, those gains may be hard to realize in practice. Consequently, the robustness of these gains is particularly important.

Far less attention has been given to the likely distribution of the gains among countries. Empirical studies generally find that the gains from cooperation are asymmetric, and it is usually very difficult to find ways of improving the lot of the countries that benefit least from coordination (Hughes Hallett, Holtham, and Hutson 1989). These are important results because they suggest that, whatever the overall gains, (1) it will be hard to secure *and maintain* a coordination agreement in the face of significant uncertainties, and (2) if those who make the gains and those who shoulder the burden of adjustment are different sets of people, then securing any agreement will be politically difficult.

Cooperation through Information Exchanges The gains from coordination relative to noncoordination may well be smaller than those of efficient noncooperative policies relative to strategies that ignore predictable policy changes abroad or elsewhere in the system. Thus coordination in the sense of *information exchanges,* rather than a negotiated solution across all variables, may supply the major part of the improvements. If this is so, an important function of international policy discussions or policy meetings is going to be the exchange of information among policymakers concerning their policies, their aims, and the state of their economies. The implication is that much of the value of policy coordination may in fact lie in tying the national policymakers into a regime in which it is far more difficult for them to make poorly designed or misguided policy choices either through misplaced self-interest or through ignorance rather than in introducing qualitatively different policies.

Coordination Substitutes: Avoiding Conflicts over Shared or Linked Targets None of the original studies of policy coordination considered exchange rates to be a target of policy. Yet the policy debate has often been concerned with exchange rate management, with the aim of either stabilizing exchange rates or of making controlled realignments. When exchange rates are included among the targets during policy selection, they can either be included in the associated objective function evaluations (in which case exchange rate stability becomes a target

in its own right) or excluded from those evaluations (in which case exchange rates are just an intermediate target, instrumental in securing improvements elsewhere, but of no interest in itself). In the former case, the gains from coordination appear larger than before, at about 3 6 percent of GNP as estimated across seven multicountry models. If exchange rates are treated merely as intermediate targets, the gains are significantly smaller and much as in the earlier literature cited above (Holtham and Hughes Hallett 1987).

The point here is that an exchange rate is a shared variable whose domestic impact is the same whether exchange rate changes originate at home or abroad. By contrast, most other variables exert impacts that are significantly smaller internationally than domestically. The need to limit exchange rate spillovers is therefore greater in problems with shared targets than in those with other linkage variables.

Second, success with shared targets, whether treated as intermediate or not, requires a measure of coordination in how they are controlled and also some consensus about the target path that they should pursue. If this is missing, countries will inevitably waste policy power pushing against one another in a vain attempt to achieve the impossible. This holds in particular for the n 1 problem. In that case, there is one fewer independent exchange rate (or current account) than the number of independent policymakers so that not all n target values can be reached at once. At least one must be missed, or be allowed to float free. On the other hand, it is not true that any agreed target path is better than none. Jointly specifying exchange rate target paths independently of any other objectives is frequently more damaging than moderate disagreement about what that target path should be. Hence the problem appears to be one of choosing an appropriate set of target paths, not one of securing precise agreement on the policies to support some path.

In addition, not only may intermediate targets serve to promote relative coordination between economies, they may also be conducive to absolute coordination. This is an important part of the rationale for joint monetary targeting or for a system

of exchange rate targets. Nevertheless there are important qualifications to this argument. The gains to exchange rate targeting may be small, hard to achieve, or badly distributed across countries. It is not just that some countries do better than others. Some may actually lose compared with the no-targeting case. Moreover, the target paths have to be very carefully chosen to achieve any of these gains (Hughes Hallett 1992). This suggests that the losses attributable to attempts to manipulate monetary policies (or exchange rates) within a given regime are generally small but may become significant in particular episodes when countries have uniform objectives or attach great weight to one objective. At other times, the potential gains to eliminating competitive policy-making are easily outweighed by the losses resulting from the attempt to achieve an extra, and possibly inappropriate, exchange rate target.

In short, since any targeting regime implies an additional constraint, the sacrifice in the other targets, which this extra constraint implies, must be less than the efficiency gains from a more effective design of the policies or a more appropriate allocation of interventions between national policy instruments and policy institutions.

The Dangers of Coordination Because the gains may not be large, obstacles to coordination may easily create losses that overwhelm those potential gains. Policymakers may decide not to cooperate if they think that other countries will not stick to their part of the bargain, or if they think that there are potential information errors or other shocks that would invalidate their calculations, or if they think that they may have misestimated the priorities of other players, or if there is a serious possibility that policymakers are uncertain or differ in their views of how the economy works (Holtham and Hughes Hallett 1992).

Sustainability Will policymakers stick to their part of the bargain? Or will policymakers cheat by redesigning their future policies once they have maneuvered the other participants into taking certain actions? The first question involves breaking a bargain, with one party finding it advantageous to deviate from what was previously agreed once the other

participants have established their policies. In that case governments try to cheat on one another. The second is the usual time-inconsistency problem in which governments cheat on the private sector over time. The latter does not involve a bargain as such but represents an internal inconsistency in one of the policy sequences. A standard example is discussed by the economist Rogoff (1985), who points out that policy coordination may actually be welfare-decreasing if the coordination process eases the constraints imposed on governments engaging in inflationary expansions. The reason is that, in reality, there is more than one set of actors per economy (the government, the central bank, and a private sector whose forward-looking expectations affect the exchange rate and, hence, policy success) so that coordination among governments may represent a coalition against the private sector or central bank, rather than full coordination. Although the example is specific, it is a general point that coordination without credibility may be counterproductive. Nevertheless, coordinated policies will prove robust against cheating if the losses the first country (or actor) would suffer under retaliation (or preemptive cheating) by its opponent are larger than the gains that the same country (or actor) could make by unopposed cheating.

Policy Errors Shocks to the system can affect the incentive to coordinate. But those shocks have to be both large and persistent (Canzoneri and Minford 1986). By contrast, coordination may reduce policy errors because decision-makers try to share the risks rather than offload them onto their rivals. Performance indicators are generally aggregations of national targets that are affected in different and mutually conflicting ways by external shocks, while coordinated policies follow by aggregating those national indicators into some global performance index. Coordinated policies will, therefore, normally be *more* robust than noncooperative policies, which lack that extra aggregation and hence that extra ability to cancel out errors.

Interinstitutional and Rule-Based Coordination Another form of policy coordination is rule-based coordination. In this case benefits arise from

the credibility associated with committing to a set of rules that are well designed and capable of being monitored easily. Rule-based coordination has the advantage that it may be used to avoid the inefficiencies of short-term policymaking, or where there are temptations to manipulate or opportunistically free ride on the expectations of others. One example is the "fiscal leadership" model in which fiscal policymakers are made to decide their policies first, with an eye to their long-run commitment to public services and the stability of public finances, under the threat that an independently run monetary policy that follows can take away any short-term or special interest gains that the fiscal leaders may be tempted to create for themselves (Hughes Hallett and Weymark 2007).

In fact, leadership under suitable conditions (that the players' reaction functions form an acute angle so that their policies could be aligned) will always induce a degree of coordination and the gains will increase the more the policymakers differ in terms of goals and priorities. A simple way to implement this idea is to give fiscal policymakers a debt target. Being a stock, not a flow, such a rule would induce the leadership we require automatically. More generally, this option opens up the whole area of interinstitutional coordination. The early studies ignored that issue, but more recent work has focused on the interactions among institutions (Foreman-Peck et al. 2007; Pappa 2004). Policy coordination is often more important in this context because the effects go through the domestic markets as well as through the international or foreign markets. Interinstitutional coordination is therefore likely to have a greater effect than intercountry coordination.

Explicit rules incorporating an automatic degree of coordination may also act as an important discipline on the actions of governments in the international arena. Although democratic governments should, and do, have appreciable freedom of action, the public choice literature emphasizes that pressure groups and special interests may exert undue influence on government policy, leading to inefficient outcomes for the economy as a whole. There may be scope for constraining government action to

more efficient outcomes on the basis that "what benefits others benefits everyone." Such rules may be internal, as in the separation of fiscal and monetary powers in some countries, or externally imposed as in exchange rate targeting or common inflation policies.

Going Forward Academic research has produced an extensive literature on policy coordination. Much of the work has been theoretical and based on simplified models. As these have abstracted from some of the difficulties of which policymakers are most aware, the literature may have a flavor of unreality to practitioners. Moreover, much of the impetus to cooperation has come from experience, not from explicit demonstrations of the benefits. Bringing theory to bear on current concerns is therefore unfinished business. But there is little sign as yet that our understanding of policy coordination needs to be revised (Canzoneri et al. 2005).

ANDREW HUGHES HALLETT

■ international reserves

International reserves are the liquid external assets (foreign currency, foreign currency bonds, and gold) under the control of the central bank. Under the Bretton Woods system, adequate reserves were measured by months of imports: the prevailing rule of thumb considered four months of imports to be reasonable coverage. This perspective fitted well in a world with limited financial integration, in which trade openness reflected a country's vulnerability to external shocks (Fischer 2001). In the absence of reserves, balance of payment deficits would have to be corrected through a reduction in aggregate expenditures, imposing macroeconomic adjustment costs, manifested in sharp contractions of investment and consumption, thereby inducing recessionary pressures. As greater trade openness increased the exposure to trade shocks, minimizing adjustment costs

required higher reserve holdings. An intriguing development since the 1960s has been that, despite the proliferation of greater exchange rate flexibility, international reserves/gross domestic product (GDP) ratios have increased substantially. Reserve holdings have trended upward; at the end of 1999, reserves were about 6 percent of global GDP, 3.5 times what they were at the end of 1960 and 50 percent higher than in 1990. Practically all the increase in reserves/GDP holding has been by developing countries, mostly concentrated in East Asia (Flood and Marion 2002).

International Reserves as a Buffer Stock The earlier literature focused on using international reserves as a buffer stock, part of the management of an adjustable-peg or managed-floating exchange-rate regime. Accordingly, optimal reserves balance the macroeconomic adjustment costs incurred in the absence of reserves with the opportunity cost of holding reserves (Frenkel and Jovanovic 1981). The buffer stock model predicts that average reserves depend negatively on adjustment costs, the opportunity cost of reserves, and exchange rate flexibility and positively on GDP and reserve volatility, driven frequently by the underlying volatility of international trade. Overall, the literature of the 1980s supported these predictions (see Flood and Marion 2002).

Post-1998 trends in hoarding reserves, especially the large increase in hoarding international reserves in East Asia, stirred lively debate among economists and financial observers. Although useful, the buffer stock model has a limited capacity to account for the recent development in hoarding international reserves the greater flexibility of the exchange rates exhibited after 1990 should work in the direction of reducing reserve hoarding, in contrast to the trends reported earlier. As an indication of excess hoarding, some observers noted that developing countries frequently borrow at much higher interest rates than what they earn on reserves.

International Reserves and Self-Insurance The recent literature provided several interpretations for these puzzles, focusing on the observation that the deeper financial integration of developing countries has increased exposure to volatile short-term inflows of capital (dubbed "hot money"), subject to frequent sudden stops and reversals (see Calvo 1998; Edwards 2004). Looking at the 1980s and 1990s, the magnitude and speed of the reversal of capital flows throughout the 1997 98 East Asian financial crisis surprised most observers (Aizenman and Marion 2003). Most viewed East Asian countries as less vulnerable to the perils associated with hot money than Latin American countries. After all, East Asian countries were more open to international trade, had sounder fiscal policies, and showed much stronger growth performance. In retrospect, the 1997 98 crisis exposed hidden vulnerabilities of East Asian countries, forcing the market to update the probability of sudden stops affecting all countries.

These observations suggest that hoarding international reserves can be viewed as a precautionary adjustment, reflecting the desire for self-insurance against exposure to future sudden stops. Self-insurance has several interpretations. The first focuses on precautionary hoarding of international reserves needed to stabilize fiscal expenditure in developing countries (see Aizenman and Marion 2004). Specifically, a country characterized by volatile output, inelastic demand for fiscal outlays, high tax collection costs, and sovereign risk may want to accumulate both international reserves and external debt (sovereign risk is the added risk, such as default of sovereign governments on debts, and nationalization, assumed by investors with funds invested in foreign counties). External debt allows the country to smooth consumption when output is volatile. International reserves that are beyond the reach of creditors would allow such a country to smooth consumption in the event that adverse shocks trigger a default on foreign debt.

Another version of self-insurance and precautionary demand for international reserves views international reserves as output stabilizers (Ben-Bassat and Gottlieb 1992; Aizenman and Lee 2007). Accordingly, international reserves can reduce the probability of an output drop induced by a sudden stop and/or the depth of the output collapse when the

sudden stop materializes. This argument is in line with the Guidotti-Greenspan rule of thumb of the 1990s — countries should hold liquid reserves equal to their foreign liabilities coming due within a year. This rule reflects the shifting focus from reserve adequacy measured in terms of trade flows of goods to flows of assets.

Back of the envelope estimation suggests that the expected benefits of following a Guidotti-Greenspan rule is about 1 percent of gross domestic product (GDP). This would be the case if a country holding reserves equal to its short-term debt reduces the annual probability of experiencing a sharp reversal in capital flows by 10 percent on average (in line with Rodrik and Velasco 1999, see Rodrik 2006) and if the output cost of a financial crisis is about 10 percent of GDP, as found by Hutchison and Noy (2006). Similar results have been obtained using more elaborated models (see Garcia and Soto 2004; Jeanne and Ranciere 2005). These authors concluded that self-insurance against sudden stops plays an important role in accounting for recent hoarding of international reserves.

While the Guidotti-Greenspan-IMF rule focused on the ratio of reserves to short-term debt, Kim et al. (2005) looked at a more flexible rule, based on the behavior of different types of capital flows during currency crises. Application to selected Asian countries leads them to conclude that the countries affected by the East Asian crisis held excessive reserves by 2003 — the affected countries have already built up more than adequate reserve levels to handle a repeat of the actual capital outflows that occurred during the 1997–98 crises scaled up to 2003 values. One may note, however, that the rapidly changing structure of the developing countries' financial integration implies that future possible crises would not resemble the previous ones. For example, Korea, one of the countries affected by the 1997–98 crisis, lifted restrictions on foreign equity ownership in the aftermath of the crisis. In response, foreigners' shareholding as a percentage of the total market capitalization has risen from 12 percent in 1997 to 40 percent by 2003. Arguably, the sizable accumulation of reserves by Korea during that period may reflect

the wish to cover short-term external debt plus some portion of foreigners' shareholdings, in the desire to reduce possible real exchange rate repercussion of future reversals of capital flows.

International Reserves: Precaution versus Mercantilism The Korean policy suggests another angle associated with international reserves — the possibility that international reserves management may lower real exchange rate volatility, which in turn may allow a smoother output and potentially higher growth rate. To put this topic in broader context, note that the literature of the 1990s identified large adverse effects of exogenous volatility on the GDP and economic growth in developing countries. An important channel that may explain such negative levels and growth effects of volatility are capital market imperfection and low levels of financial development (Aghion et al. 2006).

The views linking the large increase in hoarding reserves to growing exposure to sudden stops associated with financial integration face a well-known contender in a modern incarnation of mercantilism (Dooley et al. 2003). According to this interpretation, reserves accumulation is a by-product of promoting exports, which is needed to create better jobs, thereby absorbing abundant labor in traditional sectors. Though intellectually intriguing, this interpretation remains debatable — the history of Japan and Korea suggests the near absence of mercantilist hoarding of international reserves during the phase of fast growth, and the prevalence of export promotion by preferential financing in targeted sectors. Foundering economic growth led to the onset of large hoarding of reserves both in Japan and Korea, probably due to both mercantilist motives and self-insurance to deal with growing fragility of the banking system. These perspectives suggest that the massive hoarding of reserves by China is a hybrid of the mercantilist and self-insurance motives (Aizenman and Lee 2006). Yet mercantilist hoarding by one country may induce competitive hoarding by other countries to preempt any competitive advantage gained by the first country, a reaction that would dissipate most competitiveness gains. This view is supported by the interdependence of the demand for

international reserves among ten East Asian countries (Cheung and Qian 2006).

Overall, greater exposures of developing countries to sudden stops and reversals of hot money, growing trade openness, and the desire to improve competitiveness and to reduce real exchange rate volatility go a long way toward accounting for the observed increase in the rapid and massive stockpiling of international reserves by developing markets.

■ **intrafirm trade**

Intrafirm trade is international trade that occurs be tween different affiliates of the same multinational firm. In the United States, intrafirm trade accounted for approximately 35 percent of all international trade in 2004, and it has been a large fraction of international trade in the United States for decades. In the 2002 *Economic Outlook* of the Organisation for Economic Co-operation and Development there is some evidence of increases in intrafirm trade in other countries.

Data on intrafirm trade are difficult to find con sistently across countries. The U.S. data come from the Bureau of Economic Analysis, which undertakes annual surveys of U.S. multinational firms and their affiliates abroad as well as foreign-based multina tional firms and their affiliated firms in the United States.

The large magnitude of intrafirm trade has been emphasized by many scholars of foreign direct investment (FDI). Furthermore, many scholars have discussed the increasing importance of vertical specialization in international trade. Vertical specialization includes the segmentation of production across national boundaries, whereby different stages of the production process are done in different countries, in line with their natural comparative advantage. Yi (2003) argues that vertical specialization can help explain the growth in world trade. Still, it is important to distinguish trade in intermediate inputs from intrafirm trade, as the former need not occur within the firm.

Understanding the nature of intrafirm trade therefore requires understanding the motives behind FDI more generally, or the rationale for organizing cross-border economic activity within the firm. Theoretical models of multinational activity emphasize several possible motives for internalizing activity within the firm. For example, there may be a need to control the quality of the product, accompanied by difficulties in the formation of contracts at arm's length to ensure the reputation of the firm. Also, proprietary firm-specific knowledge can make it difficult to appropriate the gains from production via licensing, as it is difficult to charge the appropriate fee for the knowledge without revealing the knowledge itself, thus lowering the incentive to pay for it. There is evidence in favor of such motivations. For example, the literature has consistently shown a correlation between the propensity to exchange goods within the firm and the research and development intensity of production; see Borga and Zeile (2004) for an overview of findings in this area.

An additional motive for internalization is tax avoidance. Gordon and Hines (2002) undertake a comprehensive survey of international taxation and find little evidence for viewing multinational firms as financial intermediaries, facilitating the movement of capital to higher return locations. Instead, they find more support for models of multinational firms as facilitators of tax avoidance or owners of firm-specific intangible capital.

Countries tax multinational firms in a variety of ways. Some countries exempt the foreign earnings of their resident firms from taxation; these are referred to as territorial systems. Multinational firms based in such countries have an unambiguous incentive to shift income to low-tax locations. Other countries (such as the United States) tax the worldwide income of their resident firms, but they still generally allow deferral of taxation on income earned in low-tax countries until that income is repatriated. These are referred to as credit systems. Deferral, as well as other methods of lowering the residual tax due, provides multinational firms in credit system countries with a substantial incentive to shift profits to low-tax countries.

Intrafirm trade may facilitate international tax avoidance by multinational firms in several ways. By altering the prices of transactions that occur within the firm, firms can effectively shift income from high-tax locations to low-tax locations. For example, given these tax incentives, multinational firms have an incentive to overprice intrafirm trade flows originating in low-tax countries and underprice intrafirm trade flows originating in high-tax countries. Evidence that firms follow such strategies is provided in Clausing (2003), which examines intrafirm trade prices directly. Data on intrafirm trade prices are uncommon, but most of the literature in this area provides consistent, if indirect, empirical support for the importance of tax-motivated transfer pricing. Hines (1999) reviews this body of literature.

In addition to tax distortions on the pricing of intrafirm transactions, there is evidence (e.g., Clausing 2006 and references within) that firms undertake greater quantities of intrafirm trade with low-tax countries. This finding may indicate that low-tax locations are attractive places to undertake FDI, and thus intrafirm trade is also encouraged as it is complementary to multinational activity. This finding may also indicate that greater quantities of intrafirm trade are undertaken in order to facilitate tax avoidance; these two motives are difficult to distinguish given data constraints.

Aside from the tax influences on intrafirm trade, the behavior of intrafirm trade more generally has also received attention in the literature. Some scholars have argued that intrafirm trade by multinational enterprises may be more responsive to changes in economic conditions than international trade between unaffiliated entities. Feinberg and Keane (2006, 2007) consider the relationship between changes in technology, tariff reductions, the restructuring of multinational firm production, and the growth of world trade and intrafirm trade. They find that the growth in Canadian-U.S. intrafirm trade is due in large part to technical change and in particular improvements in logistics management and "just-in-time" production systems. Tariff reductions play a relatively minor role in intrafirm trade, although they are important in explaining arm's-length trade by multinational firms. So the reasons for growth in intrafirm trade appear to differ from the reasons for the growth in arm's-length trade by multinational firms.

International trade by multinational firms is a majority of all trade for the United States, and it is likely to be of similar importance for many other countries. While some of this trade occurs at arm's length among unaffiliated firms, an important part of the international trade of multinational firms is intrafirm trade. Intrafirm trade, or trade between different affiliates of the same multinational firm, may differ from conventional trade in important ways. Foremost, it is influenced by international tax incentives, but it also may respond differently to other key economic variables.

KIMBERLY A. CLAUSING

■ **intraindustry trade**

Intraindustry trade arises if a country simultaneously imports *and* exports similar types of goods or services. Similarity is identified here by the goods or services being classified in the same sector. Suppose, for the sake of argument, that we focus on the sector "cars." Intraindustry trade then occurs, for example, if Germany exports cars to France and simultaneously imports cars from Italy. On the one hand this raises the question why Germany is (at least partially) ex-

porting cars in exchange for importing cars instead of focusing exclusively on so-called *inter*industry trade, namely exporting cars in exchange for importing different types of goods (such as food or airplanes). On the other hand, this raises the question why different goods are lumped together in the same sector, as the exported Volkswagen Golfs differ from the imported Ferraris. We address these two basic questions in what follows.

Although in hindsight various antecedents can be traced, the phenomenon of intraindustry trade as such first received attention in the 1960s in studies by Pieter Verdoorn and Bela Balassa on the increased trade flows among European countries. Herbert Grubel and Peter Lloyd (1975) provided the definitive empirical study on the importance of intraindustry trade and how to measure it. Solid theoretical foundations for explaining intraindustry trade came later (in the 1980s and 1990s) with the new trade literature, to a large extent based on a monopolistic competition framework.

Types of Intraindustry Trade It is customary to distinguish between two different types of intraindustry trade, each warranting a different type of explanation, namely:

Horizontal intraindustry trade. This refers to the simultaneous exports and imports of goods classified in the same sector and at the *same stage of processing*. This is likely based on product differentiation, for example, South Korea's simultaneous import and export of mobile telephones in the final processing stage. As these mobile phones are produced using similar technology and provide similar functions they are classified in the same sector. Nonetheless, the exported Samsung telephones differ in appearance and product characteristics slightly from the imported Nokia telephones, catering to the desires of different types of consumers.

Vertical intraindustry trade. This refers to the simultaneous exports and imports of goods classified in the same sector but at *different stages of processing*. This is likely based on the increasing ability to organize fragmentation of the production process into different stages, each performed at different locations by taking advantage of the local conditions. China,

for example, imports technology-intensive computer components and uses its abundant, low-wage labor force to assemble these components in the labor-intensive final production stage, before the components (as part of a finished computer) are exported again to Europe or the United States.

Measuring Intraindustry Trade: The Grubel-Lloyd Index The most often used method for determining the extent of intraindustry trade was proposed by Grubel and Lloyd (1975). This measure, now known as the Grubel-Lloyd index, is simple to calculate and intuitively appealing. Once a country's export and import value for a particular sector and period are known, it is calculated as:

$$GL_{sector\ i} = 1 - \left(\frac{|export_{sector\ i} - import_{sector\ i}|}{export_{sector\ i} + import_{sector\ i}} \right). \tag{1}$$

If the country only imports or only exports goods or services within the same sector, such that there is no intraindustry trade, the second term on the right-hand side of equation (1) is equal to one, such that the whole expression reduces to zero. Similarly, if the export value is exactly equal to the import value ($export_{sector\ i} = import_{sector\ i}$), the second term on the right-hand side of equation (1) is equal to zero, such that the whole expression reduces to one. The Grubel-Lloyd index therefore varies between zero (indicating pure *inter*industry trade) and one (indicating pure *intra*industry trade).

Data Aggregation As already indicated, to some extent intraindustry trade can be considered a classification problem as different types of goods and services are lumped together in the same sector. In practice, international trade flows are classified in various ways. Using the SITC (standard international trade classification) we can distinguish ten different broad sectors (the so-called one-digit level). Each of these one-digit sectors can, in principle, be subdivided into ten more detailed two-digit sectors. Each of the two-digit sectors can in turn, in principle, be subdivided into ten even more detailed three-digit sectors, and so forth. Sector 6 at the one-digit level, for example, consists of "manufactured goods." One of the subsectors at the two-digit level is sector 61

"leather manufactures" while another is sector 63 "cork/wood manufactures." Analyzing intraindustry trade at the very broad one-digit level therefore classifies trade of leather manufactures in exchange for cork/wood manufactures as intraindustry trade, which seems unwarranted. Looking at the more detailed two-digit level this problem partially disappears and a smaller extent of trade is therefore classified as intraindustry trade. A further reduction occurs if we look at even more detailed levels of aggregation. The three-digit level, for example, distinguishes between cork manufacturers (sector 633) and different types of wood manufacturers (sectors 634 and 635) separately.

Table 1 illustrates the data aggregation problem for China for three different levels of aggregation (consisting of 10, 67, and 237 different sectors) by reporting a trade-weighted average Grubel-Lloyd index for a selection of years. We report the one-digit level only for the sake of argument as it is generally considered too crude a classification in practice. Three things are clear from the table. First, as we distinguish between more sectors a smaller fraction of trade is classified as intraindustry trade, for example reducing it from 58 percent to 49 percent to 42 percent of total trade in China in 2005. Second, even though intraindustry trade reduces as we identify more sectors, it does not disappear. It is, for example,

still 42 percent of total trade at the three-digit level in China in 2005. This is a general characteristic of current trade flows as intraindustry trade exists for very detailed sector classifications. Third, and most important, intraindustry trade seems to become more important over time, for example increasing at the three-digit level in China from 20 percent in 1980 to 42 percent in 2005. We now turn to this issue.

Empirical Characteristics of Intraindustry Trade
There are structural differences across sectors regarding the extent of intraindustry trade. To demonstrate this, we use the factor-intensity classification of the International Trade Center, a joint agency of the United Nations Conference on Trade and Development and the World Trade Organization, which distinguishes between five broad factor-intensity categories at the three-digit level, namely (within parentheses the number of the sector belonging to the particular category):

Primary products (83): e.g. meat, dairy, cereals, fruit, coffee, minerals, and oil.
Natural-resource-intensive products (21): e.g. leather, wood, pig iron, and copper.
Unskilled-labor-intensive products (26): e.g. textiles, clothing, ships, and footwear.
Human-capital-intensive products (43): e.g. perfumes, cosmetics, cars, and watches.
Technology-intensive products (62): e.g. chemicals, electronics, tools, and aircraft.

Table 2 depicts the extent of intraindustry trade for these different types of sectors in China for selected years. It shows that the level of intraindustry trade is particularly low for unskilled-labor-intensive sectors, particularly high for technology-intensive sectors, and intermediate for the other types of sectors. As countries such as China successfully develop, the composition of their trade flows tends to move away from primary products, initially toward unskilled-labor-intensive products and subsequently toward technology- and human-capital-intensive products. Associated with these changes there is an ultimate increase in the extent of intraindustry trade.

Table 1
Intraindustry trade and aggregation: China, selected years (trade weighted average Grubel Lloyd index, different levels of aggregation)

	3 digit 237 sectors	2 digit 67 sectors	1 digit 10 sectors
1980	0.20	0.30	0.63
1985	0.20	0.29	0.44
1990	0.36	0.45	0.60
1995	0.38	0.48	0.67
2000	0.39	0.48	0.57
2005	0.42	0.49	0.58

[a] st dev = standard deviation.

In a study summarizing the growing importance of intraindustry trade, the Organisation for Economic Co-operation and Development (OECD 2002) lists the following empirical characteristics: Intraindustry trade

- has risen significantly since the 1980s in most (OECD) countries
- is particularly high for sophisticated manufactured products (chemicals, machinery, transportation equipment, electrical equipment, and electronics; both based on product differentiation and fragmentation)
- is particularly high for very open countries ("supertrading" economies, where both imports and exports account for more than half of GDP)
- is connected to foreign direct investment inflows, particularly in Eastern European "transition" economies
- is related to preferential trade agreements, for example, the sharp increase in in-

traindustry trade in Mexico after the North American Free Trade Agreement
- is to a large extent based on intrafirm trade, either based on product variety or on fragmentation (intrafirm trade accounts, for example, for one-third of exports in Japan and the United States).

CHARLES VAN MARREWIJK

■ J-curve effect

The J-curve effect describes the time lag with which a currency depreciation or devaluation leads to an improvement in the trade balance. Although the trade balance may improve in the long run, it may worsen initially so that it follows the pattern of a *J* tilted to the right. The origin of the J-curve is usually attributed to economist Stephen Magee's (1973) attempt to find an explanation for the short-run behavior of the U.S. trade balance in the early 1970s. In 1971 a balance of trade surplus turned into a deficit, and although the U.S. dollar was devalued, the trade balance continued to deteriorate.

The theoretical basis of the J-curve effect is the elasticities approach to the balance of payments. According to this theory a currency devaluation or depreciation is expected to improve the trade balance by changing the relative prices of domestic and foreign goods. By making foreign goods more expensive in the home country and the home country's goods cheaper abroad, demand for imports will be low and foreigners will buy more of the home country's exports. Provided that the responses of importers and exporters to the price changes are strong enough, the Marshall-Lerner condition will be fulfilled and the trade balance will improve.

Importance of the J-Curve The J-curve effect is important because it has implications for the effectiveness of policies designed to improve the balance of payments. During the 1997 financial crisis in Asia, for example, the International Monetary Fund encouraged currency depreciation as part of a package of policies to stabilize the balance of payments of countries hardest hit by the crisis. If the J-curve effect is important then it will take a longer period of time before the balance of payments improves than if the adjustment to the currency depreciation had been instantaneous.

The J-curve phenomenon has also been invoked to explain the persistence of the U.S. trade deficit following the fall in the U.S. dollar from its peak in 1985. Even after two years of a falling dollar, the trade deficit failed to show a marked improvement. According to this perspective, while the U.S. trade balance was expected to improve in the longer term, the substantial lags in the adjustment of both prices and quantities to exchange rate changes contributed to the sluggish response of the U.S. deficit to the U.S. dollar depreciation.

Causes of the J-Curve The causes of the J-curve effect are generally traced to a currency contract effect and/or weak short-run responses to changes in the relative prices of exports and imports following a depreciation or devaluation of the home country's currency. The currency contract effect arises when import and export orders reflect decisions made in advance of the devaluation at the old exchange rate. Therefore, immediately after a devaluation there may be a period when contracts signed prior to the exchange rate change become due. The J-curve can then occur if the home country's exports are invoiced in the home currency but its imports are invoiced in the foreign currency: during the currency contract period the value of exports in the home country's currency is unaffected by the devaluation, but import values measured in home currency will rise, thus

worsening the trade balance. Only in the longer run when new contracts are signed will the value of home imports fall and home exports rise sufficiently to improve the trade balance.

Even in the absence of a currency contract period, a J-curve can occur if responses to the changes in import and export prices are weak, so that quantities traded do not change much in the short run. This would imply a failure of the Marshall-Lerner condition over this period. If the demand for imports is unresponsive, the total import bill could rise until the home country's buyers find suitable substitutes, while the demand for exports may be insensitive if foreign buyers do not increase their demand for the home country's goods in the short run even though their prices have fallen in the foreign country's currency.

Estimating the J-Curve Although economists have done a substantial amount of empirical work on the J-curve, the results seem to depend on the particular country and the period selected for investigation. What is clear is that the short-run response of the trade balance to a devaluation or depreciation of the currency does not follow a uniform pattern. One reason for this is that other factors may be involved. For example, the rapid improvement in the Mexican trade balance with the United States following the sharp depreciation of the peso against the dollar in December 1994 is often cited as a successful balance of payments adjustment with the absence of any obvious J-curve complications. But the massive size of the devaluation and the financial crisis that accompanied it may have persuaded exporters and importers that the devaluation was permanent and therefore speeded up their adjustment. In addition, an improvement in the trade balance may have resulted from a fall in spending on imports as government spending was cut, and prior trade liberalization may have made import and export volumes more sensitive to relative price changes.

A second factor is that the response to the exchange rate change may vary according to the level of sectoral aggregation. Countries with a high proportion of natural resources, such as crude petroleum and agricultural products, in their exports and/or imports may find their trade balance is less sensitive to exchange rate changes than countries that predominantly trade manufactured goods. A further problem is the need to look beneath the aggregate trade balance to see what is happening at the bilateral level. The trade balance may be improving in the short run with respect to one trading partner but simultaneously deteriorating with respect to another.

■ joint ventures

A joint venture is a mechanism for combining complementary assets owned by separate firms. These assets can be tangible, such as machinery and equipment, or intangible, such as technological know-how, production or marketing skills, brand names, and market-specific information. In an equity joint venture the partner firms transfer all or part of their assets to a legally independent entity and share the profits from the venture. Contractual arrangements that do not involve shared equity control are sometimes referred to as nonequity joint ventures; examples include licensing and management contracts, as well as supply and distribution agree-

ments. Shared ownership and contractual arrangements are also frequently grouped together under the term *alliances*. This entry focuses on equity joint ventures, specifically international joint ventures involving partners from different countries.

From a world economy perspective there are at least two reasons for examining international joint ventures. First, international joint ventures represent a form of foreign direct investment (FDI). Multinational enterprises often have to decide whether to wholly own a foreign affiliate or to share equity control with a local partner. This decision is a key element of the foreign investment strategy. Second, the ownership structure of a foreign investment project affects host-country welfare. A direct effect comes from the sharing of profits between the multinational and the local firm. Indirect effects arise because ownership influences investors' incentives to commit resources to the project, such as capital and technology. Some host countries impose local ownership requirements that limit the equity stake foreign investors can take in local companies. This raises the question of what the economic effects of such requirements are.

Probably the most comprehensive data on international joint ventures come from the U.S. Department of Commerce benchmark surveys. Although they are not representative for the world as a whole, these data still offer information on long-run trends in international joint venture activity for one of the most important source countries of FDI. According to Desai, Foley, and Hines (2004), who have examined these data, about 80 percent of all U.S. affiliates abroad in 1997 were wholly owned, with the remaining 20 percent equally divided between minority- and majority-owned affiliates. The ownership share is positively correlated with host-country gross national product (GNP). In the richest quartile of host countries, partially owned affiliates accounted for only 15.5 percent, whereas in the poorest quartile they made up more than half of all U.S. foreign affiliates. The data exhibit considerable variation in ownership shares across industries and over time. Since the mid-1980s there has been a downward trend in minority-owned and an upward trend in

majority- and wholly owned affiliates, partly due to changes in U.S. tax laws.

Profit-Maximizing Joint Ventures Consider a multinational firm contemplating a foreign investment project that requires a combination of its own assets and those of a local firm in the host country. What is the appropriate ownership structure of the project? The extensive literature on this issue starts from the premise that the ownership structure is a response to the presence of market failures (or high transaction costs) in asset markets. This can best be understood by assuming counterfactually that there are no such failures. This is the case, if (1) all assets and other inputs to and outputs from the project are observable and verifiable by third parties, such as courts; (2) it is possible to write contracts specifying the provision of each input, and the distribution of output and profits under all possible contingencies; and (3) these contracts can be enforced at no cost. Under these ideal conditions, the ownership structure is indeterminate, since the firms can simply use contracts to coordinate the use of their assets.

Such ideal conditions are unlikely to prevail in practice. Suppose, for example, that the project requires a combination of the multinational's production technology and the local firm's marketing know-how. It may be very difficult to specify what these assets entail, to assess how valuable each asset will be for the project, and hence to write a contract on what each party has to contribute and how profits are to be shared. Even if the two parties both knew how important the technology and the marketing know-how were, it would be next to impossible for a third party to verify this and hence to determine whether both parties have fulfilled their contractual obligations. It may also be impossible through contractual means to prevent spillovers of the technology to the local firm, which could then use it for its own purposes. Specifying appropriate management contracts to ensure that profits from the project are maximized may be difficult, especially if monitoring costs are high. In short, contracts will generally be insufficient to prevent opportunistic behavior. Retaining (partial) ownership of assets, and hence

residual rights of control over them, may then be preferable because it ensures that a firm will obtain at least some return from the project and hence have an incentive to contribute assets to the project and provide effort in running it.

Shared ownership of an investment project is only a second-best solution. First, it may be impossible to guarantee each party the full return from the use of its assets. Hence there may be too little provision of assets or insufficient investment in tailoring the assets to the project. Second, joint ventures require significant management resources due to the need to coordinate decisions between the partners. Why then would one of the partners, say the multinational, not simply acquire the other and assume whole ownership of the project? One obvious advantage of shared ownership is that it requires less capital than a complete takeover. Moreover, the multinational may be interested in only some of the assets of the local firm. If these are hard to disentangle from the local firm's other assets, a joint venture may be the better option. Incomplete information about the value of the local firm's assets provides another reason for shared ownership, since letting the local firm choose how much ownership to retain may reveal information to the multinational.

Empirically it is difficult to distinguish between different explanations for shared ownership, since the information on which firms base their decisions is often confidential. In addition, the ownership decision may be made simultaneously with other decisions concerning the firm's operations. Desai, Foley, and Hines (2004) therefore use changes in U.S. tax laws affecting ownership and the liberalization of local ownership requirements to identify possible interactions between these decisions. They find a complementary relationship between the ownership share of the multinational and the amount of intrafirm trade between the affiliate and the parent company. Firms that trade more internally are more likely to have whole or majority ownership, whereas affiliates selling more of their output or buying more of their inputs locally are more likely to be organized as joint ventures. Possible reasons for this are that

whole ownership reduces the cost of coordinating intrafirm transactions and makes it easier to set internal transfer prices to avoid taxes.

Host-Country Policy Local ownership requirements are most frequently imposed by developing and transition countries, although some high-income countries also put limits on foreign ownership in certain sectors. Possible economic rationales for requiring local equity participation in low-income countries are that they might facilitate spillovers of technology and management know-how to local firms and might secure a share of the project's earnings for the host country when the fiscal system is too inefficient to do this directly through taxes. Some authors argue that multinationals, too, may have an interest to take on a local partner to smooth relations with the host-country government and reduce the risk of expropriation.

■ knowledge-capital model of the multinational enterprise

The knowledge-capital model of the multinational enterprise (KC model hereafter) incorporates the theories of horizontal and vertical foreign direct investment (FDI) into a model of the New Trade Theory (see Markusen 2002). The KC model is then used to explore how the location decision of potential multinational firms, their production decisions, the international trade structure (and volume), factor prices, and welfare depend on relative and absolute country size, relative factor endowments, trade barriers, and investment costs.

The term *knowledge-capital model* is derived from the assumption that multinational firms have an ownership advantage compared with other firms due to some knowledge asset, such as patents, blueprints, procedures, brand names, trademarks, or reputation. Knowledge capital has three properties. First, its usage in plants is cheap to separate geographically from its creation in headquarters (fragmentation). Second, knowledge-capital creation is skilled labor intensive (skilled labor intensity). Third, once produced in the headquarters, it can be used in multiple plants within the firm (joint input). The KC model regards FDI as a flow of knowledge in the form of managerial and engineering services, financial services, reputation, and trademarks across borders.

From the central features of knowledge capital derive several location advantages that countries must have to attract FDI. Since the headquarter activity is skilled labor intensive while production is relatively unskilled labor intensive, factor costs are minimized by locating headquarters in relatively skilled-labor-abundant countries and plants in unskilled-labor-abundant countries, motivating vertical FDI. However, separation of production from the headquarters will require trade of goods across borders to serve the home market. To avoid trade costs, producing locally in several locations (horizontal FDI) may be worthwhile. Since there are plant-level fixed costs in addition to firm-level fixed costs, host country markets need to be sufficiently large because otherwise the profits from saving trade costs would not cover the additional plant-fixed costs of local production compared with exporting. If a foreign market is small, it may be optimal for the firm to abstain from production abroad and export from home instead.

Due to knowledge capital, firms favor corporate control of foreign operations over outsourcing. With international outsourcing, the knowledge capital may dissipate faster to competitors (internalization advantage).

Model Description In the standard KC model, there are two countries, two factors of production (skilled and unskilled labor), and two homogeneous goods. Countries differ in their factor endowments. Production of one good is perfectly competitive and subject to constant returns to scale (competitive sector). FDI can occur only in the second sector, which operates at increasing returns to scale, using a three-stage production process (increasing-returns sector). In the first stage, a firm must undertake some headquarter services such as R&D, management, accounting or marketing activities, and firm-level

fixed costs accrue. In the second stage, plant-level fixed costs are incurred. In the final stage, firms compete in an oligopolistic goods market, choosing simultaneously supply (Cournot competition). Markets are segmented and part of the export value is wasted (iceberg trade costs) when shipping goods of the increasing-returns sector across borders.

Assuming headquarter activities are more skilled labor intensive relative to integrated plant and final production in the increasing-returns sector, which, in turn, is more skilled labor intensive than production in the competitive sector, three firm types can emerge:

- *Horizontal* FDI firms have their headquarter activities tied to the home plant and duplicate the domestic production plant in the host country. These firms sell their entire production locally.
- *Vertical* FDI firms locate skilled-labor-intensive headquarter services in the skilled-labor-abundant home country and relatively unskilled-labor-intensive production activity in the unskilled-labor-abundant host country. Foreign affiliates of the vertical type export (part of) their production to the home country.
- *National* firms solely produce in the home country and serve foreign markets by exports.

Firm Location, Foreign Affiliate Production, and International Trade The model is too complex to be solved analytically and must be explored numerically. A standard display of such numerical analysis uses three-dimensional diagrams based on the Edgeworth box (see figure 1). Given a fixed world endowment in both production factors, the bottom of the box depicts the two countries' shares in the world endowments' skilled and unskilled labor, S and U, respectively. At the left corner is the origin of the first country denoted i where its share both in skilled and unskilled labor is zero. Conversely, the origin of the other country j is at the right corner.

First consider the effects of varying the relative size of the two countries. Along the diagonal connecting the two origins the relative factor endowments are identical in both countries. Beginning along this diagonal with the i country very small in terms of endowments, the prevalent firm types are vertical FDI firms with headquarters in i and national firms with headquarters in j. National firms of country j benefit from their large home market, saving more on foregone plant-fixed costs by exporting than losing from variable trade costs, because their foreign market is small. Vertical FDI from country i benefits also from the large market of country j, minimizing trade costs. At this stage country i firms are multinational, but they are few. There are simply not enough endowments in skilled labor to support many headquarters. Hence aggregate sales of affiliates from country i are small. Affiliate sales start rising with a proportional increase in country i's world endowment shares of skilled and unskilled labor. Horizontal FDI firms with headquarters in i enter, as the home market size grows sufficiently for operating profits to cover the fixed cost.

At still larger relative size of country i, the national firms of country j begin to turn into horizontal firms. Since j-firms then gain competitiveness on the i-market by saving trade cost, they push some i-horizontal firms out of the market, which causes a dip in aggregate affiliate sales until only horizontal firms are left.

Increasing country i's relative size further, there is a continuous rise in affiliate sales, because the larger endowments of i support continuously more headquarters of horizontal FDI firms and correspondingly more foreign affiliates. A peak in country i's affiliate sales are attained when it is slightly larger than country j.

At still a further increase in country i's relative size, its aggregate affiliate sales tend toward zero rapidly, because the foreign market size shrinks and country i's horizontal FDI firms are gradually replaced by national firms without affiliates.

Along the ray connecting the origins, the larger country exports the increasing returns and imports the competitive good because of its comparative advantage in the increasing-returns sector.

Next, the relative endowment shares are varied, keeping income of both countries and the world
Figure 1
Simulated affiliate sales based on the KC model from Markusen (2002)

endowment equal, which is approximately true for endowment combinations along the line denoted YY in figure 1. Affiliate sales of firms with headquarters in country i have an inverse U-shape along this line.

When countries are identical and trade costs sufficiently high or world endowments sufficiently large, then horizontal FDI firms prevail, and there are equally many in each country. As country i's skilled-endowment share rises relative to country j's, production plants remain equally spread. More and more headquarters relocate to country i, however, since headquarters are skilled labor intensive, absorbing the excessive skilled-labor supply there.

The peak in aggregate affiliate sales of firms with headquarters in country i occurs when the i country is moderately skilled labor abundant. Then country i is residence to a maximum number of headquarters from horizontal-FDI firms while the number of j-country horizontal-FDI firms has shrunk to zero.

Further increasing relative skilled labor abundance of country i, horizontal firms begin to switch gradually into national firms, and country i begins to export the increasing returns good in exchange for the competitive good. Since all world headquarters are already located in country i and still dispropor-

tionately much skilled labor is left in country i, the second most intensive activity production of the increasing returns good is located there, too. But this makes up national firms that do not have foreign affiliate sales. The more horizontal firms are replaced by national firms, the less aggregate affiliate sales country i firms will have.

When almost all skilled labor of the world is concentrated in country i, horizontal firms vanish and vertical FDI firms emerge next to the national firms all with headquarters in country i. Vertical FDI firms of country i have only headquarter activities there, which absorbs the largest possible amount of skilled relative to unskilled labor.

Overall, the peak of affiliate sales due to vertical FDI occurs when the home country is small and relatively skilled labor abundant. A peak of horizontal affiliate sales occurs when both countries are similar in size and relative factor endowments. National firms are prevalent when the home country is large and skilled labor abundant.

FDI Liberalization, Factor Prices, and Welfare
How does the factor income distribution and countries' welfare change if FDI is inhibited initially, and then free to exist? Such FDI liberalization

increases the skilled-wage premium (the ratio of the wage paid to skilled labor relative to that paid to unskilled labor) of the skilled-labor-abundant country, because the specialization in headquarters either of the horizontal or vertical type shifts labor demand toward skilled labor. If relative factor endowments are equal across the two countries, the skilled-wage premium will rise nevertheless whenever horizontal FDI emerges (at sufficiently similar country sizes), because horizontal FDI incurs fixed costs for two plants rather than one, and fixed costs will be intensive in skilled labor. The relative skilled-wage premium even rises in the unskilled-labor-abundant country when the relative abundance is very strong and relative country size similar. The reason is that production plants of more-skilled-labor-intensive vertical FDI from the other country begin to replace firms of the unskilled-labor-intensive competitive sector, shifting relative labor demand toward skilled labor.

Instead, when a country is very small and unskilled labor abundant or very large and skilled labor abundant, FDI is unattractive, and neither firm types nor relative factor prices change. Only a large unskilled-labor-abundant country will experience a fall in the skilled-wage premium, as national firms are replaced by affiliates of foreign vertical FDI firms, substituting skilled-labor-intensive headquarters for less-skilled-labor-intensive production activities.

Turning to welfare, countries that lose from investment liberalization are primarily large, or somewhat smaller, and very skilled labor abundant. The welfare loss arises from relocating production of the increasing-returns good to the foreign country while agglomerating the headquarter activities at home. In this case the increasing-returns good needs to be imported at trade costs and the competition on the domestic market between local producers and importers is less fierce, increasing the profit margins. Both the trade costs and the increase in the profit margin contribute to the rise in the relative price of the increasing-returns good, which decreases consumer rent and welfare.

A welfare gain for both countries arises, for example, if both countries are similar in size and relative skill endowments. Both countries gain then from the savings of trade costs and lower product prices through horizontal FDI, which must overcompensate for the additional fixed costs. Otherwise firms would not choose horizontal FDI.

Empirical Evidence The empirical evidence on the KC model is mixed. Pooling inward and outward FDI data for the United States, Carr, Markusen, and Maskus (2001) provide strong support for the KC model, finding that affiliate sales increase in the total income of the host and home countries, in skill differences, and in similarities of country size. In addition, they find that home countries, which are simultaneously skilled labor abundant and small, have higher affiliate sales.

However, Markusen and Maskus (2001) find a negative relation between affiliate sales and skilled labor abundance in the home country when investigating outward U.S. FDI only. Moreover, Markusen and Maskus (2002) cannot prove the KC model favors a horizontal model where vertical FDI is ruled out by assumption. Blonigen, Davies, and Head (2003) first reestimate the U.S. data separately on observations with negative and positive skill differences, and then apply the absolute values of differences in skill endowments and size in pooled regressions. Finding that increasing skill differences whether positive or negative decrease affiliate sales, they conclude this pattern consistent only with horizontal FDI and not with vertical FDI, hence rejecting the KC model. Markusen and Maskus (2003) in their reply call this finding inconsistent with any model.

Recently, some evidence in favor of vertical FDI in the KC model has been provided, however. Braconier, Norbäck, and Urban (2005) collect data on affiliate sales from home countries that are small and skilled labor abundant and add them to the U.S. data to have more observations where vertical FDI is expected. Moreover, they define the relative skill variable not as absolute but as relative distance, which puts more weight on large differences. Then they obtain in their estimates the typical surface of the KC model.

Extension Two stylized facts are not accounted for by the standard model. Bilateral affiliate sales are

positively correlated with FDI stocks, and there are both more bilateral affiliate sales and exports the more similar countries are in size. These two stylized facts are explained by Bergstrand and Egger (2007), assuming that plant (headquarter) fixed costs consist of physical capital from the home country (skilled labor) and that there are three instead of two countries.

Suppose there were only horizontal firms when countries are symmetric in endowments, then demand for physical capital would be at a maximum, raising the rental rate of capital and fixed cost. Since national firms have one plant less, they save on fixed costs at the expense of larger trade cost. Hence a mix of national and horizontal firms will emerge such that both types are equally well off. Bergstrand and Egger show further that the addition of a third country helps explain that both affiliate and export sales rise as two countries become more similar.

In sum, the KC model provides a rich description of the types of activities undertaken by multinational enterprises, including vertical and horizontal FDI. The degree of empirical support for the KC model is undergoing debate, with an extension to include a third country currently showing the most promise.

■ labor standards

Cross-country variations in labor market practices and protections can have implications for the pattern and terms of trade. Weak labor protections that augment the supply of unskilled labor, such as forced labor and child labor, can increase the supply of unskilled-labor-intensive exports on world markets, thereby depressing wages of unskilled workers worldwide. Inhumane labor practices may also generate negative reactions from consumers and investors globally. The external effect of one country's labor practices on its trade partners provides a basis for international coordination of labor market regulations. Internationally coordinated labor practices are commonly referred to as *international labor standards*.

Proponents of international coordination of labor standards emphasize the consequences that trade with low-wage countries will have for workers in industrialized countries. In the absence of international coordination, there may be a *race to the bottom* in labor protections. Opponents of coordination argue that international labor standards are a form of protectionism.

International coordination of labor market regulations was first advanced by Switzerland in 1881. A subsequent series of international conferences over the following 32 years produced agreements prohibiting international trade in white phosphorous matches and limits on night work for women.

Currently, labor standards in international trade agreements are limited. Article XX(e) of the World Trade Organization (WTO) Charter permits members to refuse imports of goods produced with prison labor. Broader labor standards have been incorporated into regional trading agreements such as the North American Free Trade Agreement. Further coordination of labor standards within the General Agreement on Tariffs and Trade (GATT), and subsequently the WTO, was proposed by the European Parliament in 1983 and 1994, by the U.S. government in 1986, and at every WTO Ministerial between 1996 and 2001. The Singapore Ministerial Declaration (December 1996), however, while acknowledging the importance of international labor standards, identified the International Labor Organization (ILO) as the competent body to establish and monitor labor standards.

Labor standards commonly fall into two broad groups. *Process*, or *core*, labor standards regulate the basic function of labor markets and are considered by many to be basic human rights. Core labor standards, as identified by the ILO, are (1) rights to free association and collective bargaining, (2) prohibition against forced labor, (3) abolition of exploitative child labor, and (4) elimination of discrimination in employment. *Outcome* standards place limitations on aspects of the labor contract such as hours worked and wages.

Labor Standards and International Trade Negotiations The link between domestic labor regulations and the international terms of trade has implications for international trade negotiations. A labor-scarce country that makes tariff concessions granting market access to a labor-abundant trade partner in a round of international trade negotiations can in effect offset those concessions by easing costly

domestic labor standards that adversely affect import-competing producers. The *ex post* reduction in domestic labor protections is referred to as a *race to the bottom.*

In the absence of a mechanism to restrict *ex post* changes in domestic regulations, the labor-scarce country cannot guarantee the promised market access. For this reason, efficient bargaining requires that tariffs and domestic policy be negotiated simultaneously.

More generally, a country's domestic labor practices generate an external effect on its trade partners through the terms of trade. Labor-using standards, such as a prohibition against prison labor, reduce the supply of labor relative to capital on world markets. As a consequence, the price of labor-intensive goods rises and the price of capital-intensive goods falls on the world market. Thus, labor protections improve the terms of trade for a labor-abundant country but worsen the terms of trade for a labor-scarce country. The existence of such an external effect creates an incentive for labor-abundant countries to overregulate their labor markets (from a global efficiency perspective) while labor-scarce countries have an incentive to underregulate their labor markets.

Existing provisions of the GATT have been proposed to coordinate labor practices internationally; these include anti-dumping measures (Article VI), the prohibition against export subsidies (Article XVI), the opt-out provision (Article XXXV), the Trade Policy Review Mechanism, and the Nullification and Impairment clause (Article XXIII). Of these, only Article XXIII has been found to provide a legal basis for regulating domestic policies within the WTO. Negotiations within the WTO are understood to provide each country with a certain level of access to its trade partners' markets. Any acts by the importer that nullify or impair the expected access can form the basis of a complaint and trigger renegotiation of the tariff agreement. In the context of the labor standards debate, a labor-scarce importer that relaxes its labor protections in an attempt to limit the import exposure created by its tariff reductions would then be required to make additional tariff reductions as compensation to a labor-abundant exporter. The exercise of the Nullification and Impairment clause thus internalizes the external effect of domestic labor standards policies.

Use of Article XXIII has not been pursued in the WTO for the purpose of coordinating labor practices. Rather, two other options were advocated in the 1990s to manage the interrelationship between border controls and domestic policies. Some delegates sought to extend the General Exceptions provisions of Article XX to include a range of labor practices (beyond prison labor). A social clause was also proposed that would harmonize labor standards among members of the WTO. Members were unable to agree, however, on a common set of universal standards that would be enforced within the WTO. At the conclusion of the 1996 Singapore ministerial, the task of establishing and monitoring labor standards was delegated to the ILO, and WTO members committed themselves to cooperate with the ILO on these issues.

The ILO was created in 1919 as part of the League of Nations and became part of the United Nations after 1946. The ILO promulgates conventions and recommendations concerning labor practices that member governments may or may not choose to ratify. Compliance is voluntary but the ILO provides technical assistance on improving labor practice.

Enforcement and Issue Linkage Given the lack of enforcement power within the ILO, it has been recommended that some enforcement power from the WTO be transferred to the ILO. Under linkage, a WTO member, adversely affected by noncompliance with ratified ILO Conventions by its trade partner, could make a complaint under Article XXIII that its expected market access has been nullified or impaired. Some compensation in the form of other tariff concessions could then be required.

Critics of this approach contend that simultaneous negotiations of trade and labor issues will produce stricter labor standards but less trade liberalization than would be otherwise forthcoming from two separate agreements. Issue linkage may also increase enforcement power, however. The impact of coordination depends on how countries calculate the payoffs from cooperation on the two issues. If a

failure to reach a cooperative agreement on one issue increases the value of cooperation on the other issue, these two coordination objectives are *substitutes*. In this case, countries will find it easier to sustain cooperation on either issue if negotiations on both issues are linked in a single agreement. A country considering defection on labor practices, for example, will see cooperation collapse on labor and trade if cooperation is linked in a single agreement. The consequent increase in the cost of defection achieved by linking issues will strengthen the capacity of countries to negotiate self-enforcing agreements on both trade and labor.

Market Mechanisms Market-based mechanisms have also been proposed for improving labor practices. Product labels characterizing conditions of work in the production process offer consumers an opportunity to pay a premium for goods produced under humane working conditions. Market efficiency will be achieved with a credible product label if consumers have a *private* distaste for poor working conditions.

By contrast, if the external effect of working conditions on consumers is a *public* good, product labels may not correct the market failure. In the case of child labor, firms seeking a *child labor free* label will be required to discharge underage employees. If child employment in the export sector is the first-best option for the child, termination of employment will force the child to the second-best choice. Child welfare will only improve if (1) product labeling is sufficiently pervasive that it raises the wages of adult labor above the level at which families withdraw children from the labor force, or (2) some portion of the premium paid by consumers is diverted to a fund used to provide welfare services to former child workers.

Corporate codes of conduct relating to the general conditions of work for adult employees have greater potential to improve working conditions. First, codes may simply require factories to employ more humane, though more costly, means of production in order to satisfy the demands of consumers and stockholders. Second, compliance officers may impart knowledge concerning labor management practices that are both more humane and more efficient. For example, factory managers may not fully appreciate the role harsh treatment and low wages play in increasing manpower turnover and retaining investment in skill trainings. Production inefficiencies such as poor line organization may have the effect of increasing overtime, thereby reducing productivity and wages. Third, corporate compliance officers that enforce codes requiring free association and collective bargaining may also inhibit monopsonistic employment practices, such as exploiting the lack of market experience of young female employees.

At the end of 2007, labor standards in the world economy are limited to voluntary initiatives and regional trading arrangements. Individual countries establish their own labor protections within the confines of a set of global ethical and domestic political considerations. Concern with the impact of trade on labor ebbed during the early part of the 21st century. Continuing integration of global labor markets may increase the pressure to implement labor protections, however.

■ Latin American debt crisis

The Latin American debt crisis officially began in August 1982 with Mexico's announcement that it

could no longer meet its interest payment obligations. External debt in Latin America had quadrupled from a 1975 level of $75 billion to more than $315 billion by 1983, which was about 50 percent of gross domestic product for that region. Variable interest rate loans meant that debt service (interest payments and the repayment of principle) grew even faster, rising to $66 billion by 1982 from $12 billion in 1975 (Gruppen 1986). The crisis was set in motion in the early 1970s when private bank lending to Latin America began to expand rapidly, eventually overtaking international development bank lending as the primary source of external funding for many rapidly growing Latin American countries.

This excessive private lending has roots in the oil price dynamics of the early 1970s. In 1973, the Organization of the Petroleum Exporting Countries (OPEC) cut production for the first time, resulting in a fourfold increase in the price of oil worldwide. This phenomenon, combined with the fact that oil bills were paid almost exclusively in dollars, resulted in large inflows of dollars into oil-producing countries. For the most part, oil-rich OPEC countries lacked an industrial manufacturing infrastructure that could absorb significant new domestic investment in the short term. The only choice for OPEC countries was to deposit dollars in what was by then a relatively well-established Eurodollar market. This consisted mostly of U.S. and Japanese banks with branches in Europe that accepted dollar deposits. These massive deposits quickly became known as petrodollars. The stage was set for a massive lending spree from private banks to newly industrializing countries, especially in Latin America. Most scholars agree that there was significant overlending during the period from 1973 to 1982. The important question is why.

From Boom to Bust On the supply side of the loanable funds market, the answer is relatively clear. Eurodollar deposits dramatically increased banks' desire to lend. Banks saw in oil-exporting less-developed countries (LDCs) an opportunity for big profits. Given that traditional business-sector demand for loans in developed countries (DCs) had all but dried up due to the supply shock induced recession (a sudden inward shift in the aggregate supply

curve caused by the dramatic increase in oil-related manufacturing costs), the Latin American loan market served as an attractive alternative. Moreover, authoritarian governments were standing at the ready to accept and guarantee repayment of private bank loans. This was a bonus for banks, which worked on the principle that sovereign loans (that is, loans to governments) carried very little risk of default compared with private sector loans.

On the demand side of the loanable funds market, Latin American countries exhibited considerable eagerness to borrow. One reason for this eagerness stemmed from the exigencies of state-led growth. By the late 1960s, Latin American newly industrialized economies (NIEs) faced the end of what scholars have referred to as "the easy phase" of import-substituting industrialization (ISI). The import-substituting strategy was first employed by most Latin American countries in the 1930s in an effort to break dependence on primary exports by producing previously imported consumer goods for the domestic market. By the late 1960s, continued growth under the ISI model meant producing more capital intensive consumer goods. This meant that if state-led growth was going to continue at comparable rates, new investments in heavy manufactured goods (i.e., cars and other consumer durables) would have to take place (Krueger 1993). Moreover, the majority of Latin American NIEs were governed by bureaucratic authoritarian regimes whose legitimacy hinged on the continued ability to deliver rapid industrial growth.

Some scholars have argued that Asian countries were better equipped to deal with the external shocks of the 1970s because they had already begun to shift their policies from import substitution to an export-oriented economy (Sachs 1985). In Latin American countries, the choice to deepen ISI rather than abandon it for an export-led approach was reinforced by the fact that the 1973 oil crisis caused severe recession in most developed countries, thus drying up the potential export market for Latin American NIEs. One consequence of the push toward heavy manufactured products in Latin America was that non-oil exporters became desperate for funds to

cover increasing production costs and growing balance of payments deficits.

Certainly, these countries could have turned to their traditional source of balance of payments financing, the International Monetary Fund (IMF), but the fact that they could borrow from private banks allowed them to avoid IMF conditionality, which had always been a point of political discontent (Bird 1996). But even the oil-exporting LDCs in Latin America, Mexico and Venezuela in particular, saw the availability of private bank credit as an opportunity for industrialization backed by state leadership.

The most obvious incentive for Latin America to borrow during the 1970s grew out of financial market conditions. Inflation had skyrocketed after the 1973 oil price hikes while nominal interest rates had leveled off and even fallen in some cases due to the credit glut. Together these phenomena resulted in extremely low and even negative real interest rates. For a time, banks were paying Latin American governments to take their money (Sampson 1981). Ultimately, the buildup of excessive debt in the 1970s grew out of a coincidence of political and economic interests among Latin American NIEs and private banks.

The stage had been set for a major crisis when another oil crisis hit in 1979. This time oil prices did not rise by nearly as much as they had in 1973. The effects of 1973 had been stagflation: severe recession coupled with accelerating inflation. This time, the crisis led to deepened recession but very little inflation. Part of the reason was that the Federal Reserve Board, under Paul Volcker's conservative monetary leadership, opted to raise interest rates to fight inflation despite continuing recessionary conditions. As a result, real interest rates on existing variable rate loans began to rise rapidly. For non-oil-producing LDCs, the combination of high oil prices, recession, and skyrocketing loan commitments spelled disaster. But even Mexico, the model debtor, had come to discover that its oil fields were much less extensive than originally predicted, while it still faced all of the aforementioned challenges. Meanwhile, lenders became increasingly hesitant to make new loans as the

credit glut conditions of the early 1970s had largely disappeared. Not surprisingly, although it seemed to take the major players by surprise, Mexico announced in August 1982 that it could not meet even its interest payments on its massive debt obligations, thus triggering the debt crisis.

Crisis Resolution and Reform In response to the crisis, the Baker Plan (named for then U.S. treasury secretary James Baker who proposed the plan) focused on rescheduling payments and arranged a $12 billion rescue package funded primarily by the United States and the IMF to Mexico. The Mexico loans were part of a larger $29 billion proposal for the Latin American and several other debtor nations (Bogdanowicz-Bindert 1986). The plan did not get banks to resume lending, although banks did eventually discount, forgive, and/or reschedule existing debt. Ultimately, the crisis underscored a problem of debt dynamics rather than sheer mass. In other words, the Latin American debt crisis points to a breakdown in the cycle of lending and repaying. The amount of debt buildup in the 1970s was by no means unique historically, but the breakdown or interruption of the financial system cycle of lending and repaying was unprecedented (Fishlow 1985). In a panicked response to Mexico's announcement that it could not pay, banks immediately stopped lending to all developing countries, which triggered a massive and unprecedented debt crisis because even relatively sound borrowers could not make payments on existing loans without access to new lines of credit. This dynamic problem of debt buildup and repayment problems has led to considerable debate on the merits of debt relief and debt forgiveness. The Debt Laffer Curve suggests there is a critical debt stock beyond which both the lenders and borrowers lose. That is, as the external debt stock rises, the indebted country will try to produce less (discouragement effect) or intentionally default on the existing debt (sabotage) so the foreign lenders will receive less than full repayment. If the debt stock is already above this level, as it certainly was in 1982, it may be in the interest of the lenders to forgive some of the debt.

In the end, the lasting story behind the Latin American debt crisis revolves around its consequences

for Latin American countries and particularly the most vulnerable segments of the population. Between 1982 and 1984, the net transfer of capital from Latin America to developed countries' banks approached $75 billion, an amount equal to one-quarter of all Latin American exports for the same period. Growth rates and living standards declined in the region for virtually the entire decade of the 1980s, a decade now commonly referred to as "the lost decade" in Latin America.

The Latin American debt crisis had long-lasting political, economic, and social repercussions. Ultimately, the debt crisis led to an abandonment of import substitution industrialization policies and a move toward trade and financial liberalization. Proponents of neoliberalism thus see the debt crisis as a difficult but necessary lesson for policymakers and their constituents about the inefficiency of state interventionist policies. Opponents of neoliberalism view the debt crisis as a tragedy that put Latin American countries in the unenviable position of having to choose between adopting neoliberal policy reform and remaining cut off from global financial markets. Regardless of which view one takes, there is little dispute that the Latin American debt crisis triggered an era of neoliberal reform.

■ **lender of last resort**
The classical role of a lender of last resort (LOLR) is to provide solvent participants of the financial system with liquidity in times of crisis. In practice, however, the LOLR function of central banks has been used to help banks in distress. Rules with respect to the LOLR are often ambiguous. In the European Monetary Union (EMU) in particular, the European Central Bank (ECB) as well as national central banks are assigned LOLR responsibility. On the international level, the International Monetary Fund (IMF) is sometimes viewed as a LOLR for governments.

The Financial System Safety Net Banks have a special role in the financial system as the main providers of liquidity. Behind the commercial banks, a central bank uses monetary policy instruments to control the availability of liquidity in an economy. In some countries central banks are responsible for financial supervision, and banking supervision in particular, as well as monetary policy. In other countries, a financial supervisory authority is responsible for the "safety and soundness" of individual banks, while the central bank retains responsibility for the payments system.

As a result of the important role of banks in the payments system and the risk of runs on banks, most countries have developed a "safety net" for banks, in particular. The safety net includes a LOLR function along with deposit insurance, capital requirements, regulation, and supervision. These aspects of the safety net should jointly protect the banking system while providing banks with the appropriate rules and incentives to allocate credit efficiently.

Two Views of the LOLR The classical formulation of the LOLR function goes back to Henry Thornton in 1802 and Walter Bagehot in 1848, and the term goes back even further to Sir Francis Barings, who referred to the Bank of England as the "dernier resort" providing liquidity to banks in times of crisis. Bagehot's classical formulation as interpreted by Humphrey (1989) and Gaspar (2006) includes the following characteristics:

1. The LOLR has the objective of protecting the integrity of the financial system rather than individual institutions;
2. The LOLR supports the central bank's monetary policy objectives;
3. Insolvent institutions should be allowed to fail;
4. LOLR assistance should be provided to solvent, illiquid institutions;
5. LOLR lending should be granted at penalty rates;
6. LOLR lending should be granted only against good collateral; and
7. Conditions for LOLR lending should be announced and well understood before a crisis event.

Although these characteristics lack specificity with respect to, for example, rate setting, acceptable collateral, and operational definitions of liquidity and solvency, they quite clearly identify the LOLR function as an aspect of monetary policy in times of potential or actual liquidity problems in the economy. Thus, in this classical view, the LOLR stands ready to lend to any entity offering collateral and willing to pay the penalty rate. An example of this LOLR function in practice occurred on September 11, 2001. After the terrorist attacks on New York and Washington, the Federal Reserve in the United States pronounced its readiness to supply liquidity "to support the economic and financial system," and the European Central Bank (ECB) also stood ready to "support the normal functioning of the markets" (see Gaspar 2006).

The more common interpretation of the LOLR, as well as the most commonly practiced role, is that the central bank supplies emergency liquidity assistance to specific financial institutions. In this case, the LOLR function becomes part of the crisis management framework for specific institutions in distress.

The requirement that LOLR lending should be reserved for solvent banks facing liquidity problems remains valid under this interpretation. The rationale for this LOLR function is the common view that contagion of one bank's problem to other solvent banks can occur as a result of the problems of evaluating the risk level of individual banks. Thus LOLR activities become oriented toward specific banks.

The difficulty of distinguishing between liquidity and solvency problems in a banking crisis often leads central banks to provide assistance to insolvent banks. Thereby, the LOLR function of central banks can become the source of moral hazard in banking; if emergency assistance can be expected, bank managers' incentives to extend risky loans increase. Furthermore, emergency assistance to insolvent banks causes delays in closing the banks. Thereby, the final costs of a bank failure for creditors and taxpayers may increase.

When a central bank provides liquidity assistance it faces a trade-off between reducing the risk of contagion and reducing the moral hazard problem caused by expectations of aid to insolvent banks.

The EMU System For international banks working within the jurisdictions of several central banks it can be important whether the home or the host country central bank serves as the LOLR. In the EMU, responsibility for monetary policy, which includes the LOLR function, lies clearly with the ECB.

The assignment of responsibility with respect to emergency liquidity assistance for an international bank is less clear. On the face of it, one expects that emergency liquidity would be provided by the central bank in the country where the bank is incorporated. Subsidiaries are often strongly integrated with the parent, however, and therefore indirectly beneficiaries of home country assistance. Assistance to a bank in crisis can arise suddenly and conflicts of interest with respect to burden-sharing are likely. Furthermore, emergency assistance by a LOLR is only one form of assistance to a bank in distress. Thus there is a need to coordinate activities of the central bank, financial supervisors, and fiscal authorities.

In the EU and, therefore, in the EMU, responsibility for financial stability, bank supervision, and crisis management is decentralized to the national level. Thus, LOLR responsibility in the form of emergency liquidity assistance rests with the individual countries, while the classical LOLR function as a provider of liquidity to the financial system as a whole is the responsibility of the ECB.

The ambiguity in the EMU arises because emergency liquidity assistance by a national central bank has monetary implications. Monetary policy can be conducted only by the ECB, however. As pointed out by the European Shadow Financial Services Regulatory Committee (1998) a committee of independent experts analyzing and publicly commenting on regulatory issues "any operation that is undertaken on the national level has EMU-wide monetary repercussions. For example, an interest rate subsidy to a local problem bank may in the end be paid for by other banks in the EMU and their customers." The committee recommended that procedures for emergency liquidity assistance should be established within the EU to resolve this ambiguity.

According to some commentators a degree of "constructive ambiguity" is desirable in crisis management on the grounds that it can reduce the moral hazard problem discussed earlier. Indeed, ambiguity is what EU law provides with respect to the division of LOLR responsibility between the ECB and national central banks in the Euro system. It may take a first pan-European crisis to bring some clarity to the division of LOLR responsibilities within the EU.

The IMF as International Lender of Last Resort The International Monetary Fund's (IMF's) role in helping Mexico during the Tequila crisis in 1995 has been widely blamed for contributing to the Asian crisis in 1997 by causing expectations among lenders that loans to sovereign countries are safe. The IMF does not protect banks directly but through its assistance to countries like Mexico in balance of payments crises or when the threat of crisis is substantial, it may provide indirect protection for banks that have lent to the government in a crisis country.

The proper role of the IMF in sovereign crises has been the subject of debate after the Mexican and

Asian crises. Prominent economists like Meltzer (1998) have suggested that the IMF should limit its role in crises to serve as a LOLR in the classical sense. In other words, the IMF should provide loans to bridge a crisis only in the case of pure liquidity crisis. In such a crisis a country's fundamental ability to repay loans is not impaired. Instead, the crisis could arise because a country has run out of foreign exchange reserves, and liquidity is not forthcoming in international financial markets as a result of a lack of information about a country's prospects. In this situation, based on its superior access to information about countries' prospects, the IMF could step in.

Focusing the IMF's role in country crises as an LOLR when there are liquidity crises could require financial resources beyond the capability of the IMF. Many observers argue, however, that the IMF's involvement, even on a small scale, will increase the willingness of private lenders to extend loans to countries in crisis, since the IMF is considered particularly well informed about economic conditions in member countries.

CLAS WIHLBORG

■ linkages, backward and forward

Linkages are input-output relationships between firms or industrial sectors in the same economy. A firm purchasing inputs from a local supplier is an example of a backward linkage, while a firm selling intermediate inputs to another firm creates a forward linkage. The importance of such linkages with the local economy for economic development has long been recognized in the economics literature. For example, Marshall (1920) argues that input-output relationships between firms are one of the advantages of localized industry, since "subsidiary trades grow

up in the neighborhood, supplying [the firm] with implements and material, organizing its traffic, and in many ways conducing to the economy of its material" (271).

In an early view, Hirschman (1958) discusses the importance of linkages between sectors in an economy in the context of his strategy of unbalanced growth for developing countries. At the heart of this strategy is the suggestion that developing countries should aim at generating imbalances in demand and supply in order to achieve continuing growth. An important part of the unbalanced growth strategy is the potential to develop linkages between sectors in which a leading sector, through linkages with a follower sector, may foster the development of the latter industry.

The issue of local linkages has regained importance in the last decades of the 20th century due to the increasing globalization of the world economy, where many inputs and outputs can be internationally traded, and therefore, inputs can easily be sourced locally or abroad. Given the increasing significance of foreign direct investment and multinational companies in many developed and developing countries alike, a particular focus of interest has been on interfirm linkages between foreign multinationals and indigenous firms, which to some extent echo the role of linkages in Hirschman's earlier work.

Whereas in Hirschman's concept of unbalanced growth "leading sectors" (which have the highest potential for linkages creation) induce growth in other sectors, the more recent view on multinationals largely sees these as "leading firms" inducing growth in local enterprises. Hence one can think of the former concept as intersectoral linkages, while the latter are interfirm linkages. Essentially, the interfirm linkage is at the heart of the Hirschman-style intersectoral linkage, since a sector is composed of a number of firms. The concept of interfirm linkages is a much wider and richer concept, however, and the intersectoral linkage leading to economic development is only one of many effects of interfirm linkages.

Intersectoral Linkages Hirschman's (1958) theory of unbalanced growth suggests that development policy should focus on promoting the growth of "leading sectors," which would result in growth being transferred from these key sectors to the followers. The way of linking key sectors and induced sectors is the development of backward and forward linkages between these sectors. In his words: "The input-provision, derived demand, or *backward linkage effects* . . . will induce attempts to supply through domestic production the inputs needed in that activity," and "the output-utilization or *forward linkage effects* . . . will induce attempts to utilize outputs as inputs in some new activities" (100).

Clearly, Hirschman has linkages between different sectors in mind when he defines these concepts. Also, linkages are seen as a causal (ex ante) concept, that is, linkages from the leading sector A to the following sector B allow sector B to develop; in effect, sector B would not have come into existence without the linkage from sector A. This point indicates the importance of intersectoral linkages and the benefit of these linkages for the development of other sectors and for the economy as a whole.

Intersectoral linkages are generally measured using input-output (I-O) tables, that is, tables of all inputs and outputs of an economy's industries, including intermediate transactions, primary inputs, and sales to final users. As a crude measure, backward linkages can be estimated as the proportion of an industry's output that are purchases from other industries, while forward linkages are the proportion of an industry's total output that is not directed to final demand but rather is an input used by other industries. Based on this idea several more refined indexes based on input-output tables have been suggested in the literature to measure linkages (e.g., Yotopoulos and Nugent 1976; Lall 1980).

These ratios measure only the degree of interdependence of different sectors, to what degree a sector uses inputs from other sectors, and not necessarily the true, induced, linkage effects, however. Although the true linkage is a causal concept, that a sector develops strictly as a result of a linkage to a leading sector only, one could also find sectors with high ratios that are not due to linkage effects but are only due to sectoral interdependence. In this case, the sector did not de-

velop as a result of linkages to another sector but rather *in tandem* with it.

Interfirm Linkages In the more recent literature the focus on local linkages has shifted away from being concerned with sectors to individual firms. Hence, research has attempted to determine what the implications of such linkages between firms are for the development of the local economy. Another focus is the measurement of linkages, in order to determine whether individual firms create backward linkages specifically through the purchase of inputs in the local market or whether they create forward linkages through selling output as intermediate inputs to other local firms.

One reason for the interest in interfirm linkages is the increasing globalization of production and the importance of multinational companies and foreign direct investment for host countries. A crucial question is whether foreign multinationals create linkages with the host economy or whether they operate in so-called enclave sectors with no links to the domestic economy that surrounds them. This issue is important in a world economy where many inputs and outputs can be internationally traded. In such a context it seems important to establish whether firms create backward or forward linkages with the local economy or whether they import and export most or all of their inputs and output. Of course, the answer to this question may change over time, as multinationals may initially source inputs from suppliers in their home country but over time develop relationships with local suppliers.

Furthermore, backward interfirm linkages become important when analyzing local content requirements in international trade agreements. Regional trade blocks, such as the European Union or the parties to the North American Free Trade Agreement, frequently impose minimum requirements of domestic inputs that foreign firms must use in their production. An analysis of backward interfirm linkages shows the extent of local buying and may indicate whether or not local content requirements are met by foreign multinationals in the host economy.

In a world with imperfect competition and economies of scale, interfirm linkages between mul-

tinationals and domestic firms can have positive effects on firms through the emergence of externalities. This issue has attracted considerable attention in the economics literature, and various positive effects of interfirm linkages have been identified. Most directly, interfirm linkages can have effects on the creation of secondary (or indirect) employment generated in supplier firms. If firms are linked through seller-supplier linkages, sellers will have a role to play for employment in the supplier firms.

Theoretical models and empirical research furthermore show some more indirect effects of linkages between multinationals and domestic firms. For example, linkages may encourage the establishment and growth of local companies in the same or different sectors in the host country (Markusen and Venables 1999). Backward linkages, created through the purchase of intermediate goods by final good producing multinationals, can reduce costs for local intermediate good suppliers by increasing the scale of their production. These reduced costs imply, in turn, that final good producers have to incur fewer costs for intermediate products, which is the forward linkage. In such a setting, if multinationals increase demand for intermediate products through backward linkages, indigenous intermediate good suppliers, in turn, can establish forward linkages with indigenous final good producers. Thus backward linkages by multinationals can foster the development of both indigenous suppliers (through expanding their output) and indigenous final good production (through lowering their costs for intermediate inputs).

Related models also discuss the possibility that firms that are linked through production inputs may tend to agglomerate geographically (Krugman and Venables 1995). The existence of input-output linkages and imperfect competition creates positive externalities that benefit the agglomeration of industries in particular regions. These agglomerations can occur both within narrowly defined industrial sectors only or across all industries.

The importance of interfirm linkages has also been emphasized in the literature on technology transfers from multinationals to indigenous firms (Javorcik 2004; Moran 2001). The main argument is

that in the case where firms are interlinked, local firms can improve their productivity as a result of forward or backward linkages with multinationals affiliates. For example, local firms supplying inputs to multinationals may be able to improve the quality of their output as multinationals set high quality standards for them and, as case study evidence for developing countries shows, may even instruct them in the use of advanced production technology.

Measuring interfirm linkages is, at least in theory, straightforward, as it involves determining the amount of inputs purchased from local suppliers, or output sold as intermediate inputs to domestic customer firms (e.g., Görg and Ruane 2000). A number of issues arise, however. First, these absolute values need to be expressed relative to some firm characteristic in order to be comparable across firms. For forward linkages it is generally expressed as locally sold output relative to total output, while backward linkages are usually calculated by dividing local inputs by either total inputs or total output. The simple ratio of local inputs to total outputs could be misleading as an indicator of backward linkages, however. A firm with a low ratio of local inputs to output could source all of its inputs in the local economy, since total inputs are not considered in this expression. This possibility could, for example, be a particular problem in industries that have a high content of value added but only a relatively low input content, such as, for example, software development or software production.

For forward linkages, the main difficulty is to determine what amount of output is directed to other firms as an intermediate input (i.e., the linkage) as opposed to output sold directly on the market to final consumers.

Policy Implications The purpose of measuring intersectoral linkages in the spirit of Hirschman (1958) is to determine key sectors in the economy, those sectors in which resources should be concentrated to achieve the highest growth. The interfirm linkage concept analyzes the extent of integration of firms, particularly affiliates of foreign multinationals into the host economy.

Although the empirical estimation of backward and forward linkages using the interfirm approach can be seen as an approximate indicator of the degree of a firm's integration into the host economy, this measurement in itself provides only limited information, giving no consideration to the effectiveness of these linkages. For a complete analysis more relevant to policy, there would need to be an examination of their effects, for example, on the development of local firms, indirect employment generated in domestic firms, the emergence of agglomerations, or the transfer of technology to linked local firms. This issue forms an important research agenda for academics and policymakers.

HOLGER GÖRG

■ liquidity trap, the

The liquidity trap refers to a state in which the nominal interest rate is close or equal to zero and the monetary authority is unable to stimulate the econ omy with monetary policy. In such a situation, be cause the opportunity cost of holding money is zero, even if the monetary authority increases money supply to stimulate the economy, people hoard money. Consequently, excess funds may not be converted into new investment. A liquidity trap is usually caused by, and in turn perpetuates, deflation. When deflation is persistent and combined with an extremely low nominal interest rate, it creates a vi cious cycle of output stagnation and further expec tations of deflation that lead to a higher real interest rate. Two prominent examples of liquidity traps in history are the Great Depression in the United States during the 1930s and the long economic slump in Japan during the late 1990s.

Conventional Monetary Policy Ineffectiveness

An economy's monetary authority typically tries to manipulate money supply through open market operations that affect the monetary base for ex ample, buying or selling government bonds. As long as banks are legally required to maintain a certain level of reserves, either as vault cash or on deposit with the central bank, a one-unit change in the monetary base leads to more than one-unit change in money supply the ratio between the two is referred as the money multiplier and is usually greater than one. The reason for this relationship is that banks do not have any incentives to hold reserves, which typically do not earn interest, beyond the legal requirement, and therefore they lend out any excess reserves. Nonbank firms and individuals behave in parallel with the banks' behavior; they have no incentive to hold excess money or funds above transaction needs, so they invest it in interest-earning financial assets such as bonds and bank deposits. Thus excess money or funds go back to the hands of banks, leading to rounds of lending known as money creation. How ever, the important assumption for such behavior is that the nominal interest rate is positive, or not ex tremely low. In other words, money creation arises as long as the opportunity cost of holding money is greater than zero.

When the nominal interest rate is very close or equal to zero, the opportunity cost of holding money becomes zero, and economic agents banks, firms, or individuals tend to hoard money even if they have more money than they need for transaction purposes. More important, traditional monetary policy becomes ineffective in stimulating the econ omy because the money creation process does not function as theory predicts. Even when the monetary authority increases the monetary base, money supply becomes unresponsive or even falls. In such a situa tion, because the nominal interest rate cannot be neg ative, there is nothing the monetary authority can do.

When an economy falls in a liquidity trap and stays in recession for some time, deflation can result. If deflation becomes severe and persistent, people effectively expect negative inflation going forward. Accordingly, the real interest rate (which is defined as

nominal interest rate minus expected inflation) will be expected to rise. This in turn harms private investment through increased real cost of borrowing and thereby widens the output gap. Thus the economy falls into a vicious cycle. A persistent recession causes deflation, which raises real interest rates and lowers output even further, while monetary policy is ineffective.

In the case of the Great Depression in the United States, between 1929 and 1933, the average inflation rate was 6.7 percent. It was not until 1943 that the price level went back to that of 1929. In the case of the more recent Japanese slump, deflation started in 1995 and continued till 2005, although the degree of deflation was not as severe. Indeed, during the deflationary period, the average inflation rate was 0.2 percent.

Such a spiral deflationary situation is highly likely to involve failures in the financial system. Financial failure can intensify a liquidity trap because unexpected deflation increases the real value of the debt. Borrowers' ability to repay their debt, which is already weakened by the overall slump in consumption and investment, declines and banks' portfolios become burdened with nonperforming loans loans that are not repaid. Both the Great Depression and the Japanese 1990s slump involved banking failures. In such circumstances, banks often try to reduce the amount of new loans and terminate existing loans credit contraction called credit crunch in order to improve their capital conditions, which are worsened by writing off nonperforming loans. A credit crunch can feed the vicious cycle by making less capital available to potential borrowers, and therefore contracting investment and output. An increase in the amount of nonperforming loans in the overall economy can result in banks with good capital conditions becoming more even more cautious in their extensions of credit. Furthermore, in an economy with a fragile financial system, a liquidity trap can occur when the nominal interest rate does not reach zero because holding nonmoney financial assets may involve the risk of losing the assets and once the risk is incorporated, an extremely low level of the nominal interest rate would be essentially the same as zero.

Overcoming a Liquidity Trap Because conventional monetary policy becomes ineffective in a liquidity trap, other policy measures are suggested as a remedy to get the economy out of the trap. The monetarist view suggests quantitative easing as a solution to the liquidity trap. Quantitative easing usually means that the central bank sets up a goal of high rates of increase in the monetary base or money supply and provides liquidity in the economy so as to achieve the goal. It has been argued, for instance, that the Great Depression was caused and aggravated by the misguided policies of the Federal Reserve Board, that is, monetary contraction subsequent to the stock market crash in 1927 (Friedman and Schwartz 1963). According to this viewpoint, unconventional money easing or money gift, in Friedman's words would be the appropriate policy measure. Between 1933 and 1941, the U.S. monetary stock increased by 140 percent, mainly through expansion in the monetary base. More recently, after lowering the policy target rate to zero in February 1999, the Bank of Japan implemented quantitative easing policy and set a goal for the reserves available to commercial banks from March 2001 through March 2006.

The monetarists also suggest other unconventional market operations that include the direct purchasing by the monetary authority of other financial assets such as corporate papers and long-term foreign and domestic bonds. They argue that purchasing merely short-term assets in open market operations does not function as a remedy to a liquidity trap. The idea is that because long-term bonds and securities are still assumed to be imperfectly substitutable to short-term assets even in a liquidity trap situation, the former can be purchased in open market operations to drive the long-term interest rate down.

In the Keynesian view, expansionary fiscal policy is the conventional measure to overcome a liquidity trap; the government can implement deficit spending policy to jumpstart the demand. A typical example of expansionary fiscal policy is the implementation of the New Deal policy by President Franklin Roosevelt in 1933. This policy included

public works programs for the unemployed, including the Tennessee Valley Authority project. In the case of the Japanese liquidity trap, the Japanese government spent about ¥100 trillion (equivalent to 20 percent of GDP in 2005) for a series of public works programs over the course of a decade.

Blanchard, Olivier. 2006. *Macroeconomics*. 4th ed. New York: Pearson/Prentice Hall. One of the chapters of this book presents a basic IS LM framework to explain the mechanism of a liquidity trap and analyzes the U.S. Great Depression and the Japanese 1990s recession.

Friedman, Milton, and Anna J. Schwartz. 1963. *A Monetary History of the United States*. Princeton, NJ: Princeton University Press. This book is a seminal work in which the authors examine the development of the U.S. economy in the post Civil War era. The biggest con tribution of this book is their monetarist views on the cause of the U.S. Great Depression; they argue that the Federal Reserve Board is responsible for worsening the Great Depression by implementing monetary contrac tion immediately after the stock market crash in New York.

Krugman, Paul. 1998. "It's Baaack: Japan's Slump and the Return of the Liquidity Trap." *Brookings Papers on Economic Activity* 2: 137 87.

———. 2000. "Thinking about the Liquidity Trap." *Journal of the Japanese and International Economies* 14 (4) (December): 221 37. In these two papers, Krugman presents his Keynesian views on the Japanese recession of the 1990s and policy solutions to it. The author em phasizes the importance of creating expected inflation to get the economy out of the liquidity trap situation and doubts the effectiveness of any monetarist policies such as quantitative easing.

Svensson, Lars E.O. 2001. "The Zero Bound in an Open Economy: A Foolproof Way of Escaping from a Li quidity Trap." *Monetary and Economic Studies* 19 (S 1): 277 312. The author agrees with Krugman in that creating expected inflation will help the Japanese econ omy out of a liquidity trap. However, he clearly differs

from Krugman's view in that he proposes a fixed ex change rate policy to create expected inflation until the liquidity trap situation disappears.

HIRO ITO

■ location theory

Location theory addresses the important questions of who produces what goods or services in which locations, and why. As many government policies involve attempts to shift production, one must first examine the basis for the initial location deci sions in order to understand the impact of altering incentives.

Nearly 200 years ago, the primary concern of early location theorists, most notably Johann-Heinrich von Thünen (1783 1850), was the optimal location of cities and farms, balancing both land costs and transport costs. In von Thünen's model, concentric rings of agricultural activity develop around a city. The production of perishable goods and/or goods needing to get to market quickly locate in the rings closer to the city, and other activities such as ranch ing locate in outer rings. Since von Thünen, many other scholars have proposed more complex location models, incorporating the production of industrial and agricultural goods and services.

Many of the questions addressed in location the ory are highly relevant to international economics. For example, trade theory explains patterns of in ternational production and trade. Similarly, much of the research on foreign direct investment (FDI) looks at where multinational firms locate various activities. Policy applications of location theory have examined ways in which different countries, states, and regions can actively compete to be production locations for both trade and FDI. Before turning to the applica tions of location theory in international economics, it is important to review the basic elements of location theory.

Standard Assumptions Most theories of eco nomic location start with these main assumptions:

1. The production process for particular goods is uniform, independent of locations.

Producing corn requires a certain amount of a particular quality of land, farm machinery, chemicals, climate, etc. Therefore, some locations are more suitable for producing corn than others. Factors of production cannot be substituted for one another. For example, superior farm machines cannot substitute for scarce land to grow corn in a big city.

2. The demand for products is separated from the production, or supply, of the products. Corn producers want to put the money they earn from farming into banks in cities. Bankers in cities want to consume agricultural goods. Therefore, transportation costs affect where goods are produced. If both Iowa and Nebraska have the same amount of corn-producing factors of production, but most of the demand for corn is in New York City, other things being equal, Iowa's shorter distance to New York makes Iowa the better location for producing corn.

3. Factors of production are immobile. Inhabitants of New York City cannot import Iowa's cheap land to grow corn locally, and Iowans cannot import New York's bankers. While some factors (capital, migrant workers) are in fact mobile, land and most natural resources are not.

Theories based on these assumptions generate the clear prediction that, to minimize production and transportation costs, certain locations will specialize in the production of particular goods and services and "export" these goods to other locations.

Trade Theory There is considerable overlap between location theory and trade theory. Krugman (1993) compares and contrasts location theory and trade theory. Differences aside, the theories are ultimately quite similar in the questions they address and the assumptions they make. Neither trade theory nor location theory is inherently international. Optimal production locations could be within one country, such as Iowa and New York City in the example already given.

Neither location theory nor trade theory identifies the specific countries or regions in which production

of particular goods will be located. Trade theory speaks to characteristics of production locations, such as relative endowments of factors of production required to produce particular goods, or comparative advantage in producing one good relative to another. Location theory speaks to the optimal location of production given the cost of factors of production and transportation costs to consumers. In order to determine specifically which countries or regions will specialize in producing which goods, researchers have tested these theories using data on the production characteristics of particular goods, the factor endowments of countries, and transportation costs. In *Sources of International Comparative Advantage*, Leamer (1984) tests the precise relationships specified in neoclassical trade theory and predicts the specific countries in which production for export should be located. The evidence is, at best, an imperfect fit with the predictions of both location theory and neoclassical trade theory.

Location of FDI Location theory is frequently applied by researchers wanting to understand factors that influence where multinational firms (MNCs) choose to locate their foreign operations. Typically lacking data on the production costs of individual MNCs or data on an MNC's costs in countries where the firm does not operate, researchers tend to study features of the different locations that should make them more or less attractive, such as a country's corporate tax rate. These features include factors related to a country's policy, economy, and technology environments, and strategic considerations for individual MNCs. These are discussed in detail below.

Host-Country Policies The policy environment of a country has an important impact on its attractiveness. Policies such as corporate tax rates affect the costs of an MNC. Hence disproportionate amounts of FDI (relative to gross domestic product, GDP) occur in low-tax countries such as Ireland and tax havens such as the Cayman Islands. Conversely, some countries put restrictions on FDI such as not allowing wholly owned subsidiaries, requiring technology transfer, limiting the repatriation of profits, and mandating a certain proportion of added value

be produced in the local market. Other things being equal, countries with more restrictive policies toward FDI tend to be less attractive FDI locations. Despite a global trend of liberalization of policies toward FDI (OECD 2006), restrictions continue in some form in almost every country.

Other features of a country's policy environment also affect its attractiveness. Labor market institutions such as the degree of unionization affect FDI flows. Similarly, the protection of property rights and intellectual property, strong institutions for contract enforcement and capital market governance, environmental regulation, and trade policy may also affect MNCs' FDI location choices (Javorcik and Spatareanu 2005).

Recently, researchers have studied various types of political risk as influences on MNCs' FDI location decisions. MNCs make location decisions based on expected future profits, and greater risk creates greater uncertainty with regard to future income streams. Thus, other things being equal, risk reduces FDI inflows. Countries that are politically risky in the sense of having a history of expropriating FDI, weak institutions, endemic corruption, autocratic governments, periodic coups d'état, or ethnic tension tend to receive negligible FDI flows (or far less than would otherwise be expected). Many of the poorest countries in the world, for example, Haiti, Honduras, and much of sub-Saharan Africa, are beset with political risk and receive very little FDI. To a greater or lesser extent, some of the aforementioned risks are present in many countries, some of which, for example, China and Nigeria, are recipients of large FDI inflows, as other things are not equal. Nigeria is one of the most oil-rich countries in the world, and China has the largest population in the world and a rapidly growing economy. These factors offset some of the risk MNCs encounter in China and Nigeria. However, if these countries were less risky, they likely would enjoy even larger inflows of FDI.

Economic Environment Features of a country's economic environment are also important determinants of FDI location. Capital, and human and natural resource endowments such as labor in China and oil in Nigeria, continue to be significant influences on FDI location choices. The importance of neoclassical factors of production (e.g., land, labor, capital, raw materials) to MNCs' FDI location choices is consistent with the predictions of location theory.

Factors of production can be intrinsic or created. The Silicon Valley area receives large inflows of FDI due in part to the quality of its human capital. The geographically concentrated pool of specialized human capital arose, in part, from the presence of leading-edge domestic companies and the entry of foreign companies. Hence, specialized labor in Silicon Valley can be viewed as a created and dynamic factor of production: created in the sense that high-tech workers developed their knowledge through their experience working at different Silicon Valley firms, dynamic in the sense that the entry of more firms into the area expanded the skill set and enlarged the pool of specialized labor.

The size of a country's economy is another important economic influence on FDI location decisions. Market size can be viewed as an indirect measure of transportation costs, since it reflects the ability of a firm to reach many consumers at a relatively low cost. The attractiveness of large countries is particularly true when an economy is both large in terms of absolute size (GDP) and wealthy in terms of GDP per capita. Brainard (1997) finds that proximity to customers is an important factor in an MNC's FDI location choices.

Finally, like political risk discussed above, economic risk is also an important influence on FDI location decisions. Countries that have experienced very high rates of inflation or currency exchange rate shocks may have difficulty attracting FDI. Similarly, other things being equal, highly indebted countries and countries with periodic fiscal crises are typically not recipients of large FDI inflows.

Technology and Agglomeration Economies Studies of the effects of spillovers, external economies, or agglomeration economies on FDI location choices date back to Alfred Marshall (1920). Agglomeration economies are benefits that accrue to firms that locate in geographically concentrated areas or "clusters" such as Silicon Valley.

Several types of benefits can arise when firms collocate. First, a geographically concentrated cluster of activity in a particular sector creates a specialized pool of skilled labor that can lower a firm's search and training costs. Second, due to labor mobility and social networks, firms can potentially gain some knowledge about the proprietary technology and processes of their competitors. At the same time, of course, firms also risk losing some of their own proprietary knowledge in this context. Third, specialized suppliers often locate near clusters, again, lowering firms' costs and giving firms more choice in make-or-buy decisions. Fourth, when clusters exist, firms and states often make significant investments in infrastructure development such as building roads, upgrading airports, and improving local universities. These features of industrial clusters create an environment where firms can potentially reap benefits larger than their direct costs.

The existence of spillovers and their influence on the location decisions of MNCs has been a controversial topic that has received considerable attention from academic researchers. Since spillovers are nearly impossible to measure, their very existence is controversial. Firms in the same sectors often do tend to locate in clusters. Some researchers take this empirical fact as prima facie evidence for the existence of agglomeration economies. However, Head, Ries, and Swenson (1995) point out that clusters could exist for many reasons that have nothing to do with spillovers. Firms might collocate for economic reasons such as the local presence of factors of production or strategic reasons such as the ability to better monitor competitors. Local governments wanting to attract high-quality jobs might offer subsidies to firms in particular industries. Thus the fact that firms do cluster is not, in itself, evidence of spillovers.

Another controversy in the literature on agglomeration economies is the question of what, if any, effect they have on the production cost of firms and hence firms' decisions to collocate. If knowledge spillovers exist, why would a leading-edge firm risk locating close to competitors that could free-ride on its investments in proprietary technology? Similarly, clusters often do eventually result in crowding. After

experiencing rapid growth, the Silicon Valley area became such a high-cost location for land and labor that many firms wanting to move there were ultimately priced out of the market. Crowding should eventually increase the production costs of all firms, including early entrants into the cluster.

Spillovers of knowledge have a less straightforward effect on firms' costs in the sense that some firms might gain and others might lose. By focusing on micro mechanisms such as buyer-supplier relationships between firms, recent research allows us to better understand which firms would benefit from knowledge spillovers. Since firms do tend to collocate, and since proprietary technology is so important to firms, further research in this area will help us better understand the complex links between spillovers, production costs, and FDI location decisions.

Firm Strategy Strategic factors that influence the location choices of MNCs include the need to locate near important clients or customers, to locate close to key rivals in order to monitor their actions, or to deter the entry of key rivals. For example, service firms such as advertising agencies often locate their foreign operations near important clients.

This literature uncovers some fundamental motives underlying firms' FDI location decisions. First, and perhaps most important, although FDI flows are often discussed in the aggregate by economists and policymakers, it is important to remember that these aggregate flows represent the sum of a great many decisions made by individual MNCs. Since firms are so different from one another, clearly, their own state variables will be very important in determining where they choose to locate. Second, the heterogeneity of firms implies that all the aforementioned characteristics of locations will not be equally attractive to all firms. Advertising agencies probably will not care about the presence of natural resources such as coal, and even manufacturing firms might not care about labor or natural resources if they are trying to decide where to locate a research and development (R&D) laboratory.

Thus, in focusing on micro mechanisms underlying FDI location choices, recent research on firm strategy has considerable potential to shed light on

which location characteristics will be valued by what type of MNC. Moreover, by looking at different kinds of location decisions such as the location of manufacturing plants and the location of R&D, this research should contribute valuable insight into the conditions under which some location characteristics may be more or less important. The recent availability of large new data sets on multinational firms such as the data from the U.S. Department of Commerce, Bureau of Economic Analysis, should help advance research in this area.

Empirical Research on FDI Location Empirical studies of FDI location have typically used one of two general research designs. First, using aggregate data on FDI flows into different countries, researchers have studied the correlation between aggregate FDI flows and many of the location characteristics discussed earlier. The problem with this type of research design is that FDI locations are chosen by individual firms, and aggregate data do not give us much insight into the micro mechanisms underlying firms' choices.

The second type of research design uses micro data on multinational firms to examine decisions to enter particular markets. Entries are generally observed as discreet data points. For example, an MNC that has operations in Canada and the United Kingdom in 1989, and then has operations in Canada, the United Kingdom, and France in 1990, has "entered" France. Although entry data give us much more insight into decisions at the firm level, there are two problems with using this type of research design in studies of FDI location. First, with only a few exceptions, publicly available data on MNCs that contain reliable information on entries often do not contain information on the size of the entry or the purpose of the entry (e.g., production facility, R&D lab, distribution operation, etc.). Second, and perhaps more important, most location decisions made by MNCs are incremental. MNCs might choose, for example, to reduce the scope of their existing operations in Canada and double the scale of their existing facilities in India. If the researcher only observes countries in which the MNC has operations, no location change would be noted. In this example,

however, there has been a fundamental shift in the locations in which the MNC operates. In the day-to-day operations of MNCs, the decision to enter a new market is made relatively infrequently. In contrast, MNCs with established subsidiaries in many different markets frequently make decisions about how much to reinvest in their existing foreign operations.

A consequence of the widespread use of entry studies in research on FDI location is that we know very little about how the location characteristics that are correlated with MNCs' entry decisions affect decisions about growing or shrinking existing operations at the margin (see Feinberg and Keane 2001). From a policy standpoint, most countries are at least as concerned about retaining, growing, and upgrading existing FDI as they are concerned about luring new FDI. Therefore, additional research on MNCs' incremental FDI location choices could contribute significantly to FDI policy.

New Location Theory: Random Chance and Time Recently, researchers applying location theory to international trade and FDI have begun to incorporate important new theoretical developments such as the role of chance and dynamics. Random chance plays a critical role in determining real-world patterns of production. For example, Krugman (1991) traces the location of the carpet industry in Dalton, Georgia, to Catherine Evans, who in 1895, by chance, made a tufted bedspread as a wedding gift. The bedspread was regarded as so beautiful that neighbors began demanding tufted items. From that beginning, with the addition of modern technology, the carpet industry grew and became concentrated in Dalton. A general theory of location or trade could not account for the chance events that give rise to global production locations such as carpets in Dalton. Rational planning, rather than historical accident, would be more consistent with the predictions of location or trade theory. The Dalton, Georgia, carpet industry example shows how chance events combine with dynamic factors such as new or increased demand, technological and infrastructure development, and the entry of new firms to create permanent global production locations. Chance and

dynamics are both present in the Dalton example because the bedspread maker could have been born anywhere.

In contrast, agglomeration economies often do not arise by chance, but they do have a dynamic component. For example, the San Francisco Bay area location of the Silicon Valley tech cluster is much less surprising and random than the Dalton, Georgia, carpet location. The Bay area is home to several of the top research universities in the world and numerous government research laboratories. The state of California has a large and thriving defense industry. Thus both demand and supply conditions favored the creation of the Silicon Valley technology cluster.

A final new contribution to the literature on location theory, FDI, and trade is the literature on hysteresis, or path dependence. Hysteresis occurs when temporary economic shocks such as exchange rate volatility result in permanent transformations in global patterns of production and trade. For example, many Japanese auto and auto parts manufacturers that exported cars to the United States endured considerable economic hardship in the 1980s when the U.S. dollar began to decline. Since there was no certainty as to when the dollar would stop falling, many firms eventually decided to relocate production from Japan to North America. Thus the global pattern of production and trade was permanently changed as a result of transitory exchange rate shocks (see Baldwin and Krugman 1989).

The idea that temporary changes in the economic environment can cause permanent changes in global production patterns potentially gives significant discretion to policymakers to use short-term policies such as subsidies and tax breaks to attract global production. However, as we discuss below, when the use of such policies is widespread both within countries and internationally, bargaining power tends to shift from states to firms, and billions of dollars in dead-weight economic loss arise every year from competition to redistribute global production.

Policy Applications In a policy context, researchers have studied the following question: What can policymakers to do to enhance the attractiveness of their locations and thus increase the likelihood

multinational firms will decide to choose the particular location? Much of the work in this area evolved from two important areas of research.

First, New Trade Theory (see Krugman 1994) introduced economies of scale into theories of international trade. In the extreme, some industries such as airplane manufacture and semiconductor fabrication are so costly to set up that the world might support only a very small number of firms. In such a case, a country could "win" a two-country game in which both countries decide whether to subsidize its own firm so that firm is able to lower its cost and take the entire world market for producing a particular good (see Brander and Spencer 1985). This type of policy is often referred to as "strategic trade policy." Despite there being no empirical evidence for the existence of industries with such extreme production structures that support only a single global firm (suitable subsidy targets), many billions of dollars are wasted every year by countries and states in subsidy games designed to "win" a larger share of global production. Knowing countries and states are willing to offer payments to lure and keep production gives firms an incentive to threaten to move. In many cases, these threats lead to bidding wars that reduce firms' costs at the expense of countries and states.

Second, Porter's *Competitive Advantage of Nations* (1998) directly considered a positive role for governments in making locations more attractive. Unlike proponents of strategic trade policy, Porter advocated broader types of policy actions to enhance the attractiveness of a location. These actions include increased spending on education and R&D, government spending on infrastructure, institutional development, and the like. This goal of these policies would be to create Silicon Valley like clusters by improving the quality of domestic factors of production such as labor and capital. Since high-quality factors of production can be deployed across many different sectors, there is much less waste involved in policies that improve factor quality than in policies that merely seek to redistribute the location of existing economic activity.

Location theory addresses the important questions of who produces what goods or services in

which locations, and why. Ideas from location theory have been widely used in international economics, in particular, to predict which countries will specialize in the production of certain goods for export, and which countries MNCs will choose as production locations. In early location models, factors of production were given rather than created, and technologies for producing particular goods were unalterable. Clearly, modern applications of location theory to trade, FDI, and international economic policy have considerably expanded the scope of these location models. However, fundamental insights from the earliest theories of location such as the importance of factors of production, trade, and transportation costs remain powerful explanations for the location of global production today.

■ Louvre Accord

The Louvre Accord is an agreement reached in Paris on February 22, 1987, among the Group of Six countries (the United States, Canada, Japan, Germany, France, and the United Kingdom) to stabilize the value of the dollar. Since the Plaza Accord in September 1985, the nominal dollar exchange rate against other major currencies had fallen more than 25 percent. The goal of the Louvre Accord was to arrest the decline of the dollar and to stabilize it around the prevailing levels.

Although the U.S. dollar began falling in 1985, the U.S. current account deficit in 1986 and 1987 remained large. United States treasury secretary James Baker sought to correct the imbalances by encouraging trading partners to stimulate their economies and therefore to purchase more U.S. exports (Frankel 1994). If trading partners did not want to grow more quickly, he would allow the dollar to fall more, which would stimulate U.S. net exports while reducing the net exports of America's trading partners. Baker secured an agreement during the Tokyo Summit of May 1986 to use macroeconomic indicators such as gross domestic product (GDP) growth and inflation to guide Group of Seven policy discussions. This indicator approach was intended to prompt the Japanese and Europeans to stimulate their economies in order to reduce U.S. current account deficits.

Although the Japanese and Europeans viewed this approach as an intrusion into their domestic policy arena, the Japanese, in particular, were willing to accept it in order to obtain relief from the strong yen (*endaka*). The yen had appreciated from almost 240 to the dollar before the Plaza Accord to 155 to the

dollar a year later. Profit margins of Japanese exporting firms had fallen drastically, and Japanese officials did not want the yen to appreciate further.

U.S. policymakers were also concerned about the dollar depreciating further. The U.S. current account deficit had reached 3.5 percent of GDP and was financed heavily by foreign capital flows. United States officials were concerned that expectations of further depreciations could make dollar assets less attractive to foreign investors and force U.S. interest rates to increase. Such a destabilizing shift in portfolio preferences was sometimes referred to as the "hard landing" scenario (see Marris 1985; Frankel 1994).

Components of the Louvre Accord The Louvre Accord, as negotiated a few months later, stipulated:

1. The United States would reduce its budget deficit from 3.9 percent of GDP in fiscal year 1987 to 2.3 percent in fiscal year 1988.
2. Japan would cut its policy interest rate (discount rate) by 0.5 percent and enact a fiscal stimulus package.
3. France and Germany would cut taxes.
4. All countries would fight pressure from interest groups to enact tariffs and other impediments to free trade (Meyer et al. 2002).

The participants agreed in the accompanying statement to keep exchange rates within ranges broadly consistent with economic fundamentals (Funabashi 1989). The closing rates from February 20, 1987, were to be used as midpoints. Appreciations or depreciations of the dollar by 5 percent or more would trigger obligatory consultation on policy responses, appreciations or depreciations of 2.5 percent could lead to voluntary mutual intervention, and appreciations or depreciations between 2.5 and 5 percent would lead to progressively stronger interventions.

Despite heavy intervention by the United States and Japan, the dollar fell another 10 percent against the yen over the next two months. James Baker and Paul Volcker, then the chairman of the Federal Reserve, became increasingly concerned about a hard landing. In April 1987 Baker expressed the most alarm he ever had about the fall of the dollar. Volcker

warned Congress of the incipient dangers and emphasized the need to cut the budget deficit (Funabashi 1989).

Germany and Japan While the United States made slow progress in reducing its budget deficit, Baker lobbied hard for Japan and Germany to stimulate their economies. Japan proposed an urgent stimulus package. German officials demurred, however, claiming that their economy had already reached its potential output level. The German central bank (the Bundesbank) even raised the discount rate in September 1987. The unwillingness of Germany to stimulate its economy led to open conflict between Baker and German finance minister Gerhard Stoltenberg (see James 1996). On September 27, 1987, Baker said that surplus countries would have to pay more attention to their macroeconomic indicators, meaning that they would have to stimulate their economies more to help the United States reduce its current account deficit. On October 18, 1987, he again called on Stoltenberg to undertake stimulative policies and threatened to let the dollar depreciate further if Germany did not. When the market opened the next day, the Dow Jones industrial average fell 23 percent.

James (1996) notes that, before the confrontation between the United States and Germany, the Bank of Japan had been contemplating raising the discount rate to slow down a developing bubble. After watching the conflict unfold, however, Japan went along with U.S. demands to pursue expansionary policies. In the face of this pressure from the United States, monetary policy in Japan was perhaps too expansionary (Bernanke and Gertler 1999). In 1989 and 1990 the Bank of Japan finally raised interest rates to prick the well-developed asset price bubble. Share prices then fell 90 percent between 1989 and 1992 and remained stagnant thereafter. The bursting of the bubble was disastrous for Japan because of its bank-based financial system. Falling asset prices eroded bank capital and restricted banks' ability to extend credit (Okina and Shiratsuka 2003). This in turn contributed to the "lost decade" of the 1990s, a period during which the Japanese economy remained stagnant.

Following these events, disillusionment with international policy coordination grew. Many came to view coordination efforts as thinly disguised attempts by the United States to get other countries to rescue it from the effects of its own unwise domestic policies (McCallum 1996). Even mild forms of macroeconomic policy coordination became difficult for developed economies to achieve.

■ Maastricht Treaty

Maastricht is the city in the Netherlands where heads of government reached agreement on a document that would give birth to the European Union. The treaty represents a landmark in the process of European integration as it would define the rules of the game under which member states would eventually gain membership into the single currency area. Originally, the European Union (EU) consisted of 12 member states when the treaty first came into force in November 1993. Later, there would be further enlargements, the most recent occurring in 2004 when 10 new member states were admitted. In 2007, 2 more member states (Bulgaria and Romania) were admitted, bringing the total EU membership to 27 countries that would eventually subscribe to the treaty.

Because it was designed to deal with existing member states, not ones that would join in future, the original Maastricht Treaty could not cope with enlargement. Consequently, the Maastricht Treaty was followed by the Treaty of Amsterdam in 1997 and the Treaty of Nice in 2001. The most important change to the original Maastricht Treaty dealt with voting rules for policy approval: the Maastricht Treaty required unanimous approval of policy changes at the EU level, whereas succeeding treaties allowed for majority approval. The system in place in 2007 essentially assigned a weight to each country's influence in the EU roughly based on population size. Although some decisions require unanimity (e.g., foreign policy questions), others would henceforth require a qualified majority, that is, a vote that reflects the relative importance of some EU members based on their population (e.g., measures affecting the operations of the internal European market). Even when a qualified majority is used to make a decision, the number of votes must exceed a threshold (more than 50 percent of votes) before any decision can be adopted.

The grand objective behind the Maastricht Treaty was to put in place institutions and policies that would advance the ideal of a unified Europe. Although the centerpiece of the treaty concerned the rules intended to foster economic and monetary union, it also included social and legal provisions to harmonize existing laws and regulations among the member states and to develop common foreign and security policies. Some governments objected to particular provisions. The United Kingdom, for example, found the Social Chapter, a legal provision that dealt with policies concerning wage setting and health and safety regulations, unacceptable and opted out of the relevant provisions. Denmark rejected the treaty after putting it to a vote in a referendum. Eventually, the United Kingdom and Denmark received an opt-out agreement that would give them the option to join the monetary union in the future.

Maastricht Convergence Criteria The road map to monetary union was first laid out in the Delors Report of 1989, named after the former French politician who is also a former president of the European Commission. Critical to achieving monetary union were the so-called convergence criteria. The goal was a simple one in principle, namely to ensure that the members of the area that would form a monetary union would have comparable

macroeconomic environments. This would, first, facilitate the introduction of an unalterable fixed exchange rate, to be followed by the introduction of a common currency. The original report called for European Monetary Union (EMU) by 1999. At the end of 1995, leaders of the EU announced plans for a single currency that would be called the euro.

The road to the single currency proceeded in three stages. The first stage, which began in January 1990, was intended to liberalize the movement of capital. The second stage began in January 1994 when member states began to enact economic policies that would lead to a form of convergence as defined in the treaty. It is perhaps the so-called convergence requirements that have received the most attention among policymakers and academics over the years. These continue to form the core of the treaty. The member states that joined the enlarged EU in 2004 are also required to adhere to the convergence requirements in order to adopt the euro. Unlike Denmark or the United Kingdom, however, all new members of the EU eventually must adopt the euro.

The convergence criteria consist of five elements:

1. Inflation rates up to a maximum of 1.5 percentage points above the average of the three lowest national inflation rates.
2. Interest rates up to a maximum of 2 percentage points above the average of the three lowest national long-term interest rates.
3. Budget deficits up to a maximum of 3 percent of gross domestic product (GDP).
4. An accumulated public or government debt of up to 60 percent of GDP; and
5. Maintenance of stable exchange rates for at least two years.

Although the convergence principles seem clear, they are not unambiguous. Over the years countries have haggled over the exact definition of stability in the exchange rate and what could or could not be included in the deficit calculations. Disputes over the precise interpretation of the deficit principle eventually led to a separate agreement known as the Stability and Growth Pact, which laid down a series of fiscal rules that themselves are subject to continuing debate. Similar concerns arose with respect to the

debt to GDP ratio principle. The treaty suggests that if the 60 percent threshold is not met, the ratio should show signs of diminishing sufficiently in the future and, consequently, approach the reference value of 60 percent at a "satisfactory pace." The wiggle room in the convergence criteria allowed Belgium, Italy, and Greece to join the euro area. It is, therefore, clear that the inflation convergence requirement is first among equals in the list of Maastricht convergence principles.

The third stage began in January 1999 with the establishment of a European Central Bank and culminated in the introduction of the single currency in January 2002.

■ market access

Acquiring market access is one of the main motives that drive multinational firms to invest abroad. To serve foreign markets, firms are often faced with two choices: exports versus foreign direct investment (FDI). In the presence of large trade costs (e.g., tariff and transportation costs), firms are less inclined to

export to the foreign market. Instead, they are more likely to supply foreign consumers through local production. This incentive to avoid trade costs by producing inside a foreign market is also referred to as the tariff-jumping motive. As a result, multinational firms duplicate their production in the foreign countries and expand horizontally. The FDI arising from this consideration has been defined by the researchers as the horizontal type of FDI. This horizontal type of FDI is distinguished from vertical FDI, in which a firm shifts production to a low-cost location and serves all markets from there.

The Proximity-Concentration Trade-off The theoretical literature on horizontal FDI is led by the seminal work of Markusen (1984), one of the first authors to show from an international trade perspective that multinationals may arise endogenously in equilibrium. A key ingredient of the models in this literature is the interaction of trade costs and plant-level scale economies. While multinational firms are able to avoid trade costs by operating local production plants in foreign countries, they must pay a plant-level fixed cost for each additional plant. In contrast to the trade costs that prompt firms to produce the same goods and services in multiple countries, the plant-level scale economy encourages firms to concentrate their production in one location. Hence, as predicted in these studies, multinational activity is more likely to arise in industries that require a relatively small plant-level fixed cost and in countries that impose large trade costs on imported goods. Moreover, multinational activity should be concentrated among countries that are similar in both market size and factor endowment.

These predictions have been formally examined in several important empirical studies, including Brainard (1997); Carr, Markusen, and Maskus (2001); and Yeaple (2003) among others. These papers formally examine the extent to which the decision by multinationals to invest overseas is affected by their motive of maximizing proximity to consumers and the trade-off in plant-level scale economy.

Multinational firms' market access motive is broadly confirmed. Based on mainly the U.S. inward or outward FDI data, these studies show that multinationals'

affiliate sales increase with both the tariff rate the foreign country imposes on the parent country and the transportation cost between the two. When the plant-level fixed cost, measured by the average size of a plant in terms of production workers, is larger, however, the affiliate sales decrease. Furthermore, Carr, Markusen, and Maskus (2001) find that the smaller the difference between two countries in market size (i.e., GDP) and factor endowment (i.e., capital labor ratio), the greater the FDI flow between the two. These results strongly suggest the existence of horizontal FDI that is motivated by market access.

Market Potential A more recent study by Head and Mayer (2004) further extends the notion of market access. They introduce the importance of market potential in multinationals' location choice and point out that, while the ability to access a foreign market at little cost motivates firms to locate production in that country, the ability to access other markets from that country also matters. In other words, the definition of "market" in the market access motive should not be limited to the market of the host country; it should include all the markets that can be more easily accessed by the host-country plant.

To test this idea, Head and Mayer (2004) construct a measure of market potential for each potential host country. This measure represents the demand of all markets weighted by the trade costs required to export to these markets from the host. Countries with better access to other markets due to, for example, geographic proximity have greater market potential. Using a sample of Japanese multinational firms, Head and Mayer (2004) offer important evidence that regions with a larger market potential indeed attract more multinationals.

The Impact of Regional Economic Integration Given the role of market access in foreign direct investment, any change in market accessibility is expected to have an impact on multinationals' activities. In particular, regional economic integration, by reducing the trade barriers between participating countries (and keeping barriers against the rest of the world intact) will likely alter the location decision of multinational firms in the integrated region.

First, a decline in trade costs between home and host countries raises the profit associated with exporting. Multinationals' market access motive may hence be weakened and even dominated by their incentive to concentrate production geographically and achieve economies of scale. As a result, FDI could be replaced by exports. For example, a great concern in Canada during the formation of the Canada-U.S. Free Trade Agreement was that U.S. multinational affiliates located in Canada would leave Canada and serve the Canadian market through exports originating in the United States. This expectation is, however, inconsistent with the evidence. The study by Feinberg and Keane (2001) offers direct empirical insights to this issue. They show that reductions in the Canadian tariff against the United States have little impact on the U.S. multinational firms' affiliate sales in Canada and, moreover, reductions in the U.S. tariff against Canada increase the U.S. multinationals' export sales from Canada to their home countries. These findings suggest that regional economic integration does not necessarily lower multinationals' incentive to invest abroad; it may in fact increase multinationals' incentive to produce in the integrated foreign country and export back to home.

Second, regional economic integration that improves the market access among member countries could also affect the location decision of outsider firms. As the benefit of improved market access is exclusive to firms located within the integrated region, outsider firms have an increased incentive to produce in a member country and supply the rest of the region through exports. The underlying logic is closely related to the notion of market potential in Head and Mayer (2004): regional economic integration increases members' market potential and thus their ability to attract multinationals. This intuitive prediction is derived and empirically examined by Ekholm, Forslid, and Markusen (2007), who emphasize multinationals' exports to third countries. As demonstrated in this study, after the formation of a preferential trading bloc both insider and outsider firms tend to adopt an export-platform FDI strategy, in which they increase their investments in some

members of the bloc and supply the other member countries through exports.

In sum, market access, or more generally market potential including the ability to better access other markets, is an important motivation for firms to engage in FDI and establish production facilities abroad. Regional economic integration, by lowering internal trade barriers, can make a region more attractive to multinational firms and lead to an expansion in export-platform FDI into the region.

■ **market efficiency**

See interest parity conditions; forward premium puzzle

■ **market size and foreign direct investment**

Market size is an important factor in determining bilateral activities of multinational firms, regardless of whether these activities are measured as foreign affiliate sales, affiliates' employment, or foreign direct investment (FDI). FDI reflects the objective of es tablishing a lasting interest by a resident enterprise in one economy in an enterprise that is resident in another economy. Discussions often focus on the market size of the host country, although the size of neighboring countries and other countries more easily reached from the host country also play a role. Market size refers mainly to the size of markets for goods and services. Although market size of the host country is widely considered, the size of the home country is also important for bilateral FDI. Larger and more advanced countries are home to more multinational firms. The pool of knowledge neces sary to generate the specific advantages that enable firms to survive in a foreign environment increases along with a country's size and level of development.

Empirical Evidence and the Gravity Equation Most FDI flows toward large markets. Since the 1980s, the United States has received the largest in flows and holds the largest FDI stocks. Among the developing countries, China has gained the domi nant position. The size effect of the host country has been the object of empirical studies since the early 1960s. The market size hypothesis states that FDI flows are positively related to the host country's market size. Various studies have found that market size and market growth affect FDI flows positively.

Gravity equations explain activities between two countries by the size of the source and the destination country and the distance between the two. Originally developed to explain international trade, the gravity equation successfully explains aggregated activities of multinational firms such as foreign affiliate sales or FDI as well. Using bilateral data at the country or sector level, about 60 percent of the variation in multinational firms' activities are explained by these three variables. The effect of the size variables (mostly gross domestic product or population) is found to be robust and positive (Brainard 1997; Buch et al. 2005). Moreover, the relationship is robust over different time periods and against changes in the analyzed sample. In particular, no systematic dif ferences are found with respect to the size variables in studies explaining FDI in developing countries

relative to FDI in members of the Organisation for Economic Co-operation and Development (OECD).

Market size as a determinant of FDI has received increasing attention because the expansion of FDI activities after 1985 has predominantly been among OECD countries. The bulk of the FDI flows involves the same countries as home and as host countries even within narrowly defined industries. Thus factor cost differentials could not have been the source of this increase in FDI activities. The motive behind the increased FDI activities has not been found in lower production cost but in improved market access for products. Thus the new theoretical explanation for the emergence of multinational firms placed goods market access and therefore market size in the center of the analysis.

FDI for Market Access According to this line of the literature, named proximity-concentration theory, or theory of the horizontal firm, the choice of a particular mode of market access drives the internationalization of firms. Firms invest abroad to serve the foreign market by production abroad instead of exporting there. Producing abroad saves distance costs and improves market access. Distance costs comprise all costs that come with segmented markets, including transportation costs, tariffs, quotas, information costs, and registration costs.

At a given level of distance costs, a firm is more likely to decide in favor of production abroad the larger its sales are in the foreign country, because distance costs savings through production abroad are per-unit savings. Sales of the firm in the foreign country in turn depend on the foreign country's market size. Thus a firm is likely to realize larger savings the larger the foreign country's market. The additional costs associated with producing in the foreign country, in contrast, are fixed costs, that is, costs independent of sales. These fixed costs can be huge, so it does not pay to replace exports by production abroad if per-unit distance cost saving are not large enough. Hence a larger country attracts more foreign multinational firms, because market size increases the per-unit cost saving but leaves the fixed costs unaffected.

While market access is important, it is certainly not the only factor determining the decision of a firm to go abroad. Factor costs are also important (Braconier, Norback, and Urban 2005). The high explanatory power of market size in the gravity equation does not necessarily mean that goods market access is the most important motive of engagement in FDI. The size of host country's *factor* markets can also affect FDI positively. A large pool of well-trained labor with specific skills drives FDI in areas such as finance or software development to London and Bangalore, respectively. The large supply of cheap labor attracts FDI in manufacturing to China.

Factor market potential also stands behind the positive effect of the *home* country's size on FDI. The relevant factor here is knowledge capital, as Markusen (1995) calls it. Knowledge capital can be proprietary product or process know-how, efficient organizational structures, a brand name, or reputation. Knowledge capital enables firms to generate the firm-specific advantage that is necessary to produce successfully in a foreign environment. Knowledge capital increases with the stage of development and with population, since knowledge is embodied in people. Hence knowledge capital, that is, the ability to generate the firm-specific advantages, rises with the market size of the home country.

Policies to Attract FDI Given that market size is such an important determinant of FDI, restrictions on market access have been used to attract FDI. That has mainly been done by excluding or obstructing other channels to supply the market, mainly trade. FDI carried out to circumvent trade barriers has been named tariff-jumping FDI. Such tariff-jumping FDI has been found to be important for Japanese FDI to the United States and to Europe (Barrel and Pain 1999). Tariff jumping has also been a motive for FDI in Latin American countries, particularly Brazil, during their period of import substitution.

Although restricting trade is an option to attract FDI, particularly for large countries, the opposite strategy has proven more successful. By regional integration, that is, through the reduction of trade barriers, countries in the European Union (EU) and in East Asia have successfully enlarged their markets

in order to attract FDI. Regional integration has increased the market potential of individual countries tremendously. Ireland, for example, is chosen as host country by many multinational firms from outside the EU that aim at supplying goods and services in the whole EU. In addition to the increase of FDI from outside, regional economic integration has increased FDI within the region. That can be observed in the EU, as well as in the North American Free Trade Area (NAFTA) and in East Asia. Reducing internal barriers to trade alters location decisions within the regions. Firms can exploit cost differences within the region, which motivates increased FDI from within the region.

In sum, there is strong empirical support for the importance of market size as a determinant of multinational activity. This has spurred theoretical research that has found market access to be a strong motive for FDI. The market access motive has received support by intensified FDI flows following market size growth through establishing regional integration areas such as the EU and NAFTA.

■ Marshall-Lerner condition

The Marshall-Lerner condition establishes the circumstances in which a country's trade balance, or current account balance of payments, would improve as a result of a currency devaluation or depreciation. It was named after the economists Alfred Marshall and Abba Lerner, who are thought to have first discovered it. The theoretical basis of the Marshall-Lerner condition is the "imperfect substitutes model," which is a workhorse model of international trade that assumes that neither imports nor exports are perfect substitutes for domestic goods. It is also closely linked to the so-called elasticities approach to the balance of payments and the J-curve effect, since the answer depends on how responsive (or "elastic") imports and exports are to changes in their relative prices.

The Marshall-Lerner condition is the specific condition under which a real currency depreciation, interpreted as a fall in the relative price of exports in terms of imports, will improve the current account. More specifically, if the current account balance is initially zero neither a deficit nor a surplus the

Marshall-Lerner condition requires that the sum of the absolute values (ignoring signs) of the price elasticity of export demand, which measures the response of exports to the fall in the relative price of exports, and the price elasticity of import demand (the numerical response of import demand to the rise in the relative price of imports) exceed one. The export and import demand elasticities will be "elastic" if a 10 percent change in their prices brought about by the fall in the currency leads to a change of more than 10 percent in the quantities demanded. Moreover, the greater the amount by which the sum of these elasticities exceeds one the greater the improvement in the current account. On the other hand, a currency appreciation or revaluation will worsen the current account.

Intuitively, the reasoning is that when foreign goods become more expensive in the home country, fewer imports will be demanded and when the home country's goods become cheaper abroad, foreigners will buy more of its exports. Thus, provided the responses of buyers of imports and exports to the price changes are strong enough, the Marshall-Lerner condition will be satisfied. Export values will rise and import values will fall so the net effect will be an improvement in the current account.

Note that this is the simplified version of the Marshall-Lerner condition, which focuses on the responses of demand for exports and imports and assumes that responses on the supply side, measured by the elasticities of import and export supply, are both set to infinity. This implies that the home country is small in terms of its influence on international prices, meaning that it can buy all the imports it wishes at a given international price and is willing to sell to foreign countries as much as they want at a fixed price. The outcome is more complex if this assumption is relaxed and/or the current account is not initially zero. In addition, the predicted outcome for the current account is conditional on holding everything else constant, such as the effects of the fall in the value of the currency on incomes in both the home country and abroad.

Importance of the Marshall-Lerner Condition
The Marshall-Lerner condition is important because it enables policymakers to predict the effects of

changes in the exchange rate on the balance of payments (equivalent to the current account if capital flows are ignored). This is especially relevant to developing countries that find it difficult to sell their goods abroad because their currencies are "overvalued," or overpriced, or that wish to devalue their currencies in an attempt to reduce their current account deficits. In 1994, for example, a number of countries belonging to the African Financial Community franc zone, an arrangement under which several former French colonies fix their currencies to the French franc, devalued simultaneously by 50 percent to improve their balance of payments. But the condition is also of interest to developed countries, including the debate over the sustainability of the large U.S. current account deficit and the extent to which this can be reduced by a depreciation of the U.S. dollar.

The Marshall-Lerner condition also has important implications for the stability of the foreign exchange market. A foreign exchange market is stable if a disturbance that upsets the balance between the supply and demand for foreign exchange is corrected automatically through adjustment of the exchange rate. If, however, market movements in the exchange rate result in a movement further away from a supply and demand equilibrium, then the foreign exchange market is unstable. Although it is possible to establish conditions for the stability of the foreign exchange market based on the supply and demand curves for foreign exchange, these cannot be measured empirically. It turns out, however, that if the Marshall-Lerner condition is fulfilled, the foreign exchange market will also be stable, so all one has to do is to measure the price elasticities of demand for exports and imports.

Empirical Studies Not surprisingly, there has been a substantial amount of empirical work testing the Marshall-Lerner condition both for one country's trade with the rest of the world and for trade flows between two countries. Early work following Marshall's (1923) original publication tended to support the condition giving rise to the expression *elasticity optimism* but later studies in the 1940s and after World War II were more "pessimistic"

and suggested that the sum of the demand elasticities might be below or close to one. In the 1990s and early 21st century many of the earlier methodological and measurement problems associated with the testing of the Marshall-Lerner condition have been addressed and a consensus picture has emerged.

Relative prices do seem to play a significant role in determining exports and imports so the Marshall-Lerner condition is likely to be satisfied for most countries, but there are some important qualifications. First, although studies measuring export and import demand elasticities for samples of countries are generally supportive of the condition, other studies looking at individual countries over a long period of time have found little evidence of a systematic relationship between the trade balance and the relative prices of exports and imports. One also has to distinguish carefully between developed and developing countries and countries that have a high proportion of natural resources, including crude petroleum, and services in their exports and imports, since these structural differences in their economies may result in differences in their responses to export and import price changes. Third, it is crucial to allow for the fact that export and import demand may adjust only slowly over time to changes in relative prices. In particular, elasticities measured over a six-month period following the currency depreciation may be substantially less than one and may give rise to the "J-curve effect." Even short-run elasticities based on a one-year delay could still be quite low. Only when a longer period has elapsed can one be confident that the responses are large enough to satisfy the Marshall-Lerner condition.

Finally, one has to be careful to allow for episodes in history that may make the measured elasticities unreliable or unrepresentative of normal behavior, such as following the reunification of Germany in 1989, or the establishment of the North American Free Trade Agreement among Canada, Mexico, and the United States in 1994.

PETER WILSON

■ **mercantilism**

A school of economic thought developed in 16th- and 17th-century England, mercantilism argued that a country's primary economic objective should be the achievement of a trade surplus with the associated inflow of gold. The central idea was that trade was a zero-sum game and that a country could amass gold through a balance-of-trade surplus only at the expense of another country. Mercantilism is therefore a form of economic nationalism, with foreign trade used to enhance the wealth and power of one country at the expense of others.

Mercantilism is not a unified body of thought; however, Thomas Mun's *England's Treasure by Foreign Trade*, published in 1664, is typical of mercantilist writings. The policy implications of the mercantilist position included the limitation of imports and the promotion of exports. Mercantilism formed the basis for the organization of Britain's trade with its colonies, with the colonies restricted to supplying the raw materials for Britain's emerging manufacturing sector. The colonies were prohibited from competing with these so-called enumerated goods, and the entire colonial trading system was organized to promote the economic strength of the mother country and produce a trade surplus. The popularity of mercantilist thinking has been attributed to the realities of 16th- and 17th-century statecraft, in which the ability to fight foreign wars depended on having the gold resources to finance such adventures; in this case, gold accumulation through export surpluses did contribute to national power.

Adam Smith and Mercantilism The protectionist implications of mercantilism led Adam Smith to identify mercantilism as one of the erroneous systems of political economy that he sought to displace with his *An Inquiry into the Nature and Causes of the Wealth of Nations* (1776). For Smith, the mercantilists were guilty of a simple confusion about the nature of wealth, believing that it consisted of gold rather than the human and physical stock of capital. Smith believed free trade was the appropriate policy. David Hume's essay "Of the Balance of Trade" (1752) demonstrated that the objective of a balance-of-trade surplus was self-defeating, as the specie-flow mechanism would lead to domestic price level changes, which would bring the trade balance back into equilibrium. In arguing this, Hume developed an early version of the quantity theory of money. By the mid-18th century, therefore, mercantilism had been discredited and was entirely eclipsed by the theory of comparative advantage and the associated benefits of free trade developed by David Ricardo in *Principles of Political Economy and Taxation* (1821). Britain abandoned mercantilism and its associated trade restrictions in the 1840s.

Mercantilism was gradually replaced by free trade and comparative advantage as the new economic orthodoxy at the theoretical level, although one of the mercantilists' central policies protectionism continued to have its adherents, especially in Germany and the United States, the late industrializers of the 19th century. Both Friedrich List and Alexander Hamilton, influential German and American thinkers, respectively, advocated protectionist policies to spur their countries' industrialization. Even where free trade had become the orthodoxy, such as in Britain, protectionist policies returned in the face of the economic disaster of the 1930s. Even John Maynard Keynes, in *The General Theory of Employment, Interest, and Money* (1936), included the mercantilists among his predecessors in believing that an increase in the money supply could increase domestic production. Keynes argued that there was an "element of scientific proof in mercantilist doctrine" (335).

Neomercantilism In the post-1945 period, the successful late, late industrializers of East Asia, especially Japan, South Korea, and Taiwan and in the 1990s and early 21st century, China have been described as "neomercantilist." These economies ran trade surpluses during much of their post-1950 rapid growth periods, based on import restrictions, the promotion of exports, and an exchange rate pegged to the U.S. dollar (at artificially low levels, according to some). The trade surpluses enabled the East Asian economies to achieve rapid economic growth over a long period without being subject to a balance of payments constraint a constraint that affected many other developing countries' growth prospects, especially in Latin America. The prefix *neo* in *neomercantilism* therefore referred to the new period in which countries pursued trade surpluses as well as the economic, as opposed to military, definition of "national power." The term is usually used in a normative way to indicate that East Asian countries, and occasionally others, have been following nationalist policies at the expense of other countries.

PAUL BOWLES

◼ Mercosur

Traditional rivals in the southern cone of Latin America, Argentina and Brazil first explored economic collaboration in the early 1980s. For the first time in centuries, the moment was right. Both countries underwent political transitions in the mid-1980s from military rule to civilian regimes Argentina in 1983 and Brazil in 1985. The reestablishment of democratic governments provided an opportunity to seek policies that would consolidate the democratic process and limit the sphere of influence of the armed forces. In November 1985, newly elected democratic presidents met to inaugurate a new bridge at Iguaçu Falls on the border between the two nations. They agreed to create a binational commission to study the possibilities of increased economic cooperation and integration. In 1986, the Argentine-Brazilian Program for Integration and Cooperation was announced. In 1986, the two presidents signed the Act of Brazil-Argentine Friendship in Brasília. It was also announced that the two countries would pursue a policy of peaceful nuclear development.

In July 1990, the heads of state of Argentina and Brazil signed the Act of Buenos Aires. The document called for the creation of a common market by 1995, instead of by the earlier announced date of 1999. The Treaty of Asuncíon, signed in March 1991, brought Paraguay and Uruguay into the common market process and marked the creation of a "Common Market of the South," or Mercosur. This new organization's principal goal was to have a free trade area in place among all four countries and a common external tariff (CET) created by 1995. At the time of this writing, the deadline had been extended to 2010. The Protocol of Ouro Preto came into effect in December 1995 and established a new institutional framework for Mercosur. In addition to the Administrative Secretariat located in Montevideo, Uruguay, and the Common Market Council and Common Market Group, set up in 1991, it was decided to add a Joint Parliamentary Commission, a Trade Commission, and a Socio-Economic Advisory Forum. A new date of 2006 was established for the creation of a full common market. As the institutional structure evolved, Chile (1996), Bolivia (1997), Peru (2003), Colombia (2004) and Ecuador (2004) were added as Associate Members (Associate Members enjoy tariff reductions but are not subject to the CET system). In December 2004, Mercosur signed a cooperation agreement with the Andean Community trade bloc, and they published a joint letter of intention for a future negotiation toward integrating all of South America. A year later, President Alvaro Uribe of Colombia signed a law that ratified a Free Trade Agreement with Mercosur. In June 2006, Mercosur expanded further and incorporated Venezuela as a full member.

Tariffs among the four Mercosur member countries were gradually eliminated in the 1990s, and the common market was essentially completed by 1995 with the reduction of 85 percent of tariffs and nontariff trade barriers. Trade expanded rapidly among the Mercosur countries, especially between the two largest countries. According to the IMF's *Trade Statistics Yearbook*, Argentina's exports to Brazil climbed from $3.6 billion to $5.3 billion between 1995 and 1996, and Brazil's exports to Argentina

grew from $4.0 billion to $5.2 billion in the same period.

In retrospect, the late 1990s were the high point of southern cone integration. A maxi-devaluation of the Brazilian currency in January 1999 was the first shock to disturb Mercosur's consolidation. Argentina experienced an institutional crisis in 2001 2 that led to the resignation of President Fernando de la Rua, the collapse of the convertibility plan that had linked the peso to the dollar (one to one), and a massive default on the country's outstanding debt. As a result of the crisis in Argentina, Uruguay's economy stalled and growth rates plummeted and only revived a few years later.

There was little activity in Mercosur in the years following the Argentine-Uruguayan crises. Chile decided that its development goals were best served by negotiating bilateral trade agreements and did so successfully with the United States and China. In an effort to reinvigorate the organization, the heads of state convened the 30th presidential summit, held in Córdoba, Argentina, in July 2006. The formal agenda included discussions of pending trade agreements with external allies, a common customs code, the appointment of members to the Administrative Labor Court, and the establishment of a consistent Mercosur negotiating position for the all-but-collapsed World Trade Organization Doha Round.

Many observers believe that the Córdoba meeting marked the end of Mercosur as it was conceived in 1991. By the end of the two-day meeting, Mercosur appeared to be more of a political organization than a trade facilitating mechanism. The summit addressed the growing importance of political and social integration in addition to strengthening the common market. There were two dramatic aspects to the meeting: the addition of Venezuela as a full member and the attendance of President Fidel Castro of Cuba. The addition of President Hugo Chávez spoke to the increasingly political nature and societal orientation of Mercosur. His public calls to destroy neoliberalism and fight for social justice revealed his ambitions to expand Mercosur's political scope. The

noncommittal responses from the other members, however, suggested internal divisions within Mercosur itself. Nevertheless, for the first time in the history of the common market, the five full members organized a social summit, bringing together civil society leaders who met in a parallel summit to spell out the social needs and goals of the organization.

In a surprise decision, member states addressed the issue of a pending trade agreement between Cuba and Mercosur that would dictate the reduction of tariffs on a number of goods traded between the two entities. Although nominally for economic purposes, the trade agreement emphasized a growing political solidarity that could be interpreted as less than friendly to the United States.

The increasing political nature of Mercosur had been made clear during the Fourth Summit of the Americas in November 2005, held in Mar del Plata, Argentina. At that meeting, the 34 member states of the Organization of American States failed to reach consensus to move ahead with negotiations to conclude the Free Trade Area of the Americas (FTAA). Although 29 states voted to continue the dialogue, with the strong backing of the U.S. delegation led by President George W. Bush, the five dissenting votes cast by the then four full members of Mercosur and by Venezuela were sufficient to destroy the already foundering process.

Although the increasingly political nature of the common market is notable, there are other developments that threaten the future development and consolidation of Mercosur. Paraguay and Uruguay believe that they benefit the least from its current structure. And the reality is that Brazil and Argentina, with more developed and sophisticated industrial agricultural sectors, have benefited disproportionately when compared with the two smaller states.

A 2006 conflict between Argentina and Uruguay highlights the inherent conflict between the two large states and the two smaller partners. Uruguay successfully concluded negotiations to have Spanish and Finnish companies construct two paper mills along the Uruguay River, which forms a natural border between the two states. The mills, estimated at a cost

of $1.6 billion, would represent the largest foreign investment in Uruguay's history. Argentina objected strenuously to the project, arguing that the mills would destroy the river's environment and threaten the fishing and tourism industries. The issue was taken to the International Court of Justice in The Hague; the tribunal's decision favored Uruguay but the government of President Nestor Kirchner in Argentina continued its opposition. As of 2007, it was thought that the principal motivation of the Kirchner government was internal politics there were to be national elections in Argentina in 2007, and this nationalist stance plays well with the voters on the Argentine side of the river.

As of 2007, there were other pending disagreements between the two smaller states and Argentina and Brazil. There was talk in both Paraguay and Uruguay of leaving Mercosur and negotiating trade agreements directly with the United States. Under current rules, Mercosur does not allow bilateral trade agreements outside of the common market. Whether either or both countries would decide to proceed was an important pending issue for the future of the organization.

The institutionalization of Mercosur has been difficult and little had been achieved by late 2007. In this regard, structures were broad but not very deep. The heads of state made all major decisions in periodic summits. The technical staff in Montevideo was small and marginal. The reluctance to give up national sovereignty plagued the organization it was impossible to develop dispute resolution mechanisms, for example, unless member states were willing to cede decision-making authority to supranational tribunals.

There was a growing impression that Mercosur is most valuable to its members as a political counterweight to the United States. That raises doubts about the future. The group dashed the hopes of the United States for a revival of FTAA talks in Mar del Plata. Efforts by the United States to revive the Doha Round discussions met strong resistance from the Mercosur countries, acting within the broader structure of the Group of Twenty (G20), created in 2003 in Cancún, Mexico, as a means of protesting agricultural protection in the European Union and the United States.

Like that of other regional trade movements such as the stalled FTAA, Mercosur's viability has been called into question, and the organization will need to prove it can provide benefits for all member countries to stay intact. As member countries grow disillusioned and increasingly court bilateral trade agreements, Mercosur's unity, influence, and economic potential have diminished. Thus the original goals of Mercosur set forth in the early 1990s have not been achieved, and the organization has taken a polemical turn that deemphasizes integration and gives preference to regional and hemispheric politics.

RIORDAN ROETT

■ mergers and acquisitions

A merger is the amalgamation of two or more firms into a single firm. This is typically accomplished when one firm acquires the assets of the other firm(s). Such transactions are referred to as mergers and acquisitions (M&As). There are three types: *horizontal* mergers involving firms in the same industry, *vertical* mergers between firms at different stages of the production chain, and *conglomerate* mergers between firms in unrelated industries.

M&As may not involve a complete takeover of another firm's assets. Rather, an investor may acquire a majority or even only a minority stake. This raises the question of what the appropriate ownership structure of the newly created entity should be. Partial ownership entails the sharing of control rights and implies different levels of commitment by the parties involved. There is no clear dividing line between M&As and other forms of organization that allow firms to share assets and coordinate their interests, such as joint ventures.

It is interesting to examine M&As from an international perspective for at least three reasons. First, cross-border M&As have fueled the growth in international production for more than a decade. Since the 1990s, most foreign direct investment (FDI) has been carried out through the acquisition of foreign firms' assets rather than the creation of new firms (the latter also known as greenfield investment). Second, there is evidence that economic integration affects M&A activity by increasing the incentives to undertake cross-border M&As and by forcing industries to

restructure. This restructuring is often accomplished through M&As. Third, both cross-border mergers and mergers between domestic firms engaged in international trade pose challenges for competition policy. Such mergers affect several countries and hence are subject to review by different national competition authorities. These authorities may come to conflicting conclusions, especially if some countries bear more of the costs while others receive more of the benefits of the merger. A prominent example of such conflicts is the merger between two American companies, General Electric and Honeywell, which was approved by U.S. authorities but was ultimately blocked by the European Commission.

Cross-border M&As account for a significant and growing share of total M&A activity. They make up around 25 percent of worldwide M&As. Between 1996 and 2005, the annual average value of cross-border M&As worldwide was U.S. $533 billion, or about 70 percent of annual world FDI flows (UNCTAD 2006). Cross-border M&As, like all M&A activity, tend to occur in waves. In 2000, for example, cross-border M&As peaked at $1.14 trillion. Most cross-border M&As involve developed-country firms. FDI in developing countries is still dominated by greenfield investment. Horizontal mergers account for roughly 70 percent of all cross-border mergers, vertical mergers for around 10 percent. Mergers are much more common in the service sector than in manufacturing (UNCTAD 2000).

Horizontal mergers have attracted the most attention both from scholars and from governmental authorities concerned with competition. The study of these mergers typically involves an analysis of the following two aspects. First, horizontal mergers tend to be anticompetitive. They raise industry concentration and therefore potentially lead to higher prices for consumers or, in the case of intermediate goods, for downstream industries. Another consequence of increased industry concentration is that competitors may benefit even more from the merger than the merging firms themselves. Specifically, as prices rise following the merger, competitors will be tempted to

increase their output, thus gaining market share at the expense of the merging firms.

Second, a merger may allow firms to realize synergies and thus become more efficient. Firms will merge provided that these synergies are sufficiently big to offset the competitive disadvantage outlined in the previous paragraph. If the efficiency gains from the merger are large, prices for consumers may even fall as a result of the merger. But even if they do not, a competition authority may approve a horizontal merger provided that the efficiency gains in production are larger than the losses suffered by consumers due to higher prices. How competition authorities should weigh consumer well-being and economic efficiency in their decisions is an issue that has generated some debate.

The preceding analysis did not distinguish between domestic and cross-border M&As, simply because it applies to both. Still, it is important to point out some of the distinguishing features of cross-border mergers. The main motive for horizontal cross-border M&As is to establish a market presence abroad. They are therefore an alternative to greenfield FDI or exporting. Compared with these alternative choices, cross-border M&As tend to raise industry concentration, thereby potentially hurting consumers and benefiting local competitors. They also offer additional efficiency advantages, however. These include the avoidance of set up costs and of the fixed costs of operating a production facility arising in the case of greenfield FDI, and the avoidance of transportation costs and trade barriers associated with exporting.

Economic integration affects M&A activity in at least two ways. First, it puts pressure on firms to restructure. Specifically, less efficient firms in an industry are forced by import competition to contract or close, whereas improved access to export markets offers more efficient firms an opportunity to expand. An empirically important way in which this restructuring is accomplished is through M&As, whereby efficient firms acquire the assets they need to expand from less efficient firms (Breinlich 2006). Second, trade liberalization raises the incentive to undertake

cross-border mergers. A simple example illustrates the point. Suppose there are two countries, *A* and *B*, each with one firm. When trade barriers are high, there is no incentive for the firms to merge, since each already has a monopoly in its market. As trade barriers fall, competition between the firms increases, giving them an incentive to merge in order to reduce competition.

Except in the European Union, where large cross-border mergers and mergers involving domestic firms with a significant market share in other EU member countries are reviewed by the European Commission, competition policy generally remains the responsibility of national authorities. This may cause problems exactly for the reasons that have led the EU to implement a unionwide competition policy. A simple example helps illustrate them. Consider an industry in which two locally owned firms in country *A* export all their output to country *B*, and suppose there are no local competitors in *B*. A horizontal merger between the two firms allows them to monopolize the market in *B*. This hurts consumers in *B*, but raises profits for the firms in *A*. Synergies involving the elimination of fixed production costs have no effect on prices and hence only boost profits. Provided that competition authorities are guided by considerations of national social welfare, the competition authority in *A* would approve the merger and the one in *B* would prohibit it. This raises the possibility that a merger would be blocked even if the efficiency gains accruing to the firms in *A* outweigh the losses suffered by consumers in *B* so that a merger would raise the overall welfare of the two countries.

The case of the GE/Honeywell merger mentioned earlier is much more complicated than the case illustrated by this simple example. In particular, it has not only a horizontal dimension (both companies produce jet engines for regional aircraft), but also a significant vertical dimension. Specifically, Honeywell is a leading supplier of an intermediate good, namely engine starters, to GE and its two main competitors in the market for large jet engines. A merger between GE and Honeywell may thus have

allowed them to cut off supplies to these two competitors, thereby monopolizing the engine market.

Vertical mergers are best viewed as an alternative to vertical contractual arrangements also known as vertical restraints between firms and their suppliers and/or distributors. An analysis of vertical mergers as in the case of horizontal mergers involves weighing efficiency-enhancing against competition-reducing effects.

■ migration, international

International migration involves the movement of people, on either a temporary or permanent basis, among the countries of the world economy. Throughout human history these changes of residence have helped to alleviate human suffering, enhance technological progress, and promote cultural exchange. As of 2006 approximately 200 million people, or 3 percent of the world's population, lived outside their country of birth. Although by historical standards this percentage is low, international migration has doubled since 1980. Migration continues to be a key dimension of globalization, albeit one that has complex determinants and outcomes.

As a field of inquiry, international migration has received less attention from social scientists than many other aspects of the world economy. Nonetheless, it is one with a relatively long intellectual history that originally goes back to Ravenstein (1889), with modern contributions going back to Lee (1966). Theoretical and empirical research into international migration underwent a significant renaissance beginning in the 1990s, and multilateral financial institutions gave increased amounts of attention to the subject (e.g., World Bank 2006). A grounded understanding of migration requires an investigation of its recent history, types of migration, the migration decision itself, impacts of migration on both source and destination countries, and current policy debates.

Recent History The modern era of globalization began in the late 19th century. A central component of this was the "Age of Mass Migration" described by Hatton and Williamson (1998). Between 1850 and 1914, approximately 55 million Europeans migrated, most of them unskilled males who settled in

the United States. As Manning (2005) emphasizes, however, the Age of Mass Migration was not just European in nature, with 50 million Chinese and 30 million Indians also migrating (not all voluntarily), primarily to serve as unskilled laborers in British colonies in Africa and the Pacific.

The transatlantic mass migration increased the New World labor force by a third and reduced that of the European economies by an eighth. As a result, the wage gap between North America and the leading European countries narrowed, and flows of migrations from traditional sources slowed. Yet as Western Europe was reaching the end of this migration cycle, other less-developed countries in Eastern Europe were just getting started, giving rise to new sources of migration. The new migration proved to be politically controversial, however, and in 1917 the United States introduced a literacy test for new migrants. This, as well as the outbreak of World War I and its accompanying restrictions on movements of people, effectively brought an end to this era of migration.

Starting in 1917 and continuing throughout the 1920s, isolationist policies characterized much of the Western world. The onset of the Great Depression and the outbreak of World War II only reinforced this trend. International migration declined dramatically. In the aftermath of World War II, however, resurgent nationalism and the spread of communism sent millions of refugees across the European continent. In Western Europe, once a major source of migrants, rapid economic growth in the late 1940s and 1950s led to a shortage of low-wage labor. Initially, the demand was met by migrants from southern European countries, but such sources quickly proved insufficient. By the 1960s, countries across Western Europe were admitting millions of guest workers from Turkey and North Africa. Although the 1973 oil crisis and the ensuing high unemployment brought an abrupt end to these programs, the oil-exporting countries in the Middle East later replicated and expanded the guest-worker model, thereby ensuring that flows of low-skilled migrants remained a significant component of world migration.

In the mid-1960s, Australia, Canada, and the United States overhauled their immigration policies, allowing for a much greater volume of flows and opening the door to migration from countries in Asia, Africa, and Latin America. Together with the precipitous decline in the cost of intercontinental transportation and communication, these reforms have led to steady growth in both the volume and diversity of migrant flows. Yet, as international migration became subject to expanded legal provisions, increasing numbers of migrants opted to forgo legalities altogether. Consequently, undocumented migrants posed increasing challenges for destination countries.

Since the late 1980s, migration flows have continued to grow rapidly. Although Western Europe is an increasingly popular destination for migrants, the United States accepts more immigrants than any other country in the world. The Gulf countries of the Middle East have also emerged as a major destination for migrants, particularly for low-skilled workers from South and Southeast Asia. As of 2006, Mexico and the Philippines were significant sources of low-skilled labor, the latter having 10 percent of its population in foreign countries. China and India predominate as sources of high-skilled migrants.

Types of Migration Migrants leave their home countries and are admitted into destination countries for a wide variety of reasons, and distinct administrative channels have evolved to facilitate these flows. Following are some of the major channels, both legal and unregulated, that define the current international migration system.

Permanent high-skilled migration. Over recent decades, Australia, New Zealand, Canada, and the United States have selectively granted permanent residence to a limited number of high-skilled foreigners who are likely to offer these countries positive economic benefits. Whereas Australia, Canada, and New Zealand operate a "points" system to rate the desirability of potential immigrants, the United States primarily relies on nominations of potential immigrants by local companies that wish to hire them. Among source countries, India and China lead the way, although some high-income countries such

as South Korea and the United Kingdom also supply significant numbers of this kind of migrants. Several Western European countries have recently adopted similar programs to citizenship in order to entice high-skilled migrants.

Temporary high-skilled migration. In many developed countries, programs that grant permanent residence to foreigners who do not have ties to the destination country can be politically controversial. In such cases, governments may seek to fill occupational shortages through the recruitment of high-skilled migrants on a temporary basis. Historically, these flows have been concentrated in education and health-related services. During the 1990s, however, booms in information and communications technology (ICT) led to a shortage of related skills in many high-income countries, resulting in a jump in flows of technology professionals, mostly from India. In the early years of the 21st century, even nontraditional immigration destination countries, such as China and the Czech Republic, began to grant temporary work visas to high-skilled foreigners.

Temporary low-skilled migration. Despite the fast growth of temporary high-skilled migration, these flows are dwarfed by temporary low-skilled migration, in which countries admit migrant workers to provide low-cost services on a strictly temporary basis. Countries typically implement these programs when rapid economic growth has improved the wages and work conditions of the local workforce and left them correspondingly unwilling to work at low-wage jobs. One of the best-known programs of this kind was the West German *Gastarbeiter* program of the 1960s and 1970s in which West Germany recruited large numbers of Turkish and North African guest workers. These programs were rolled back in the low-growth, high-inflation period of the 1970s, but low-skilled migration programs have since grown significantly in the Middle East. In 2006, approximately 10 million temporary low-skilled migrants were employed in the Saudi Arabia, Kuwait, and the UAE. India and Pakistan are major sources of manual laborers and construction workers, with domestics, nurses, and other service workers coming primarily from Sri Lanka, the Philippines, and Thailand. The

rights of temporary low-skilled migrants, however, are often not well defined or protected.

Family migration. Family migration is among the largest official channels of migration and represents a disproportionate share of flows from low- and middle-income countries to high-income countries. This mode of migration enables foreign spouses of citizens, children born abroad, and even foreign-born parents and siblings of citizens to gain permanent residency in the country of the respective relative. Although almost all countries in the world permit some form of family migration, countries differ significantly in their definitions of which types of relatives are eligible to migrate, and which are not. Over recent years, many high-income countries have tightened restrictions on family migration in order to limit the volume of politically controversial inflows of migrants from low-income countries.

Coethnic and national priority migration. A number of programs provide permanent residency to foreigners on the basis of their ethnic background, religious affiliation, or national origin. In many European countries, coethnic migration functions through the liberal application of the *jus sanguinis* citizenship tradition, whereby citizenship rights can be inherited through long lines of ancestry. Israel's Law of Return is one of the most controversial instruments of coethnic and national priority migration as it provides a path to permanent residency to all those who practice Judaism, irrespective of any other criteria. The United States operates dedicated paths to permanent residency for migrants from Cuba and a number of other countries, while also operating a "diversity visa" lottery of the United States, purportedly to diversify immigration flows, but which in fact was originally proposed by lawmakers as a means to provide a new channel for Irish migration to the United States.

Asylum seekers. The 1951 Geneva Convention protects persons with a "well founded fear of persecution [by state agents] for reasons of race, religion, nationality, membership of a particular social group, or political opinion" from return to their country of origin. Asylum seekers commonly invoke the 1951 convention in seeking permission to remain perma-

nently in a destination country. In order to assess asylum claims, major recipient countries have established elaborate administrative legal procedures, including access to counsel and the right to appeal initial decisions. As a result, individual claims can sometimes take years to resolve. In some destination countries, asylum seekers qualify for social services. In others, they are granted only the right to work. In yet others, they remain in detention until a final decision on their application is reached.

Refugees. Groups of people who have fled to neighboring countries due to war, famine, environmental collapse, or political strife are considered refugees. Refugees are often hosted in makeshift camps set up by international humanitarian agencies along the border of the affected country with the expectation that they will return to their country of origin at the conclusion of the disturbance. Where this is not possible, the United Nations High Commissioner for Refugees (UNHCR) might seek to resettle refugees in a third country or help them to settle in the country of refuge.

Undocumented migration. Reliable data on the number of people involved in undocumented migration are limited and estimates vary widely. There is evidence, however, that flows increased markedly in the 1990s and the early years of the 21st century, particularly to Europe, where the implementation of the free movement of labor within the European Union has increased the potential rewards for illegal migrants who reach a member country. Major flows also exist between Mexico and the United States and among countries in West Africa, Southern Africa, and Southeast Asia. Flows of undocumented migrants include those who move voluntarily and those who are trafficked against their will.

Visa-free migration. Visa-free migration exists (with some exceptions) within the European Union, as well as between New Zealand and Australia. This channel grants citizens the right to work for an unlimited time in any of the countries that are party to the agreement.

The Migration Decision The economic, social, and psychological consequences of migration to the individual are profound, and it can be very difficult

for anyone to predict with any certainty whether migration will actually improve their life. The inherent unpredictability of migration tends to discourage people from leaving their home countries, even when doing so would increase their expected income. Those who do choose to migrate are often unusual in their willingness to tolerate risk. The predominance of young males in migration flows reflects this reality.

Migration is an expensive endeavor in terms of both the direct costs involved and the opportunity costs of leaving a livelihood in the home country. These costs prevent a large number of people from migrating even if they wish to do so. This, in conjunction with the unwillingness of those earning high incomes to migrate, gives rise to the so-called migration hump. That is, those with the highest inclination to migrate come from middle-income countries, where wages are high enough to provide the base level of wealth necessary to finance migration, but also low enough to generate significant financial incentives for migrating to high-income countries. Thus as incomes in middle-income countries increase, migration rates tend to decline. On the other hand, when incomes rise in low-income countries, migration rates tend to increase. Such was the case during the Age of Mass Migration, with significant increases in emigration rates following industrial revolutions by four or more decades.

Another important factor that can either spur or restrict migration is the presence of familial or trusted contacts in the destination country. If a large number of people from their community have migrated, potential migrants have easy access to information on the experiences of other migrants and relatively high confidence that their migration experience will conform to what they are told. Immigrant communities can also provide essential services to new arrivals, such as accommodation and employment, thereby lowering the cost and risk of resettlement.

In some cases, neither financial resources nor information networks in destination countries allow migrants to fully assess their prospects. Some high-skilled migrants, for example, fail to secure a job that

utilizes their skills. This causes what analysts refer to as brain waste.

Impacts on Source Countries High-skilled migrants are commonly trained at substantial costs to the taxpayers of source countries through public education systems. Their departure thus has profound effects in the form of what is known as *brain drain*. Source countries can also lose tax revenues that migrants would have generated. More important, many of the skills sent from less-developed to more-developed countries are already scarce in source countries. In the case of medical services, for which more-developed countries have a strong desire and less-developed countries an urgent need, brain drain can potentially imperil the quality of medical care. In many southern African countries, high emigration rates for health care professionals have existed alongside unprecedented medical crises brought on by the HIV/AIDS pandemic. In Malawi, for example, it is estimated that approximately half of the country's nursing staff has been lost to migration. Meanwhile, the rate at which Malawian women die during pregnancy and childbirth doubled during the 1990s to one of the highest levels in the world.

The emigration of skilled workers does not always create problems for source countries. In some cases, emigration alerts outside investors to a large or relatively underused skill base of the source country. The success of skilled Indian migrants in the United States, for instance, possibly helped to spur the large inflow of ICT-related foreign direct investment (FDI) to India seen over recent years. Thus, when the conditions are right, skilled migrants are able to generate networks of investment, trade, and technology transfer that increase the productivity and demand for skills in the home country while extending the global technology frontier and lowering the cost of products used by billions of people worldwide.

Another potentially compensating benefit of the brain drain is that it tends to increase the demand for skills in the source country by raising the rate of return to education. Some researchers have suggested that, even accounting for the emigration of skilled individuals, the increase in demand for education generated by the brain drain may actually *increase* the number of skilled workers in the population. This is known as a brain gain. Although brain gain outcomes are possible, they depend on large responses in the supply of education and training. They are not, therefore, a *general* outcome of high-skilled migration.

The most easily quantifiable benefit of emigration to source countries is the flow of money, or *remittances*, sent by migrant workers to their home countries. Recent estimates suggest that the total remittance flow to developing countries exceeds U.S. $200 billion. In a number of countries, remittance inflows are larger than inflows of FDI and can compose up to 10 percent of national incomes. Such flows can make a significant difference for families living in poverty in source countries, which is a common reason for communities to allow and sometimes even encourage their family members to seek work abroad.

Under the auspices of the World Trade Organization (WTO), the liberalization of services trade has occurred in a number of sectors, such as finance and telecommunications, of interest to developed countries. The WTO's General Agreement on Trade in Services recognizes the *temporary movement of natural persons* as a way to export certain labor-intensive services such as housekeeping and construction. Given the natural comparative advantage of developing countries in such labor-intensive services, this channel could be of great importance to their trade and development prospects. The WTO protocol on the temporary movement of natural persons, however, is largely limited to the exchange of corporate personnel and is not designed to enhance the delivery of labor-intensive services.

Impacts on Destination Countries The world's most productive economies often depend on and benefit greatly from the presence of migrant workers. Currently, the world's richest countries continue to import labor at high rates. For example, in Southeast Asia's richest country, Singapore, migrants make up around one-quarter of the workforce. In Europe, those countries with the highest number of migrant workers, such as Switzerland and Luxembourg, are

also the wealthiest. In Dubai, currently among the world's fastest expanding areas of economic activity, as of 2006 there were nine times as many migrant workers as resident nationals.

Across all regions of the world, the correlation between levels of economic growth and immigration is clear, not only because migrants wish to move to where they can earn the highest wages, but also because immigration is often much less politically controversial when an economy is growing quickly and unemployment is low, thereby easing the liberalization of migration restrictions.

Critics of immigration are usually concerned with its impact on social fabric, national culture, environment, social welfare programs, or the wages of low-skilled workers. Correspondingly, advocates of increased immigration have turned their attention to the potential role further inflows could play in ensuring the sustainability of pension systems in the face of aging populations.

A common claim against migration is that migrants, particularly those who are low-skilled or undocumented, consume far more in public services than they contribute in tax revenue to destination countries. However, many studies paint a different picture. Research in Europe, for instance, indicates that immigrants (even undocumented immigrants) contribute more in taxes and pension funds than they consume in benefits or other public services. Interestingly, some commentators have argued that increased migration will actually be critical to the survival of social security systems in high-income countries over the coming decades. For instance, as the proportion of retirees in the population increases, many social security systems will need to find sources of tax revenues in order to fund pension payouts. Migrants are one potential source through which tax revenues might be increased.

The contention that migrants "take the jobs" or reduce the wages of native workers is probably the most common argument advanced against migration. Economic theory suggests that increasing the size of the labor force will lower the wage level, all other things being equal. Yet when a region receives an influx of immigrant labor, native workers may

choose to move to other regions, thereby masking any changes in the aggregate wage. Firms may also decide to move into a region experiencing such an influx, causing local wages to increase. Accordingly, it has been very difficult for studies to accurately assess the impact of migration on unemployment or wage levels and fierce academic debates continue to rage on the topic.

Unlike statistically testable hypotheses regarding the effect of migration on public finances or low-skill wages, claims that immigrants alter culture or threaten national cohesion are difficult to assess. Fears that migrants threaten the cultural or social order remain among the most instrumental sources of resistance to migrant inflows. Yet the historical record shows that many of the perceived cultural idiosyncrasies of migrants fail to outlive the first generation, while others, such as music, cuisine, and sport, are co-opted by the native culture due to their popularity among natives.

Policy Priorities Migration has always been and will continue to be a central feature of the world economy. It does, however, involve a number of important policy issues that have not yet been resolved: increased multilateral coordination of migration flows, prevention of human rights abuses, care of refugee populations, facilitation of the temporary movement of natural persons in services trade, the harnessing of remittance flows for poverty-reducing investments, management of brain drain, and reduction of brain waste. These priorities compose a large and important policy agenda for better harnessing this important socioeconomic process for development purposes in the modern world economy.

■ migration governance

People migrate from one nation state to another, and
governance of international migration refers to the
national and international laws and norms regulating
such movements. Even though international migra
tion by definition involves two nation states, and the
people moving between them, most migration oc
curs under the national laws of receiving states, al
though these national laws may be shaped by inter
national norms.

The best example of international governance of
migration applies to refugees, about 5 percent of the
world's 200 million migrants. The 1951 Geneva
Convention relating to the Status of Refugees and its
1967 Protocol define a refugee as a person who,
"owing to well-founded fear of being persecuted for
reasons of race, religion, nationality, membership of
a particular social group or political opinion, is out
side the country of his nationality and is unable or,
owing to such fear, is unwilling to avail himself of the
protection of that country." The 138 signatories to
the Convention and Protocol pledge not to return or
"refoul" persons who satisfy this definition to their
countries of origin.

Geneva Convention countries sometimes resettle persons recognized by the UN High Commissioner for Refugees (UNHCR), as when the United States resettled Vietnamese who fled to Thailand and other Southeast Asian countries in the late 1970s. Other countries that do not resettle refugees often participate in burden sharing, providing funds to support refugees who have taken refuge in poor countries, such as Afghanis in Pakistan, and supporting repatriation when their countries of origin become safe.

Countries also establish systems to screen foreigners who arrive and apply for asylum, with those who need protection being allowed to stay. Countries differ in how they implement the Geneva refugee convention, with traditional immigration receiving countries such as the United States and Canada resettling more refugees, while European countries such as Britain and France deal with asylum seekers. National laws determine exactly what assistance refugees and asylum applicants receive. European countries often provide housing and other assistance to both refugees and applicants for asylum, while the United States relies on private organizations such as churches to integrate refugees and care for asylum applicants.

Governance and Migration The 1995 report of the Commission on Global Governance defined governance as "the sum of the many ways individuals and institutions, public and private, manage their common affairs . . . a continuing process through which conflicting or diverse interests may be accommodated and cooperative action taken." Governance of international issues is agreed to by nation-states that see advantages in creating rules and norms, and institutions to ensure that they are followed. For example, the World Trade Organization (WTO) establishes rules for international trade in goods and services, establishing mechanisms to resolve trade disputes, and the International Labor Organization (ILO) promotes policies that protect workers. Nation-states may delegate a part of their national sovereignty to international institutions such as the WTO and ILO, agreeing to incorporate the agreements or conventions they establish into national laws governing trade and worker rights.

International organizations such as WTO and ILO set rules for the behavior of nation-states, while organizations such as the International Organization for Migration (IOM) provide services to states. IOM began as an intergovernmental organization that moved refugees and displaced persons to new homes at the end of World War II. It has evolved into an organization of 118 countries that aims to improve migration management by providing services as well as advice to governments. IOM acts as secretary for a variety of ad hoc efforts to improve migration management, including the Berne Initiative that led to the International Agenda for Migration Management, a "non-binding reference system and policy framework."

The stock of international migrants doubled between 1985 and 2005 to almost 200 million; migrants are persons outside their country of citizenship a year or more, regardless of their legal status and reason for being abroad. International migration is likely to continue increasing because of demographic and economic inequalities among countries as well as revolutions in communication and transportation that make it easier to learn about opportunities abroad and travel over national borders to take advantage of them. Winning international agreement on a system to manage migration is difficult, however, because sovereignty includes the right to determine who enters and stays in a country. With no consensus on whether migration is good or bad for sending and receiving countries, there is no legal and institutional framework for dealing with migration cooperatively on a global scale except for UNHCR and the protection of refugees.

Developing a global policy framework is difficult because policy contradictions at the national level are mirrored at the international level. This occurs in other areas with global frameworks, as when national governments promote freer trade at the WTO but protect their farmers with subsidies and import barriers, making it hard for a WTO that operates by achieving consensus among its nation-state members to lower farm trade barriers. Similarly, if industrial countries want to encourage the best and brightest from developing countries to work and settle, they

may retard economic development and accelerate unwanted migration of less-skilled workers, so that global discussions of such migration can quickly devolve into arguments over compensation for the brain drain.

Top Down, Bottom Up Most international organizations operate in a top-down fashion, seeking to establish norms that protect migrants in nation-states that ratify conventions and protocols approved by the organization's members. International human rights conventions give individuals the right to leave their country, but there is no comparable right to enter or stay in another country. The ILO approved major conventions in 1949 and 1975 to protect migrant workers, and the United Nations General Assembly approved a more expansive migrant convention in 1990. Finally, the UN approved two protocols in 1998 aimed at curbing smuggling and trafficking in persons over national borders.

The ILO's Convention 97 (1949) established the fundamental principle of equality of treatment for migrant workers, meaning that migrants should be treated as other workers in the countries in which they work. The ILO called for migrant workers to move across national borders under the terms of bilateral agreements and to have labor rights ranging from the right to organize unions to the right to work-related benefits. ILO Convention 143 (1975) emphasized the steps governments should take to minimize illegal migration and to promote the integration of settled migrants.

Both of these controversial provisions, ILO migrant conventions have fewer-than-average ratifications, 42 for Convention 97 and 18 for Convention 143 as of 2005. The reluctance of countries to ratify ILO migrant conventions is often attributed to provisions in the conventions that conflict with national legislation. For example, migrant workers in the United States have the same union rights as U.S. workers, but if unauthorized migrants are unlawfully fired because of their union activities, they are not entitled to pay for the time they did not work. The U.S. Supreme Court held in Hoffman Plastics (2002) that requiring back pay for unauthorized migrants would "encourage the successful evasion of

apprehension by immigration authorities, condone prior violations of the immigration laws, and encourage future violations." In effect, the court ruled that an unauthorized worker's violation of immigration laws was more serious than an employer's violation of labor laws.

On December 18, 1990, the UN General Assembly approved the International Convention on the Protection of the Rights of All Migrant Workers and Members of Their Families. This 8-part, 93-article convention went into force in July 2003 to "contribute to the harmonization of the attitudes of States through the acceptance of basic principles concerning the treatment of migrant workers and members of their families." The UN Convention has been ratified by 35 major emigration sending countries, in part because it goes beyond the protections of ILO Conventions to cover all migrants, authorized and unauthorized.

The major employment-related protections of the UN Convention are in part III, particularly articles 25 27, which prescribe equality in wages and working conditions for authorized and unauthorized migrant and national workers, assert that migrants should be allowed to join unions, and call for migrant workers to receive benefits under social security systems to which they contribute, or to receive refunds of their social security contributions on departure. Authorized migrants should have additional rights set out in part IV, including the right to information about jobs abroad before they arrive as well as a list of "equal treatments," including freedom of movement within the host country, freedom to form unions and participate in the political life of the host country, and equal access to employment services, public housing, and educational institutions.

The United Nations has a High Commissioner for Human Rights that examines compliance with seven "core human rights treaties" that implement the Universal Declaration of Human Rights (1948). These include the International Convention on the Elimination of All Forms of Racial Discrimination (1965); the International Covenant on Civil and Political Rights (1966); the International Covenant on Economic, Social, and Cultural Rights (1966);

the Convention on the Elimination of all Forms of Discrimination against Women (1979); the Convention against Torture and Other Cruel, Inhuman, or Degrading Treatment or Punishment (1984); the Convention on the Rights of the Child (1989); and the International Convention on the Protection of the Rights of All Migrant Workers and Members of Their Families (1990).

Other international instruments and declarations also call for equal treatment for migrants. The Vienna Declaration and Programme of Action on Human Rights (1993) and the Cairo Programme of Action of the International Conference on Population and Development (1994) affirmed the importance of promoting and protecting the human rights of migrant workers and their families, and the Beijing Platform of Action of the Fourth World Conference on Women (1995) paid special attention to the rights of women migrants and urged that migrants be protected from violence and exploitation. The World Conference on Racism, Racial Discrimination, Xenophobia, and Related Intolerance in 2001 issued the Durban Declaration and Program of Action, calling on countries to allow migrants to unite their families and to make active efforts to reduce discrimination against migrant workers. The UN General Assembly in 2000 adopted the Convention against Transnational Organized Crime, which has two additional protocols: the Protocol to Prevent, Suppress, and Punish Trafficking in Persons, especially Women and Children, and the Protocol against the Smuggling of Migrants by Land, Sea, and Air.

The UN in 2006 held a high-level dialogue on migration and development, endorsing a new "moving forum" to discuss best practices to maximize the development impacts of migration, remittances, and migrants' returning or staying abroad but forging new trade and investment links to their countries of origin. The forum is an alternative to proposals for a new "World Migration Organization" analogue to the WTO, advocated by some as a way to improve the governance of international migration.

Most migration is governed unilaterally by receiving countries, which decide whether they are destinations for immigrants, guest workers, and other types of foreigners and establish rules governing entries and stays. Since most migration occurs between neighboring countries, however, there are many bilateral and regional agreements dealing with migration. The world's largest bilateral migration flow involves an average 200,000 Mexican immigrants, millions of nonimmigrant visitors and guest workers, and the settlement of perhaps 400,000 unauthorized Mexicans each year in the United States. There are regular consultations between Mexican and U.S. immigration officials, and former Mexican president Vicente Fox (2000 2006) made improving the status of Mexicans in the United States his top foreign policy priority.

The Regional Migration Conference, or the Puebla Process, an initiative launched by the Mexican government in the city of Puebla in 1996 in response to voter approval of Proposition 187 in California in 1994, includes 11 countries that meet at least once a year to discuss migration issues: Canada, the United States, Mexico, and Central American countries plus the Dominican Republic. The discussions cover changes in national migration policies, the link between migration and development, migrant trafficking, cooperation for the return of extraregional migrants, and the human rights of migrants.

Puebla Process consultations are credited with paving the way for the United States to legalize the status of many Central Americans who fled to the United States during civil wars in the 1980s, and to grant temporary protected status to Central Americans in the United States when Hurricane Mitch carved a path of destruction in 1998 and after El Salvador had severe earthquakes in 2001, and with encouraging cooperation to improve safety at the Mexican-U.S. and Mexican-Guatemalan borders. There are many other regional migration forums, including those between the European Union and North African countries, among African countries, and among the Andean countries of South America. These forums discuss economic issues such as remittances and development as well as migration management issues such as traffickers and criminals (International Organization for Migration 2005b).

Whither Migration Governance About two-thirds of the world's migrants are in the high-income countries that have one-sixth of the world's people but five-sixths of the world's economic output. Even though there are almost as many migrant workers from developing countries in other developing countries (about 30 million in 2005) as there are developing country migrants in industrial countries (31 million), most unresolved governance issues involve developing and industrial countries. For example, one major issue is conditionality, or whether industrial countries that provide aid or open doors for guest workers can require sending countries to cooperate to accept the return of apprehended nationals.

Many observers believe that bringing governments together to talk about migration is the first step toward improved governance. Major concrete outcomes of regional organizations aimed at improving migration governance include making it more difficult for unauthorized foreigners to apply for asylum in more than one country. Both the United States and Europe have persuaded neighboring southern countries to prevent the transit of migrants headed for their borders (pushing the borders out), sometimes with financial assistance, as when the United States helps Mexico to prevent the transit of third-country nationals headed for the United States.

Most migration occurs within regions, and regional organizations that discuss migration issues can be more informal and flexible than global organizations that fix rules and enforcement mechanisms. Most regional organizations include sending and receiving countries but do not develop binding rules. It is generally far easier to achieve consensus in a closed-door meeting on regional migration issues than to negotiate global rules in forums in which national interests may vary widely.

The role of migration governance in the modern world economy is to establish rules governing the movement of workers over borders for temporary periods of employment. The fundamental principle in international conventions protecting migrants is equality, treating migrant workers as local workers. The gap between this equality goal and migrant realities is often large.

■ Millennium Development Goals

The Millennium Development Goals (MDGs) were introduced in the Millennium Declaration, which was signed by 189 states and adopted by the General Assembly of the United Nations during the United Nation's Millennium Summit on September 6 8, 2000. The 8 MDGs and 18 targets formulate a comprehensive set of development objectives to be attained by 2015. Additionally, the United Nations observes 48 indicators to measure progress toward the MDGs. As the MDGs have been endorsed by a large number of UN member governments and international organizations, they also provide a framework of accountability for the outcomes of international development efforts.

Specifically, the Millennium Declaration establishes the following goals and targets:

Goal 1: Eradicate extreme poverty and hunger.
  Target 1: Halve, between 1990 and 2015, the proportion of people whose income is less than $1 a day.
  Target 2: Halve, between 1990 and 2015, the proportion of people who suffer from hunger.
Goal 2: Achieve universal primary education.
  Target 3: Ensure that by 2015, children everywhere, boys and girls alike, will be able to complete a full course of primary schooling.
Goal 3: Promote gender equality and empower women.
  Target 4: Eliminate gender disparity in primary and secondary education, preferably by 2005, and at all levels of education no later than 2015.
Goal 4: Reduce child mortality.
  Target 5: Reduce by two-thirds, between 1990 and 2015, the mortality rate among children younger than five.

Goal 5: Improve maternal health.
  Target 6: Reduce by three-quarters, between 1990 and 2015, the maternal mortality rate.
Goal 6: Combat HIV/AIDS, malaria, and other diseases.
  Target 7: Have halted by 2015 and begun to reverse the spread of HIV/AIDS.
  Target 8: Have halted by 2015 and begun to reverse the incidence of malaria and other major diseases.
Goal 7: Ensure environmental sustainability.
  Target 9: Integrate the principles of sustainable development into country policies and programs and reverse the loss of environmental resources.
  Target 10: Halve by 2015 the proportion of people without sustainable access to safe drinking water and basic sanitation.
  Target 11: Have achieved a significant improvement by 2020 in the lives of at least 100 million slum dwellers.
Goal 8: Develop a global partnership for development.
  Target 12: Develop further an open, rule-based, predictable, nondiscriminatory trading and financial system (including a commitment to good governance, development, and poverty reduction, nationally and internationally).
  Target 13: Address the special needs of the least-developed countries (including tariff- and quota-free access for exports of the least-developed countries; enhanced debt relief for heavily indebted poor countries and cancellation of official bilateral debt; and more generous official development assistance for countries committed to reducing poverty).
  Target 14: Address the special needs of landlocked countries and small island developing states.
  Target 15: Deal comprehensively with the debt problems of developing countries through national and international

measures to make debt sustainable in the long term.

Target 16: In cooperation with developing countries, develop and implement strategies for decent and productive work for youth.

Target 17: In cooperation with pharmaceutical companies, provide affordable access to essential drugs in developing countries.

Target 18: In cooperation with the private sector, make available the benefits of new technologies, especially information and communication.

The United Nations measures progress toward these goals and targets using 48 Millennium Development Indicators, such as the proportion of people living on less than U.S. $1 per day, the net enrollment rate in primary education, the ratio of literate women to men (ages 15 to 24), the mortality rate of children younger than five, HIV prevalence among women ages 15 to 24, the proportion of land area covered by forest, and the level of official development assistance.

As of mid-2007, progress toward achieving the MDGs was uneven. For example, the World Bank's *Global Monitoring Report 2006* observed that the share of people in developing countries living on less than U.S.$1 per day was expected to fall to 10.2 percent by 2015, from 27.9 percent in 1990. Most of this progress was accounted for by large declines in poverty rates in Asia, while poverty rates in sub-Saharan Africa had improved only modestly since 1990, from 44.6 percent in 1990 to 44.0 percent in 2002, and under 2007 projections were expected to fall to 38 percent by 2015, far above the target of 22.3 percent.

By specifying quantitative targets for development outcomes, the MDGs also provide a framework for holding development agencies, international organizations, and recipient countries accountable for the outcomes of development assistance. For example, they lend themselves to analyses of whether aid commitments are consistent with or fall short of the goal of attaining the MDGs. (The *Global Monitoring Report 2006* suggests that, in most cases, aid commitments fall short of the goal.)

The commitment to attaining the MDGs has contributed to (or at least coincided with) an increase in official development assistance, which has risen from an average of U.S. $59 billion annually (1996 2000) to U.S. $106 billion in 2005 for Organisation for Economic Co-operation and Development (OECD) donor/creditor countries, partly reflecting an increase in debt relief and the emerging international response to HIV/AIDS. Although the 2006 data on external aid showed no further increase in external aid (excluding debt relief) for OECD countries, aid specifically to sub-Saharan Africa was expected to increase, in line with commitments made at the G8 Summit in Gleneagles in 2005, and some "new" donor countries, most notably China, had increased their aid commitments.

Have the MDGs been effective? Although it is too early (as this is written in 2007) to answer this question, recent experience provides some pointers. Overall aid has increased during the period the MDGs relate to, although these increased efforts fall short of what would be required to meet the MDGs. Nevertheless, the MDG targets provide a measure of accountability for aid outcomes, and therefore reinforce or sustain the momentum toward increased development aid.

MARKUS HAACKER

■ monetary conditions index

A monetary conditions index (MCI) is a simple device that combines movements in different financial variables, notably the interest rate and the exchange rate, into a single number. It serves as an easy-to-understand reference or information variable to financial markets and the general public at a point in time relative to some point in the past. In addition, a MCI can function as a short-term operating target in the conduct of monetary policy in small open economies.

The Bank of Canada pioneered the construction of a MCI in the early 1990s. The original MCI consisted of a weighted average of the real short-term interest rate and the real exchange rate, the respective nominal rate adjusted for inflation and the price of domestic relative to foreign goods. In practice, however, the MCI has been stated in terms of the nominal short-term interest rate and the nominal exchange rate, two of the most readily observable financial variables in the economy.

The basic idea behind the MCI is that in an open economy, both the real interest rate and the real exchange rate help determine aggregate demand. They can be combined to produce a simple gauge that measures the influence of both variables on aggregate demand. This indicator captures changes in the stance of monetary policy and the associated effects on the exchange rate. In addition, it records changes in the exchange rate that are not accompanied by changes in the interest rate, such as terms of trade shocks or loss of confidence. Finally, it registers movements of the interest rate and exchange rate in opposite directions in situations where, for instance, an announced policy change lacks credibility.

Explaining the MCI In its simplest form an aggregate demand relation can be modeled as follows:

$$y_t = -a_1 r_t - a_2 e_t + v_t \qquad a_1, a_2 > 0$$

where

y_t = aggregate demand,

r_t = real interest rate,

e_t = real exchange rate (rise implies that domestic currency is appreciating, all other things being equal), and

v_t = other factors that influence aggregate demand.

The size of a_1 and a_2 reflect the relative effect of the real interest rate and exchange rate channel on aggregate demand. Both parameters are important ingredients in the construction of the MCI:

$$MCI_t = (r_t - r_0) + \frac{a_2}{a_1}(e_t - e_0) + 100$$

The MCI at time t is a weighted sum of the change in the real rate of interest and the change in the real exchange rate relative to the base period. The interest rate is measured in percentage points while the exchange rate appears in index form with 100 being its value in the base period. The selection of the base period is arbitrary. The weight on the real exchange rate is typically less than or equal to one.

According to the above specification, a one-point rise in the real interest rate at time t is associated with a one-point rise in the MCI. If the relative weight on the real exchange rate is one half, then a two-point rise in the real exchange rate also leads to a one-point increase in the MCI. It is important to keep in mind that the absolute level of the MCI is meaningless. Changes in the MCI reflect changing monetary conditions between two points in time. An increase (decrease) in the index indicates that monetary conditions have tightened (eased).

MCI in Practice MCIs figured prominently in monetary policy deliberations at the Bank of Canada and the Reserve Bank of New Zealand in the 1990s. The rationale for constructing these indexes was grounded in the assumption that a central bank can wield considerable control over monetary conditions and that in a small open economy changes in monetary conditions are reflected mainly by changes in the interest rate and the exchange rate, which in turn affect aggregate demand. The level of aggregate demand is the most important factor in determining the rate of inflation. With price stability being an important, if not the overriding, goal of monetary policy, it was incumbent on the central bank to establish desirable monetary conditions that are consistent with price stability. In practice, the central bank prepared a path for the monetary conditions index that was compatible with inflation forecasts. In

the interval between inflation forecasts, the bank monitored the actual MCI to see if it diverged from its desired path or range. In the event that marked differences appeared, the central bank would adjust the interest rate to correct the course of the actual MCI. If evidence emerged for a change in expected inflation, the central bank adjusted the path of the MCI to be compatible with the inflation objective. Given the close attention both central banks paid to the MCI in the day-to-day operation of monetary policy, it seems clear that the MCI served as a short-term operating target.

For other central banks, MCIs have figured less prominently as indicator variables next to the term spread or monetary and credit aggregates. The International Monetary Fund and the Organisation for Economic Co-operation and Development, as well as commercial banks, have also published monetary conditions indexes for various countries. These MCIs serve primarily as information variables: the banks use the actual MCI to assess current monetary conditions and their likely effect on inflation and real economic activity.

Beginning with the new millennium, the prominence of MCIs has waned considerably. Central banks, international organizations, and commercial banks still calculated and monitored MCIs as of 2007, but they played a minor role in monetary policy deliberations. The virtual demise of the MCI is due to several factors, some of which are related to its construction and underlying view of the transmission mechanism. Interpreting observed changes in the index can also be problematic as they depend on one's view of how the economy works.

Role of Exchange Rate An important issue in the construction of a MCI pertains to the determination of the relative weight on the real exchange rate. The two parameters a_1 and a_2 that make up the relative weight are not observable and must therefore be estimated. Whichever relative weight appears in the MCI depends on the specification of the model chosen to estimate aggregate demand. Empirical studies have shown that the range (statistical confidence intervals) for the empirical estimates of the key parameters is excessively wide and often includes zero as a possible estimate. Other issues pertain to the selection of interest rates and exchange rates: real versus nominal, short-term versus long(er)-term interest rates, trade-weighted versus bilateral exchange rates.

The usefulness of a MCI is also hampered by its rather narrow view of the monetary transmission mechanism. In essence, the conception of the original MCI rests on the assumption that the real exchange rate affects aggregate demand and that aggregate demand in turn affects the rate of inflation. Direct effects of the real exchange rate on the rate of inflation through import prices are thus ruled out. Yet in an open economy this direct exchange rate channel plays an important role in determining overall inflation.

The literature explaining the design and use of an MCI warns against mechanically adjusting the interest rate in the wake of a weaker or stronger exchange rate. Careful analysis of the circumstances that gave rise to the change in the exchange rate is warranted before a central bank contemplates a change in the policy instrument. Shocks that originate in the real sector of the economy and lead to changes in the real exchange rate call for a change in monetary conditions, whereas lack of credibility in the conduct of monetary policy or portfolio shocks, that is, shocks in financial sector of the economy, that lead to a weakening of the real exchange rate are to be countered by increases in the interest rate so as to leave monetary conditions unchanged.

It is conceivable that different constellations of the interest rate and the exchange rate could yield the same level of the MCI. In such a situation monetary conditions are the same and the policymaker may be tempted to choose a particular mix of the interest rate and the exchange rate. Yet the outcome for real economic activity and the rate of inflation will most certainly depend on the particular mix chosen, especially if time lags play an important role in the transmission process of monetary policy.

MCIs were still being published around the world as of 2007, because they provide a simple gauge of monetary conditions in an economy. Although MCIs are of some use to financial markets and the general public as an information variable, they play

only a minor role in the implementation of monetary policy at central banks.

■ monetary policy rules
Monetary policy rules (MPRs) are one of many mechanical processes that guide the implementation of monetary policy. Other processes include a cur- rency board, an exchange rate crawl, or a money growth rate rule. This discussion will be limited to the type of MPR made famous by the Taylor rule (Taylor 1993).

A monetary policy *rule* is an alternative to a *dis- cretionary* policy framework. There are many reasons why rules might possibly be seen as a better option by economists and policymakers. First, rules are more transparent than discretion and, as such, easier to understand and use as the basis for decisions. This, in turn, assists with establishing and maintaining a credible central bank and monetary policy regime. Second, rules are able to convey greater information about the future direction of policy. Third, outcomes under a rules-based policy tend to be better than those from discretionary policy.

Constructing a Monetary Policy Rule An MPR is an algebraic representation of a policy rule that stipulates how an instrument of monetary policy will react to key economic variables and therefore achieve a specific policy objective. There are three main components to the MPR. The first is the policy in- strument. This is the variable that the policymaker adjusts to affect its monetary policy. In the Taylor rule, the MPR is a short-term interest rate.

In the subsequent literature on MPRs, economists have investigated the use of other possible instru- ments of policy. These include the exchange rate, a combination of the interest rate and the exchange rate (a monetary conditions index, or MCI), and even a monetary aggregate such as the monetary base, or M2. Whichever one is used, the instrument is essential for two reasons: it represents the policy lever and therefore must be subject to the policymaker's control, and it must be able to influence economic activity to the extent that it satisfies the policy ob- jectives.

The second component of an MPR is the set of variables to which the policy instrument responds. These variables convey information about the stance of monetary policy and signal how the instrument ought to react so that the policy targets are met. In the basic Taylor rule, the variables to be included are the deviation of inflation from a preannounced target and the deviation of output from a long-run value

designed to represent full employment. Under this specification, the Taylor rule essentially implies that the inflation and output deviations contain sufficient information about the stance of monetary policy to adequately drive interest rate movements.

Although not explicitly stated in the rule, the third component of an MPR is the policy regime that it is supposed to represent. The monetary policy regime most commonly pursued with MPRs is inflation targeting. As such, the boundaries of the MPR reflect how the instrument should react to the right-hand-side variables in a manner that achieves the stated policy.

But how does one link the policy objective to the MPR? The answer is through a statement of central bank objectives usually depicted by a central bank loss function. The loss function is an algebraic representation of the policymaker's objectives and will typically detail the variables that the central bank is interested in targeting. If there are multiple objectives, the weight that the central bank attributes to each objective becomes important. The minimization of the loss function subject to the constraints imposed by a macroeconomic model will yield an MPR.

The MPR emerging from this minimization exercise is known as an *optimal* MPR one that is derived from an explicit policy objective. The Taylor rule itself is an example of a *simple* MPR, one where the rule is specified without reference to explicit objectives. In this instance, the variables captured by the MPR reflect the policy objectives. For example, if the simple MPR contains expressions for output and inflation deviations, then it is assumed that these are the objectives of policy regardless of the model used to depict the macroeconomy. Under an optimal rule, the variables that appear on the right-hand side may not actually be policy objectives they may simply be variables that appear as part of the model used for optimization. Herein lies the difference between simple and optimal MPRs. Optimal MPRs are highly dependent on the model used to derive the rule but are explicitly reflective of the actual policy preferences of the central bank. Simple MPRs are imposed on a macroeconomic model and, as such, do not explicitly reflect central bank policy preferences, but are likely to be robust across many model specifications.

Exchange Rate and Monetary Policy Rules The role the exchange rate ought to play in the adoption of an MPR is a common subject of debate. There are two broad discussions in this area. The first relates to whether the instrument of monetary policy should react in a significant way to the exchange rate when setting policy. The second is whether the exchange rate ought to be used as an instrument, or coinstrument, of policy (see Cavoli and Rajan 2007).

The literature on inflation targeting using MPRs makes it clear that the exchange rate should have no part in the implementation of policy and, if using simple MPRs, should not appear at all in the MPR. The reason for this is that a policy trade-off between the exchange rate and domestic objectives may occur it may be difficult to address both objectives with a single policy instrument. This may well appear to be an appropriate strategy for large, relatively closed economies such as the United States, but the debate is more complicated for open, developing economies. The simple reason for this is that the exchange rate may contain information (about global events or capital flows) that is important in the operation of a MPR that is not contained in other variables (such as output and inflation). This is so even if the exchange rate is not itself an objective of monetary policy. Hence, under these conditions, there is a strong argument for the inclusion of the exchange rate in the rule it helps provide all the necessary information for the attainment of domestic policy.

Once the decision is made to include the exchange rate in the rule, how might one manage the possibility that the exchange rate and inflation may suggest opposing instrument changes? One possibility is to use a partial adjustment. Under this process, the MPR instrument will react to both current and lagged exchange rates. Then, if there is a shock that requires a strong reaction to the current exchange rate but is an inappropriate reaction for inflation, then that reaction can be partially offset next period.

The second issue relates to the possibility of using the exchange rate as an instrument of policy. There are two lines of research here. The first examines a policy rule called a monetary conditions index (MCI). The MCI is an MPR in which the policy instrument is a linear combination of the interest rate and the exchange rate. They are effectively coinstruments of policy. The main premise behind the MCI is that both interest rates and exchange rates indicate monetary conditions and that, for example, a tightening of these conditions can be brought about by an interest rate rise, an increase in the foreign currency value of the domestic currency, or both. As such, it is possible that the variables can move in opposite directions so that monetary conditions are not affected. Therefore, it is the imperative of the policymaker that if a change in one of the variables leads to changes in monetary conditions, the other must be moved to maintain the present policy position and offset monetary changes.

The way that the MCI is typically captured in an MPR is by both the exchange rate and the interest rate appearing on the left side of the rule (see Ball 1999). The economist Laurence Ball (2001), however, believes that this situation is broadly equivalent to an MPR where the interest rate is the main instrument and the exchange rate appears on the right-hand side. Under this version of an MPR, the implicit assumption is that the interest rate is the main instrument of policy and is able to be competently controlled by the policymaker. The exchange rate still offers the policymaker information about the relative tightness of policy and can still guide movements in the instrument and therefore the direction of policy.

The second way that the exchange rate can be used is as a policy instrument in its own right. There is a line of research (particularly in relation to Singapore) where variables such as the nominal bilateral or nominal effective exchange rate (NEER) appear on the left side of an MPR as the sole policy instrument. Underlining this rule is the ability to control the nominal exchange rate (in the conventional manner through foreign reserves). This rule works in precisely the same way as the Taylor-type specification

using the nominal interest rate the right-hand side of the rule would contain expressions for the inflation gap, output gap, possibly lagged exchange rate term, and any other variable deemed to possess information sufficiently important to guide the exchange rate toward the policy objective (Cavoli and Rajan 2006). The overall policy objectives need not be any different from the Taylor-type MPRs; the rule simply reflects the opinion of the policymaker that the exchange rate does a better job at reaching the policy target.

■ monetary versus fiscal dominance

The terms *monetary dominant* and *fiscal dominant* refer to a central bank's ability to pursue goals of its own choice. Under a monetary dominant regime, the central bank is free to pursue its main goal: stable prices. By contrast, under a fiscal dominant regime, the central bank is not free to fight inflation, since it must print money to fill a fiscal financing gap, now or in the future.

The distinction between monetary and fiscal dominance is of great practical importance for policymakers. For example, central banks have adopted inflation targeting programs in increasing numbers. Inflation targeting, or any other independent monetary regime, is not viable if there are other competing demands on the central bank, such as financing the government's fiscal deficit (when expenditures exceed revenues). In the face of such competing demands, the central bank can limit inflation only in the short run and only with interest rates that are high enough to keep government debt attractive to investors. Upward pressure on interest rates can also be exacerbated if a country suffers capital outflows or adverse shocks to risks as perceived by potential investors in the country.

Economists disagree, however, about how to implement the notions of fiscal or monetary dominance. All agree that markets must be convinced that the central bank is indeed free from other demands. The disagreement lies in exactly how "tight" or "disciplined" fiscal policy must be, currently or prospectively, in order to convey that message. How large must the primary (noninterest) surplus be in order to ensure that the central bank can restrain inflation without excessively high interest rates? The case of Brazil in 2002 3 helps illustrate this point. At that time, Brazil's fledgling inflation targeting program faltered. Even while interest rates were kept high,

the central bank failed to meet its inflation target. Fiscal policy was not overtly "undisciplined." Rather, the government attempted to stabilize its debt when it raised the primary surplus to more than 3 percent of gross domestic product (GDP). Nonetheless, adverse shocks threatened to raise public debt further still, against policy intentions. Fears that the central bank would be forced to buy this extra debt by printing money fiscal dominance thus jeopardized the inflation targeting program (Blanchard 2005).

Explaining Dominance The economists Sargent and Wallace (1981) envisaged a standoff between a central bank and a fiscal authority. They asked what might happen if the central bank signals an unwillingness to satisfy a long-run financing gap. They conclude that, in some cases, even while money is tight and interest rates are high *today*, inflation might still rise *today*.

Their starting point was the government's *intertemporal* budget constraint:

$$B_t/P_t = PV(ps) \qquad (1)$$

where B_t is the nominal value of government claims today (time t), P_t is today's price level, and $PV(ps)$ is the present value of real primary (noninterest) surpluses from today forward. Note that B_t/P_t is real government debt: nominal government debt deflated by the price level. Equation (1) is often called the government's "intertemporal solvency," or "present value," condition. This condition says that, barring default (either explicitly or through a surprise inflation), today's real debt B_t/P_t must be paid for either now or in the future with primary surpluses (ps); the present value of all current and future primary surpluses must be enough to pay off the debt.

Under a monetary dominant regime the fiscal authority meets condition (1) by adjusting the primary surplus (i.e., fiscal balance net of interest payments on existing debt, that is, raising revenues and/or reducing expenditures). If there is an adverse fiscal shock in some period an unanticipated increase in expenditures or fall in tax revenues the fiscal authority should respond by raising taxes or cutting expenditures at some future date. Such an adjust-

ment must offset the initial shock in present value terms. In this sense, primary surpluses are said to be *endogenous*. Since such a policy environment is typically featured in discussions of the Ricardian equivalence hypothesis named after the economist David Ricardo (see Barro 1974), a monetary dominant regime is also called a Ricardian one.

By contrast, under a fiscal dominant (or non-Ricardian) regime, primary surpluses are set exogenously. Even if a shock occurs, the fiscal authority will not adjust its policies. Instead, market participants immediately recognize that the present value of primary surpluses $PV(ps)$ has fallen and is now insufficient to amortize the real value of outstanding debt B_t/P_t. Instead, as equation (1) implies, the real debt B_t/P_t must also fall.

How does this happen? The government might simply announce that it will default on a portion of its debt (or impose a capital levy). A default need not be explicit, however. When market participants themselves recognize that their bonds will not be fully backed by future surpluses, they attempt to reduce their bond holdings. Although any single individual can sell his or her bonds, the market as a whole (in a closed economy) cannot. Instead, when all market participants attempt to sell their debt in exchange for goods, the price of goods will rise just enough to maintain the equality in (1). Sargent and Wallace show how, in such an environment, the inflation rate might rise today, even while money remains tight (see Sargent and Wallace 1981).

The Role of Money and the Fiscal Rule In traditional models, people first exchange their bonds for money and then for goods. In a fiscal dominant regime, money, which is passively supplied by the central bank, bridges the fiscal financing gap. Then, when all agents attempt to purchase goods with their newly printed money, prices rise. Money's role is not essential, however. The economist Woodford (2000) has discussed a case in which paper money is replaced entirely by electronic accounts. According to Woodford, although money itself is not required to pin down the price level, a Ricardian, or monetary dominant, regime is.

Concretely, under such a regime, the primary surplus would be determined according to a rule like:
$$(ps/y)_t = \kappa + \alpha * (b/y)_{t-1} \qquad (2)$$
where ps is the real primary surplus, $b = B/P$ is real debt, and y is real GDP. Such a rule may be tacit; it need not be legally stipulated. Note that, if $\alpha = 0$, for any value of κ, fiscal policy is non-Ricardian. In some countries, $\kappa < 0$; this suggests that the government is giving a rebate to current taxpayers (potentially at the expense of future taxpayers). It can be shown that, for (1) to hold ex ante, primary surpluses and debt must rise together ($\alpha > 0$), but not necessarily on a one-to-one basis ($\alpha < 1$). More precisely, to ensure that (1) holds, α must exceed zero even if only by a small amount.

A rule like (2), in which κ typically equals zero, often appears in the computable general equilibrium real business cycle models that emerged in the 1990s, which are increasingly used by central banks in many countries to guide policy decisions (including inflation targeting programs). Such a rule pins down the price level in the model.

The condition $\alpha > 0$ (κ unrestricted) is a very weak one. For example, if
$$0 < \alpha < [(\rho - \gamma)/(1 + \gamma)] - [\kappa/(b/y)_{t-1}],$$
where $\rho \equiv$ long-run interest rate, $\gamma \equiv$ long-run GDP growth, the debt ratio b/y grows over time. To be sure, the solvency condition (1) is satisfied, but only because primary surpluses ps/y themselves also grow over time passing an ever larger fiscal burden to future taxpayers. A more stringent policy would be one in which the authority attempts to stabilize the debt ratio b/y, specifically $\kappa = 0$ and $\alpha = (\rho - \gamma)/(1 + \gamma)$. This means that the primary surplus is large enough to cover interest payments, minus an adjustment for growth:
$$(ps/y) = [(\rho - \gamma)/(1 + \gamma)]^* (b/y).$$

Such a policy appeals to intergenerational equity: both debt b/y and the primary surplus ps/y stay constant over time. In this way, current and future taxpayers face similar burdens.

Current Practical Approaches for Policymakers In practice, what does it take to reassure market participants that the central bank will not face

pressures to finance deficits? Is it enough that the government has kept itself solvent in the past (i.e., $\alpha > 0$)? Not necessarily. Unless primary surpluses are expected to equal or exceed $[(\rho - \gamma)/(1 + \gamma)]^*(b/y)$, the debt ratio b/y will grow. Such a policy is *unsustainable*: as b/y rises, so too must the primary surplus ps/y. Markets recognize that future fiscal adjustments may be *politically* difficult for the government to achieve.

Even under a debt-stabilizing policy, where primary surpluses equal, on average $(ps/y) = [(\rho - \gamma)/(1 + \gamma)] * (b/y)$, markets may not be convinced that the central bank is free to stabilize prices. This is especially true in developing countries, where external shocks affect debt ratios through their impacts on interest rates, exchange rates, and GDP growth. Often, adverse shocks are not immediately offset by favorable ones. In this case, under a debt-stabilizing rule $(ps/y) = [(\rho - \gamma)/(1 + \gamma)]^*(b/y)$ there is a 50 percent chance that the debt ratio will rise.

This also implies a 50 percent chance that another fiscal adjustment will be needed. Markets may find this probability too high. Governments may wish to reduce that probability. To do so, their primary surpluses must on average *exceed* their debt-stabilizing value. For example, the primary surplus might also be linked to the *volatility* of the fiscal burden (*vol*):

$$(ps/y) = [(\rho - \gamma)/(1 + \gamma)]^*(b/y) + \omega^*(vol),$$

where $\omega > 0$ reflects policymaker preferences. Thus a policy of $\omega^*(vol) > 0$ may be justified as a preemptive cushion that reduces the probability of future adjustments. But, in addition, if $\omega^*(vol) > 0$, public debt will *fall*.

Hence, more recent views have emphasized that, in order to guard against fiscal dominance, governments should aim to *reduce* public debt not just stabilize it. While all governments face a trade-off between costly primary surpluses and the cushion they provide, each will choose a precautionary cushion according to its own circumstances.

In this vein, gauging fiscal dominance (or market perceptions thereof) may require more than simply estimating an equation like (2). For example, some authors have recently developed Monte Carlo techniques (i.e., simulation exercises) that yield estimates of the *probability* that the debt will rise to a certain level during a certain time horizon. And, with an eye toward policy, several papers (see, for example, Tanner and Samake 2008) suggest a method to calculate the primary surplus required to obtain a desired probability. Because such techniques clearly present the trade-off between higher primary surpluses and more security, they should lead to better and more informed policy.

EVAN TANNER

■ money laundering

Money laundering involves the transformation of the proceeds of crime into riches, which can then be enjoyed while disguising their illegal origins. It generally includes three steps: the introduction of the criminal proceeds into the financial system; hiding the proceeds through a variety of transactions and financial vehicles; and investing the laundered proceeds in financial and related assets. These operations often involve international transactions as a means of "layering," or obscuring, the source of the funds. National governments and the international community have worked for many years to combat money laundering, but these efforts were redoubled and expanded to include terrorist financing after the terrorist attacks of September 11, 2001, on the United States.

Measurement of the global volume of money laundering is extremely difficult given that the intrinsic nature of the transactions is intended to disguise the source of funds. Several indirect measurements of the volume of money laundering have been derived, using, for example, estimates of activity in the underground economy and the income generated from criminal activity. The range of these estimates is very broad, from less than one-half to several percent of gross domestic product.

Combating terrorist financing has become an integral part of the international efforts on anti money laundering. Terrorist financing can be defined as the processing of property from any source (perhaps a legitimate one) to finance terrorist activity that has been or will be committed. This activity is thought to use many of the techniques of money laundering and many of the possible countermeasures are similar. Furthermore, several terrorist organizations are known to finance their activities out of the proceeds of crime. Nonetheless, terrorist financing differs from money laundering in several ways that affect public policy. It may be much more difficult to detect terrorist financing than money laundering, since it is mainly directed at future activity: it is possible that the only offense that has been committed when the financing takes place is conspiracy to commit a terrorist act. Also, the amounts of money needed to finance terrorism are widely believed to be relatively small. The September 11 terrorist attack was believed to have required less than $1 million in financing. This compares with the typical volumes of money being laundered by, say, large drug trafficking operations, which in total might approach several hundred billion dollars a year.

International efforts to combat money laundering (and terrorist financing) reflect both a law enforcement strategy to "follow the dirty money" and a

me

concern to protect the global financial system from abuse by criminal elements. When an institution is used unwittingly by criminal elements or terrorists, it risks damage to its reputation. Once the integrity of an institution or financial center is brought into question, its long-term viability is put at risk, with potentially serious economic consequences. If the staff of a financial institution collude with criminal elements to launder funds or channel financing to terrorists, the damage can be much greater. The most serious dangers arise when important financial institutions are controlled by criminals, since these circumstances can compromise the integrity and operations of the whole financial system by corrupting the allocation of resources, misallocating investment, and lowering economic growth.

Combating Money Laundering Money laundering is intrinsically global. If one country or jurisdiction sharpens its focus to prevent money laundering and combat the financing of terrorism (AML/CFT), money-laundering activity will quickly shift to a less-regulated environment. Hence the efforts to combat money laundering and terrorist financing have also been global, centered on the development of international codes and standards that all jurisdictions are expected to follow.

A prerequisite for an effective anti-money-laundering regime is to have in place an adequate general legal framework. Such legislation needs to define and criminalize money laundering and terrorist financing with suitably graduated penalties. It has to cover a wide set of "predicate crimes" that is, the criminal activity that gives rise to the cash or other valuables to be laundered and define the scope of the AML/CFT regime. Commercial banks are generally obligated to be especially vigilant given their role in the payment system. However, as criminals will exploit loopholes, wide sectoral coverage is needed.

The typical measures that financial institutions have to apply include checks on the identity and legitimacy of their clients the "know-your-customer" requirements. Major shareholders and senior managers in financial institutions demonstrate that they are "fit and proper" to hold these positions of control and oversight. Financial institutions must establish systems of identifying and reporting unusual or suspicious transactions. The financial institutions themselves need to train their staff adequately to spot activities that raise a suspicion of money laundering and to have clear processes in place to report back to the authorities. The reporting of unusual transactions and "know-your-customer" rules need to be supported by adequate record keeping. When the authorities, for example, investigate a suspicious transaction, a financial institution must be able to help establish an audit trail.

Typically, financial sector regulators are responsible for supervising the AML/CFT procedures of financial institutions and for checking that their managers and owners meet the "fit and proper" test. Much of this supervision is not separable from other aspects of prudential supervision. For example, a bank supervisor will have to review a commercial bank's internal control procedures to prevent internal fraud or imprudent behavior and, at the same time, can check on whether the bank has in place the means to limit vulnerability to money laundering.

Many countries have also set up specialized agencies called financial intelligence units (FIUs). These agencies investigate, analyze, and pass on to the competent authorities financial and related information concerning suspected proceeds of crime. A key component of an FIU's work is to collaborate with like agencies in other countries in sharing information on suspicious transactions.

A number of organizations are involved in the international efforts on AML/CFT. This includes the Financial Action Task Force (FATF), which sets the global AML/CFT standards; a number of FATF-style regional bodies, such as the Caribbean Financial Action Task Force, which have focused on the development of sound AML/CFT regimes within their regions; as well as the International Monetary Fund, the World Bank, and the United Nations. Together, these bodies provide a network for the global assessment of jurisdictions' compliance with the AML/CFT standards. These assessments identify potential weaknesses in the AML/CFT regimes and develop plans of corrective action. Several of these bodies support the global AML/CFT efforts through train-

ing and technical assistance and through their typologies of money laundering and terrorist financing.

One of the key challenges for any anti-money-laundering regime is that criminal elements are very adept at finding ways to avoid the controls. In an effort to fill possible loopholes in the anti-money-laundering regimes, in 2003 the FATF expanded the AML/CFT standards that countries should comply with to cover a range of new sectors outside of regulated financial institutions, and tightened requirements on existing sectors. The revised standard is comprehensive and demanding, and a number of jurisdictions, especially but not limited to low-income countries, have had difficulty meeting its rigorous requirements. The application of the standard illustrates an ongoing anti-money-laundering issue: how to balance the costs on consumers and industry of tightened regulation with the benefits, when the volume of money laundering has proved difficult to measure.

R. BARRY JOHNSTON

money supply

Money has been used by civilized societies for millennia, but in its modern macroeconomic context it is identified with "the money supply." Almost all economies have moved beyond commodity money to paper money; however in economies with reliable banks, most money takes the form of bank deposits. To the extent that they are transferable by check, bank deposits satisfy the official definition of money as "a generally acceptable means of payment."

Economists define a country's money supply along a spectrum ranging from high to low liquidity: the ease with which an asset can be used as a generally acceptable means of payment, or at least converted into a means of payment. Various monies can range along a spectrum from coin and paper currency ("cash"), called M0; to M1, which is M0 plus checkable bank deposits; to M2, which is M1 plus savings and other similar short-term but noncheckable deposits; to M3, which includes longer-term deposits; and so on. The precise definitions vary from country to country.

What matters from a macroeconomic point of view is, first, how controllable is the money supply, and second, how much and how quickly it affects output, interest rates, exchange rates, and the overall price level. Governments wish to control their own money supplies in the short run to stimulate output in the face of unemployment, and in the long run to control inflation.

Controllability of Money Supply Controllability of the money supply has long been a matter of debate, but economists generally agree that any central bank with a monopoly on issuance of its domestic currency can control its country's money supply as long as it is not committed to buy and sell foreign currencies at a fixed exchange rate. On the other hand, a central bank that is committed to a fixed exchange rate will be forced to sell or buy unlimited quantities of domestic currency in exchange for foreign currency and will be forced to contract or expand its money supply in the process. The phrase *impossible trinity* refers to the fact that monetary control, fixed exchange rates, and unrestricted international currency flows cannot coexist.

However, controllability is subject to a second constraint. The link between central banks' "instruments" of control and the money supply itself is neither tight nor predictable. One way of conceptualizing this link is via the monetary base, or what is sometimes called "high-powered money": the sum of a country's cash (coin plus paper money, both in circulation and inside banks, or "vault cash") and, more sizably, its central bank's deposits in domestic commercial banks.

Central banks conventionally control money supplies by depositing or withdrawing their deposits with commercial banks, sometimes in exchange for

purchases or sales of government bonds on the open market, and sometimes by other means. Commercial banks then use these "central bank reserves" (defined as central bank deposits plus vault cash) to leverage the creation of deposits   that is, money. They do this by purchasing interest-bearing securities (typically government bonds) and by writing loans, in return for which they issue deposits to sellers of the securities or recipients of the loans. Commercial banks need these reserves at minimum for check-clearing purposes, but also for prudential purposes, against unforeseen cash drains. The central bank often also requires that commercial banks hold a minimum ratio of reserves to deposits.

The problems with trying to control the money supply via the monetary base are threefold. First, the public's desired ratio of cash to deposits is variable and partially unpredictable. When commercial bank deposits expand via an injection of central bank reserves into the banking system, the public will choose to withdraw a fraction of their new bank deposits as cash. This depletes the banks' vault cash and thus their reserves. For prudential and perhaps also regulatory reasons, banks will be forced to reduce their rate of deposit expansion. Hence central banks try to anticipate such cash withdrawals by injecting reserves ex ante, and they also try to reverse unanticipated cash withdrawals by injecting reserves ex post.

Second, the commercial banks' desired ratio of reserves to deposits is also variable and partially unpredictable. Even if, as in many countries, they are required to hold a minimum ratio, they will likely hold some "excess reserves" to guard against unwanted cash withdrawals. How much they choose to hold depends on their opportunity costs: notably, on the yields they earn on alternative assets, such as government treasury bills.

Third, the extent to which banks, after receiving new reserves, choose to expand "demand" or "time" deposits is also variable and unpredictable. Demand deposits (i.e., those on which checks can be written) require more reserves for prudential reasons than do time deposits (i.e., noncheckable) because the likelihood of withdrawals for cash is greater.

In short, the ratio of a country's money supply to its monetary base is variable and partially unpredictable because the public's desired cash-to-deposits ratio, the banks' desired reserves-to-deposits ratio, and the banks' desired mix between demand and time deposits are all unpredictable. Hence the central banks' control of the money supply via the monetary base is imperfect. Of course much of the response of the money supply to the monetary base *is* predictable: it generally rises with income (because the cash-to-deposits ratio falls with income), and it also rises with interest rates (because the excess reserves ratio falls and the time-to-demand-deposits ratio rises). This means that not only is the central banks' job of controlling the money supply made more simple, it also means that money supplies expand and contract endogenously with upswings and downswings in the business cycle, lessening the need for exogenous control by the central bank.

Macroeconomic Implications of Money Supply Growth The second major macroeconomic issue surrounding money supplies is their impact on interest rates, exchange rates, output, and the overall price level. In theory, and subject to many simplifying assumptions, when a country's money supply increases, short-term interest rates will fall in the short run, the exchange rate (in terms of units of domestic currency needed to buy one unit of foreign currency) will rise in the short run, output will rise but perhaps not permanently, and in the long run, overall prices will also rise. The rationale for these effects is that the economy's demand for money depends in the short run negatively on interest rates and in the long run positively on output and overall prices. In the short run, interest rates will fall in order to raise money demand to the new level of money supply, and as a result, the price of foreign currency will rise. In the long run, nominal income   which is the product of output and the price level   will rise. Other things being equal, the increase in nominal income will cease when money demand has increased sufficiently to match the initial rise in money supply. Interest rates and exchange rates will return to their previous levels.

This simple scenario becomes more complex once we consider the dynamics of interest rate and price adjustments between the short run and the long run. In the medium run, the fall in interest rates as well as the increased availability of money for spending will cause macroeconomic demand to increase. This will induce more output   that is, more production of goods and services. The rise in the exchange rate will also increase foreign demand for the country's exports, which will induce a further increase in output. Whether this output increase is temporary or permanent will depend on whether inputs   so-called "factors of production" like labor and capital   are already fully employed. If workers are unemployed and factories are operating at less than full capacity, output can increase permanently. Otherwise, the effect of an increased money supply in the long run is simply to raise prices.

More realistically, we should consider increases in the rate of growth of the money supply, rather than simply its level. In the short run, until factors of production are fully employed, increasing monetary growth increases the rate of increase of output. In the long run, increasing monetary growth increases the rate of increase of prices   that is, it increases the inflation rate   rather than the level of prices per se. Long-run interest rates, which rise with expected inflation, will also rise.

Money Supply in an Open Economy The causes and effects of increased monetary growth are radically modified once we open an economy to inflows and outflows of capital from abroad. If the exchange rate is fixed and foreign currency can readily flow into and out of the country, interest rates will not fall except in the very short run. This is simply a manifestation of the "impossible trinity" mentioned earlier. Any attempt by a central bank to increase monetary growth will result in a small and short-lived decrease in short-run interest rates that will cause foreign currency to flow out until the increase in monetary growth is reversed. Since the central bank is committed to a fixed exchange rate, it will sell enough foreign currency to accommodate the outflow, and in the process it will buy domestic currency,

thereby taking it out of circulation. Interest rates (risk adjusted) will remain unchanged, at "world" levels.

Finally, it is important to understand the effects of the money supply on the exchange rate if it is *not* fixed by the central bank. Briefly, if and when an economy's factors of production are fully employed, a permanent increase in monetary growth will, in the long run, increase the nominal domestic-currency value of foreign currency but leave the "real" value unchanged. A permanent increase in monetary growth is accompanied by a permanent increase in inflation. The country will gradually price itself out of export markets unless it offers an increase in domestic currency per unit of foreign currency equal to the increase in its inflation rate minus any increase in its trading partners' inflation rates. This leaves the "real" exchange rate unchanged.

In short, the rate of growth of a country's money supply is the crucial determinant of its long-run inflation rate. It is also a determinant of short-run interest rates, short-run exchange rates, and short-run rates of output growth. Whether central banks can or should attempt to control short-run interest rates, exchange rates, and output growth by manipulating money supplies is a matter of both theoretical and policy controversy. Indeed, the controversy is moot for central banks that are committed to fixing their exchange rates, since in a world with globalized capital flows they simply have little or no control over their own money supplies.

■ monopolistic competition

Most products in the world, even standard com modities such as oil and wheat, are naturally differ entiated because nature is not uniform. But such generic differentiation is quite different from the economic heterogeneity that arises from a deliberate investment in a location, patent, plant, process, or personnel. One must think of the firm as purchasing the differentiation with some sort of investment of fixed resources. This gives rise to monopolistic competition, because other firms can produce a similar or even identical variety at a different location with a high degree of substitution for the original variety. This means that there is free entry but also some degree of monopoly power for each firm. The prototypical example of a differentiated product in international trade is the automobile. Indeed, one can think of the auto industry as monopolistically competitive, with free entry by conglomerate firms such as Toyota, General Motors, Nissan, Mercedes-Benz, and Ford into various segments of the motor vehicle market, such as sport utility vehicles and sport cars. Since an aggregation of customers in every country demands all or most of the varieties offered on the world stage, intraindustry international trade

is the major consequence. In most advanced coun tries, intraindustry trade constitutes more than 50 percent of exports and imports.

Models of Monopolistic Competition The the ory of monopolistic competition was developed in dependently in the 1930s by Robinson (1933) and Chamberlin (1933). This model is strictly partial equilibrium and involves free entry with firms pro ducing output levels that are short of the optimum scale, with the higher costs of production viewed as the cost of variety. To apply the model to interna tional trade, theorists have been quite explicit about tastes, costs, and resources. The most realistic model, offered by Lancaster (1979), assumes heterogeneous consumers with each choosing a preferred variety. This approach, however, is complex because it in volves the distance of each consumer's favored variety from the next best variety to that consumer. Conse quently, the most popular approach has been to as sume a representative consumer who buys some of each variety offered by an industry. This follows the pioneering paper by Dixit and Stiglitz (1977). Dixit and Norman (1980) and Krugman (1979, 1981) applied the Dixit-Stiglitz model to international trade in a way that has now become standard.

In a world of perfect competition, there are gains from trade because a country can import things that would otherwise be produced at home at a higher cost. The gains from trade under monopolistic competition need not be from comparative advan tage, but rather from achieving greater variety and/or lower costs for those differentiated goods. With dif ferentiated products and free entry, the larger market from international trade allows each country to ex ploit economies of scale for some selected products but at the same time give consumers even greater variety from other countries.

The basic idea of the model of monopolistic competition is simple: abstract completely from comparative advantage and make the simplest as sumptions regarding preferences and costs. Thus it is assumed that all products are produced by labor alone, as in the Ricardian trade model, but each va riety has exactly the same production function. Thus

consider the set of products to belong to an industry in which all the varieties are close substitutes. This can easily be captured by a constant-elasticity-of-substitution utility function, $u = \left(\Sigma c_i^a \right)^{1/\alpha}$. With this utility function for each consumer, each variety, regardless of how many, faces the same demand at the same price. As in standard trade models, there is full employment and adjustment costs are ignored in the interests of focusing on the long run. Finally, to capture the features of monopolistic competition, products are always produced under economies of scale and there is free entry and exit of firms. Under these conditions, each firm will be identified with a unique product. Two or more firms could not produce a unique variety unless the average cost curves were U-shaped, which is ruled out by assumption.

Understanding monopolistic competition involves two concepts: economies of scale caused by the fixed costs of setting up a new variety of a particular product, and the elasticity of substitution between the varieties of a certain generic product. The elasticity of substitution between X and Y is simply the percentage increase in the relative demand for good X, defined as X/Y, caused by a 1 percent change in the relative price of good Y, defined by the price ratio p_y/p_x. The higher the elasticity of substitution between two products, the higher the numerical value of elasticity of demand for each of the products. Generally speaking, such a numerical elasticity of demand for good X will be somewhat smaller than the elasticity of substitution, because when the price of good X falls, causing a greater quantity of good X to be demanded, people will buy less of good Y, which increases the elasticity of substitution over the elasticity of demand (because X/Y increases more than X). The more varieties of a single product that exist, of course, the closer the elasticity of demand for any variety will be to its elasticity of substitution with other varieties.

The economics of monopolistic competition is straightforward. Consumers have a love for variety that is reflected in the elasticity of substitution. The higher the elasticity of substitution, the *smaller* the love for variety. With an infinite elasticity of substi-

tution, consumers would be indifferent between the two products: essentially no love for variety. The greater the love for variety, the smaller the elasticity of substitution and, therefore, the smaller the elasticity of demand. But the smaller the elasticity of demand, when firms have control over the price, the higher the markup over marginal cost. Thus the love for variety translates into greater potential profits for introducing a new variety. But this comes into conflict with the fixed cost of introducing the new variety, or the economy of scale. The formula is thus simple: smaller elasticity of demand (greater love for variety) and small fixed costs translate into more varieties of product. Note that the love for variety gives rise to a profit incentive for more variety.

This is where international trade or the size of market comes into play. The larger the market, which is what international trade represents, the less important are fixed costs or economies of scale as an impediment to more varieties of product. Thus international trade results in more varieties being produced, but also more of each variety. When trade opens, the producers of existing varieties find their profits increasing, thus giving an incentive for new firms with different varieties to enter. Consumers are better off because they have more varieties to choose from at lower prices.

Following Dixit and Stiglitz (1977) and Krugman (1979, 1981), the model can be described by just three equations if we assume that all varieties face the same demand and costs: a profit-maximizing equation that is the same for each variety, marginal revenue (MR) equal to marginal cost (MC); a free entry equation, the same price (p) equal to same average costs (AC) for each variety; and a full employment equation, the supply of labor (L) equal to demand, which is simply the number of varieties multiplied by the same labor demand of each variety. Labor is the numéraire, so the wage rate is unity. Let $F =$ fixed costs in terms of the amount of labor required to produce any particular variety, and $c =$ marginal costs in terms of how much labor is required to produce another unit of any variety, which we assume to be constant. If $x =$ the output of each firm,

the $AC = F/x + c$. Each firm will charge a price p that is a markup k over marginal costs. The equilibrium price, p, the output of each firm x, and the number of varieties, n, are then determined by:

$$p = kc \qquad (1)$$

$$p = F/x + c \qquad (2)$$

$$L = n(F + cx) \qquad (3)$$

The markup in equation (1) decreases if there are more varieties. The second equation (2) represents free entry. The last equation (3) is for full employment of the labor resources devoted to the industry. Even though there are three equations, we can represent the model by a diagram with only two variables, the price of each variety and the number of varieties. This is because the last two equations can be used to eliminate x, and to write

$$p = c[(n/L - nF) + 1] \qquad (4)$$

as a substitute for (2) and (3). This equation shows free entry as well as the average cost of production as an increasing function of the number of varieties.

Equations (1) and (4) are shown in figure 1. The curve PP is the price equation (1), which shows that the price of each variety falls as more varieties are produced because individual firms face more competition from substitutes and must lower their prices to maximize profits. The cost equation (4) is CC (ignore the C*C* and C°C° for the moment). It is upward sloping because an increase in the number of varieties, for any labor supply, must reduce the output of each product. But with economies of scale, average costs must then rise so that the free entry price must rise. The equilibrium, a, is the autarky solution for the country in question.

The model is intuitively straightforward. What happens if there is an *increase* in L? This will initially shift all demand curves for the existing n varieties proportionately to the right, without affecting the elasticity of demand at the initial price. Now new firms enter because profits are positive, and this forces all firms to lower p until all profits are again eliminated. Each firm moves down its AC curve and more of each variety is produced, both the old ones and the new ones. With a lower price and more varieties, per capita well-being must increase.

This tells us what happens with international trade. Suppose there are two countries, Home and Foreign. Assume Home and Foreign are identical in all respects but the labor force L, where the foreign L* exceeds home L. In figure 1, PP is the same; but with Foreign being larger than Home, C*C* for the foreign country must lie to the right of CC for the home country since a larger number of varieties is compatible with the same costs. This is clear from equation 4. With free trade and zero costs of transferring goods, the world economy works like one large economy. The cost curve for the world economy is C°C°, which lies to the right of the foreign C*C*. We can see in figure 1 but also by general reasoning that the free trade level of output for each firm will exceed
Figure 1

A model of monopolistic competition

the autarkic levels simply because the price of the variety is smaller. But each country will produce a smaller number of varieties because with the same labor force, the only way full employment can be maintained with a larger output of each variety is to reduce the number of varieties produced compared with the number of varieties produced under autarky. Note that with free entry and exit which varieties are produced by which country cannot be determined. To the extent that comparative advantage is not involved, the pattern of trade is indeterminate. When economies of scale are involved, who exports what can be determined by the accident of history.

Now it should be clear that the smaller of the two countries will gain the most from international trade. This is because the price will fall more in that country and the number of varieties will increase. This is clear from the vertical axis of figure 1 and the comparison of the free trade solution at point w with the autarky solution at point a. This is a much stronger theorem in the model of monopolistic competition than in the analogous Ricardian theorem (Ruffin 1988). In the Ricardian model, the result depends on there being only two countries. With more than two countries, the Ricardian result can vanish because the smallest country could have a comparative advantage in between the comparative advantages of the larger countries. But this will never be the case in the present model.

Clearly, this model gives us an explanation of intraindustry trade because in each country all varieties are consumed. All trade is intraindustry in this model because there are no comparative advantages for any industry. Krugman (1981) and Dixit and Norman (1980) show that we can combine intraindustry trade with comparative advantage in a simple way by assuming two such monopolistically competitive industries, but with immobile specific labor assigned to each. Countries can now be defined as having different relative quantities of specific labor, say L_1 and L_2. This allows us to examine the interaction between comparative advantage and intraindustry trade.

Since the price of every variety in this simplified case is the same, we can measure the total output of the industry i as simply the labor supply devoted to that industry divided by the price of the product, p_i, *because if labor is the numéraire, the price of the variety is the amount of labor used in a unit of the product. Thus:*

$$Q_i = L_i / p_i \qquad (5)$$

Since in free trade $p_i = p_i^*$, it follows from equation 1 that

$$Q_i / Q_i^* = L_i / L_i^* \qquad (6)$$

In other words, the relative size of an industry across countries exactly reflects the relative amounts of industry resources across countries. Now if $L_1/L_1^* > L_2/L_2^*$, the home country will on net export commodities in industry 1 and import commodities in industry 2. It should be clear that the greater the difference in factor endowments between countries, the larger the volume of interindustry trade and the smaller the volume of the intraindustry trade.

Thus this simple model can explain why a country such as Japan or Australia would have a much smaller amount of intraindustry trade than the United States or any of the European countries. Japan has a much smaller relative endowment of land and Australia a much larger relative endowment of land than the rest of the world, leading to more interindustry trade because Japan must import more raw materials and Australia must export more primary products.

Intraindustry trade enhances the gains from trade through better exploitation of economies of scale rather than through comparative advantage as trade leads countries to concentrate on a limited number of varieties within any particular industry. This leads to an expansion of world output because of the saving of fixed costs.

As Adam Smith himself observed, specialization within industrial categories may also stimulate innovation more than specialization in primary products such as wheat, oil, and copper. A manufactured good often suggests its own shortcomings or new varieties to the human imagination. Producing a greater variety and number of goods

increases our general knowledge about technology, and greater knowledge implies smaller costs of knowledge accumulation. This has led to the theory of endogenous growth, which augments the model of monopolistic competition with a dynamic structure in which consumers maximize over an infinite horizon and firms innovate to make a profit in such a way that there is still a free entry equilibrium. In this free entry equilibrium, arbitrage profits cannot be made by selling the firm and investing the proceeds. Endogenous growth occurs because every new variety lowers the cost of future new varieties (Grossman and Helpman 1991; Ruffin 1994).

The role of monopolistic competition in international trade is to show how intraindustry trade can arise even in the absence of comparative advantage, and to demonstrate how the gains from trade result from both lower prices and more variety. The model also provides a framework for studying innovation and growth in the world economy.

■ multilateral environmental agreements

Since 1933, hundreds of agreements have been negotiated among sovereign nations to protect natural resources and the environment. The United Nations Environment Program (UNEP) (2004) identifies the first multilateral environmental agreement (MEA), dating to 1933, as the Convention Relative to the Preservation of Fauna and Flora in Their Natural State. From 1940 until 1960, UNEP lists an additional 23, including the International Convention for the Regulation of Whaling (1946), the International Convention for the Protection of Birds (1950), the International Plant Protection Convention (1951), and the Antarctic Treaty (1959).

Since 1960, hundreds more have proliferated. Among the most well-known are the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES 1973), the UN Convention on the Law of the Sea (1982), the International Tropical Timber Agreement (1983, amended 1994), the Montreal Protocol on Substances That Deplete the Ozone Layer (1987, 1990, 1992, 1997), the Rio Convention on Biological Diversity (1992), the Kyoto Protocol to the UN Framework Convention on Climate Change (1997), the Basel Protocol on Liability and Compensation for Damage Resulting from Transboundary Movements of Hazardous Substances and Their Disposal (1999), and the Cartagena Protocol on Biosafety to the Convention on Biological Diversity (2000).

Even this small sample of MEAs presents a legal, jurisdictional, and monitoring thicket. Many different international institutions and groups are empowered with implementation and oversight of these agreements, including more than a dozen agencies in addition to UNEP in the UN alone. Apart from the problem of the internal coherence of the many MEAs, throughout the 1990s these agreements were often at odds with other international obligations forbidding restrictions on the free flow of goods and services in international trade, setting up the "trade and environment" debate (Runge 1994, 2001). The World Trade Organization (WTO) and its predecessor, the General Agreement on Tariffs and Trade (GATT), were criticized for undermining environmental obligations under MEAs, as several celebrated cases brought attention to the potential for conflict.

Perhaps the most famous were the pair of "Tuna-Dolphin" disputes in the 1990s, in which environmentalists argued that the GATT articles had been used to overturn a U.S. embargo on tuna harvested by Mexico and other countries using nets that also killed dolphins as by-catch. In imposing the embargo, the United States argued that such fishing methods violated the U.S. Marine Mammal Protection Act (MMPA). The U.S. embargo was overturned by a GATT panel decision in 1994, which concluded that it violated GATT prohibitions on quantitative restrictions to trade and that the MMPA did not qualify for exemptions granted under GATT Article XX(g) "relating to the conservation of exhaustible natural resources."

This infuriated parts of the environmental community, which saw GATT and later the WTO poised to strike down many trade sanctions designed to protect natural resources authorized under both domestic legislation and MEAs.

In 1994, partly in response to this furor, the WTO established a Committee on Trade and Environment (CTE) to respond to these questions. However, as Esty noted, the CTE "has failed to make any policy recommendations of consequence" (Esty 2003). Furthermore, the balance between MEAs and the WTO has been a continuing source of anxiety in environmental circles. In general, analysts have concluded that MEAs lack the coherence, reach, and financial backing of the WTO, leaving them vulnerable to challenge when they attempt to use trade barriers, sanctions, or embargoes as mechanisms of compliance: "Judged in terms of size and teeth," one analyst wrote, "we might regard the WTO as a large tiger and MEAs as a ragged collection of small cats" (Eckersley 2004, 24). This comment is qualified by the observation that there are hundreds of such cats, the herding of which is increasingly difficult.

First, can the tension between MEAs and the WTO be dealt with under existing institutional arrangements? Second, what alternative arrangements might remedy these tensions and provide greater

clarity and coherence to the large number of MEAs? Third, how might these alternatives be approached and successfully implemented in the years ahead?

MEAs and the WTO: Which Way Out? The asymmetrical relationship between the WTO and the multifoliate pattern of MEAs arises from both the structure and content of each set of norms. The structure of the WTO that emerged in the Uruguay Round after nearly 50 years operating under the GATT articles was first developed in the 1947 Havana Charter. In many ways, in 1995 the WTO achieved a vision of an International Trade Organization conceived after World War II as one of three international economic foundations (including the World Bank and International Monetary Fund) to buttress the global economy and resist a return to the beggar-thy-neighbor trade policies of the interwar years. Then, as now, such institutions induced anxiety among those who saw an international trade authority as a threat to national and even intranational sovereignty. In the 1990s, this anxiety extended to national and subnational environmental protection. Whereas the current structure of WTO rules is considered relatively "hard" law in dispute resolution, MEAs are much "softer." And although the contents of MEAs are often tested for consistency with trade rules, trade rules are seldom challenged as inconsistent with MEAs. The result is to discourage the development and implementation of new and existing MEAs and to reinforce their subservience to the trade regime.

There is doubt, given this asymmetry (which many in the trade community consider appropriate), whether a more balanced relationship can be achieved under existing institutions. A number of institutional "fixes" have been proposed. One is to amend GATT Article XX, pertaining to exhaustible natural resources and other exceptions to the rules of nondiscrimination, to better account for MEAs (Nissen 1997). Some precedent for this is reflected in exceptions (article 104) to the North American Free Trade Agreement (NAFTA) for three specific MEAs: CITES, the Montreal Protocol, and the Basel Convention. A less incremental but more direct approach would be to create a new WTO agreement dedicated

specifically to MEAs (Brack and Grey 2003, 36). This could define the general scope of MEAs, the possible use of specific trade measures to enforce or implement their environmental objectives, and criteria for making more nonspecific measures consistent with Article XX. A third proposal, advanced by Switzerland in a submission to the CTE in 2000, would create a clear division of responsibility between the WTO and MEAs, defining their respective trade versus environmental competency. The WTO's responsibility would extend to questions of trade discrimination and disguised protection, while the MEAs' responsibility would be determining environmental objectives and "choosing the means, instruments, mechanisms and measures necessary to achieve these objectives" (CTE 2000, 2). Such an agreement would reduce the asymmetry between trade and environmental measures by asserting the absence of hierarchy and the importance of mutual support and deference.

There is, however, considerable mutual suspicion and derision between the trade and environmental communities resulting from the trade/environment battles of the last two decades. This has led a number of authors to propose the less incremental and more sweeping creation of a World Environment Organization (WEO) (see also Biermann 2000; Esty 2000; Runge 2001).

The WEO Alternative In the early 1990s, transnational environmental policy challenges led to calls for a World Environmental Organization (WEO). By 2000, support extended from the French prime minister Lionel Jospin and president Jacques Chirac to the former WTO director general Renato Ruggiero, the *Economist* magazine, and others. The argument for a WEO arose primarily from those who felt that the WTO system was ill-equipped to respond when trade questions intersected with environmental issues, including MEAs. Apart from trade/environment conflicts, however, the anarchy of the MEA arrangement also suggested a need for better-coordinated multilateral responses to transnational environmental issues even if trade was largely unaffected. In other words, whether or not the WTO could be "greened," international environ-

mental challenges clearly required their own multilateral responses, and these responses required greater coherence and consistency. Just as the GATT/WTO system had evolved out of growing *commercial* interdependence following World War II and had helped to foster a set of rules by which the trade game should be played, so *ecological* interconnections created the need for a more unified set of global environmental rules. The parallelism of trading rules and environmental rules arose from the fact that interdependent states could not cope with commercial *or* environmental challenges solely through unilateral or ad hoc solutions. Moreover, the coexistence of multilateral trade and environmental rules gave rise to the questions of priority and consistency noted earlier.

A prototype for such an overarching institution arose from the environmental side agreement to NAFTA. In late 1993, NAFTA was ratified by the U.S. Congress, together with provisions that would create the North American Commission for Environmental Cooperation (CEC), headquartered in Montreal. By late 2007, the CEC had survived more than a decade of service, although it remained underfunded and often unsupported by the governments of Canada, Mexico, and the United States. Despite its small size, the CEC's mandate extended beyond the trade effects of NAFTA on the environment to include an array of transborder ecological issues. It also provided for a dispute settlement mechanism for environmental questions. From a legal perspective, the CEC derived from an executive agreement, which "steers clear of the normative realm and concerns itself with things institutional, primarily because it is the product of an intergovernmental process between entities that each want to set their own standards" (Johnson and Beaulieu 1996).

The basic design of a WEO modeled on the CEC would be the creation of a Secretariat and a Multilateral Commission on Environment. The Secretariat would be the formal, ministerial-level body of government representatives, meeting periodically to affirm certain policies. The commission would be a policy-oriented group of environmental experts drawn from nongovernmental organizations (NGOs), academia, business, and government. Although the representatives to the WEO Secretariat would, like WTO representatives, be government officials, expert environmental and business involvement, similar to the International Labor Organization (ILO), could occur via the commission. The commission would thus be composed of a standing group of environmental experts and government and business representatives from all member counties. Its meetings would be open to the public and would allow worldwide access to the data and analysis underlying its work. The primary focus of this work would be to propose ways to harmonize national environmental standards and MEAs, while carefully considering the technical issues and problems of this process. This task would resemble in some respects the technical harmonization of food and safety requirements under the Food and Agriculture Organization affiliated Codex Alimentarius. The process would allow for public comments from any group, governmental or nongovernmental, opening the WEO to full public participation and review.

The Years Ahead The CTE's limited terms of reference clearly suggest that the WTO does not care to bring order to MEAs, except insofar as they impinge on trade rules. This substantial institutional gap can be filled by a WEO dedicated to transnational environmental challenges that may or may not have direct linkages to trade, but which have given rise to the crazy-quilt of MEAs.

Until such an overarching structure is articulated, two fundamental questions will challenge MEAs, individually and collectively. First, if MEAs involve explicit trade measures or sanctions, they will be subject to continuing challenges under the WTO. Second, the hundreds of existing MEAs, and those that may be negotiated in the coming decades, cannot be adequately managed without linking them to an overarching set of norms. In the short to intermediate term, waivers to WTO rules have been proposed for some MEAs, renewable over regular time intervals. The presumption that trade ministers should vet each MEA, however, would seem to place them in regular and recurring judgment of

environmental policy measures, a position which they evidently prefer to avoid.

Over the longer term, there appears to be a clear need for the overarching role of a WEO Secretariat to coordinate disparate environmental efforts and MEAs and function as a go-between and buffer relating MEAs or other environmental policies to the WTO system. MEAs (and national environmental programs) designed to minimize trade-distorting effects and advance market-based environmental initiatives such as trading schemes could contribute to this institutional oversight. When obvious conflicts between MEAs and WTO rules arose, a WEO could help to prepare sound arguments in favor of an Article XX exception, based on the necessity of trade measures in an MEA, a waiver if deemed appropriate, or some other GATT-legal "window" allowing an exception for the environmental measure.

An even more significant function might be the consolidation of claims made under myriad environmental agreements into a unified dispute settlement process, in which NGOs and other interested parties could participate. Precisely because an independent entity such as WEO is lacking, a greater temptation exists to use trade measures to enforce environmental obligations. Trade interests may condemn the use of such measures for environmental goals, but in the absence of effective multilateral environmental rules and an overarching entity such as the WEO, environmentalists may claim that they have no recourse. Although it is naïve to imagine that these two realms of policy can be entirely disjoint, the creation of a WEO would assist in separating many issues that do not need to be in conflict. The weaker the perceived ability of environmental groups to influence international policies, however, the greater their incentive to use "linkage" destructively: to threaten the trading system in order to gain environmental concessions.

■ **multilateral trade negotiations**

Broadly defined, a multilateral trade negotiation is any trade negotiation occurring between more than two countries. However, since the advent of the General Agreement on Tariffs and Trade (GATT) in 1947, the term has come to refer specifically to the periodic negotiating "rounds" (meetings) conducted under the auspices of the GATT and successor, the World Trade Organization (WTO). There have been nine such rounds since 1947, with the most recent—the Doha Round—not yet completed as of 2007. The purpose of these rounds is to reduce barriers to international trade and establish or modify rules of conduct for trade policy. What distinguishes them as multilateral is that participation is open to all member countries and the results generally apply to all members on a nondiscriminatory basis. As each successive round builds on the results of the one before, the GATT/WTO system evolves, as both the product of multilateral trade negotiations and the framework in which the negotiations are conducted.

Basic Concepts and Terminology Throughout history, countries have sought to obtain access to foreign markets for the goods and services they export, while protecting their own domestic markets from foreign competition. This behavior is reflected in the terminology of trade negotiations. If a country lowers one of its tariffs or otherwise opens its market to imports from another country, it is said to have granted a "concession" to that country. Trade negotiators view receiving a concession as beneficial and granting a concession as costly, though the magnitude of the benefits and costs may vary from sector to sector. The mutual exchange of concessions of roughly equal value is known as "reciprocity."

Both economic theory and ample empirical evidence have shown that, in general, concessions produce welfare benefits to the affected exporting countries that outweigh whatever welfare costs are experienced by the importing country granting the concession, provided the concessions are nondiscriminatory, that is, provided the concession is granted to all exporters. This suggests that if all countries exchange concessions on a reciprocal and nondiscriminatory basis, then all stand to benefit. This insight is at the heart of multilateral trade negotiations. Indeed, the stated purpose of the GATT is to raise incomes, employment, and growth "by entering into reciprocal and mutually advantageous arrangements directed to the substantial reduction of tariffs and other barriers to trade and to the elimination of discriminatory treatment in international commerce" (Preamble of the General Agreement on Tariffs and Trade, 1947).

Pre-GATT Trade Negotiations Prior to the GATT, countries negotiated trade agreements on a bilateral basis. Two countries interested in expanding trade with each other would meet and negotiate reductions in trade barriers, usually tariffs, on a more or less reciprocal basis. Early trade agreements negotiated in this way were relatively few in number, short in duration, and usually discriminatory (i.e., concessions applied only bilaterally). This changed substantially in the mid-19th century, however. A surge in global trade, fueled by the industrial revolution and technological improvements in transportation and communications, coincided with changes in the political and intellectual landscape in favor of freer trade. Many countries responded by opening their markets, both unilaterally and through bilateral agreements.

The most important bilateral agreement of the period was the Cobden-Chevalier treaty of 1860 between the United Kingdom and France, which cut

tariffs between two of the largest trading nations of the time. It also included the most-favored-nation (MFN) clause, under which both countries committed to giving each other the best treatment they offered to any other country. This had the effect of guaranteeing that neither country would discriminate against the other in any subsequent agreements they might negotiate with other countries. A wave of bilateral MFN agreements followed, as countries rushed to avoid being the victims of discrimination, so that by 1870, almost all major traders were involved in a web of nondiscriminatory bilateral agreements.

The successful bilateral trade regime of the 19th century was suspended during World War I and suffered a series of setbacks until the end of the World War II. The most notable setback was a global trade war touched off by the U.S. Smoot-Hawley Tariff Act of 1930. Four years later the United States attempted to reverse the slide toward protectionism with the passage of the Reciprocal Trade Agreements Act (RTAA), which gave the president wide latitude to negotiate bilateral reciprocal trade agreements on an MFN basis. Although this effort to revive the bilateral system was cut short by World War II, many of the concepts, rules, and procedures of the RTAA were subsequently incorporated into the GATT after the war.

Negotiations in the GATT Era In 1946, the United Nations, responding to a proposal from the United States, established a preparatory committee to draft a charter for an International Trade Organization (ITO). The ITO was meant be a multilateral trade organization with open membership, founded on the principles of reciprocity and nondiscrimination, to serve as the trade counterpart to the organizations set up by the Bretton Woods conference of 1944 the International Monetary Fund and the World Bank. At its first meeting in London, the preparatory committee established procedures for conducting multilateral trade negotiations, which were put to use at a meeting held in Geneva in 1947 involving 23 countries: Australia, Belgium, Brazil, Burma, Canada, Ceylon, Chile, the Republic of China, Cuba, the Czechoslovak Republic, France, India, Lebanon, Luxembourg, Netherlands, New

Zealand, Norway, Pakistan, Southern Rhodesia, Syria, South Africa, the United Kingdom, and the United States. The countries exchanged concessions in the form of tariff "bindings" maximum limits on tariff levels covering thousands of manufactured products. They also agreed that all signatories should grant one another MFN status, and they drafted a set of general rules on the use of other trade-related policies, such as subsidies and quantitative restrictions, to ensure that countries did not circumvent their tariff obligations. The concessions and rules together constituted the General Agreement on Tariffs and Trade (GATT), and the Geneva meeting became known as the first GATT round. The GATT was supposed to be incorporated into the ITO Charter. Although the charter was finally completed in Havana in 1948, it was never ratified, however. Thus, the GATT emerged as the basis of the multilateral trading system.

Subsequent rounds of multilateral trade negotiations were held in Annecy, France (1949), Torquay, United Kingdom (1950), and Geneva (1956). After this, rounds were given names: the Dillon Round (1960 61) was named after the U.S. undersecretary of state C. Douglas Dillon, the Kennedy Round (1963 67) after the U.S. president, and the Tokyo (1973 79) and Uruguay (1986 94) Rounds after the places where they were launched. The Doha Development Round, so named because issues of developing countries were supposed to be high on the agenda, was launched in Doha, Qatar, in 2001. A summary of these rounds is found in table 1.

Subjects and Modalities At the beginning of each round, the participating countries convene to decide on the subjects to be negotiated and the "modalities" the rules and procedures for conducting the negotiations. In the first five GATT rounds, the primary subjects were tariff concessions on manufactured products and the accession of new members. New members are required to negotiate tariff concessions and other terms with existing members prior to their entry. In the Kennedy Round, the scope of the negotiations was broadened to include concessions on nontariff barriers to trade in manufactures. The Tokyo Round continued this

Table 1
GATT/WTO rounds, 1947 2007

Name of round or meeting	Period	Number of parties	Subjects and modalities	Results
Geneva	1947	23	Tariffs: item by item request offer negotiations	Concessions covering 15,000 tariff lines
Annecy	1949	33	Tariffs: item by item request offer negotiations	5,000 tariff concessions; 9 accessions
Torquay	1950	34	Tariffs: item by item request offer negotiations	8,700 tariff concessions; 4 accessions
Geneva	1956	22	Tariffs: item by item request offer negotiations	Modest reductions
Dillon Round	1960 61	45	Tariffs: item by item request offer negotiations.	4,400 tariff concessions.
Kennedy Round	1963 67	48	Tariffs: formula approach (linear cut) and item by item negotiations. Nontariff measures: anti dumping, customs valuation	Average tariffs reduced by 35%; 33,000 tariff lines bound; agreements on customs valuation and anti dumping
Tokyo Round	1973 79	99	Tariffs: formula approach with exceptions. Nontariff measures: anti dumping, customs valuation, subsidies and countervail, government procurement, import licensing, product standards safeguards, special and differential treatment of developing countries	Average tariffs reduced by one third to 6 percent for OECD manufactures; voluntary codes of conduct agreed for all nontariff issues except safeguards
Uruguay Round	1986 94	117	Tariffs: formula approach and item by item request offer negotiations. Nontariff measures: all Tokyo issues, plus services, intellectual property, preshipment inspection, rules of origin, trade related investment measures, dispute settlement, transparency and surveillance of trade policies	Average tariffs again reduced by one third; agriculture and textiles and clothing subjected to rules; creation of WTO; new agreements on services and TRIPs; majority of Tokyo Round codes extended to all WTO members
Doha Round	2001	150	Tariffs: formula approach and item by item request offer negotiations. Nontariff measures: trade facilitation, rules, services, environment

trend and added voluntary codes of conduct on various trade-related policies. The Uruguay Round expanded into the areas of agriculture, services, intellectual property, and trade-related investment measures.

Elaborate modalities have been developed for the negotiation of concessions on market access. The first five rounds used the procedure known as the item-by-item, request-and-offer method. Under this method, each participating country simultaneously submits a "request list" to each of its trading partners. A request list is a list of concessions (products and tariff cuts) that the country requests from its trading partners. Each trading partner responds with an offer list, a list of concessions that the country is willing to make. Each participating country has full flexibility on granting concessions on individual products and is free to refrain from concessions on any item. Moreover, countries may request concessions only on products for which they are among the largest suppliers to the countries from which the concessions are asked. This is known as the "principal supplier" rule. The reason for this rule is that all concessions in GATT negotiations must be made on an MFN basis, which means that they must be extended to all GATT members. If a small supplier were to request a concession, then to grant that concession would imply that most of the benefit, in terms of improved market access, would accrue to countries (the large suppliers) that did not request the concession and therefore would be unlikely to "pay" for it with reciprocal concessions. Countries that receive concessions via MFN without paying for them are free riders. The principal supplier rule is a method for containing the free-rider problem.

The Kennedy Round brought two significant changes in modalities. First, it was agreed that negotiations would center on across-the-board linear tariff cuts. Countries were expected to cut tariffs on all manufactured products by an equal percentage (50 percent was the agreed number) but could submit lists of exceptions. These lists are referred to as "negative lists" (lists of tariffs *not* to be reduced, or reduced by less than 50 percent), as opposed to the "positive lists" (list of tariffs to be reduced) in the

item-by-item approach. The second change was the adoption of special and differential treatment for developing countries. In particular, it was decided that less-developed countries should not be expected to reciprocate tariff reductions made by developed countries. These changes in modalities reflected a growing concern about the unwieldiness of the item-by-item approach as the number of GATT members grew. They also reflected concern among developing countries that trade liberalization would interfere with their development policies and that negotiations based on the principal-supplier rule had put them at a disadvantage.

The Tokyo Round operated with a similar procedure as the Kennedy Round, except that instead of a linear tariff cut, countries used a more complicated formula designed to achieve larger reductions on tariffs that were initially high. This became known as the "formula" approach. The Uruguay Round involved a mixture of the formula approach and the item-by-item approach. Some countries, led by the European Union, used the formula approach with negative lists, while the United States and other countries used the item-by-item approach, submitting positive lists.

Negotiations are normally carried out by representatives from each individual country. However, in some cases, countries join coalitions and negotiate as a group. The most common form of this is the customs union. A customs union is a group of countries with free trade among them and a common external tariff. Examples include the European Union, the South American customs union Mercosur, and many others. Typically they send a single representative to negotiate changes in the common external tariff. Other coalitions will typically form around a common interest in a specific topic. For example, agricultural exporters have created coalitions to make common offers on agricultural tariffs and subsidies. Small countries often create coalitions to gain greater weight in negotiations.

Results Of the first five GATT Rounds, the first was by far the most productive in terms of tariff concessions. It involved on the order of 45,000 concessions on 15,000 tariff lines, covering about

$10 billion worth of trade. Such extensive tariff reductions were not repeated until the Kennedy Round, at which point the GATT had more than twice the number of members. The lack of productivity of the negotiations during the intervening rounds, however, does not mean that trade liberalization was halted. In fact, tariff cuts agreed to by Europe and Japan in 1947 were rendered largely ineffective by quantitative restrictions and exchange controls in those countries, until the late 1950s. As these measures were eliminated on a unilateral basis in the late 1950s and early 1960s, the international trade of these countries soared.

The linear approach to tariff reductions used in the Kennedy Round proved effective, though tariffs were ultimately reduced by an average of only 35 percent, instead of the 50 percent target, and many countries opted out of the linear reduction entirely. This round also produced agreements on customs valuation and anti-dumping. The Tokyo Round achieved similar tariff reductions and added voluntary codes of conduct on subsidies, technical barriers to trade, import licensing, government procurement, customs valuation, anti-dumping, meat and dairy products, and civil aircraft. The Uruguay Round cut tariffs again by a third, created a new organization, the WTO, with a revised organizational structure, and strengthened the dispute settlement system.

The creation of the WTO did not fundamentally change the nature of multilateral trade negotiations; however, it did create additional opportunities for countries to discuss trade policy on an ongoing basis. An important innovation is the Ministerial Conference, which meets every two years. This conference is attended by the top trade representative of each country and is intended to provide direction and political impetus for moving trade negotiations forward. The Doha Development Round was launched at the Doha Ministerial Conference in 2001.

It is fair to conclude that multilateral trade negotiations have played, and continue to play, a key role in shaping the modern world trading system. They have established the general rules and terms that now govern the trade of more than 150 countries and have brought about dramatic, if uneven, reductions in tariffs and nontariff barriers since 1947. Whether they will continue to work as the primary mechanism for trade liberalization in the future is unknown. Increases in membership and greater complexity of the issues under negotiation have made recent multilateral negotiations slow and difficult. Preferential trade agreements, such as customs unions and free trade areas, negotiated bilaterally or among small groups of countries, have been on the rise since the mid-1990s. They offer greater speed and focus than negotiations involving the whole WTO. Whatever the ultimate effect of preferential arrangements, however, multilateral trade negotiations will continue to be important, because they are the only option for addressing trade issues of global consequence.

RODNEY LUDEMA

■ **multilateralism**

With a membership of more than 150 nations in the World Trade Organization (WTO) and a broad mandate covering trade in goods and services, the multilateral trade system has come a long way since its inception in the early postwar years as the General Agreement on Tariffs and Trade (GATT) a provisional treaty that was signed by merely 23 founding member countries (contracting parties).

Under the GATT, member countries agreed to adhere to specific rules and principles relating to goods trade and to participate in periodic rounds of multilateral trade negotiations to lower trade barriers. The Uruguay Round of multilateral trade negotiations (1986 94) created the WTO subsuming the GATT under it and adding two new agreements for the WTO to oversee: the General Agreements on Trade in Services and the Agreement on Trade-Related Aspects of Intellectual Property Rights. Although the WTO is a complex and multifaceted institution, its core purposes are to serve as a forum in which countries reach *agreement* on rules governing their trade policies and on reductions in their trade barriers and to *enforce* these agreements.

It may seem surprising that the theoretical literature on international trade relations does not unconditionally prescribe a multilateral institution to mediate trade relations among nations. Specifically, it is well known that in perfectly competitive contexts, a "small" country maximizes its national welfare by *unilaterally* choosing free trade. This benchmark setting offers no reasons for trade negotiations between countries. When a country is "large" enough to influence prices in international markets, however,

a rationale for trade negotiations emerges. Although the exercise of market power by a large country through the imposition of trade restrictions leads to an improvement in its terms of trade (the relative price of its exportables to its importables) and welfare, global welfare declines. Large countries may therefore find themselves in a "prisoner's dilemma": individually rational behavior leads them to impose trade barriers on one another, even though they would all be better off (relative to this outcome with mutual barriers) by lowering their trade barriers instead (Johnson 1953 54; Bagwell and Staiger 1999). Clearly, negotiations may help to move these countries to the superior outcome with lower trade barriers. It may be noted that domestic political factors may prevent even a "small" country from achieving free trade. Here, too, international negotiations involving reciprocal trade liberalization by partner countries may induce countries jointly to liberalize trade by suitably altering the factors influencing domestic politics and decision making.

The WTO system provides mechanisms in the form of explicit and implicit rules, norms, and principles to increase the incentives for agreements to be reached and for agreements to be enforced. Primary among these are *reciprocity* and *nondiscrimination*. Although *reciprocity* has not been formally defined in the WTO, in practice it calls for a balance of "concessions" to be made by the parties to an agreement. Since the initial trade barriers may be suboptimal to begin with, lowering them may improve welfare, and thus this need not be regarded as a "concession" in the first instance. Nondiscrimination, formally explicated in the GATT (Article I), requires that no member country be discriminated against specifically that imported goods need to be treated equally regardless of country of origin.

In the multilateral system, reciprocity and nondiscrimination alter the incentives for agreement to be reached and for agreements to be enforced. Where trade barriers come about due to countries' exercise of market power, unilateral liberalization may reduce welfare by worsening the liberalizing country's terms of trade. Reciprocal trade liberalization, on the other hand, will allow countries to maintain their terms of

trade while achieving enhanced production and consumption efficiency. When tariffs are determined by domestic political factors, such as the political strength of the import-competing sector, reciprocal liberalization, by improving outcomes for domestic exportable sectors, enhances the prospects for trade liberalization. Note that nondiscrimination can add significant leverage to reciprocity. By ensuring that one country's liberalization extends to all partners, nondiscrimination creates a wider set of reciprocal liberalization obligations. This, in turn, again due to nondiscrimination, creates an even wider set of reciprocal liberalization obligations. Nondiscrimination coupled with reciprocity may thereby create a virtuous circle of liberalization. On the other hand, some argue that nondiscrimination creates "free-rider" problems within the system, since countries not engaging in liberalization of their own nevertheless benefit from the liberalization of others. In practice, however, the scope for free riding is minimized by exercising selectivity and exclusion of goods chosen for liberalization (that is, a country may liberalize trade only in those specific goods that are relevant to a reciprocating partner country and exclude those goods that may be of value to other nonliberalizing countries).

Enforcement of WTO agreements is achieved through a well-specified dispute settlement mechanism that involves a series of steps progressing through consultation between members, adjudication by WTO panels, and adoption by its dispute settlement body. Thus transgressions of WTO agreements require that the affected parties be offered compensation by the transgressor or that they be allowed reciprocally to withdraw "equivalent concessions" (compensation may be preferred, as raising trade barriers in retaliation may be costly for the retaliating country as well).

Nondiscrimination implies that more than one country will be affected by transgression of WTO agreements the withdrawal of equivalent concessions by all of these affected parties increases the costs of violating WTO agreements. Multilateral punishments may also be valuable in sustaining the system and "leveling the playing field" when there are trans-

gressions of WTO agreements on a bilateral basis (discussed later) and when countries are asymmetric in their economic power or vulnerability (Maggi 1999). Thus reciprocity and nondiscrimination acting together play an important role in the enforcement of agreements as well.

WTO agreements provide a number of provisions that allow for temporary, and sometimes even permanent, suspension of previously undertaken obligations. To protect industries against a sudden surge of imports, the GATT permits countries to take "safeguard" actions that are temporary, nondiscriminatory, and transparent (Article XIX). The GATT also allows for anti-dumping duties to be imposed on imports that are being sold at prices lower than costs or lower than prices in the exporter's home market (Article VI). Countervailing duties may be imposed on imports from suppliers who have been "unfairly" subsidized by their governments (Article VI). In contrast to "safeguard" actions, which must, at least in principle, be applied on a nondiscriminatory basis, anti-dumping and countervailing duties are generally country specific. The multilateral retaliation that supports enforcement of agreements in the multilateral trade system is clearly weakened in these cases.

In a significant derogation of the GATT's nondiscrimination principle, member countries are permitted to enter into preferential trade agreements (PTAs) in the form of *free trade areas* and *customs unions* (Article XXIV). Although PTAs are subject to the requirement that trade restrictions imposed by the members of the preferential agreement on nonmember countries will not be more restrictive than before the preferential agreement and a further restriction that the member countries eliminate barriers to "substantially" all trade among themselves, violations of these restrictions abound with the WTO showing limited enforcement ability.

PTAs have rapidly proliferated in recent years, as have uses of nontraditional (and bilaterally implemented) forms of protection such as anti-dumping and countervailing duties. Reining in these significant challenges to multilateralism will require the multilateral trade system to strengthen its

enforcement mechanisms and to revitalize interest in its nondiscriminatory liberalization mechanisms.

PRAVIN KRISHNA

■ multinational enterprises

The multinational enterprise (MNE), also referred to as the multinational corporation, the international corporation, the global firm, or the transnational corporation, is a multiplant firm that controls and co ordinates operations in at least two countries (Caves 2007). Although there is a tendency to associate the control and coordination of an MNE's inter national operations with majority-owned foreign affiliates (undertaken through foreign direct invest ment, or FDI), both control and coordination may be achieved through a minority ownership and in some cases through nonequity means.

Historically, FDI and MNE activity have been synonymous. International and national agencies that maintain and collect data on MNE activity generally define the MNE as a firm that *owns* and controls value-adding operations in more than one country (Dunning 1993). Although FDI is one of the main modes by which MNEs engage in cross-border value-adding activities, the MNE may also control and engage in value-adding activities through nonequity means, such as through co operative agreements and outsourcing, sometimes without de jure ownership of the productive assets but de facto controlling the operations of the nonlegally affiliated operation. Therefore, the use of the term *MNE* as a synonym for FDI is in creasingly inaccurate (Wilkins 2001).

The MNE has traditionally also been regarded as having a distinct "home country" where its head quarters are located and which acts as the command center, providing primary strategic direction for its affiliates in various "host countries," as well as pro viding the primary or core assets on which the affil iates base their operations. Indeed, the home country establishment is referred to as the "parent firm," implying that the home country is at the top of a hierarchy of affiliates or subsidiaries. Furthermore, residents of the home country are assumed to own (and therefore control) the international operations of the MNE. Although most MNEs are still orga nized along these lines, there are a growing number of firms in which ownership and control are spread across several countries, as well as several cases where an MNE may locate its headquarters in a country other than its home country. Furthermore, a number of MNEs have multiple headquarters located in different countries, with strategic control distributed along geographic, product, or functional lines.

The nature, structure, and organization of the MNE has changed considerably since it has become an object of specialist study, and this change has been exacerbated by development associated with the globalization of products, markets, and services, as well as political and economic developments associ-

ated with shifting political hegemonies and economic liberalization (Narula 2003). Thus a more accurate and current definition of an MNE is: a firm that engages in international business activities, has affiliates in more than one country, and whose operations and activities in different locations are actively coordinated by one or more headquarters organizations. Emphasis is placed on the presence of interdependencies between the various economic units in different locations, and their active coordination and control across borders, and not on the ownership structure (Narula 2003).

Significance of MNEs United Nations Conference on Trade and Development (UNCTAD) data indicate that in 2004 there were an estimated 77,135 MNEs worldwide, with 773,019 affiliates of various types (UNCTAD 2006). Although MNEs are often regarded as large, global firms, the majority of MNEs are small and medium-sized enterprises, with relatively small international operations, often concentrated in their home region.

Despite the importance given to MNEs, they do not account for a dominant or even a major share of the world's economic activity. In terms of employment, the world's largest nonfinancial MNEs employed 14.9 million people in 2004. This number represented only 6 percent of total global employment. Despite the relatively small role of MNEs on an aggregate level, the situation differs substantially across countries. MNEs account for less than 5 percent of the total employment in countries such as Japan and Indonesia, but this figure rises to well over 40 percent in countries such as Malaysia, Argentina, and Ireland. The significance of MNEs in terms of sales, value added, and ownership of assets is of similar magnitude. In the United States, value added, exports, imports, and research and development (R&D) by foreign MNEs in 2002 as a percentage of total activity by all private businesses were 5.7, 19.8, 27.9, and 14.4 percent, respectively.

Two characteristics of the operations of MNEs stand out. First, larger MNEs have been found to be concentrated in the more "dynamic" sectors of the economy. Thus even though they play a relatively small role in most economies in terms of the level of total employment, MNEs often play a disproportionately large role in two different types of industrial sectors. They tend to be most active in dynamic sectors typified by high growth rates and the use of new and emerging technologies (e.g., electronics, communication equipment, and industrial machinery), and also in mature sectors where economies of scale, branding, and advertising determine market share (e.g., petroleum products, chemicals, automobiles, food and beverages, and consumer goods). In mature sectors, while the technology underlying these industries may be diffused and codified, capital limitations and marketing capabilities can cause just a few MNEs to maintain a large share of the global market.

A majority of MNE activity is associated with firms from developed countries. As data on value adding and ownership are not readily available in a comparable form for all MNEs, most analyses rely on outward FDI data as a proxy for MNE activity. Approximately 87 percent of all outward FDI stock in 2004 was associated with MNEs whose ultimate beneficiary owner was based in the developed countries. Of the U.S. $1.4 trillion of outward FDI from developing countries, a vast majority some 90 percent is associated with 20 emerging market and transition economies and about 100 MNEs. These trends reflect the strong positive correlation between the level of economic development and the growth of firms from these economies with the technological and organizational capabilities to compete globally with the more established MNEs in world markets (UNCTAD 2006).

History of the MNE The MNE as a cross-border-coordinating, organizational entity (as it is known today) is a relatively new phenomenon that arose toward the end of the 19th century. During the 18th century, the large trading houses (state owned or state sanctioned) engaged primarily as traders, moving natural resources from the developing world to Europe and manufactures in the other direction. Although there were considerable foreign investments abroad, these were mainly associated with long-term capital flows the financing of debts, bonds, and other financial instruments required to support large-scale private and public projects in the

colonies. Firms were *international*, but not *multinational*. International business and economic activity was *extensive* in the sense that the value of goods and capital exchanged was considerable and involved numerous countries and actors. But it was not *intensive*, in that activities were largely not integrated across borders, with the possible exception of the large trading companies and other state-sanctioned de facto monopolies (Held et al. 1999). In addition, where private investments by individuals occurred, these were freestanding companies companies established by investors of a foreign nationality who were located in the host country, but not part of any firm located in the investor's home country. They were not strictly domestic firms, since their capital (and entrepreneurial basis) came from abroad, but they did not represent a direct investment since the foreign-located firm was not a subsidiary of another firm in another country. Jones (1996) notes that such investments were often associated with colonial interests. Indeed, even by 1914, the number of freestanding companies far outnumbered true MNE subsidiaries by a large order of magnitude. Both types of MNEs were predominantly in services and natural resource extraction. Most activities were *trade-supportive* in nature and involved little interdependence.

The first MNEs did not blossom until well into the 20th century, as the concept of large firms did not make its debut until late in the 19th century. The importance of size arose for several reasons, some technological. First, the large firm emerged about the time of the second industrial revolution, which featured innovations associated with mass-production techniques. These innovations particularly benefited more capital-intensive industries that were characterized by economies of scale and scope, such as refineries (both for sugar and petroleum), animal and vegetable oils, chemicals, iron, copper and aluminum (both primary processing and products), and packaging and processing of food products; by standardized machinery; and by the development of large-scale enterprises. Second, developments in transportation and communication made efficiently coordinating far-flung activities much more feasible.

Third, the brief period of free trade that had flourished in the 19th century was replaced after about 1880 by high trade barriers. FDI continued to be dominated by MNEs from the major European colonial powers Netherlands, the United Kingdom, and France and the United States, which was by this time firmly established as the technological and economic hegemon. These four countries accounted for about 87 percent of FDI stock in 1938 (Jones 1996).

Motives for MNE Investment There are four main motives for investment: to seek natural resources, to seek new markets, to restructure existing foreign production through rationalization, and to seek strategically related created assets. The first three represent motives that are primarily *asset-exploiting* in nature: the investing company's primary purpose is to generate economic rent through the use of its existing firm-specific assets. The last is a case of *asset-augmenting activity*, whereby the firm wishes to acquire additional assets that protect or augment its existing created assets in some way.

Typology of MNE Subsidiaries The literature on subsidiary development has greatly expanded over the last 20 years, evaluating the dynamics behind the evolution of subsidiary roles, beginning with the seminal work of Bartlett and Ghoshal (e.g., 1989). The strategic management literature on the role, dispersion, and development of subsidiaries is now well developed (see e.g., Pearce 1989; Birkinshaw and Hood 1998).

The nature of the activities undertaken by a subsidiary and its potential level of embeddedness in the host economy vary according to the level of competence of the subsidiary and the scope of its activities. The typology of subsidiaries can be analyzed according to these two scales. A typical value chain can be viewed from a "level of competence" perspective consisting of "strategic" and "operational" elements. Activities such as sales and manufacturing are operational in nature, while R&D centers and headquarters functions are strategic in nature. In general, strategic elements tend to be located close to locations regarded as important to the MNE. There is a close link between the influence of the subsidiary and the

strategic importance of its local environment. Strategic elements perform a critical role in a network of units, adding value through contributing their own expertise as well as by coordinating the flow of knowledge within the network. Second, there is considerable variation between subsidiaries in the scope of their activities, with certain subsidiaries performing single and specialized activities, and others performing a larger variety and of greater value.

Truncated miniature replicas. As their name implies, truncated miniature replicas are essentially a duplication of the parent firm, although not with the same scale of production and not all components of value adding activity. Typically, they do not undertake basic research but may modify and adapt products originally developed by the parent. Although truncated miniature replicas vary in the extent to which they are truncated, they tend to have a low or medium level of competence. Truncated miniature replicas tend to have an extensive market scope, in the sense that they have a large product range, but supply a limited and isolated market. Truncated miniature replicas tend to have a considerable autonomy in their activities, although the parent company exerts overall strategic control. This means, for instance, that the parent decides new additions to the product range. They are nationally responsive and, apart from a few advantages derived from being part of a MNE network such as lower cost of capital and technology, they are similar to other indigenous firms. Their primary motive is market-seeking and most often associated with import-substituting programs. The parent-affiliate relationship is weakly developed.

Rationalized affiliates. Rationalized affiliates are much more closely integrated into the MNE network. Their operations are motivated by efficiency seeking, aimed at optimizing costs over multiple locations. There is a strategic interdependence between the MNE network and the affiliate. Two types of rationalized affiliates can be distinguished: the rationalized production subsidiary and the world product mandate subsidiary. World product mandate subsidiaries maintain global or regional control over a particular product line or functional area and are designated centers of excellence. That is, strategic activities such as R&D and headquarters functions are included in the affiliate's responsibilities and it exerts control over other affiliates in the same region or worldwide. A rationalized production subsidiary is part of the MNE's global strategy and is engaged in the production of a particular value-adding aspect based on specific competitive advantages of the subsidiary relative to other subsidiaries. Its products are often intermediate goods, or products, or services complementary to other rationalized production subsidiaries.

Single-activity affiliates. Single-activity affiliates are a cross between truncated miniature replica and rationalized production subsidiary. On the one hand, they represent an extreme version of a truncated miniature replica, in that they undertake a single aspect of value-adding activity. On the other hand, such affiliates may in fact be part of a company's rationalized strategy: the comparative advantage of the location is best suited for such activities. These affiliates are not involved in decision making or strategic planning. Such affiliates typically tend to be engaged at the extremes of the value-adding chain. The first type is *trading affiliates*, engaged in trading activities, and, in the limit, in marketing and after-sales service. The second subcategory is *resource-extractive affiliates*, at the other end of the value chain, engaged in acquiring (primarily through extractive activity) scarce or otherwise valuable crude resources, and exporting these raw materials for use in other locations, whether by another affiliate or by an unrelated firm.

There is considerable variation between industrial sectors, individual MNEs, as well as host and home country factors. For instance, in the food and beverages sectors, subsidiaries are organized primarily as truncated miniature replicas. MNEs with greater international exposure and dependence on foreign markets are more inclined toward rationalized production subsidiaries or world product mandates. Subsidiary roles evolve over time, due both to internal, MNE-specific factors and to changing non-firm exogenous developments, including liberalization of markets and regional integration.

The changing external environment inevitably induces some changes in subsidiary roles. Once an MNE rationalizes the number of subsidiaries or re-organizes the activities across borders, the remaining and/or new units will likely experience changes in scope and areas of responsibility. Increases in scope can typically be found when the number of sub-sidiaries is rationalized or local conditions encourage localization of activities (Birkinshaw 1996). Simi-larly, the scope may be narrowed to focus on specific activities and build expertise within the selected area. Hence changes in scope are often related to both organizational and spatial considerations.

MNEs and Economic Development One of the key features of policy liberalization since the 1980s has been the desire to attract FDI as a means to ac-quire or improve technological capabilities through MNE activity. The role of the MNE as an additional source of capital and technology is one of the key features of this openness. The failure of protected industries in developing and developed countries to become competitive in global markets has high-lighted the limitations of the arm's-length technol-ogy transfer approach. Hence, in recent years, both governments and supranational organizations have increasingly come to focus on the role MNEs and FDI can play in development. This has been ac-companied by a lifting of many types of regulations that previously limited the role of FDI and MNEs.

MNEs have played and are likely to continue to play an important role in the structural upgrading of countries. However, the extent and pattern of these benefits is strongly dependent on the form of eco-nomic and social development desired by the host countries and on the policies of host governments in pursuing these goals. Although not the only means available, MNE spillovers are regarded as one of the most practical and efficient means by which indus-trial development and upgrading can be promoted (Narula and Dunning 2000).

While the *potential* for MNE-related spillovers is clear, as are the opportunities for industrial upgrad-ing therefrom, it is increasingly acknowledged that the nature, level, and extent of the benefits vary considerably. Even where MNEs do seek to transfer knowledge, they prefer to use technologies that are suited (first and foremost) to their own needs and the purposes for which they have made the investment. MNEs tailor their investment decisions to the exist-ing market needs and the relative quality of location advantages, especially skills and capabilities that the domestic economy has a comparative advantage in (Lall and Narula 2004).

Once the decision to enter a given market through FDI is taken, the kinds of activity and the level of competence of the subsidiary are also codetermined by the nature of the location advantages of the host location. While MNE internal factors such as their internationalization strategy, the role of the new lo-cation in their global portfolio of subsidiaries, and the motivation of their investment are pivotal in the structure of their investment, they are dependent on the location-specific resources available for that purpose.

The relative importance of the main motives of MNE investment partly reflects the stage of eco-nomic development (Dunning and Narula 1996). Least-developed countries tend to have mainly resource-seeking MNEs and countries at the catch-ing-up stage mostly market-seeking MNEs. Effi-ciency-seeking investments, with the most stringent capability needs, will tend to focus on the more in-dustrialized developing economies (though three or four decades ago they went to countries with rela-tively low capabilities, e.g., the electronics industry in Southeast Asia in the 1970s).

Not all affiliates offer the same spillovers to host economies. A sales office, for instance, may have a high turnover and employ many people, but its technological spillovers will be limited relative to a manufacturing facility. Likewise, resource-seeking activities like mining tend to be capital intensive and provide fewer spillovers than market-seeking man-ufacturing FDI. During import substitution, most MNEs set up truncated miniature replicas of their facilities at home. The extent of truncation, however, varied by host country. The most important deter-minants of truncation   and thus the scope of ac-tivities and competence of the subsidiary   were market size and local industrial capabilities (Dun-

ning and Narula 2004). Countries with small markets and weak local industries had the most truncated subsidiaries, often only single-activity subsidiaries (sales and marketing or natural resource extraction). Larger countries with domestic technological capacity (such as Brazil and India) had the least truncated subsidiaries, often with R&D departments.

With liberalization, MNE strategies on affiliate competence and scope have changed in four ways (Dunning and Narula 2004). First, there has been investment in *new affiliates.* Second, there has been *sequential investment* in upgrading existing subsidiaries. Third, there has been some *downgrading of subsidiaries*, whereby MNEs have divested in response to location advantages elsewhere or reduced the level of competence and scope of subsidiaries. Fourth, there has been some *redistribution of ownership* as the result of privatization or acquisitions of local private firms. In many, but certainly not all, cases this also led to a downgrading of activities.

MNEs are taking advantage of liberalization to concentrate production capacity in a few locations, exploiting scale and agglomeration economies, favorable location, and strong capabilities. Some miniature replicas have been downgraded to sales and marketing affiliates, with fewer opportunities for spillovers. Countries that receive FDI with the highest potential for capability development are those with strong domestic absorptive capacities.

MNEs transfer technology to local firms in four ways: backward linkages, labor turnover, horizontal linkages, and international technology spillovers. Studies of backward linkages have identified various determinants, including those internal to MNEs and those associated with host economies. The ability of the host economy to benefit from MNE linkages has been found to depend crucially on the relative technological capabilities of recipient and transmitter: the greater the distance between them, the lower the intensity of linkages.

Again, MNE motives and strategies matter. Market-oriented affiliates generally purchase more locally than export-oriented firms because of lower quality requirements and technical specifications.

MNEs create more linkages when they use intermediate goods intensively, communication costs between parent and affiliate are high, and the home and host markets are relatively similar in terms of intermediate goods. Affiliates established by mergers and acquisitions are likely to have stronger links with domestic suppliers than those established by greenfield investment — which is a subsidiary that has been established from scratch, as opposed to the acquisition of an existing facility — since the former may find established linkages that they are likely to retain if the linkages are efficient. Linkages vary significantly by industry. In the primary sector, the scope for vertical linkages is often limited, due to the use of continuous production processes and the capital intensity of operations. In manufacturing, the potential for vertical linkages is broader, depending on the extent of intermediate inputs to total production and the type of production processes.

Furthermore, the individual MNE's choice of mode of entry — whether to create a wholly owned subsidiary or engage in a joint venture or minority ownership — plays a significant role in the extent that spillovers and externalities accrue to host locations and firms. For instance, MNEs may be more likely to transfer sophisticated technologies and management techniques to wholly owned subsidiaries than to partially owned affiliates.

MNEs and unrestrained flows of inward FDI may well lead to an increase in productivity and exports, but they do not necessarily result in increased competitiveness of the domestic sector or increased industrial capacity, which ultimately determines economic growth in the long run. FDI *per se* does not provide growth opportunities unless a domestic industrial sector exists that has the necessary technological capacity to profit from the externalities from MNE activity. To put it simply, FDI is not a sine qua non for development (Lall and Narula 2004).

Political Economy, International Regulation, and MNE The role of foreign capital and foreign capitalists — as MNE activity was referred to in the literature prior to the 1950s — has historically been seen with some suspicion, due in part to the association of MNEs with imperialism, consequential

dependent development, and political and economic intervention by the home countries of MNEs on their behalf. MNE activity has often been inhibited as a result of protectionism, techno-nationalism, and the support of domestic industry against the possible negative effects of MNEs on domestically owned firms.

Economic liberalization whether voluntary, imposed as a condition for lending by international institutions, or as a precondition for membership of a regional integration program has led to a sea change in the policies of many countries. However, although policies may have changed, the underlying attitudes have not. The politics of state-MNE relationships have remained strongly associated with national interests, domestic interest groups, and the importance of protecting the state as a political and economic sovereignty. Supranational agreements such as the North American Free Trade Agreement and the agreements that formed the European Union and the World Trade Organization have reinforced, accelerated, and created standardized regulation for economic activity, acting as a virtuous circle with regard to economic integration that had been occurring as a matter of course.

■ multiple currencies

When multiple currencies circulate in a country or region, it is possible to pay for most goods and services there with more than one currency. This entry focuses on government-issued currencies. The entry on *currency competition* discusses the interaction of government-issued money with privately issued monies.

Historically, it has been common for multiple currencies to circulate in a given area. In medieval Europe, for example, and in the United States before the Civil War, coins from many countries circulated side by side. More recently, multiple currencies have circulated in developing countries, notably in South America and Asia, and in some areas of developed countries. In certain parts of England, for instance, most goods and services can be purchased with euros and pounds sterling.

In developed countries, multiple currencies circulate mainly for convenience, to attract or accommodate the business of merchants or tourists. In developing countries in which multiple currencies circulate today, the purpose may be different. The possibility of using dollars or euros protects people in these countries from the cost of inflation of their domestic currencies and provides a way to discipline their monetary authorities.

Benefits of Multiple Currencies Central banks today issue fiat money, or money that is intrinsically worthless and is not backed by an asset or a commodity at the central bank. Fiat money has value because people anticipate that others will agree to exchange goods and services for the money. It is generally well understood that issuance of fiat money suffers from a time inconsistency problem, in which the government chooses to change its policy from that promised earlier, often after other actors have made decisions or investments based on the previously announced policy. The monetary authority, or the government that controls it, has an incentive to issue too much money because the cost of producing an extra unit of money is lower than the value of the money.

Businesses and consumers can choose to trade in another currency, one that they expect will retain its value. This gives them some protection from the inflation tax, a term that refers to the erosion of purchasing power. For this reason, one would expect multiple currencies to circulate in countries that have suffered from high inflation. Further, one would expect that the foreign currency that circulates is issued by a central bank with a reputation for maintaining the value of its currency.

Over the last 20 years, the Federal Reserve's record of keeping inflation low in the United States has been much better than that of a number of developing countries. Moreover, the institutional setting in which the Federal Reserve operates suggests that the U.S. dollar is unlikely to suffer from high inflation in the future. This is also true of other currencies, such as the euro. Hence, it is not surprising that the dollar or the euro often circulate in other countries.

The circulation of multiple currencies can also help discipline a monetary authority because it reduces the incentives to set high inflation. The easier it is for businesses and consumers to trade with another currency, the more constrained the monetary authority is. In some extreme cases, the local currency can disappear entirely and be replaced by a foreign currency. Because multiple currencies can serve to discipline a monetary authority, they can also be used as a commitment device in a country where institutions make it difficult for the monetary authority to commit to low inflation. This means that the impetus for multiple currencies may come from a government, rather than consumers and businesses. In such a case, the government aims to signal that it wants the monetary authority to refrain from implementing high inflation.

Costs of Multiple Currencies Although multiple currencies have benefits, they also have a number of costs. An important cost is the loss of flexibility in the conduct of monetary policy. It is generally believed that central banks can help smooth the fluctuations affecting an economy with the judicious use of monetary policy. In a recession, an expansionary monetary policy can stimulate the economy; in an expansion, a tight monetary policy can prevent the economy from growing too fast.

Multiple currencies reduce the central bank's ability to stimulate the economy with an expansionary policy that increases the rate of growth of the money supply. Moreover, monetary policy is less effective since it affects only a fraction of the economic activity. The central bank is unable to stabilize the local economy as well as it could if multiple currencies did not circulate. The consequence is volatility that hurts businesses and consumers.

Of course, the constraint imposed on monetary policy by multiple currencies is partly by design. The benefits of multiple currencies arise because the monetary authority has a tendency to choose a monetary policy that is too loose. There is a trade-off between reducing the incentives of the monetary authority to choose high inflation and giving it flexibility to stimulate the economy. Multiple currencies can be socially desirable if the costs of high inflation are higher than the benefits of stabilization policy. This is likely to be the case when the monetary authority finds it especially difficult to implement low inflation.

The use of multiple currencies also reduces flexibility in other areas, such as the ability of the central bank to implement lender-of-last-resort policies. In cases of financial crises, the central bank can sometime enhance the stability of the financial system by temporarily providing a large amount of liquidity. The effectiveness of this kind of policy is likely to decline in the presence of multiple currencies. This is especially true if the financial system relies heavily on the foreign currency. For example, a lender-of-last-resort policy to prevent bank runs is less effective if a large fraction of deposits at banks are denominated in dollars. An additional cost of multiple currencies is the inconvenience experienced by businesses and consumers when they have to deal with several currencies, such as keeping track of inventories for each currency.

Need to Weigh the Costs and Benefits Multiple currencies protect consumers from the inflation tax if their monetary authority is unable to keep inflation low. They impose discipline on the monetary authority and can be used as a commitment device to signal an intention to keep inflation low. Multiple currencies also reduce the ability of a country's monetary authority to smooth fluctuations, however, and can reduce the effectiveness of lender-of-last-resort policies. Because of these costs, multiple currencies are likely to circulate only in countries with a history of high and/or volatile inflation rates.

■ Mundell-Fleming model

The Mundell-Fleming model, named for J. Marcus Fleming (1911 76) and Robert A. Mundell (born 1932), in its most familiar form is the "internationalized IS-LM model," a diagrammatic representation of the way in which a small, open economy responds to shocks that take the form of internal policy initiatives. The innovation in this approach is that the exchange rate regime is a crucial determinant of the policies' effects on economic variables, and specifically on the level of gross domestic product (GDP) generated by the country under analysis. In two particular cases, contrary to expectations, these initiatives do not have an impact on output in the

small, open economy in the perfect capital mobility setting. This is true both for monetary policy under fixed exchange rates and for fiscal policy under flexible exchange rates. For these situations the model shows that the initiatives are ineffective for influencing the level of output and employment.

The clear implication is that policymakers should be aware of the impotence of these initiatives and not rely on them in a fruitless attempt to stabilize the economy. Canada was faulted in the late 1950s for depending on expanded government expenditures to end a stubborn recession. Fleming's ineffectiveness result demonstrates that the impact of Canada's fiscal policy was vitiated because the Bank of Canada allowed the price of its dollar to be determined in the financial markets, rather than fixing it at a given value. The clumsy conduct of monetary policy by the Bank of Canada at the time was particularly unfortunate because this flexible exchange rate regime enhanced the potency of that policy. Although these observations were articulated by Fleming and Mundell a few years after these events, the intuitive feeling at the time was that something was amiss at the Bank of Canada, and dissatisfaction with its policies lay behind the impeachment of its governor in 1961.

The Hallmarks of the Mundell-Fleming Model
The Mundell-Fleming model is based on a small group of papers, including Fleming (1962) and Mundell (1963). Others, such as Mundell (1960, 1961, and 1962), at times have been incorporated into the rubric, but doing so risks jeopardizing the key insights derived from the central papers. Some of Mundell's papers (e.g., Mundell 1960) present models designed to generate comparative static results that are independent of the nature of the exchange-rate regime in effect. Others (e.g., Mundell 1961) find comparative static results that contradict the ineffectiveness conclusions of the central papers. A key reason for this is that many of these papers assume that monetary policy can be gauged in terms of the level of interest rates rather than the quantity of money outstanding. Still others (e.g., Mundell 1962) are phrased entirely in dynamic terms rather than in the comparative statics one finds in the central papers.

Readers of these central papers face daunting challenges, as the mathematics presented is either elliptical (Mundell) or complicated (Fleming). But what is distinctive about these papers is that they employ a definition of monetary policy that maintains its coherence when capital mobility becomes perfect, and that they deal consistently with the flexible exchange rate case.

Diagrammatic Representation The Mundell-Fleming model is portrayed in figure 1. On the axes are two variables central to macroeconomic performance: on the horizontal axis, Y measures domestic output (GDP) produced in the small, open economy; on the vertical axis, r is the level of domestic interest rates. Two of the loci are familiar from Hicks's (1937) classic article: XX, representing equilibrium in the domestic goods market; and LL, representing equilibrium in the domestic assets market.

The XX locus is negatively sloped because some expenditures are sensitive to interest rates. With a higher interest rate, such expenditures are reduced, and other things being equal, this causes output to decrease. One of the variables held constant in drawing this curve is the value of the exchange rate. Defining the exchange rate as the domestic-currency price of one unit of foreign currency, we note that a rise in the exchange rate's value tends to raise the price
Figure 1
The Mundell Fleming model

of foreign goods relative to domestic goods. The resulting lower relative price for domestic goods increases demand for them and, according to the Keynesian view of supply, output responds to this rise in demand at constant prices. With such a change, the XX locus would shift to the right. We proceed with the assumptions that the quantity of money in this small economy does not have a direct impact on the goods market equilibrium condition, and that the domestic-currency price level has a value which is given.

The LL locus is positively sloped, being drawn for a given quantity of money and given values of domestic-currency prices. Everywhere along this locus the quantity of money demanded is constant, consistent with its given supply, so that for these points there is equilibrium in the domestic financial assets market. The reason is that an increase in interest rates causes the quantity of money demanded to be lower, since now bonds, an alternative form in which to hold funds, provide a higher yield. If this is matched by an increase in output, then the resulting higher volume of transactions necessitates an increase in the quantity of money held. In the right proportions, these two influences on money demand exactly offset each other and demand is back at its original (equilibrium) value. An increase in the money supply will cause a rightward shift in the LL curve.

The argument concerning the LL locus, for the simple case in which domestic-currency prices are taken to be constant, can be represented algebraically as follows:

$$M = l(r) \cdot Y \qquad (1)$$

This specification is consistent with the one in Fleming, in that it assumes a unitary income elasticity of demand for money, where l is the inverse of velocity. If l depends negatively on the interest rate, then a rise in r must be matched by a rise in Y in order to keep the product of the two factors on the right-hand side of this equation constant. This is necessary in order to maintain equality to the given value of the money supply, M, in this equation. This specification employs the assumption of the standard model that demand for money is independent of the exchange rate.

As noted, these two curves are identical to those in Hicks (1937). Hicks's model is the basis for the simplified presentations of conventional macroeconomic theorizing, so little further discussion is needed here, except to note that the XX locus is relevant for equilibrium in the domestic goods market alone. No separate analysis needs to be carried out for the market for imports, since this small economy is able to obtain all the foreign-produced goods it demands.

The final curve, FF, was added by Mundell to represent equilibrium in the foreign exchange market. In the perfect capital mobility case shown, this locus is horizontal: if domestic bonds are perfect substitutes for foreign bonds, then their rates of return must be equated. No matter what the level of domestic output, the yield on domestic bonds must equal the yield available from holding foreign financial instruments, denoted by r_w.

The economy is assumed to start in equilibrium at point Q_0, where there is clearing (so that supply and demand are equated) of all the markets analyzed here.

Policy Shocks This diagram can be used to derive the effects of monetary policy (changes in the quantity of money, causing the LL locus in figure 1 to shift) and fiscal policy (changes in the level of expenditures by government, which shift the goods-market clearing condition, XX in figure 1, independent of displacements caused by exchange rate changes) under fixed and flexible exchange rates. These are the central applications of the Mundell-Fleming model. The difference between these two exchange rate regimes is that under fixed exchange rates the value of the exchange rate is given, and the central bank, in pegging the exchange rate at a particular value, uses changes in the quantity of money to maintain this value. That is, for this regime the money supply becomes a variable that responds to shocks, while the value of the exchange rate does not change. In contrast, for flexible exchange rates the quantity of domestic money outstanding is treated as a given, and the value of the exchange rate moves reactively in order to reequilibrate the system.

The effects of expansionary monetary and fiscal policy actions can be stated easily when the exchange

rate is flexible: in that case fiscal policy has no impact on output, whereas monetary policy has the effect to which we are accustomed. These conclusions derive directly from equation (1).

If the money supply is held constant in the face of an increase in government expenditures, then the level of output does not change. With such a shock, M is fixed, and the value of l, as well, is constant, because the perfect capital mobility assumption views the interest rate as unchanging. If both M and l are given, then Y cannot change, as equation (1) shows. This is the famous "crowding out" or "ineffectiveness" result Fleming derived, which Mundell repeats.

In contrast, changes in the money supply, due to monetary policy initiatives, cause output to change in proportion to those changes. This conclusion is an unusual but straightforward implication of the Fleming specification of money demand. Once again the derivation depends on the assumption of perfect capital mobility, which causes the value of l to be given because it is a function of only the interest rate, whose value is set by world market conditions.

These results are portrayed in figure 2. An increase in government expenditure shifts the XX locus to the right by a multiple of the amount of increase. With its original position shown as XX, this shift generates a new position for this locus shown by X'X', drawn as a
dotted line to emphasize that this is the new displaced position of that curve.

If the exchange rate is fixed by the central bank, then it must provide the larger quantity of money that is required at an unchanged interest rate. As this happens, the LL locus shifts to the right; this process continues until the locus attains the position shown as L'L'. The new equilibrium is at point Q_1 where output and the money supply have increased (with output now having a value shown by Y_1 whereas its previous value was Y_0), and the values of both the interest rate and the exchange rate are unchanged.

In contrast, the same increase in government expenditures will have no effect on output and employment if the central bank is pursuing a flexible exchange rate regime. For this case, the money supply is held constant, and the value of the exchange rate must change in order to clear the various markets. Since money demand does not depend on the value of the exchange rate, its changing value does not alter the position of LL, which continues to run through point Q_0. Instead, it is the XX locus that shifts back to its original position, as the value of the exchange rate falls, in order to reequilibrate all of these markets. Since the equilibrium under this exchange rate regime does not move, it is clear that any increased government expenditures come at the expense of exports and imports. There is complete crowding out of such expenditures, so the composition of expenditures on domestic output changes, but its total quantity does not.

This idea   that with high capital mobility, fiscal policy has a more limited impact on output under flexible exchange rates than its does under fixed   is usually associated with Rhomberg (1964), who did the original empirical work on the Canadian experiment with flexible exchange rates in the 1950s. He appears to have inspired Fleming's interest in this topic, as the Canadian experience seemed to suggest that flexible exchange rates vitiated fiscal policy. Mundell, as well, credits Rhomberg's work in this area.

The argument is reversed for monetary policy. In this case the increase in the money supply is the given impulse that moves the money market equilibrium locus to position L'L'. Does this locus maintain this position, setting up an equilibrium level of output

Figure 2
The Mundell Fleming model: Changes in government expenditures and money supply

equal to Y_1, or does its revert to its original position, so that output remains at Y_0? The answer depends again on the exchange rate regime.

For fixed exchange rates, the quantity of money in the domestic economy is used to peg the value of the exchange rate. If that value is not changed, then there is no reason why the equilibrium quantity of money should change either. This means that the quantity of money quickly reverts to its former value (or perhaps does not move at all). The end result is that output is not affected by monetary policy in the fixed exchange rate case.

The quantity of money is a responding variable under a fixed exchange rate regime. So there is the logical problem that the quantity of money cannot legitimately be changed in an arbitrary fashion. As McCallum (1996) noted, one should describe this Hume impotency conclusion as demonstrating not the ineffectiveness of monetary policy, but rather its unavailability.

For flexible exchange rates, there is no commitment to keeping the value of the exchange rate at a particular peg. As a result, the decision to increase the quantity of money causes the money market locus to move to the dotted position shown, $L'L'$. In that case the value of the exchange rate must rise to clear the various markets. As domestic currency depreciates against foreign denominations, the goods market locus shifts over to the dotted position, $X'X'$. Output in this case increases to Y_1 showing that monetary policy is effective in influencing the level of domestic economy activity in the small country case.

Coining of the Expression The central articles in the Mundell-Fleming canon were written in the early 1960s. The expression *Mundell-Fleming model* was introduced, at the earliest, five years later. Soon after the term became part of the everyday vocabulary of researchers in international finance, but it was only after 1975 that the expression was used in print. Although many economists have used the alphabetical ordering of the names in the expression (Kenen 1985; Boughton 2003), and some have referred to it as just the "Fleming model" (Cooper 1976), *Mundell-Fleming model* came into common use by economists in the later 1970s and 1980s. During this period even significant extensions of the basic framework were still identified as being part of the Mundell-Fleming model (Marston 1985; Frenkel and Razin 1987).

The economists Maurice Obstfeld and Kenneth Rogoff (1996), in their monumental graduate textbook in international finance, refer to the Mundell-Fleming-Dornbusch model, and they do not use the conventional name. In the 1990s, Obstfeld and Rogoff developed the New Open Economy Macroeconomics (NOEM) model, which has the potential of supplanting the standard model as the basic benchmark formulation of the ideas and mechanisms of international financial analysis.

Boughton, James. 2003. "On the Origins of the Fleming Mundell Model." *IMF Staff Papers* 50 (1) (April): 1 9. Analyzes the writing of Fleming's 1962 contribution to the Mundell Fleming model and concludes that Fleming's work was substantially independent of Mundell's.

Cooper, Richard N. 1976. "Monetary Theory and Policy in an Open Economy." *Scandinavian Journal of Economics* 78 (2) (June): 146 63. Provides an analysis of financial policies in the open economy and calls the conventional framework at the time "the Fleming model."

Fleming, J. Marcus. 1962. "Domestic Financial Policies under Fixed and under Floating Exchange Rates." *IMF Staff Papers* 9 (4) (November): 369 79. Considered to be the classic contribution by Fleming, this paper reports both verbally and mathematically the ineffectiveness result for fiscal policy, and the proportionality result for monetary policy for the flexible exchange rate, perfect capital mobility case.

Frenkel, Jacob A., and Assaf Razin. 1987. "The Mundell Fleming Model a Quarter Century Later." *IMF Staff Papers* 34 (4) (December): 567 620. Characterized by the authors as a survey piece, this paper presents a complicated two country model of the world economy in the perfect capital mobility setting. Since the analysis specifies the asset markets in a portfolio balance manner, the connection between this framework and

what is usually termed the Mundell Fleming model is unclear.

Hicks, John. 1937. "Mr. Keynes and the 'Classics': A Sug gested Interpretation." *Econometrica* 5 (2) (April): 147 59. The diagram included in this article has been the basis for most textbook presentations of closed economy macroeconomic theory right up to the present. The longevity of this framework has surprised both its pro ponents and its many critics.

Kenen, Peter B. 1985. "Macroeconomic Theory and Policy: How the Closed Economy Was Opened." In *Handbook of International Economics*, vol. 2, edited by Ronald W. Jones and Peter B. Kenen. North Holland, Amsterdam, 626 77, chapter 13. A survey piece that covers the tra ditional way of thinking about the development of the open economy macroeconomic model, using a number of distinct models and different modes of analysis.

Marston, Richard C. 1985. "Stabilization Policies in Open Economies." In *Handbook of International Economics*, vol. 2, edited by Ronald W. Jones and Peter B. Kenen. North Holland, Amsterdam, 859 916, chapter 17. Presents a portfolio balance analysis of the effects of standard macroeconomic shocks. The author uses a complex model and the stock specification of the asset markets. He describes his framework as a "modified Mundell Fleming model."

McCallum, Bennett T. 1996. *International Monetary Eco nomics*. New York: Oxford University Press. A standard presentation of open economy macroeconomic topics. The author concludes that Mundell's 1962 and 1963 papers are his central contributions to the Mundell Fleming model.

Mundell, Robert A. 1960. "The Monetary Dynamics of International Adjustment under Fixed and Flexible Ex change Rates." *Quarterly Journal of Economics* 74 (2) (May): 227 57. Includes a model specifically designed so that the comparative static responses of the values of real variables are independent of the nature of the ex change rate regime. Despite its title, this article includes neither the money supply nor the exchange rate in the central mathematical model, which one finds in its ex tensive appendix.

———. 1961. "Flexible Exchange Rates and Employment Policy." *Canadian Journal of Economics and Political Science* 27 (4) (November): 509 17. Although the fixed exchange rate case is not treated explicitly in this pre sentation, its conclusions appear to conflict with those published in the famous paper two years later. In par ticular, monetary policy seems to have potency under fixed exchange rates, and fiscal policy is reported as being effective under flexible exchange rates.

———. 1962. "The Appropriate Use of Monetary and Fiscal Policy for Internal and External Stability." *IMF Staff Papers* 9 (1) (March): 70 77. Presents in a dynamic form an argument found at the end of another Mundell article, which deals with the appropriate response to a situation of internal and external imbalance. This article has been the basis for the author's thinking about the "policy mix" and supply side economics.

———. 1963. "Capital Mobility and Stabilization Policy under Fixed and Flexible Exchange Rates." *Canadian Journal of Economics and Political Science* 29 (4) (No vember): 475 85. Mundell's most frequently cited pa per. Reports results like those in Fleming (1962), espe cially for the flexible exchange rate, perfect capital mobility case. Juxtaposes the Fleming and Hume inef fectiveness results and presents the famous "inter nationalized IS LM" diagram.

Obstfeld, Maurice, and Kenneth Rogoff. 1996. *Foundations of International Macroeconomics*. Cambridge, MA: MIT Press. A monumental textbook presenting the state of the subject at the time of publication. The analysis focuses on current account dynamics for its real coverage, and on the flexible exchange rate case in its monetary topics. It has an extensive treatment of the Dornbusch "over shooting" framework, which the authors call the "Mundell Fleming Dornbusch model"

Rhomberg, Rudolph R. 1964. "A Model of the Canadian Economy under Fixed and Fluctuating Exchange Rates." *Journal of Political Economy* 72 (1) (February): 1 31. Finds that government expenditures are likely to lead to an appreciation of domestic currency in the in termediate run. This argument may have inspired Fleming to write down his model so as to explain how the effects of fiscal policy were vitiated in Canada in the late 1950s.

■ **New Economic Geography**

Abundance of natural resources, proximity to natural means of communication, and climatic conditions vary from place to place. These variations, however, provide only a partial explanation of the pronounced differences in development that exist even between areas that have fairly similar characteristics. Other forces inherent to the functioning of economic interactions are able to cause uneven development even across otherwise identical places.

While geographers have proposed a rich list of such forces, since the mid-1990s the work of regional scientists and urban economists called "New Economic Geography" (NEG) has gained momentum in mainstream economics. What distinguishes NEG from other approaches is its focus on the localized market rather than nonmarket interactions within a "general equilibrium" framework that emphasizes the determination of good and factor (capital, labor and land) prices as well as the importance of economywide budget constraints.

Location Decision The cornerstone of NEG is the location decision of the firm. This is a nontrivial practical problem provided that the shipment of goods and factors across space as well as the fragmentation of production affect the firm's total costs due to the presence of trade obstacles and plant-level scale economies, respectively. It is also a well-defined theoretical problem provided that the firm has some market power, because plant-level scale economies are incompatible with a perfectly competitive equilibrium. Increasing returns to scale at the plant level and costly transportation generate an economic trade-off between the proximity to dispersed customers and suppliers on the one hand, and the concentration of production in a few large plants on the other. Proximity reduces transportation costs but requires the firm to fragment production across many small plants. Concentration allows the firm to exploit scale economies but increases its transportation costs. Accordingly, the firm will prefer to run several small dispersed plants when returns to scale are weak and transportation costs are large. It will prefer to concentrate production in a few large plants when returns to scale are strong and transportation costs are small. Other things being equal, transportation costs and scale economies also imply that the firm will be attracted to markets with large local demand. This is sometimes called the home market effect, whereby firms tend to solve the trade-off between proximity and concentration by locating in the larger market and serving the smaller one from there rather than vice versa. The more significant the home market effect, the lower the transportation costs and the stronger the scale economies.

The location decision of the firm is made more complex by the presence of competitors because its

geographical position with respect to them affects the market power that necessarily stems from plant-level economies of scale. Generally speaking, firms have market power when they do not take market prices as given, as perfectly competitive firms would, and therefore trade quantity against price in making their profit-maximizing decisions. This price-making behavior is the essence of imperfectly competitive market structures that arise when competitors are a small group (oligopoly) or when they are a large group offering differentiated products (monopolistic competition). Although NEG models focus mainly on the latter, in both cases location turns out to be a crucial decision variable for profit maximization because it allows firms to increase market power and thus profits by carefully choosing their production sites.

In terms of social welfare, the presence of market power implies that prices, on which households and firms base their consumption, production, and location decisions, do not fully reflect the corresponding social values. Thus market interactions generate "side effects" for which no quid pro quo is paid. Side effects that are associated with market transactions are called "pecuniary externalities" and imply that the location decision of the firm does not fully take into account its effects on customers, suppliers, and competitors. Approaches other than NEG prefer to focus instead on "technological externalities." These are independent of any market interaction; they materialize through sheer physical proximity. Because they are the outcome of non-market interactions, by definition no quid pro quo is paid for them. As an example, consider an industry ("upstream") that supplies intermediates to another industry ("downstream"). A positive pecuniary externality for the downstream industry is the fall in intermediate input prices due to the increase in upstream competition triggered by the entry of a new technologically advanced supplier; a positive technological externality is the increase in productivity that other upstream suppliers may experience through informal knowledge transmission (spillover) generated by their proximity to their new technologically advanced rival. Although both concepts

have their own merits, the logical advantage of pecuniary externalities lies in the possibility of relating their emergence to a set of well-defined microeconomic parameters. So far this has proven to be quite difficult in models based on technological externalities because these remain mostly black boxes. Models with pecuniary or technological externalities do, however, share similar welfare implications: the free-market economic landscape is inherently inefficient and appropriate public intervention is generally needed.

Cumulative Causation No matter whether through market or nonmarket interactions, the attractiveness to a firm of alternative production sites depends on where other firms locate. This may activate a mechanism of cumulative causation among firms' location decisions through which firms' interactions may alter the economic landscape implied by natural resources, natural means of communication, and climatic conditions.

To understand how cumulative causation might work, let us go back to the previous example of upstream and downstream industries. For simplicity, consider a stylized economy made of two initially identical locations, A and B. Both host similar production chains in which there are three vertically linked activities: intermediate production, final production, and consumption. For simplicity, assume that final production uses only intermediate inputs, intermediate production employs only labor, and workers are the only source of final demand and are geographically immobile. If for any reason a new firm starts producing intermediates in A, it will increase local labor demand and intermediate supply. Due to excess demand and supply, respectively, local wages will go up while local intermediate prices will fall. This is bad news for the other local intermediate producers (market crowding effect due to competitor proximity). It is good news, however, for local final suppliers since they experience falling production costs and higher demand by richer workers. As new final producers are induced to enter the market in A, the expansion of final production will feed back into stronger intermediate demand so that intermediate suppliers will benefit (market expansion effect due to

customer proximity). Clearly, when the latter effect dominates the former, both final and intermediate firms will end up being agglomerated in A. Through these processes, cumulative causation among firms' location decisions can generate persistent differences even among places that are initially identical.

Both labor mobility and capital accumulation tend to reinforce the market expansion effect through the additional income they generate. Intermediate entry expands labor demand and final production, which itself feeds back into stronger demand and hence increased production of intermediates. If labor is geographically mobile, the associated rise in wages in location A attracts workers from B. As these migrate, demand in the final market increases, generating a second cycle of cumulative causation between firms' and workers' location decisions. Analogously, the expansion of intermediate and final markets increases firm profitability, thus fostering investment in capital accumulation and innovation. The additional income generates a third cycle of cumulative causation.

As a parallel and opposite cycle of income and expenditures contraction arises in location B, even small and transitory location-specific shocks can give rise to large, permanent geographical imbalances. Thus there is a priori great flexibility on where particular activities locate. Once the agglomeration process has started, however, spatial differences take shape and become quite rigid, a process known as putty clay geography.

Trade Liberalization Although cumulative causation is present in many models of regional development with localized externalities, the crucial contribution of NEG is that its microeconomic foundations allow the evolution of the spatial landscape to be related to measurable microeconomic parameters. A first example is the prediction that agglomeration is more likely to take place in sectors where increasing returns are more intense and product differentiation is more pronounced. The reason is that in those sectors the market crowding effect is weaker as more intense returns to scale reduce the number of active competitors and more product differentiation reinforces market power. A second

example highlights what is arguably the most celebrated insight of NEG models: the impact of freer trade on the economic landscape.

NEG argues that the level of trade barriers affects the balance among market expansion and market crowding. Consider a situation in which some factors such as land are immobile and ubiquitous. Assume also that the incomes they generate are spent locally. With extremely high trade barriers, firms will be dispersed as scattered customers can be reached only through local production. As trade barriers fall, however, it becomes economically viable to serve scattered customers remotely. This unleashes cumulative causation so that regional imbalances may arise endogenously through the location decisions of firms and mobile factors. As trade barriers keep on falling, however, firms' geographical positions gradually become immaterial in terms of product market interactions. Eventually what is left is only the dispersion force due to the higher prices of immobile factors in the crowded place. As agglomeration unfolds in the process of moving toward low-level trade barriers, trade liberalization has a nonlinear effect on the spatial concentration of economic activities by promoting agglomeration at early stages and dispersion afterward.

Multilocation Economies The results surveyed so far are typically derived in stylized economies in which there are only two locations. A more realistic description of the geographical space entails investigating the behavior of multilocation economies. Considering more than two locations does not affect the agglomeration effect of more intense scale economies and stronger market power. It also does not affect the nonlinear impact of trade barriers on the spatial concentration of economic activities as agglomeration is still likelier for intermediate obstacles to trade. Nonetheless, with more than two locations, relative market sizes are not enough anymore to determine where firms cluster. The relative positions of locations within the network of trading relations are also crucial: locations that have better accessibility will be more likely to attract firms.

In two-location models the home market effect implies that an expansion of expenditures in a certain

location causes a more than proportionate increase in local supply thanks to the influx of new firms. This effect, which is at the source of cumulative causation, does not generally survive scrutiny in multilocation economies. The reason is that, even in the presence of only a third location C, if this is large and well connected to both A and B, an increase in A's expenditure share may well map into a less than proportionate increase in its output share as location C drains away some firms. In more extreme cases, an increase in the expenditure share of a location may even lead to a decrease in its output share. This would be the case, for instance, if location C were a transport hub or gate. A hub is a location with better accessibility to all other locations; a gate is a location through which most goods flow in and out of a country. Positive demand shocks to any other location could result in supply expanding in the hub or in the gate and contracting elsewhere. Hence, agglomeration is more likely to take place in the presence of and close to hubs and gates. By analogy, preferential trade liberalization attracts firms to liberalizing countries while repelling them from other countries. The reason is that liberalizing countries improve their accessibility and become better export bases: they gain better access to one another's markets while maintaining the same ease of access to other countries' markets.

In contrast to the home-market effect, other insights of two-location models survive scrutiny for multilocation economies. First, if a location has a sufficiently large share of the economy's expenditures, a single cluster will emerge and will be hosted by that location (dominant market effect). Second, starting with prohibitive trade barriers, freer trade initially leads to a more uneven spatial distribution of firms (magnification effect).

Finally, having more than two locations allows one to model complex economies in which countries are themselves divided in regions. In this more complex scenario, one has to distinguish between international and interregional trade barriers while also keeping in mind that labor mobility is negligible at the international level but much greater at the regional level. The result is that agglomeration within countries is shaped mainly by interregional trade impediments while agglomeration between countries is shaped mainly by international trade barriers. This result has been derived both with and without interregional migration as well as with and without input-output linkages.

To summmarize, by relating the emergence and the strength of localized externalities to a set of well-defined microeconomic parameters, NEG allows one to understand the effects of international trade, migration, and capital flows on the geographical patterns of economic development in the world economy.

■ New Open Economy Macroeconomics

The New Open Economy Macroeconomics (NOEM), also referred to as new Keynesian open economy models, is a class of models that addresses open economy issues in a framework with dynamically optimizing agents with nominal rigidities (prices or wages that change slowly in response to shocks) and market imperfections (firms or households with some ability to set their own prices or wages). The NOEM model has become a "workhorse" framework for studying a variety of questions in international macroeconomics. These questions include whether international policy coordination could increase the welfare of households by improving economic outcomes, the welfare implications of simple monetary policy rules in an open economy, and how exchange rate behavior is affected by how firms set prices. As NOEM is more a framework than a particular model and one that economists use as the basis of current investigations, the assumptions of the model are still evolving. What follows is a short description of the original NOEM model written by the economists Maurice Obstfeld and Kenneth Rogoff (see Obstfeld and Rogoff 1996, 2000; Obstfeld 2001), some of its key results, and then several extensions of the model.

The Baseline NOEM Model Assume that in two symmetric countries, home and foreign, each household produces a differentiated good. Households produce goods using only their own labor but require increasing amounts of labor to produce additional goods (i.e., the production function exhibits decreasing returns to scale). Each product is distinct and is produced only by a particular household, such that each household has some market power in other words, some scope to choose the price at which it sells its good. Knowing what the demand for its good will

be at every price, each household chooses the price of its good in its own currency (called "producer-currency pricing," PCP), and during the following period the good's price will be fixed. Admittedly, this last assumption is somewhat ad hoc, but it is meant to capture the empirical fact that prices for most goods are not updated continuously, perhaps because there are some costs associated with changing prices. Since the price is set above the household's marginal cost, in the short run it is in the household's interest to supply more goods at the fixed price in response to small fluctuations. Both the law of one price (each foreign good costs its price set in the foreign currency converted to home currency by the nominal exchange rate) and purchasing power parity (which in one form says that the foreign bundle of goods costs the same as the home bundle of goods when converted into the home currency) hold. Note that this setup is equivalent to a profit-maximizing firm setting prices and wages paid to households, and the households supplying their labor to the firm as demanded.

Home and foreign households' utility depends on their consumption and work: they are made happier the more they consume and less happy the more they have to work. In particular, households would like to consume some of each of the goods produced in both the home and foreign economies. Households face budget constraints, however. Their income from selling their products, accumulation or decumulation of assets (which include both money and internationally traded bonds), and transfers from the government must equal their spending on consumption and the taxes they pay. This budget constraint must be satisfied across time, so home households could borrow from foreign households to purchase goods during a particular period but would have to pay foreign households back with interest. Each household chooses how much to produce in order to maximize its lifetime utility subject to its budget constraint.

This model will have some of the same effects found in the Mundell-Fleming model. For example, monetary policy, in the form of an unexpected

increase in the money supply in the home country, will lead to households in the home country increasing their demand for all consumption goods both home and foreign. It also will lead to a depreciation of the exchange rate, which temporarily raises domestic income relative to foreign income, and results in a current account surplus for the home country. This current account surplus increases the home country's net domestic claims on foreigners. All of these effects are largely permanent. Households in the home country will increase not only how much they consume today but also how much they consume in all future periods, because they will use some of their current income increase to acquire more assets. Although the real interest rate may move to offset some of this effect, changes to relative consumption demand will be permanent because domestic and foreign households face the same real interest rate.

Contrast with Earlier Models This baseline NOEM model is different in several key ways from both the Mundell-Fleming model and the intertemporal approach to the current account that preceded it. Unlike the intertemporal approach to the current account (earlier multiperiod optimizing models of the open economy), the NOEM model includes nominal rigidities and market imperfections. These features allow the NOEM model to look at the short-run effects of policy decisions, including any effects of monetary policy. Unlike the Mundell-Fleming model, this NOEM model is a dynamic general equilibrium model: it has explicit microfoundations (all agents are given objective functions to determine their behavior) and it has intertemporal choice (agents are making choices taking into account future periods). These differences allow the models to look at the *dynamic* effects of policies or shocks (as opposed to solely comparative *statics*), in particular on the current account and budget deficits. In addition, the NOEM model can evaluate different policies based on explicit welfare criteria that are consistent with the structure of the model.

For example, unlike later versions of the Mundell-Fleming model, in reaction to the home central bank loosening monetary policy this version of the NOEM model has no exchange rate overshooting,

where the exchange rate moves by a greater amount immediately than it will in the long run. This result is of interest to international economists because they would like to explain why exchange rates seem to move more than can be explained by changes in other macroeconomic variables or in ways contrary to what their models would suggest. For the reasons described earlier, home consumption relative to foreign consumption will immediately move to its new level, as will the relative money supplies in the two countries, and therefore the exchange rate.

Moreover, in the Mundell-Fleming model, the unexpected easing of home-country monetary policy raises output in the home country and lowers it in the foreign country, as the depreciation of the exchange rate makes home goods cheaper for foreigners. The depreciation is therefore said to have a beggar-thy-neighbor effect. In contrast, in the original version of the NOEM model, home and foreign households benefit equally from the easing of monetary policy in the home country. Both gain because households in each country have some monopoly power over their output and produce less individually than they would if society as a whole would choose their output for them. Monetary policy increases the utility of all households because it causes the expansion of output, and because both home and foreign households are equally affected by the market distortion. The point, however, is not so much the differences in results extensions to the original model can restore some of the conclusions from earlier models but rather the ability to look at dynamics and welfare conclusions.

Extensions of the Original NOEM Model Although the quantity of published research makes it difficult to discuss all of the extensions, some extensions of the original model have changed its basic results sharply. For example, the exchange rate will "overshoot" in response to a monetary policy shock if the two countries are no longer symmetric. If households in each country have "home bias" that is, prefer their own country's goods more than the other's goods or if some of the goods that each produces are not traded (such as most houses and some services), then the real exchange rate (the exchange rate adjusted for differences in each country's

inflation) will move in response to shifts in wealth between the two countries and differences in the real interest rate in the home and foreign nations. Because the tastes of the two households are no longer identical, purchasing power parity will no longer hold.

Extensions to the model can also change its welfare implications. Differences in the symmetry of home and foreign households can result in shocks, such as the home monetary policy shock, having a larger effect on the welfare of one country. With nontraded goods or home bias, households in the home country will gain more when domestic output increases. The degree to which households would be willing to substitute between goods (also called the elasticity of substitution), in other words, consume alternative goods, either another home good or a foreign good, can affect how they benefit from (or are harmed by) shocks. Therefore, if households are more willing to substitute for goods from the other country than they are for goods from the same country, then the unexpected home monetary policy expansion will benefit the home country more than the foreign one. If the difference between the two elasticities of substitution is large enough, then the welfare of the foreign country will be reduced a different version of the beggar-thy-neighbor effect from earlier models. If instead households are more willing to substitute for a good from the same country than for a good from the other country, perhaps because each country specializes in a certain type of goods, the foreign country will gain more: the home country has to work more but cannot consume as much because of the strong adverse movement in the cost of its imports relative to its exports, its terms of trade. The policy may even have a "beggar-thyself" effect if the difference in elasticities is large enough.

One extension that has been particularly discussed in the literature is whether agents use PCP or price their goods in the currency of the other country, referred to as "local-currency pricing" (LCP). Assuming LCP is attractive because it helps the model explain several things we observe in the real world: the nominal and real exchange rate will be perfectly correlated in the short run; changes in exchange rates will have little or no short-term pass-through to consumer prices; and because the exchange rate has to move more to affect the relative import price, the nominal exchange rate will be more volatile. Assuming LCP, however, means that, contrary to empirical evidence, a country's terms of trade will improve when its exchange rate depreciates (Obstfeld 2001). Several papers try to have agents optimally choose which currency to price in; this choice can depend on how easily people in both countries can share risk, how variable the exchange rate is, and the size of a firm's market share in the other country.

Neither PCP nor LCP makes the distinction between consumer prices and wholesale or intermediate prices, and as a result neither can capture both the relatively low pass-through of exchange rate movements to consumer prices and the larger pass-through to wholesale import prices. A number of authors explore this distinction by extending the model to include marketing and a distribution network goods require transportation and retail services, which are two nontraded goods, in order to be sold to households or to have nontraded goods produced by combining imported and domestically produced intermediate goods. Moreover, including a distribution sector in the model can help explain the behavior of the real exchange rate relative to movements in other macroeconomic variables, such as consumption.

In our description of the original NOEM model, all agents had perfect foresight and shocks were completely unexpected; in other words, they thought they knew everything that was going to happen in the model, and that anything could change came as a complete surprise to them. A number of researchers have extended NOEM models to a stochastic framework in which agents know that unexpected events will hit the economy and may even know the distribution of these shocks, but they do not know in any given period what the shock will be. In a stochastic model, where some prices or wages are set in advance of shocks, uncertainty or the volatility of variables can affect the means of variables in the economy, because households do not like risk. So risk can affect things such as welfare, the exchange rate, terms of trade, consumption, and how prices are set.

For example, since workers like to consume more but dislike working, if households are able to consume a large amount at the same time they are required to work more, they may wish to have higher wages to reduce the amount of work they have to do.

To take the example of monetary policy again, with floating exchange rates, more variable monetary policy (with no other shocks) can lead to a more variable nominal exchange rate and higher preset wages. These changes can increase the volatility of household consumption and move production in the economy farther away from the optimal level, and as a result lower welfare in the economy. One question that has particularly interested international economists is whether exchange rate volatility reduced the flow of goods, services, and assets traded in the world. The economists Philippe Bacchetta and Eric van Wincoop (2000) show that nominal exchange rate volatility does not necessarily have a negative effect on trade flows, although it probably has a negative effect on capital flows. Despite this theoretical work that shows a link between exchange rate uncertainty and both prices and real macroeconomic variables, however, earlier empirical results are mixed.

Researchers have also used the NOEM framework, with its explicit specification of a welfare criterion, to evaluate a variety of simple monetary policy rules and to solve for "optimal" monetary policy rules in an open economy. Whether a monetary policy rule, an equation for the central bank's policy instrument, includes some form of the exchange rate depends in part on the degree of pass-through from exchange rate to consumer prices. When firms price their goods only in their own currency, the home country's monetary policy may affect only the home country's producer currency prices since there is complete pass-through from exchange rate movements; foreign producer prices denominated in foreign currency will not change. In this case, the central bank should attempt to stabilize only domestic prices. With incomplete pass-though firms may charge higher export prices to compensate them for exchange rate risk. Because the central bank can affect the variability of the exchange rate and there-

fore possibly lower the risk premium charged on imports, it should no longer target the domestic price level only. Because policy decisions in one country can have implications for welfare in other countries, economists have also looked at whether policy coordination among policymakers in different countries yields welfare benefits.

In addition to the extensions outlined here, researchers have tried to address a variety of other questions, including currency crises, the short-run sustainability of the current account, the persistence of changes in the exchange rate, and the implications of agents not being able to completely share risk across markets. Policymakers use these models as well. For example, in recent years central banks in a number of countries as well as international organizations have built empirically relevant NOEM models to forecast the economy and to analyze alternative scenarios.

■ **New Trade Theory**

New Trade Theory is the descriptive term for theories that assume imperfect competition and increasing returns to scale (internal scale economies at the firm level) in order to explain international trade. In contrast, traditional trade theories, such as the Ricardian or the Heckscher-Ohlin model, assume perfect competition and constant returns to scale, and attribute the emergence of international trade to cross-country opportunity cost differences (i.e., comparative cost advantage) caused by either differences in production technology (Ricardian model) or factor endowments (Heckscher-Ohlin model).

Reasons for Developing New Trade Theory
The New Trade Theory originated in the late 1970s and early 1980s when advances in the industrial organization literature were incorporated into trade theory. It was developed to explain four major stylized facts (Helpman and Krugman 1985):

Fact 1: *The increase in the trade to income ratio, and the high and increasing percentage of trade taking place between industrialized nations, even though these countries are seemingly becoming more similar.*

Traditional models predict that trade benefits increase the more different trading partners are. This is puzzling because, in reality, trade is much more prevalent between quite similar countries, in particular between industrialized nations. For example, in 2005, the United States exported (imported) $186.4 ($308.8) billion worth of goods and services to (from) the European Union. In the same period, the U.S. export (import) value to (from) Africa was only $15.5 ($65.2) billion (Census FT900 Report).

Fact 2: *The high percentage of intraindustry trade, particularly between industrialized nations.*

Traditional trade theories cannot explain the existence of intraindustry trade. In the Ricardian and the

Heckscher-Ohlin models, only interindustry trade takes place. That is, if one country exports cars to another country, it does not import cars from the same country. In contrast, trade statistics for industrialized nations consistently reveal intraindustry trade to account for well above 50 percent of total trade. Although part of this may just be an aggregation problem, that is, different products are aggregated into one industry so that actual interindustry trade appears as intraindustry trade, it is clearly not the whole story.

Fact 3: *Intrafirm transactions and foreign direct investment by multinational firms.*

In the constant returns perfect competition world of the traditional theories, it is essentially impossible to talk about the scope of activities carried out within firms because there is no true concept of "a firm," the number and size of firms being indeterminate.

Fact 4: *Trade liberalization and the associated increase in factor productivity in spite of only limited resource reallocation.*

According to the traditional theories, trade liberalization results in substantial factor reallocation, most notably in the Ricardian model, where one industry closes down completely and all resources concentrate in the industry for which a country has a comparative advantage. The effect is qualitatively similar in the Heckscher-Ohlin framework, except that specialization is incomplete. In reality, however, trade liberalization seems to cause rather limited resource reallocation.

Some, usually nonacademic, literature claims that the raison d'être of the New Trade Theory is to provide arguments against free trade. Although there is research showing that active trade policy may improve welfare under imperfect competition, these findings are usually too assumption-dependent to warrant a recommendation for a widespread deviation from free trade.

Models in the New Trade Theory can be distinguished by the type of imperfect competition. The first approach uses the monopolistic competition model with differentiated goods, typically as proposed by Dixit and Stiglitz (1977). Research in this area began with seminal articles by Krugman (1979,

1980, 1981). The second approach, starting with Brander (1981) and Brander and Krugman (1983), uses an oligopolistic setup.

Explaining Intraindustry Trade The basic model (Krugman 1979) assumes that consumers value variety, but it is also possible to set up the model so that each consumer has a preferred variety that differs across consumers (Helpman and Krugman 1985). Each variety is produced by a single firm using labor. The cost function of the firm consists of fixed and variable costs; marginal cost is constant, and average cost is decreasing (internal economies of scale). The consumers' utility function is such that the price elasticity of demand for any variety is finite and exceeds one, so that the profit-maximizing price exceeds marginal cost by a positive markup. The number of firms is limited by the zero profit condition.

When the domestic country opens up to trade with an otherwise similar economy, foreign consumers create additional demand for domestic varieties. In equilibrium, individual consumption per variety and the price-wage ratio both fall. The trade-induced increase in demand allows firms to move down their average cost curve and increase production. At the same time, the full employment condition still holds. Hence, since firm-level production increases, the number of domestic firms goes down. Yet the number of varieties, domestic plus foreign, available to domestic consumers increases.

Gains from trade arise for two reasons. First, trade allows firms to better exploit economies of scale; as a result, the domestic real wage rises. Second, domestic consumers have access to a larger number of varieties.

To analyze the impact of transportation costs and home market effects, consider two differentiated industries *A* and *B* and two groups of consumers in countries *1* and *2* (Krugman 1980). The first group consumes only products from industry *A* and the second group only products from industry *B*. Type *A* consumers have a higher population share in country *1* and type *B* consumers in country *2*, while country population levels are the same. Due to positive transportation costs, the consumption ratio of foreign to domestic goods is below one in both coun-

tries. In this case, each country will produce relatively more of the product for which it has the larger home market. If countries' tastes are sufficiently dissimilar (i.e., if the population shares of A-consumers in 1 and B-consumers in 2 are high), specialization will be complete: industry A will be located only in country 1 and industry B only in country 2. The model thus explains how a bigger home market can give an industry a comparative advantage.

To investigate the determinants of intraindustry trade shares, consider two differentiated-goods industries and two sector-specific inputs (Krugman 1981). To keep things simple, let the two countries have equal population size, but country 1 has a share z < 50 percent of industry B specific labor and country 2 has a share z of industry A specific labor. Whereas the trade volume is constant and does not depend on z, the share of intraindustry trade becomes maximal as z approaches 50 percent. This model can thus explain why we see more intraindustry trade between countries that are more similar in terms of factor endowments.

Intraindustry trade also arises in a model with one domestic and one foreign market and two firms, domestic and foreign, who produce a homogeneous good and compete Cournot style (i.e., each firm treats the output level of its competitor as fixed) in both markets (Brander 1981). The markets are segmented, and shipping goods from one country to the other is costly. In this case, as long as the per unit transportation cost does not exceed the monopoly price markup over marginal cost, both firms will sell goods in both markets, so intraindustry trade arises.

Topics in New Trade Theory Traditional trade theory shows that small countries (those that cannot influence world market prices) typically have nothing to gain from pursuing an active trade policy. This seems at odds with the empirical observation that trade intervention is widespread across countries and industries. Although both monopolistic competition and oligopoly models can provide additional reasons for active trade policy (see Helpman and Krugman 1989; Rivera-Batiz and Oliva 2003), the literature on what is known as strategic trade policy has focused more on oligopoly. Using active trade policy, the domestic government can alter the strategic position of domestic firms against foreign competitors and help them capture additional rents. Oligopoly models can also be used to explain why a government may prefer tariffs over quotas or other nontariff barriers and vice versa; in contrast, tariffs and quotas are usually equivalent in the perfect competition model. Although imperfect competition can be used to show why active trade policy may make sense, this does not imply that free trade should be abandoned. In the absence of correct information about market structure and cost, governments can easily lower welfare by using active trade policy. Recent research, using asymmetric information models, has investigated whether governments can induce firms to reveal this information.

Models of imperfect competition can also be employed to explain multinational corporations, outsourcing, and the exporting decision of firms. Summarizing Dunning (1988), multinational corporations arise due to three reasons (OLI theory):

1. *Ownership advantage*: Knowledge capital (headquarter services) can be used at the same time by different production facilities.
2. *Location advantage*: Having a subsidiary in a foreign market makes sense when the market is large and trade costs are high (for horizontal firms) or when trade costs are low and factor prices differ substantially across countries (for vertical firms).
3. *Internalization advantage*: Transfer of knowledge-based assets in order to have other firms produce inputs for one's own firm is risky.

This last point leads to the question of firm organization; namely, when would firm A want to build a subsidiary instead of outsourcing production to another firm B? The answer depends on transaction costs. Letting firm B produce the required input may be more efficient in terms of production costs, but problems may arise because of input specificity and the related holdup problem. Suppose the input that firm B manufactures can be used only by firm A. Assuming incomplete contracts, firm A can then

force firm *B* to sell below production value (holdup problem). Foreseeing this, firm *B* may be tempted to produce an input that is not well suited for *A* but can be more easily sold to other firms. Grossman and Helpman (2002) and Antras (2003), among others, have integrated the transaction cost approach into a monopolistic competition trade model to investigate when outsourcing will occur.

In reality, only a small fraction of firms actually export. The question of which firms will export can be addressed in a monopolistic competition model, where different firms have different variable costs and face per unit transportation costs and fixed costs of exporting (Melitz 2003). In this framework, it can be shown that when a country opens up to trade, less productive firms will exit the market and only a more productive subset of the remaining firms will decide to export.

New Growth Theory (Grossman and Helpman 1991) and New Economic Geography (Fujita, Krugman, and Venables 1999) are closely related to the New Trade Theory since they also heavily rely on the Dixit-Stiglitz model of monopolistic competition and emphasize the importance of trade. These theories are usually not considered part of the New Trade Theory, however, and are thus not discussed here any further.

The New Trade Theory, based on the concepts of imperfect competition and increasing returns to scale, complements traditional trade theories and has contributed substantially to a better understanding of the world economy and its patterns of trade.

See discipline

■ **nondiscrimination**

The nondiscrimination obligation commits World Trade Organization (WTO) members to avoid dis criminating among products solely on the basis of their national origin. This obligation is manifested in two basic provisions in the WTO. The most-favored-nation (MFN) clause essentially requires that equal treatment be afforded to all imported goods, irre spective of their origin, as long as they are "like"; the basic incarnation of MFN is found in Article I of the General Agreement on Tariffs and Trade (GATT). The other nondiscrimination principle is the na tional *treatment* (NT) *obligation, w*hich appears in its original form as Article III in the GATT. It requires WTO members to treat imported goods no less favorably than domestically produced "like" prod ucts. By virtue of the MFN obligation, a WTO member cannot treat goods originating in a non-WTO member better than a like good originating in a WTO member. The MFN obligation applies not only to trade instruments (tariffs), but also, by virtue of Article I.1 GATT, to all *domestic* measures that affect trade. NT, on the other hand, covers domestic instruments only. Both MFN and NT are relevant irrespective of whether tariff commitments have been entered on a particular good. Thus, with respect to tariffs, for example, MFN is relevant both for the tariff levels that members agree not to exceed the "bound rates" and for the tariff levels that are ac tually applied (which may be lower).

The MFN principle has a long history. For in stance, Hudec (1988) reports that the medieval city of Mantua (Italy) obtained from the Holy Roman emperor the promise that it would always benefit from any privilege granted by the emperor to "what-soever other town." According to Jackson (1997, 158), the term *MFN* appears for the first time at the end of the 17th century. During the 19th century, the provision appeared in a number of treaties across European states. For instance, the Cobden-Chevalier Treaty of 1860, liberalizing trade between Great Britain and France, included an MFN clause guaran teeing that a signatory would not be treated worse than any other state with which the other signatory had, or would assume, trade relations. Such schemes, however, did not amount to a worldwide nondis criminatory trade; if at all, nondiscriminatory trade existed between a subset of all states, those that had entered into a similar contractual arrangement es pousing the MFN clause.

Nondiscrimination provisions appear in the WTO Agreement in all three Annex 1 Agreements, that is, in the General Agreement on Tariffs and Trade (GATT), in the General Agreement on Trade

in Services (GATS), and in the Agreement on Trade-Related Aspects of Intellectual Property Rights (TRIPs). The GATS and the TRIPs contain MFN and NT provisions that are essentially identical to those in GATT, as described above. However, the GATS NT provision (Article XVII) covers only domestic instruments with respect to sectors that a WTO member has decided to liberalize, and to the extent that no liberalization commitment has been entered, it is of no relevance. We will focus on the MFN and NT obligations in the GATT context. There are also NT-like provisions in some of the other agreements constituting the WTO Agreement. For instance, the "consistency" requirement embedded in Article 5.5 of the Agreement on the Application of Sanitary and Phytosanitary Measures (SPS) has a strong flavor of NT by requiring that WTO members treat comparable risks associated with imported and domestic products in similar fashion.

WTO adjudicating bodies have understood MFN and NT to ban both de jure and de facto discrimination. The former concept covers cases where a discriminatory treatment is afforded by virtue of the origin of the product; the latter refers to cases where treatment that is nondiscriminatory on its face effectively confers an advantage to the domestic good. While the de jure cases are easy to delineate, this is not the case with de facto violations, where case law has developed in a rather erratic manner.

Nondiscrimination and Negative Integration
The inclusion of the nondiscrimination obligations is largely the direct result of the decision to construct the GATT as a negative integration contract: policies are defined unilaterally and, to the extent that there are international spillovers, they will be internalized by virtue of the nondiscrimination obligation. This means that a WTO member can in practice adopt any regulation (rational or irrational) to the extent that it does not discriminate. The agreements on Technical Barriers to Trade (TBT) and Sanitary and Phytosanitary measures (SPS) do request a certain degree of rationality from regulatory interventions, but without negating the nondiscrimination discipline. For example, a WTO member has (at least in principle) to base its SPS regulations on scientific evidence. Regulation not based on scientific evidence (when such evidence is available) is SPS-inconsistent, even if nondiscriminatory.

A widespread view among policymakers, lawyers, and many economists is that there are a number of strong economic rationales for nondiscrimination. For instance, it seems to be commonly believed (in particular among noneconomists) that nonuniform tariff structures give rise to inefficient production and consumption patterns in a static sense. Other arguments in favor of nondiscrimination hold that it eases tariff negotiations, or may prevent the formation of preferential trading agreements that are formed to exploit market power in world markets. However, a general theoretical prima facie case for nondiscrimination is not as easily advanced as might be thought. Indeed, Johnson (1976, 18) goes as far as arguing that "the principle of non-discrimination has no basis whatsoever in the theoretical argument for the benefits of a liberal international trade order in general, or in any rational economic theory of the bargaining process in particular."

Nondiscrimination in the Form of Most-Favored-Nation Treatment The MFN obligation, as interpreted in case law, consists of the following elements:

1. with respect to, in principle, all measures that affect trade either de jure or de facto, any advantage granted to goods originating anywhere in the world;
2. must be extended to the like products;
3. originating in any WTO member;
4. immediately and unconditionally.

It emerges from the case law that two products sharing the same tariff classification will be deemed *like*. There is no WTO agreement on rules of origin, and, consequently, every WTO member can unilaterally define its own policy in this respect and apply it in a nondiscriminatory manner. *Immediately* means that the importing WTO member has to grant an advantage with no passage of time. *Unconditionally* means that it cannot impose conditions that it has not imposed to another beneficiary. The standard of review applied by WTO adjudicating

bodies in MFN cases is quite favorable to the complainant: there is no need to demonstrate intent to discriminate, and there is no need to demonstrate the resulting trade effects either.

There are two important exceptions to MFN: preferential trade agreements (PTAs), and special and differential treatment for products originating in developing countries that, by virtue of their origin, are granted in donors' markets better treatment than like products originating in developed countries.

A number of factors contribute to make an economic analysis of MFN complicated. First, in a world where free trade maximizes global welfare, there is of course no scope for tariffs at all, discriminatory or not. Any meaningful analysis of the desirability of MFN must therefore include a reason why there are tariffs at all. Consequently, it will involve comparisons of distorted equilibria, with associated second-best problems. Also, a study of MFN must involve at least three countries, with the plethora of different possible trade patterns and analytical difficulties this typically incurs.

Yet another difficulty in analyzing MFN is the fact that there is no general well-defined uniform structure with which to compare the nondiscriminatory tariff structure. This is problematic since it is a priori clear that the arbitrary choice concerning this level will have a profound effect on the outcome: if the uniform level is the same as the lowest discriminatory tariff, the uniform structure will most likely be preferred, while an equally nondiscriminatory structure, but set at the level of the highest discriminatory tariff, will most likely be worse from a welfare point of view. In neither case can the outcome be said to be related to discrimination, however. More generally, we lack a meaningful measure of the *degree* to which a structure fulfills MFN; it is not possible to simply "turn up" the degree of non-MFN and observe the outcome.

Despite these inherent complexities, several strands of economic theory can shed light on the impact of an MFN clause. Both the literature on optimal taxation and the industrial organization (IO) literature on price discrimination suggest reasons why discrimination may be socially desirable. For instance, if the raison d'être for tariffs is to raise government revenue, tariffs (like taxes in general) should be levied so as to minimize the resulting distortions, and this will often call for nonuniform structures.

Economic analyses of MFN can be divided into two categories. The first comprises models in which governments set tariffs unilaterally. In a typical setup, firms decide on investment, the level of which is influenced by firms' perceptions of tariff treatment, and thus on whether MFN has to be respected or not. A basic mechanism here is that MFN hinders ex post opportunistic taxation of economic rents and may thereby increase the ex ante private incentives for the creation of such rents. This mechanism lies behind several observations. For instance, by affecting the strategic interaction between firms and governments, an MFN clause may have a positive welfare impact even if the government would choose to set nondiscriminatory tariffs in its absence; and a government that, absent an MFN clause, would choose to discriminate may gain from being prevented from discriminating.

A second and more recent strand of literature is concerned with the role of MFN for multilateral trade liberalization, and in particular tariff negotiations. One fundamental role of trade agreements is to prevent negative externalities from nationally pursued trade policies. These international externalities may work through a number of different routes. For instance, they may take the form of changes in terms-of-trade, or through domestic prices affecting import demand. Bagwell and Staiger (2002) suggest that a central role of MFN is to channel these externalities through the terms of trade. This is important, since tariff negotiations can directly address terms-of-trade externalities, but are less effective to address other forms of externalities. Bagwell and Staiger also show how MFN may work in concert with other characteristic features of the GATT/WTO system, such as reciprocity, to make multilateral trade agreements immune to Article XXVIII GATT renegotiations.

The complexity of multicountry tariff negotiations is reflected in the wide variety of intuitively plausible but often contradictory arguments that have been advanced in the informal academic

literature and in policy discussions. For example, MFN is said to promote tariff liberalization by making trade agreements more credible; the increased cost of giving concessions makes it less attractive for a party to undermine an agreement by subsequently offering better terms of market access to a third country ("concession diversion"). MFN also makes it attractive for outsiders to enter into an existing agreement, since they get access to a package of low tariffs. And since entrants have to grant MFN, insiders get access to many foreign markets through the incentives for entry. On the other hand, MFN is also claimed to reduce the incentives to liberalize. It increases the costs of giving concessions, since the latter have to be given to all countries with which a country has MFN agreements; MFN makes large countries unwilling to make concessions to small countries, since in return for "peanuts" large countries have to extend their concessions to a large volume of trade; MFN reduces the benefit from a given concession since it has to be shared with other countries; MFN promotes free riding, since countries may opt to wait for agreements between other countries to spill over via MFN, rather than contribute with concessions themselves, and MFN also prevents countries from punishing free riding; or MFN prevents subsets of countries from going further in liberalization than what is desired by the rest of the world. A number of studies examine the validity of these types of claims. We will here just mention two of these.

The role of MFN to prevent concession diversion is at focus in Ethier (2004), who takes a very long-run perspective on its impact. Governments are assumed to initially form reciprocal bilateral agreements. To be meaningful, these must include MFN to avoid concession diversion. As more and more bilateral agreements are formed, the incentives to participate in further agreements gradually diminish, since each agreement has through the partner's MFN commitment to be shared by more and more other countries, and more and more market access has to be given away through a country's own MFN commitments. A process of liberalization through bilateral agreements will therefore eventually come to a halt. It will become necessary to internalize the ex-

ternal effects of any further agreements by making the agreements multilateral. Hence, MFN causes multilateralism, not the other way around. This study can also be seen as an illustration of the more general point that bilateral negotiations conducted under MFN generally are associated with externalities, since the outcome of such negotiations affect parties who are not present in the negotiations.

MFN may potentially cause free riding in at least two ways. One is that a country rejects an offer in order to let other countries reach agreements that it can benefit from without having to make concessions itself. This would be inefficient either because there would be delays in achieving an agreement, or because the agreement would feature higher tariffs compared to some other (undefined) situation. This possibility has as far as we know not found any support in the literature so far. For instance, Ludema (1991), which is one of the few studies that employ a noncooperative sequential bargaining model to study the impact of MFN on multilateral bargaining, shows how negotiators may find it optimal to devise equilibrium offers such that free riding does not occur, despite there being incentives and possibilities to free-ride.

As mentioned, in this entry we do not for the most part cover the literature on PTAs, since it tends not to focus on MFN as such. Nevertheless, some recent work on PTAs is of direct relevance to the issues at stake here. In particular, the literature has highlighted the interplay between the domestic political system and the formation of PTAs, as exemplified by the studies by Grossman and Helpman (1995), Levy (1997), and Krishna (1998), all of which suggest that MFN may have desirable welfare consequences by constraining the domestic political process.

Finally, there are some intuitively important aspects of MFN that have not been formally scrutinized, as far as we know. For instance, as noted already by Viner (1931), the administration of discriminatory tariffs is costly because of the need to keep track of product origin, and MFN thus significantly simplifies customs procedures. Another aspect that we believe is of considerable importance is the fact that MFN reduces the cost and complexity of

negotiations by reducing the number of possible bids and outcomes. Finally, under MFN countries may have incentives to use narrow product classifications in order to avoid having to extend concessions granted on an MFN basis. There should thus be reasons for countries to try to manipulate customs classification schemes.

To conclude, the implications of MFN for multiparty tariff negotiations are inherently complex. A large number of partial effects have been suggested, but the economic theory literature has only examined a few of these. It does support some of the claims concerning beneficial effects of MFN, but provides a far too scattered picture to serve as a basis for any more general claim concerning the desirability of MFN.

Finally, it is sometimes argued that MFN is today of limited practical importance, given the low average tariffs of developed countries on imports of industrial products. However, current tariffs are the result of a system built on MFN, and there is no guarantee a priori that the same levels could be supported in its absence. Also, there are important sectors such as agriculture, textiles, and services where barriers are still high and where MFN (or its absence) might clearly be important. Furthermore, as discussed above, the MFN principle does not apply only to tariff negotiations in the rounds, but also to many other facets of the WTO.

Nondiscrimination in the Form of National Treatment Article III GATT divides domestic policy interventions into fiscal (Article III.2) and nonfiscal (Article III.4) measures. With respect to fiscal measures, any tax differential across two "like" products will violate the NT discipline, whereas the tax differential across two "directly competitive or substitutable" (DCS) products must operate "so as to afford protection to domestic production," in order to be in violation of NT. Case law so far has held that large tax differentials across DCS products suffice for this requisite to be fulfilled. Two products are in a DCS relationship if they are considered by consumers to be interchangeable. A demonstration of interchangeability can be based on either econometric or noneconometric indicators. Two products are like if they are DCS *and* also share the same tariff

classification, to the extent that it is detailed enough. Turning to nonfiscal measures, a measure roughly speaking violates NT if it affords to an imported good less favorable treatment than that afforded to a domestic like product. The term *like* has here been interpreted in a manner that roughly corresponds to the DCS notion for fiscal measures.

Two domestic instruments are by virtue of Article III.8 GATT excluded from the coverage of NT: production subsidies and government procurement. But the GATT does not contain a list of domestic instruments that have to observe the NT discipline. WTO adjudicating bodies have adopted an all-encompassing attitude in this respect and have never so far refused the application of Article III GATT on the grounds that a particular measure does not come under its coverage. There is indirect legislative support for this approach: Article III.2 GATT stipulates that imported products shall not be subject "directly or indirectly" to higher taxation or levies than those imposed "directly or indirectly" to like domestic products. Hence fiscal measures that only indirectly hit products are covered by the NT discipline as well. Likewise, the term *affecting* in Article III.1, which includes nonfiscal as well as fiscal measures, is in the same broad vein; finally, the Interpretative Note to Article III states that measures enforced at the border should still be considered domestic, if they are designed to regulate both domestic and imported goods.

Case law has established that violations of the NT discipline can be justified through recourse to one or more of the public order grounds reflected in Article XX GATT. The intellectual merits of constructing Article XX as an exception to Article III are highly doubtful however, since both provisions contain a nondiscrimination clause. There is no doubt, though, that NT can lawfully be disrespected on national security grounds (Article XXI GATT).

Turning to the rationale for NT, the most striking feature of the economic literature is the near-complete nonexistence of studies of NT. The question of what role NT plays in trade agreement is part of the larger question of why trade agreements typically treat internal measures very differently from border

measures. Border measures are largely explicitly regulated; tariff levels are bound, import and export quotas as well as export subsidies are prohibited, and so forth. Internal measures, on the other hand, are left to be unilaterally determined by the contracting parties. Intuitively, the reason for this asymmetry seems to stem from a combination of two facts. First, a trade agreement is typically in place for a long period of time because of the costs of negotiating it, even if only binding border measures. Second, during the life span of the agreement various nonprotectionist regulatory needs are likely to arise. The agreement must therefore leave sufficient flexibility for the contracting parties to use domestic instruments for nonprotectionist reasons. It would be extremely costly to condition the agreement on all possible developments; on the other hand, it cannot leave internal instruments completely unregulated, since this would enable countries to use internal measures to undo whatever restrictions are agreed on regarding border measures. NT is the first line of defense against such behavior. That is, NT can be understood as an attempt to remedy problems caused by incompleteness of the agreement.

In order to save on contracting costs, an NT provision is likely to impose a less than perfectly flexible discipline on domestic measures. The question therefore arises as to whether the restriction increases welfare. Horn (2006) shows how an extreme version of an NT provision a dictum never to tax foreign products higher than domestic products may improve the contracting parties' welfare even if it would be desirable to tax foreign products higher from an efficiency point of view. Basically, the NT restriction makes internal instruments blunter tools for protectionism: domestic instruments can be used against foreign products, but they also have to hit domestic like products to the same extent. As a result, taxes will be used less to protect, and countries may go further in their tariff liberalization, creating overall gains from the imposition of the NT provision. Such a strict NT restriction will not completely eradicate the problem caused by incomplete contracting, however.

A fundamental weakness of the whole incomplete contract trade agreement literature is the fact that the structure of the incompleteness   what is contracted and what is not   is simply assumed. In practice, parties to an agreement can choose not only tariff levels, say, but also whether or not to include an NT provision. A natural question, therefore, is when, if at all, an NT provision is likely to be part of an optimal agreement. Horn, Maggi, and Staiger (2006) employ a model with explicit contracting costs to endogenously determine the incomplete structure of a trade agreement. It is shown how a strict NT-like provision of the above-mentioned type may be an optimal component of a trade agreement, by combining limited contracting costs with a degree of discipline on countries' use of domestic taxes for beggar-thy-neighbor purposes.

Overall, the analysis of the implication, and even more the optimal design, of NT has only just begun. This is an unfortunate state of affairs, considering the importance of NT and NT-like provisions in the WTO Agreement and in high-profile WTO trade disputes. Without NT (or a provision with a similar type of effect), agreements on border measures could be rendered entirely meaningless by opportunistic domestic policies; to take the simplest case, a domestic tax on imported products could perfectly replace a tariff that is bound through a trade agreement. Nonfiscal measures can be used in a similar nondiscriminatory fashion. It is thus not by chance that NT-like provisions appear in several of the main agreements regulating trade in goods, and also in regulation of trade in services and intellectual property in the WTO.

■ nongovernmental organizations (NGOs)

Nongovernmental organizations (NGOs) have been described as "private, not-for-profit organizations that aim to serve particular societal interests by focusing advocacy and/or operational efforts on social, political and economic goals, including equity, education, health, environmental protection and human rights" (Teegen, Doh, and Vachani 2004, 466). NGOs are an important and influential set of institutional actors within the broad context of the world economy. They have emerged as critical organizations in shaping governmental economic policy and practice, influencing global economic institutions and structures, and affecting corporate and business activities. NGOs have grown in number, power, and influence since the 1980s. They have contributed to a range of international economic debates and issues, and NGO activism has been responsible for major changes in global economic policy, law, and regulation.

According to Lindenberg (1999), fiscal crises, ideological shifts, and privatization have all led to a decline in the scope and capacity of the state. In response, a growing global not-for-profit sector has emerged that, in part, has begun to fill the humanitarian vacuum left by the corporate sector and the nation-state. Teegen, Doh, and Vachani (2004) argue that international NGOs constitute another face of globalization and that large, multinational NGOs have emerged, in part, to serve as counterpoints to concerns about the growing power and influence of multinational enterprises (MNEs) and international organizations such as the International Monetary Fund, the World Bank, and the World Trade Organization.

Civil Society Associations *Civil society*, also referred to as the *third sector* or the *nonprofit sector*, is used broadly to refer to all aspects of society that extend beyond the realm of the public sector and the traditional private sector. Although the term *NGO* is relatively recent, associations among like-minded individuals have been part of ancient and modern history.

When individuals or groups within civil society work together to advance a broad common set of interests, and these interests become a significant force in shaping the direction of society, social movements emerge as the outcomes of this process. Social movements are broad societal initiatives organized around a particular issue, trend, or priority. Modern examples related to economic issues include the environmental movement and the movement to improve working conditions in developing countries. When civil society groups band together to form organized relationships, the emergent entities are often referred to as NGOs.

NGO is a broad term that somewhat loosely refers to all organizations that are neither official parts of government (at any level) nor private, for-profit enterprises. Among NGOs, however, there are many different types, characteristics, and purposes.

Definitions and Classifications Scholars of political economy sometimes separate "club" and "social purpose" NGOs. Club NGOs are membership associations designed primarily to provide a benefit to their members, generally because of pooling interests. Examples of club NGOs are unions, business associations, and church groups.

In most of the contemporary literature the focus is on social purpose NGOs. Social purpose NGOs are engaged in a range of activities that have direct bearing on the world economy, including lobbying global economic institutions such as the WTO to more fully consider the environmental, labor, and developmental impacts of their activities; working with industries and companies to develop codes of conduct governing their activities; providing on-the-ground programs in the areas of health, nutrition, and poverty alleviation; and otherwise supporting institutional developments that promote social welfare.

Teegen, Doh, and Vachani (2004) further differentiate among various functions of NGOs. Advocacy NGOs work on behalf of others who lack the voice or access to promote their interests. They engage in lobbying, serve as representatives and advisory experts to decision makers, conduct research, hold conferences, stage citizen tribunals, monitor and expose actions (and inactions) of others, disseminate information to key constituencies, set and

define agendas, develop and promote codes of conduct, and organize boycotts or investor actions. In these ways, advocacy NGOs give voice and provide access to institutions to promote social gain or mitigate negative spillovers from other economic activity.

Operational (or programmatic or service-oriented) NGOs provide critical goods and services to clients with unmet needs. NGOs have long stepped in to provide critical social safety nets, where politically challenged, indebted, or corrupt states are unable or unwilling to provide for unmet needs, and where global problems defy neat nation-state responsibilities. Examples of such operational activities include relief efforts provided by the Red Cross or Red Crescent, natural resources monitoring by the World Wide Fund for Nature, and the distribution of medicinal drugs by Doctors without Borders. Although some NGOs focus primarily on advocacy or operational service delivery, many others pursue both sets of activities simultaneously, or evolve from one to the other. For example, Oxfam, the global development and poverty relief organization, advocates for changes in public policy that would provide greater support to its efforts while also contributing directly to health, education, and food security in the developing countries in which it operates. Brown and Moore (2001) add another category: capacity-building NGOs, which are large global organizations that use their expertise and financial resources to build the capability of smaller, local NGOs.

The Role of NGOs in the United States and the World Economy NGOs have assumed a significant and influential role in modern societies. The modern era of NGO activism can be traced to 1984, when a range of NGOs, including church and community groups, human rights organizations, and other anti-apartheid activists, built strong networks and pressed American cities and states to divest their public pension funds of companies doing business in South Africa. A U.S. statute banned new U.S. investment in South Africa, export sales to its police and military, and new bank loans, except to support trade. The combination of domestic unrest, international governmental pressures, and capital flight posed a direct,

sustained, and ultimately successful challenge to the white minority rule, resulting in the collapse of apartheid.

NGOs have also pushed to have greater access to trade policy and international governmental agreements and processes, systems that have historically been limited to governments acting as agents of their domestic constituencies. NGOs have expressed a great deal of interest in the trade policy dispute settlement mechanism under the General Agreement on Tariffs and Trade (GATT) and its successor agreement, the World Trade Organization (WTO), as well as in the practices and reform of the International Monetary Fund and the World Bank.

NGOs have also been active in collective efforts to develop, implement, and enforce industrywide standards, codes of conduct, and agreements. Examples of intergovernmental agreements shaped and influenced by NGOs include the WTO and the North American Free Trade Agreement, the United Nations' Global Compact on Business Responsibility, the International Labor Organization's Declaration of Principles Concerning Multinational Enterprises and Social Policy, and the Organisation for Economic Co-operation and Development's guidelines for multinational enterprises (MNEs). Examples of international codes sponsored directly by NGOs include the Social Accountability International SA8000 standard; Rugmark, a standard that certifies rugs and carpets as meeting basic standards for labor and human rights; and the Forest Stewardship Council standard that certifies lumber as consistent with sustainable practices.

According to a 1995 World Bank report, since the mid-1970s, the NGO sector in both developed and developing countries has experienced exponential growth. In terms of international development, more than 15 percent of total overseas development aid is channeled through NGOs. Indeed, a report published by the United Nations and the NGO SustainAbility notes that the global nonprofit sector, with its more than $1 trillion turnover, could rank as the world's eighth largest economy. Teegen, Doh, and Vachani (2004) argue that the emergence of civil society in general, and the activism of civic NGOs in

particular, have broad implications for the role, scope, and definition of corporations in the global economy, and therefore for international management as a research field. Doh and Teegen (2003) point out that the emergence of NGOs, in some cases, has supplanted the role of host governments in the historic business-government bargaining relationship such that NGOs yield significant power over MNEs' right to operate in developing countries.

Another vehicle used by NGOs to advance their agenda is shareholder activism. NGOs may buy shares of corporations and use ownership to promote proxies and other resolutions to effect change. They often use their status to urge institutional shareholders, such as public employee pension and retirement funds, to pursue changes in corporate governance and conduct. They also work with and through socially responsible investment funds, serving as advisors and experts on ethical and social responsibility screens used to determine the composition of such funds and by drawing attention to shortcomings in the mechanisms used by such funds to choose and retain specific stocks within their portfolios.

Challenges to NGOs NGOs face challenges, including the wide diversity of the principals they serve and the constant demands for resources. Variations in national context can also challenge NGOs, as was evidenced by a 2005 Russian law that would appear to limit their ability to mobilize.

In addition, NGOs are facing criticism and pressures over the perception that they are often less accountable for their actions than their government and business counterparts. Specifically, the corporate governance scandals in the United States and around the world have resulted in increasing attention to the role of boards, interlocking board directorates, and overlapping board memberships among corporations and NGOs. The American Enterprise Institute, in cooperation with the Federalist Society for Law and Public Policy Studies, has launched a program initiative called NGO Watch, whose mission is to highlight issues of transparency and accountability in the operations of NGOs and international organizations.

Finally, some argue that, like the MNEs and international organizations they seek to influence, international NGOs are primarily financed and supported by individuals and organizations in wealthy countries and are not as attuned to the interests and needs of the developing world (Lindenberg and Dobel 1999). As a result, many international and local NGOs have developed collaborative relationships that seek to bridge this aspect of the North-South divide.

■ nontariff measures

Nontariff measures (NTMs) are policies, rules, regulations, and practices *other than tariffs* that distort international trade flows. Tariffs are taxes imposed on imported goods as they cross borders and clear customs. Any other measures that, intentionally or unintentionally, distort international trade flows are considered nontariff measures. Most NTMs are nontariff trade *barriers* (NTBs) that reduce trade flows. Import quotas, countervailing or anti-dumping duties, and import surcharges are NTBs specifically designed to restrict international trade. Other government regulations, such as sanitary requirements or product safety standards, are directed at protecting public health and safety, but become NTBs if they also restrict imports. Not all NTMs restrict trade. *Export subsidies,* for example, distort trade flows, but increase rather than decrease international trade.

The most important of the vast array of potential NTMs can be categorized as (1) taxlike measures, (2) cost-increasing measures, (3) quantitative trade measures, or (4) government procurement policies.

Taxlike Nontariff Trade Measures Tariffs usually apply to imports from all sources and usually remain in effect at the same rates for many years. Some taxlike NTMs apply only in special circumstances to imports from selected countries and/or are only temporary.

Anti-dumping duties are additional import taxes imposed in response to the "dumping" of products by foreign firms. Dumping occurs when an exporter sells abroad at a price below the price charged for the same product in the home market, or sells abroad at a price below its average cost of production. Importing countries levy anti-dumping duties only on imports of the product from the country of the firm found to be dumping. The anti-dumping duty is set at a rate equal to the "dumping margin," which is the difference between the price the firm charges in the home market and in the importing country, or the difference between the exporter's average cost of production and the price charged in the importing country. Anti-dumping duties are imposed in addition to the standard tariff on the product.

Countervailing duties are extra import taxes imposed on goods receiving subsidies from the exporting country's government. The size of the countervailing duty normally equals the size of the subsidy. Countervailing duties also are imposed in addition to the regular tariff.

Temporary import surcharges are extra import taxes imposed in "emergency" circumstances, often in response to a sudden increase in a country's balance of payments deficit. For example, the United States imposed a temporary 10 percent import surcharge during the second half of 1971 following several years of growing balance of payments deficits.

Variable levies are taxes on imports that vary in size depending on the price of the imported product in a particular shipment. For example, the European Community's system of variable levies on agricultural imports imposed an import tax just large enough to eliminate any difference between the internal

support price and the price of the imported shipment. The variable levies ensured that agricultural goods could not enter the EC at prices lower than domestic support prices.

Cost-Increasing Nontariff Trade Barriers Some NTBs do not directly tax goods, but discourage imports by increasing either the exporter's cost of production or the cost of clearing customs and complying with import regulations.

Prior import deposits are requirements that importers submit deposits to the importing country's Central Bank equal to a percentage of the value of the shipment. These deposits usually are denominated in the importing country's currency, pay no interest, and are held for about 6 months. For example, Uruguay at one point required importers of certain products to submit prior import deposits of up to 1200 percent of the value of the shipment that were held for 6 months at no interest when the inflation rate was about 50 percent per year. Prior import deposits can create delays and impose extra costs on importers.

Product standards, technical regulations, labeling requirements, and sanitary and phytosanitary requirements make imported goods more expensive by increasing an exporter's cost of production to comply with the standard, or by imposing costs on importers due to shipment delays or inspection or certification requirements. For products subject to economies of scale in production, altering a product to comply with widely differing product standards across countries can preclude cost-reducing long production runs. Importers may also have to turn over a significant portion of a shipment for testing. Technical standards such as the European Union's (EU's) import ban on beef that has been fed growth hormones and the French ban on imports of products containing asbestos completely prohibit trade in those products.

Customs procedures that are costly, cause lengthy delays, or create uncertainty for importers discourage trade. International traders complain that inspection and customs clearance procedures in many countries are time consuming and costly. Importers may hesitate to import if they are uncertain as to how goods will be classified and thus what tariff rate will apply.

Reference prices or minimum import prices are official prices used to value import shipments to calculate the amount of duty owed. The usual basis for valuation is the amount the importer pays the exporter, including insurance and freight charges. Reference prices increase the amount of duty paid by an importer by using arbitrary (and higher) prices to value shipments. The United States for many years valued imports of benzenoid chemicals, rubber-soled footwear, woolen knit gloves, and clams at the (higher) internal "American selling price" instead of the actual cost of the shipments.

Quantitative Measures In contrast to tariffs, taxlike NTMs, or other measures that discourage imports by making them more expensive, quantitative trade restrictions directly or indirectly restrict the *quantity* of a product that can be imported or exported.

An *import quota* sets a maximum permissible volume or value of a product that can enter a country during a particular time period. The import quota limit is normally declared before the beginning of the time period. The overall quota limit is often subdivided by country of origin. Import quotas can be administered on a "first-come, first-served basis" by allowing imports until the quota ceiling is reached and then closing the border to further imports. However, governments normally distribute licenses or permits to import among importing firms. The distribution is most often determined by the amounts imported in a base year. *Export quotas* are maximum limits on the amount of a product that can be exported during a particular period of time.

Embargos are total prohibitions on trade of a particular good or trade with a particular trading partner. Most countries prohibit trade in products originating from endangered species or trade in weapons or radioactive materials. Embargos on trade with particular trading partners are usually for political reasons, such as the U.S. embargo on trade with Cuba or the United Nations embargo on trade with South Africa during the period of apartheid.

A *voluntary export restraint* (VER) is an export quota on shipments of a product to a particular importing country that is "voluntarily" applied by the exporting country, usually as the result of negotiations with the importing country. Negotiating VERs with exporting countries was a way governments could protect troubled domestic industries when they could not unilaterally increase trade barriers without violating existing international trade agreements. Exporting country governments often agreed to restrict exports to avoid even more severe unilateral import restrictions by the importing country. Major VERs included European and Japanese limits on steel exports to the United States, Japanese VERs on automobile exports to the United States and European countries, and the complicated web of VERs on textile and apparel products under the Multifiber Arrangement (MFA).

Import licensing requirements are regulations that prohibit importation of designated products without a license issued by a government agency. The agency in charge may base the number of import licenses approved on foreign exchange availability and the state of the overall balance of payments. But the authorities granting import licenses often have a high degree of discretion as to which products can be imported and which importers receive licenses. *Export licensing requirements* are the equivalent restrictions on the export side.

Foreign exchange controls are regulations requiring that exporters turn over any foreign exchange (foreign currency) earnings to the Central Bank in exchange for domestic currency. The Central Bank then allocates the foreign exchange among importers. Importers cannot import without access to foreign exchange to pay for the goods, so foreign exchange allocation decisions limit import and also determine which goods can be imported.

A *tariff quota*, or *tariff rate quota*, is a hybrid form of trade restriction that allows imports at a "within-quota" tariff rate up to a maximum quantity (the "quota" part of the tariff quota). Additional imports "over-quota" are allowed but are subject to a higher tariff rate. If imports fall short of the quota limit, then the impact of a tariff quota is similar to that of a tariff at the "within-quota" rate. If imports enter "over-quota," then the impact of the tariff quota is similar to that of a tariff at the "over-quota" rate. But if the over-quota tariff rate is so high that no imports enter in excess of the quota limit, then the tariff quota acts like an import quota. The United States, Canada, and the EU apply tariff quotas to some agricultural imports.

Local (or "domestic") content requirements indirectly limit imports of components by mandating that goods sold on the domestic market must contain a minimum percentage of local value added or a minimum percentage of components sourced from local producers. Mexico, Brazil, Argentina, Uruguay, Peru, and the Philippines have at one time required minimum local content in motor vehicle or household appliance industries. *Mixing regulations* or *quantity-linking schemes* require importers to purchase a minimum amount of domestic product before they are permitted to import that product from abroad. An example would be the requirement in Mali that sugar importers purchase one ton of sugar from the domestic sugar refinery for each ton of sugar that they import. Unless the country in question is granted a special exemption, these measures are now prohibited for World Trade Organization members under the Agreement on Trade-Related Investment Measures.

Import/export balancing requirements, sometimes called *compensatory export requirements*, force firms to export to earn foreign exchange equal to a specified percentage of the value of the goods they import. These regulations often apply to motor vehicle assembly. Firms must export motor vehicles or parts to earn foreign exchange to pay for a given percentage of their imported components.

Government Procurement Practices In most countries, regardless of the stage of development, government is the single largest purchaser of goods and services. Purchases of goods and services by governments represent a large potential market for foreign suppliers. Government procurement practices include the method of soliciting bids,

requirements placed on bidders, and the method of selecting winning bids and awarding contracts. Discrimination against foreign suppliers could take the form of allocating contracts exclusively to domestic firms, not allowing foreign bidders to participate in procurement solicitations, not providing adequate information to potential foreign bidders, or establishing preference margins for domestic firms. In the United States, for example, the Buy American Act of 1933 required government agencies to purchase only products produced domestically, unless the cost would be "unreasonable." The interpretation of "unreasonable" gave domestic firms a preference margin as high as 50 percent.

Comparison of Tariffs and NTMs Tariffs increase the prices of imported goods and shift demand toward domestically produced substitutes. Consumers bear the burden of higher prices of both imported and domestic goods. Domestic producers benefit because they sell a greater quantity at a higher price. Tariffs also provide revenue to the government. Tariffs generally result in net losses to the importing country overall because the loss to consumers from higher prices exceeds the gains to domestic producers and the government.

NTBs also increase the prices of imported goods and domestic substitutes. The taxlike NTMs provide the government with revenue, but cost-increasing NTMs raise prices to consumers without transferring revenue to the government. Quotas provide windfall profits to whoever is able to trade the good under quota. Depending on how the quotas are administered, the windfall gains may be captured by exporters, which would increase the net loss to the importing country from restricted trade.

In general, NTMs are less transparent, more discriminatory, and more discretionary than tariffs. Tariffs are said to be *transparent* because the amount by which a tariff increases the price of an imported good is clear. A 20 percent tariff increases the cost of a shipment to the importer by 20 percent. The extra cost imposed by customs procedures, inspections, and compliance with standards is far more difficult to quantify. Quantitative trade restrictions also are less transparent than tariffs because the price-increasing

effect of an announced quota ceiling expressed in tons or square yards is not immediately apparent. With tariffs it is also clear that the government receives the tariff revenue. Quantitative restrictions generally provide no government revenue, but create profits for the limited number of traders who are able to import within the quota.

The welfare impact of NTMs such as product safety standards, sanitary requirements, and labeling requirements is particularly difficult to assess. These measures generate social benefits (such as improved health, safety, or improved information for consumers) that can outweigh the costs. To the extent that these measures reduce consumer uncertainty about the quality of imported goods, they may increase, rather than decrease, international trade.

NTMs also provide more scope for *discrimination* against particular exporting countries. Tariffs normally apply at the same rate to products from most exporting countries. Import quotas, however, are often subdivided among exporting countries. VERs are more often negotiated with countries that are viewed as source of increased imports, or countries over which the importing country has more political leverage. Inspections to assure compliance with sanitary or product standards can be applied more frequently or more stringently to products from particular sources.

NTMs are often more *discretionary* than tariffs. Tariffs apply to all shipments at a preestablished rate. Import licensing, foreign exchange control systems, or import quotas give government authorities much more discretion to control what can be imported, when it can be imported, from which exporting countries, and by which importers.

NTMs in International Trade Agreements and Negotiations Two important fundamental principles of the General Agreement on Tariffs and Trade (GATT) and its successor, the World Trade Organization (WTO), are the use of tariffs as the primary form of trade barrier, and nondiscriminatory treatment of imports from all parties to the agreement. Successive rounds of trade negotiations between 1947 and 1994 under the auspices of the GATT made remarkable progress in lowering tariff rates on

trade in manufactured goods. Following the principle of nondiscrimination, the lowered tariff rates applied to imports from all exporting countries that were parties to the GATT.

As tariff rates fell, the trade-restricting effect of NTBs became increasingly apparent. Lower tariff rates made preexisting NTMs more evident. But lower tariffs also prompted import-competing industries to seek additional protection through anti-dumping and countervailing duties, VERs, and technical barriers to trade. The perceived proliferation of NTMs prompted governments to try to negotiate limitations on their spread and rules on their application.

The first negotiated agreement on NTMs was the Anti-dumping Code that emerged from the Kennedy Round (1963 67). Subsequent rounds of trade negotiations put increased emphasis on negotiations to reduce the trade-distorting effect of NTMs. The Tokyo Round (1973 79) resulted in the negotiation of ancillary codes on import licensing procedures, technical barriers to trade, customs valuation, subsidies and countervailing duties, and government procurement. The Uruguay Round (1986 94) further strengthened the rules governing the use of NTMs by specifically prohibiting VERs, replacing agricultural NTMs (such as U.S. import quotas and the EU variable levies) with tariffs or tariff rate quotas, and incorporating agreements on anti-dumping duties, subsidies and countervailing duties, and sanitary and phytosanitary measures into the main WTO agreements. An agreement was also reached in the Uruguay Round to totally phase out the Multifiber Arrangement, arguably the worst of all nontariff measures, by 2005. Despite these changes, however, NTMs still play an important role in the world trading system, and understanding their impacts is an ongoing area of study for trade policy analysts and researchers.

■ nontraded goods

Even in today's increasingly integrated world a host of goods and services — health care and housing, for example — are not traded across national borders, either because they simply cannot be traded or because barriers to trade are too high. Sometimes political barriers also may prevent trading of some goods, such as strategic military equipment. These commodities, traded exclusively at home (domestically), are broadly labeled as nontraded goods.

Nontraded goods must have their markets cleared locally, and in this respect, differ fundamentally from traded goods for which local excess demand or supplies can be accommodated in the world markets. Although recent trends in globalization, characterized by sharp declines in transportation and communication costs, tend to convert nontraded goods into traded goods, nontraded goods and services continue to represent the large majority of world consumption.

Goods that are traded internationally can be transported or provided in another country at some cost. In principle, therefore, the providers of such goods in different countries compete with one another. In contrast, nontraded goods have to be provided locally and do not involve competition among international providers. The classic textbook example of a nontraded good is a haircut (albeit a service). Though substantial differences may exist in the prices of haircuts across countries, trade does not develop by shipping haircuts from low-price to high-price countries. The cost of transporting either the barber or the customer to take advantage of the low price would far outweigh the price differential. As such, a barber in the United States need not be excited to learn that an appreciation of the pound has made haircuts in the United Kingdom relatively costlier.

The importance of nontraded goods in a trading world was discovered by Ohlin (1929) in his criticism of Keynes's (1929) views on the German transfer problem and has subsequently been illuminated by many prominent economists. Keynes and Ohlin agreed that a transfer would inevitably result in a reallocation of resources between the traded and nontraded sectors. Keynes had argued, however, that the presence of a nontraded good would shift resources away from the nontraded sector into the exporting sector to exacerbate the donor's terms of trade deterioration as a result of a transfer. Ohlin, in contrast, saw no reason for a movement in the terms of trade and expected only opposing changes in the prices of traded goods relative to those of nontraded goods for the donor and recipient.

Prices of nontraded goods are determined exclusively by local conditions that affect demand and supply, whereas prices of traded goods are determined by conditions around the globe. As such, the distinction between traded and nontraded goods becomes even more important for relatively small trading countries: a small country, through policy changes, can affect prices of nontraded goods but it cannot affect prices of traded goods.

Theories of Trade and Nontraded Goods Are the results of the models of international trade sensitive to the presence of nontraded goods? Jones (1974) presented an elegant model, in which he assumed away the possibility of import-competing production and local consumption of exports, providing a clear view of the way in which the market for nontraded goods is linked to that for traded goods. Komiya (1967) was the first to generalize the standard Heckscher-Ohlin (H-O) model for international trade to incorporate a third, nontraded good. The presence of a nontraded good removes the production indeterminacy of a two-factor, three-commodity (two traded and one nontraded) H-O model. The factor price equalization (FPE) theorem and Rybczynski theorem on the effect of a change in factor endowments on the output levels hold in the new three-commodity model. A country's trade bias (pro or anti) depends on the elasticity (or inelasticity) of the demand for the nontraded good as well as the relative factor intensities of all three commodities. Technological progress in the traded sector does not necessarily result in an increase in its output. Technological progress in the nontraded sector, however, raises the output of the nontraded goods sector if inferior goods are ruled out.

Ethier (1972) analyzed the effects of integrating nontraded goods on each of the four basic results of

the H-O model: the FPE theorem, the Rybczynski theorem, the Stolper-Samuelson theorem, and the proposition that a change in the terms of trade will cause an increase in the output of the good whose relative price has risen and a decrease in the output of the other when there are fixed-factor endowments. It can also be shown that the Rybczynski theorem for net output movements stays unaffected by interindustry flows in the two-factor, two-commodity Heckscher-Ohlin model for gross and net output movements in the presence of traded and nontraded intermediate inputs. If the nontraded commodity is a pure intermediate commodity, the Rybczynski theorem still holds with some modifications for gross and net output movements.

In a two-factor, three-commodity model where the third commodity is a nontraded good, the Rybczynski theorem holds for output movements if there is no inferiority in consumption. This is true with some modifications for gross and net output movements when interindustry flows exist. A sufficient condition for this generalized version of the Rybczynski theorem, applicable to a two-factor, three-good economy where one of the goods is nontraded and indecomposable interindustry flows exist, is that the net output change of the nontraded good is bounded by the factor changes.

Following Rivera-Batiz (1982), Komiya's results on the effect of technological changes and changes in factor endowments in the presence of nontraded goods do hold, in a framework where the number of factors and the number of goods are equal, if and only if the sum of the own price elasticities of demand for traded and nontraded goods is equal to unity. Otherwise, a Hicks-neutral technological change in the nontraded goods sector will reduce the price of nontraded goods proportionally less (more) in absolute value than the technological change when the aggregate elasticity is greater (smaller) than unity. Factor prices measured in terms of the traded goods will in general not be fixed, and factor prices measured in terms of the nontraded goods will not change proportionally to the same extent as the change in the price of the nontraded goods, as long as the aggregate elasticity is different from one. The

exact effect on the factor prices will depend in the magnitude of the aggregate elasticity and on the factor-intensity of the nontraded goods' production relative to the traded goods' production. Also, factor prices and the price of nontraded goods are affected by changes in factor endowments in this framework. If the endowment of any factor increases, the price of nontraded goods will decrease if the nontraded goods production is relatively intensive in the expanding factor. Income distribution will turn against the expanding factor. In the context of the specific-factors model, in which an extreme asymmetry in factor mobility is assumed, Clague (1985) showed that increases in the endowment of a specific factor increases the real reward of the mobile factor when nontraded goods exist.

Adding nontraded goods to a conventional factor proportions model, according to Deardorff and Courant (1990), will reduce the likelihood of FPE. Specifically, in the presence of nontraded goods, the reduction in the likelihood of FPE is equal to the fraction of income spent on nontraded goods. For given prices, the set of factor endowment combinations that are consistent with producing the same set of goods and having the same factor prices will shrink, reducing the chance that a country's factor endowments lie in the set, and therefore the likelihood of FPE is reduced. A generalization of the Stolper-Samuelson theorem to include the role of the nontraded goods sector in explaining the effects of price changes in traded goods on relative and absolute wages, provided by Beladi and Batra (2004), reveals that if the import and nontraded sectors are reduced, then freer trade can harm skilled and unskilled labor while improving capital.

Some of the standard conclusions about international trade are disrupted when market imperfection is present in the nontraded goods sector. The fact that some commodities are not traded internationally may itself suggest the presence of product market imperfections. Prohibitive tariffs, for instance, are a source of nontraded goods that may confer market power. In the presence of a monopolized nontraded good, the Rybczynski theorem remains intact as long as the price elasticity of demand for nontraded goods

depends only on relative prices. Following Cassing (1977), however, the Stolper-Samuelson theorem is modified in an important way depending on the degree of monopoly and the specific taste patterns of the factors. An increase in the relative price of a traded good will raise the nominal reward for the factor used intensively in that sector but will lower the price elasticity of demand in the nontraded sector which, in turn, will raise the price of the nontraded good relative to the gaining factor whose nominal reward improved. The real reward of the factor, used intensively in the traded sector experiencing a price increase, can fall for sufficiently high propensity of nontraded goods consumption by that factor. Within the same framework, Hazari and Kaur (1995) show that when a nontraded good is produced by a monopoly, a tourism boom can lead to a decrease in the domestic residents' welfare because of drastic movements in the terms of trade.

Policy Relevance of Nontraded Goods The existence of nontraded goods has nontrivial implications for a country's domestic or international policies. An expansionary fiscal policy in nontraded goods and an expansionary monetary policy in international bonds can have offsetting effects on a country's reserves. When the production possibility set is strictly convex (i.e., there are no economies of scale), if the highest tariff rate is reduced to the level of the next highest, welfare improves under certain conditions: specifically, no inferior goods can exist in the economy, the commodity with the highest tariff rate must be substitutable, and the nontraded goods must be substitutable. When multiple commodities share the highest tariff rate, and the highest tariff rate is reduced to the level of the next highest rate, the level of utility increases under substitutability. When all tariff rates move proportionally to a given rate (uniform tariff change), utility increases. Tariffs and production subsidies can reduce the price of nontraded goods. A consumption subsidy may be the optimal policy decision in a model with nontraded goods and production externalities.

When there exists a high intertemporal elasticity of substitution in consumption, contrary to the case with traded goods only, a temporary fiscal expansion (in the form of government spending) on nontraded goods causes real interest rates to move in different directions in each country. More specifically, a fiscal expansion of nontraded goods with a low elasticity of substitution will decrease the domestic interest rate relative to world real interest rates, deteriorating the expansionary country's current account. With a high substitution elasticity, however, the expansion increases domestic real interest rates relative to foreign real interest rates while improving the domestic country's current account. In the presence of a generalized cash-in-advance constraint, when a monetary distortion of the nontraded good is present, a tariff may not be dominated by a consumption tax.

In a two-sector economy, if one of the sectors is characterized by monopolistic competition, a tariff leads to an improvement in welfare if the differentiated good is nontraded but leads to a deterioration of welfare if the homogeneous good is nontraded. Decreases in import prices or tariffs will increase the price of nontraded goods when cross-substitution effects are dominated by the income effect. In a setting of differentiated traded goods, welfare decreases as a result of the tariff causing a demand shift away from the differentiated goods market toward the market for the nontraded homogeneous good. Devereux (1988) offers an insightful discussion on these issues.

Welfare Analysis and Nontraded Goods The relevance of nontraded goods for welfare analyses, including but not limited to the "transfer paradox" (i.e., the possibility that a transfer may reduce the recipient's welfare even when markets function perfectly), has added interest in the topic. Early attempts at identifying a distinct role of nontraded goods in welfare convincingly argued that the effects of neutral technical progress on output and welfare are sensitive to the inclusion of nontraded goods. The welfare of the host country can be shown to unambiguously improve with foreign investment in nontraded goods. The gains-from-trade proposition applies to a monopolistic competition framework that extends to include nontraded goods when differentiated nontraded goods are present as well as traded goods.

Technical progress in manufacturing increases the price of nontraded goods and improves national welfare, and deterioration in the terms of trade increases the price of the nontraded goods and improves national welfare, if the gain of the induced employment effects exceeds the direct loss of the terms-of-trade decline. Those who own traded goods suffer welfare deterioration while owners of nontraded goods experience welfare improvement following a temporary devaluation.

It is important to realize that international trade grows not only as countries trade (on the intensive margin) more of the goods they had already been trading but also when countries begin trading goods (on the extensive margin) they had previously not been trading (nontraded goods). As such, it is hardly surprising that nontraded goods continue to draw our attention even in today's increasingly globalized world.

HAMID BELADI AND AVIK CHAKRABARTI

■ North American Free Trade Agreement (NAFTA)

The United States, Canada, and Mexico are signatories to the North American Free Trade Agreement (NAFTA). In 2006, the pact covered a combined

economy of more than $14 trillion and a population of about 435 million people. In large measure, NAFTA represents the agglomeration of Mexico into the existing Canada United States Free Trade Agreement (FTA) that was signed in January 1988 and became effective a year later. Mexico initially sought a bilateral FTA with the United States; the two countries announced their intent to pursue an FTA in June 1990, which evolved into NAFTA when Canada joined the process several months later. Negotiations began in May 1991 and concluded in August 1992; U.S. president George H. W. Bush, Mexican president Carlos Salinas, and Canadian prime minister Brian Mulroney signed the agreement in December 1992.

Prior to its ratification, however, the incoming U.S. president, William J. Clinton, demanded additional commitments regarding labor, the environment, and import safeguards. Subsequent negotiations during the first eight months of 1993 produced three side agreements to NAFTA: the North American Agreement on Labor Cooperation (NAALC); the North American Agreement on Environmental Cooperation (NAAEC); and the Understanding between the Parties to the NAFTA Concerning Chapter 8 Emergency Action (that is, against import surges). In addition, the United States and Mexico signed the Border Environmental Cooperation Agreement, which, inter alia, created the North American Development Bank with the aim of funding environmental projects on both sides of the border. Together, these "side accords" supplemented NAFTA provisions and helped Clinton secure congressional approval of the pact in November 1993 by a vote of 234 to 200 in the House and 61 to 38 in the Senate. NAFTA entered into force on January 1, 1994.

Why NAFTA? NAFTA arose because Mexico needed and asked for free trade with the United States. Given the legacy of the debt crisis of 1982, low domestic savings, and an overvalued peso, Mexico needed to import technology and capital to propel economic growth. By ensuring open access to the U.S. market and making it harder to reverse Mexican reforms implemented since the *apertura* (opening) of the 1980s, Mexico expected NAFTA to complement continuing domestic reforms and create new trade and investment opportunities within the Mexican economy. In fact, the mere announcement of NAFTA talks elicited significant new commitments of foreign direct investment in Mexico in anticipation of the new trade regime with the United States.

For the United States, NAFTA served both economic and political objectives. NAFTA created new opportunities to increase trade and investment with its southern neighbor; U.S. officials also touted though greatly exaggeratedly the employment implications of the trade pact. At the same time, they saw the initiative as a way to support the growth of political pluralism and democracy in Mexico, and as part of the long-term response to chronic immigration problems.

Overall, NAFTA has had only a glancing effect on these nontrade issues. NAFTA's first decade coincided with profound changes in Mexico's political regime and the end of 70 years of one-party rule. Mexico's political reform has been a uniquely Mexican achievement, however. NAFTA deserves little credit, except to the extent that increased U.S. interest in Mexico made the 2000 election in Mexico harder to rig. On immigration, NAFTA has not met expectations. Migration from Mexico, both legal and illegal, increased over NAFTA's first decade. Demographers initially forecast increased flows of Mexican migration to the United States, followed by declines in the medium and long run as Mexican economic prospects brightened. But these estimates had to be recalibrated in light of the peso crisis, enduring poverty in states south of Mexico City, persistent rural-urban migration, and the impact of Chinese competition on Mexican industry.

What Is NAFTA? NAFTA was the first free trade agreement involving developed and developing countries that established a comprehensive set of obligations on trade and investment in goods and services. Its detailed chapters cover subjects such as customs procedures, technical standards, sanitary and phytosanitary measures, government procurement, intellectual property rights, investment and

competition policy, and sectors such as agriculture, energy, and cross-border services trade in telecommunications and financial services.

With a few notable exceptions, the pact removes barriers to trade and investment in goods and services among the three economies. It does not create a customs union; each member maintains an independent trade regime governing its transactions with nonmember countries. On agriculture, a sector often excluded from disciplines in trade accords, NAFTA comprises three bilateral pacts (U.S.-Mexico, U.S.-Canada, and Canada-Mexico). The U.S.-Mexico accord comes closer to free trade in farm goods than any other extant trade agreement and provides more pervasive liberalization of trade barriers than the U.S.-Canada pact, which contains important exceptions to the free trade regime originally included in the Canada-U.S. FTA that were carried over into NAFTA.

In addition, NAFTA incorporates six dispute settlement processes to manage and expedite the resolution of disputes among the three countries. The six processes cover chapter 11 (investment), chapter 14 (financial services), chapter 19 (anti-dumping and countervailing duties), chapter 20 (functioning of the agreement), the NAALC (labor), and the NAAEC (environment). Chapter 19 cases have been by far the most numerous; chapter 11 provisions involving investor-state disputes have been the most controversial, contrary to initial expectations. When these investor rights were first conferred, the chapter 11 provisions were hailed as a better forum than national courts for resolving investment disputes. In practice, however, the rules (e.g., the ban on indirect expropriation under article 1110 and the minimum standards under article 1105) have fostered litigation by business firms against a broader range of government activity than originally envisaged. Environmental groups, in particular, have raised concerns about the impact of chapter 11 tribunals on state and local environmental standards.

By contrast, NAFTA's institutional structure is skeletal. The signatories did not want to create a new bureaucracy; the governance structure of the pact is minimalist and its budget insufficient to achieve even its modest mandate. The pact is governed by a Free Trade Commission composed of the three trade ministers that oversee the operation of the agreement. In addition, there are more than 30 working groups that provide advice to the commission on specific issues (e.g., rules of origin), a small NAFTA Secretariat to administer the dispute settlement procedures and other work of the commission and working groups, and separate advisory bodies for the labor and environment accords.

Although the pact is comprehensive compared with other trade agreements, it has important limitations. First, NAFTA omits important rights and obligations on subsidies, energy trade, and investment, and the use of anti-dumping and countervailing duties. The pact also maintains restrictions on U.S.-Canadian agricultural trade excluded from their bilateral FTA. In addition, its side pacts on labor and the environment are primarily consultative arrangements and not backed by meaningful arbitration mechanisms or financial resources.

Second, NAFTA was not designed to cure the manifold ills of North American societies, including high levels of illegal immigration, slow progress on environmental problems, growing income disparities (particularly within Mexico), weak growth in real wages, and trafficking in illegal drugs. Some of these problems are correlates of economic integration and higher incomes; all of them require policy responses that range well beyond the competence of trade officials.

The NAFTA Experience to Date In commercial terms, NAFTA has met the stated objectives of its signatories but failed to justify either the inflated promises of its political supporters or the harsh defamations of its critics. Over its first decade, intra-NAFTA trade soared, building on the extensive network of cross-border investments already linking, in particular, the auto and electronics industries of North America. Merchandise trade among the three countries rose almost threefold and was valued at more than $800 billion in 2006; exports to and imports from Canada and Mexico accounted for 30 percent of total U.S. trade. Direct investment by the

United States in Mexico grew robustly but still represented only a small fraction of total investment in American plant and equipment by U.S. firms. The stock of U.S. holdings in Mexico was valued at more than $71 billion at year-end 2005, up from $17 billion in 1994. Canada-Mexico trade and investment also grew rapidly from a low base.

Net employment rose sharply in all three countries during NAFTA's first decade, aided by the positive add-on effects of strong U.S. economic growth. Millions of jobs were created in each country and a sizable but smaller number of jobs were lost each year. On balance, employment rose by 15 million in the United States, 3 million in Canada, and 8 million in Mexico. To be sure, employment in Mexican maquiladoras fell sharply from peak levels in 2000, but those losses resulted primarily from the U.S. economic downturn in 2001 2, changes in Mexican tax policy, and the impact of a strong peso on industrial competitiveness. In the United States, NAFTA-related job losses represented a small fraction of displaced workers whether one counts the official tally of the NAFTA Trade Adjustment Assistance program (about 60,000 per year) or the higher numbers cited by NAFTA critics.

Similarly, NAFTA's impact on wages got swamped by other factors in the massive U.S. economy. Claims that NAFTA has contributed to the suppression of U.S. wages are supported only by anecdotal evidence, not serious statistical analysis. There has been no material difference in wage rates between states and industries with a large volume of U.S. imports from Mexico and those with a small volume. By far the most important channel by which Mexico influences U.S. wages is immigration and this is a function of geography, not trade. In Mexico, real wages did take a big hit in 1995 due to the peso crisis and subsequent deep recession, but rebounded sharply in the decade following 1997.

From day one, NAFTA results were skewed by the political tumult in Mexico caused by a populist revolt in Chiapas, assassinations that marred the 1994 Mexican presidential election campaign, and the peso crisis that erupted in December 1994. NAFTA obligations helped Mexico weather the financial storm of late 1994 95 in two ways: by channeling the Mexican response toward orthodox fiscal and monetary policies instead of trade protection and subsidies, and by encouraging U.S. financial support for its troubled neighbor. The Mexican economy rebounded quickly and resumed robust growth in the second half of 1996.

Since then, Mexican economic growth has been solid but not spectacular and (as of late 2007) not good enough to redress decades of economic problems. Tight fiscal and monetary policies brought the macroeconomy quickly back into balance, but constrained growth well below levels needed to solve the problems of Mexican society. Investments in physical infrastructure, human capital, and social services have been inadequate. As a result, the Mexican government has not been able to allocate the growth dividend across a broad spectrum of society, and Mexican firms and workers have not been able to take full advantage of the opportunities created by NAFTA. Moreover the growth has been highly skewed among regions within Mexico, exacerbating income disparities between the northern and southern states.

In the United States, NAFTA has had a more profound impact on trade *politics* than on trade itself. The rancorous ratification debate in the U.S. Congress in 1993 galvanized an emerging anti-globalization movement that demanded "No More NAFTAs" and a substantial restructuring of the international economic order. Recurring claims by NAFTA critics that the pact has displaced large numbers of U.S. jobs and investment have proven unfounded, however.

Nonetheless NAFTA became a lightning rod for concerns about the adverse effects of globalization on American workers and industries. The traditional protrade coalition in Congress fractured. Democrats abandoned support for new trade initiatives in response to their labor constituents and in retaliation for the highly contentious and partisan debate in the Republican-led Congress over tax policy and social issues. "Fast-track" trade negotiating authority lapsed in 1994 and major new trade initiatives were deferred until August 2002, when the Congress

narrowly restored the trade mandate under the rebranded title of "Trade Promotion Authority" (TPA). Even with TPA, however, U.S. officials struggled to secure passage of NAFTA's phonetic cousin: the U.S. Central American Dominican Republic FTA, or CAFTA-DR, passed the House of Representatives by a narrow 2-vote margin in the summer of 2005 (contrasted with a 34-vote margin for NAFTA itself in 1993).

In sum, NAFTA has had a positive effect on economic growth in all three countries, but challenges remain. Even though each country, on balance, has profited from the regional trade deal, the aggregate gains mask adjustment problems besetting members of each society. The solution to such problems for each signatory may be in domestic policies that allow its workers, farmers, and firms to take advantage of the opportunities created by NAFTA and that retrain, retool, and provide income support for those adversely affected by the new competition.

◼ North-South trade

North-South trade refers to trade between rich (or developed) countries the North and poor (or developing) ones the South. The essence of North-South trade is that the two regions differ, and the variety of assumptions about the cause for instance, differences in capital per head or technology goes a long way toward explaining the variety of conclusions that are drawn about it. In addition, researchers vary as to (1) whether they consider North-South trade to mean trade that reflects only the differences between regions per se, or trade stimulated by reductions in trade barriers (natural or policy), (2) whether they permit other changes (e.g., in capital flows or technology), and (3) what they are seeking to explain for example, divergence between regions or within them (income distribution).

This entry presents a few data on North-South trade, discusses a number of models that predict divergence between North and South, and explores the hypothesis that North-South trade explains widening income inequalities.

The Data Traditionally North-South trade was conceived of as the trade of Northern manufactures for Southern primary goods, which bears a close relationship to analyses of the terms of trade under the so-called Prebisch-Singer hypothesis. This view of North-South commodity trade once had some empirical validity, but it is now severely dated.

Defining the North as the members of the Organisation for Economic Co-operation and Development as of 1990 less Turkey, and the South as all other countries, North-South trade accounted for 38.4 percent of world trade in 1962 and 38.6 percent in 2005 (provisionally), with an (oil-induced) high of 42.6 percent in 1981 and a low of 30.9 percent in 1988. One big change, however, was that whereas in 1962 the North exported twice as much to the South as it imported, the South had a trade surplus with the North over the period 1999 2005. Since 1962 the South's share of world exports to all destinations has increased from 18.1 to 40.7 percent. The story in manufacturing is similar, with a huge growth in Southern capacity and share of world trade see figure 1, which shows Southern exports growing from less than 5 percent of the world total to 37.5 percent. Within Southern exports to the North, the transformation from primary to secondary sector exports is striking (see figure 2). From a share of 10.7

Shares in Southern exports to North. Source: World Bank, World Integrated Trade System (WITS).

percent in 1962, manufactures now account for about 75 percent of exports to the North.

North-South Trade Models The mainstream neoclassical model of international trade the Heckscher-Ohlin model does not adequately explain the long-run differences in income and/or growth that are of interest in the North-South literature. It assumes identical technologies and, in the absence of complete specialization, it predicts equal factor prices in the North and South. Although assuming economywide Hicks-neutral technical differences could explain differences in average income within the Heckscher-Ohlin framework, this begs the question of why they exist. (Hicks-neutral technical differences between countries arise when the productivities of every factor production differs by the same proportion between them.) Similarly, a simple Ricardian model, in which the only difference between countries lies in the different efficiencies of labor the only factor in the various sectors, is thrown back on such a deus ex machina to explain North-South differences.

In order to explain unequal and possibly diverging incomes between North and South, researchers have had to delve into more fundamental characteristics. Marxian economists adopt the theory of "unequal exchange," whereas mainstream economists using, say, a Ricardian approach, take comparative advantage as given and locate North-South differences in, for example, the elasticities of demand for their products, their market structures, or their labor markets. The first two, frequently associated with Raúl Prebisch and Hans Singer, can explain the declining terms of trade of Southern countries and their inability to grow out of poverty. An early model of the labor-market style (Findlay 1980) had a "manufacturing" North with full employment and an "agricultural" South with fixed wages and surplus labor (as in Arthur Lewis's model of development). Growth arose spontaneously in the former and was transmitted to the latter via the demand for imports. With a fixed real wage and given technology, the critical variable in equilibrating the world economy was the terms of trade which, given unitary income elasticities of demand for both products, adjusted to
produce equal growth in the North and South even though the North had a higher income level. Increased Southern productivity depressed the terms of trade rather than boosted growth. Subsequent theoretical developments that allowed capital to move internationally or equalized profit rates in some other way produced divergence (unequal growth) even with unitary demand elasticities.

Nicholas Kaldor located the asymmetry in economies of scale of manufacturing, so that a country that had more manufacturing initially would achieve higher growth rates and be "Northern." Among several formalizations of this idea, Krugman's (1981) is the most elegant. Economies of scale in industry raise profits and accumulation in the North and eventually erode the South's industrial sector. The process stops only when one or both of the regions becomes completely specialized in production. It is likely that the South benefits from the earlier stages of this process and possible that it does so relative to autarky (i.e., no trade at all) even at the final point. And if capital is mobile between North and South as well as goods, such gains are probably more likely.

Kaldor thought of economies of scale in rather physical terms and hence as internal to the firm, but they are probably better thought of as external, residing, for example, in the thickness of labor or intermediate markets, backward or forward linkages, or spillovers of knowledge. This highlights the similarity of these models with those of economic geography. Knowledge spillovers could in fact operate throughout the economy, being related to, say, average levels of human capital, but provided that goods have different human capital intensities, trade and specialization would give the model the same feel as above. In such models human capital (skilled workers) may well have incentives to migrate from South to North.

Related to knowledge is innovation the ability to develop new products or varieties. If this skill differs between North and South this too can generate unevenness. Again Krugman (1979) offers an elegant model. Only the North can innovate but eventually the ability to produce any good becomes

worldwide as in Vernon's product cycle theory. Providing that it keeps innovating the North will employ at least some of its factors on "new" products and thus will export "new" goods in return for "old." It will earn higher incomes than the South via its quasi-monopoly in these products even though it has only equal productivity with the South in established (old) products. This implies that a reduction in the rate of innovation or an increase in the speed of imitation in the South could actually reduce real wages in the North. This introduces potential North-South conflict, a feature that some consider a necessary component of North-South trade models, although in the basic version of Krugman's model Northern innovation is always good for the South absolutely. If, however, capital were mobile, Southern workers could lose from increased innovation as capital flowed from South to North.

The simple innovation model has spawned many offspring. It has been located in richer models of production by combining it with factor abundance driven trade. Krugman's horizontal product differentiation (each new product is of the same quality as each old one) has been replaced by vertical differentiation whereby innovation creates better varieties. Innovation and imitation have been made costly and endogenized. And policies have been introduced: Northern trade restrictions typically slow down innovations at everyone's expense, except (possibly) Northern workers', and restrictions on Southern imitation (fierce intellectual property rights regimes) hurt the South and, quite possibly, the North as well.

The North-South trade literature has been mostly theoretical; it has been tested only informally against alleged stylized facts. In particular, there is no convincing empirical evidence that North-South trade has held the South back not least because it is so difficult to formulate a plausible counterfactual without such trade. There is, however, a vigorous debate about whether trade in general enhances Southern growth, income, or development. Early positive results from cross-country exercises were largely demolished by Rodriguez and Rodrik (2001). Even these authors admit, however, that there is no general presumption that openness harms average

incomes, and more careful research is starting to rehabilitate the positive view. Case studies also suggest that openness is commonly a key input to development.

A second component of empirical testing has plotted the effects of Northern research and development efforts on Southern productivity. It has suggested strong links via goods trade (perhaps via embodied technical progress), the importance of foreign direct investment, the need for local skills to ease adaptation, and the fact that knowledge apparently does not easily cross large skills gaps (e.g., Chad learns relatively little from the United States).

North-South Trade and Wages The second major stream of North-South trade research is shorter-run and empirical. It considers the effects of increasing global integration on North income inequalities over the last few decades. It stems from Wood (1994), which postulates a world of fairly free capital mobility and sector-neutral technology differences, and makes the critical difference between Northern and Southern countries their relative endowments of skilled and unskilled labor. Declining barriers to the South's exports of unskilled labor-intensive goods, particularly manufactures, were, he argued, a major explanatory factor in the widening differential between skilled and unskilled wages in the North. He showed that the unskilled labor embodied in a dollar's worth of Southern exports far exceeded that in a dollar's worth of Northern exports: the North was essentially importing labor. This drove down its price because countries produced different combinations of the many goods that existed, so that there was effectively specialization, and the factor price equalization theorem failed to apply.

No one denied the increasing skills wage gap and the weakness of unskilled wages and employment, but there were several challenges to Wood's explanation. Some argued that non-resource-based imports from developing countries were too small perhaps 3 4 percent of Northern countries' GDP to have such profound effects, especially given that the increase in labor supply embodied in net imports (i.e., imports less exports) was small. Others argued that in order to influence wages in the North,

Southern exports would also have to drive down the relative prices of unskilled-labor-intensive goods in the North, and this had not happened. In fact, however, this turned out to be only because technical progress was driving down the prices of electronic equipment, especially for information technology related uses. Among "traditional" goods, the relative price decline was evident.

The principal counter was that technical progress had a strong skill bias. Two pieces of evidence suggested this: first, the ratio of unskilled to skilled workers fell in virtually every sector and every Northern country. Under a pure factor abundance theory it should have risen as unskilled labor became cheaper (the declining aggregate demand for unskilled labor arising from the switch in the production bundle away from unskilled-intensive goods). Second, the skills wage gap widened in the South as well as in the North, whereas the factor abundance approach predicted a narrowing.

In fact, however, each piece of evidence admits other explanations and so does not overturn Wood's conclusions. The definitions of sectors in empirical work are very broad and almost always include tasks with widely different skilled/unskilled labor ratios. Thus offshoring the unskilled-intensive activities within a sector would be consistent with both competition from Southern imports and falling relative unskilled labor use in the North. Several explanations have been advanced for the growing skills wage gap in the South. The most interesting, by Feenstra and Hanson (1997), starts by arraying activities or sectors by increasing unskilled labor intensity: the South does the low-ranked ones and the North the higher-ranked ones. If Southern costs fell, the North would outsource its least skill-intensive activity to the South, where it would become the most skilled activity. In *both* countries, the relative demand for skills would increase. The cost decline could be autonomous or, as in Feenstra and Hanson, driven by flows of capital from North to South, which in turn may be responding to declining trade barriers.

There is, finally, the question of what causes technical progress: even if it is skills biased, it may be induced by the need to withstand competition from

cheaper labor in the South. This is certainly possible, but observe that except for very large changes over the longer run, the effect of technical progress on factor demands depends more on its sectoral composition than on which factor it tends to replace. If technical progress makes an unskilled-labor-intensive sector cheaper it will boost demand for it and hence for the bundle of factors it employs — that is, for an unskilled-intensive bundle. If North-South trade induces technical progress, the effects seem likely to be stronger in unskilled, not skilled, labor-intensive sectors.

In 2006, most economists accept that both autonomous skill-biased technical progress and North-South trade play significant roles in skills gap. Most accept that the latter effect is likely to get stronger in the future as trade and communications costs fall, allowing production processes to be even further divided. It is possible, however, that by making components cheaper, North-South trade sufficiently increases demand for products that require unskilled labor in the North (e.g., delivery services) that demand for Northern unskilled workers increases overall.

This literature does not deal directly with the effects of North-South trade on Southern development but is predicated on the South's strong expansion of production, as we have seen in Asia since 1960. Its consistency with rising skills wage gaps in the South is realistic and highlights one of the major challenges of future development — how to meet the (modest) income aspirations of the South's large less-skilled labor force.

offshore financial centers

Offshore financial centers (OFCs), despite their name, are not necessarily islands although many island jurisdictions have established OFCs nor do they have a single universal definition. One definition of an OFC is a jurisdiction whose financial sector accounts for a significant and disproportionate share of its domestic economy. Another definition is a jurisdiction where a majority of financial transactions conducted by its institutions are done on behalf of clients who reside in other jurisdictions.

Some of the largest offshore centers in terms of business volume are Bermuda, the Bahamas, the Cayman Islands, Jersey, Guernsey, and the Isle of Man. International financial centers with characteristics similar to OFCs include Luxembourg, Ireland, Switzerland, Singapore, and Hong Kong.

Historically, OFC jurisdictions were associated with one or more of the following: low or zero taxation, moderate financial regulation and supervision, and secrecy or anonymity in financial dealings. Increasingly, the successful OFCs are associated with niche markets in which they have developed extensive professional expertise (for example, in reinsurance, trust business, and private banking) and have reputations for maintaining good supervisory and regulatory systems. Tax advantages continue to be a key driving force for the domicile of financial transactions in OFCs. Some jurisdictions consider the term *offshore financial center* pejorative because of its historical association with lax regulatory and anti-money-laundering regimes. A number of international financial centers have many of the characteristics of offshore centers concerning tax advantages, development of instruments to attract international financial business, and cross-border financial transactions that are significantly out of proportion with the size of their domestic economy.

Growth and Activities of OFCs The growth of OFCs can be traced to the restrictive regulatory regimes in many advanced countries in the 1960s and 1970s. These regimes restricted the flow of capital to and from other countries (excluding trade financing) or imposed restrictions on the interest rates banks could offer, or raised banks' funding costs in domestic markets (for example, through the imposition of high non-interest-bearing reserve requirements). These restrictions, which in many cases were intended to provide governments with more control over monetary policy or to protect the balance of payments, encouraged a shift of deposits and borrowing to less-regulated institutions, including banks in OFCs not subject to such restrictions. As large multinationals and financial institutions shifted financial activity "offshore," the "euromarket" was established. These activities began in the financial centers of Europe (mostly London) and soon spread to other offshore centers.

As with international financial centers, business conducted in OFCs covers a wide range of financial sectors such as banking, insurance, securities, and some nonfinancial activities such as shipping registries and company and trust service providers. Most OFCs specialize in specific types of financial services, however. Multinational corporations and

high-net-worth persons are some of the most frequent users of OFCs.

Banking is the most prevalent business, and a significant volume of international banking transactions are conducted in OFCs. Most banks located in OFCs are branches or subsidiaries of international banks. Their main activity is collecting deposits from various markets and channeling them back to their parent institutions. Private banking is a major service offered to high-net-worth persons. Specialized services for such clients range from asset management to estate planning, foreign exchange trading, and pension arrangements.

Collective investment schemes (mutual funds and hedge funds) are also domiciled in OFCs, mainly for tax purposes. Related fund activities such as fund distribution, asset management, fund administration, custodian services, and back-office work are also conducted in these centers. Although a large number of hedge funds are domiciled and administered in OFCs, the management of the investment portfolios is normally conducted in the major financial centers such as London and New York.

Insurance business, including life, property, reinsurance (an insurance company that assumes all or part of a risk undertaken by another insurance company), and captive (a company owned by a noninsurance firm that provides insurance coverage to the owner), is also conducted in some OFCs. Innovative regulatory and legal environments have helped OFCs attract a large share of the world's captive and reinsurance market. For example, most of the new capital entering the reinsurance industry on the year following the catastrophic hurricane season of 2005 was placed in existing or start-up companies in OFCs. A large portion of the world's captive insurance companies is also domiciled in these centers.

A significant number of special purpose vehicles (SPVs) that is, financial instruments that are tailored to meet the particular financing needs of financial and nonfinancial corporations are registered in OFCs. Financial firms use SPVs for securitization, and nonfinancial corporations use them to lower the cost of raising capital. OFCs are attractive places to register SPVs because of the tax advantages they offer.

Asset protection, including the establishment of trusts, is another service offered by OFCs. Reasons for managing assets in OFCs include protection from weak domestic banks or currencies, additional legal protection from lawsuits in the home jurisdictions, and tax efficiency/avoidance.

Concerns about OFCs Some of the characteristics of OFCs raise concerns about potential risks to the international financial system. First, since the livelihood of OFCs depends on their ability to attract global financial business, competition among jurisdictions is strong. Such competition is beneficial when it contributes to innovation in financial instruments and products and lowers costs of financial services worldwide. It can also raise concerns, however, if the lower cost of financial services is achieved by lowering regulatory and supervision standards. Second, as OFCs provide financial services predominantly to nonresidents, the authorities in the transaction home countries are interested in the impact on their national economies of the operations in OFCs, especially when these operations are beyond the home country authorities' control. Third, anonymity and lack of transparency in OFCs, opaqueness of the operations of offshore corporations, and legal protections in some OFCs have created concerns. Historically, a lack of reliable data on activities in OFCs hampered analyses of the potential risk that OFCs pose to financial stability. SPVs domiciled in OFCs have been implicated in some of the large corporate frauds. Fourth, the anonymity of financial transactions makes OFCs attractive to money launderers. OFCs are a potential gateway for the proceeds of crime to gain access to and to be laundered through global financial markets. Money laundering is an international problem, and to be effective, international standards against money laundering and terrorist financing need to be applied worldwide, especially in large financial centers.

Concerns about the potential risk posed by OFCs resulted in OFCs being placed on "name and shame" lists by a number of international bodies in 2000, including the Financial Stability Forum (FSF), the

Financial Action Task Force on Money Laundering (FATF), and the Organisation for Economic Cooperation and Development (OECD). This posed significant reputation damage to OFCs. Also in 2000, the International Monetary Fund (IMF) was asked to intensify its oversight of OFCs in the context of its mandate to promote financial stability. The IMF's program has focused on (1) regular monitoring, (2) assessing OFCs' compliance with international supervisory and anti-money-laundering standards, (3) enhancing the transparency of activities in OFCs, and (4) strengthening international cooperation and information on supervisory and regulatory systems.

Because of the intensified international attention, many OFCs upgraded their supervisory and regulatory systems and improved the transparency in their operations. A number of smaller OFCs also decided to exit from part or all of their OFC activity after weighing the costs and benefits. Although a financial center can be a useful addition to an economy, a significant and costly investment in the supervisory and regulatory infrastructure is needed to provide the internationally accepted minimum supervisory system required to avoid reputation risk. At the same time, a number of new and aspiring OFCs are being established where the authorities have been willing and able to invest heavily in the necessary infrastructure.

See Organization of the Petroleum Exporting Countries (OPEC); petroleum

■ **oligopoly**

Oligopoly is a situation in which several firms compete over a given market, but there are so few firms that each one can earn a profit over and above what is earned in the more competitive industries. Barriers to entry in the form of information costs, economies of scale, franchises, and patents appear to be sufficient to keep out enough new competitors. Thus it is convenient here to think of oligopoly as imperfect competition without free entry, and monopolistic competition as imperfect competition with free entry.

Not surprisingly, international trade economists concerned with oligopoly have focused on the role of oligopoly profits. With monopolistic competition or perfect competition, there are no profits measured as the return over all opportunity costs. The existence of economic profits raises three large questions: How do those profits affect the pattern and volume of international trade? How do those profits affect who gains and who loses from international trade? And do those profits present policymakers with trade policy opportunities?

There are two approaches to studying oligopoly and trade: partial equilibrium and general equilibrium. The partial equilibrium approach concentrates on the world industry with no attempt to explain the division between exporters and import-competing firms or how oligopoly profits affect demand. This approach is most useful in studying questions involving trade policy. The general equilibrium approach seeks to examine how oligopoly profits affect the traditional trade questions of determining what is traded and the volume of trade, and identifying the winners and losers.

The Partial Equilibrium Approach In the first stage of development, the partial equilibrium approach dominated the literature with representative contributions by Dixit (1984), Brander and Spencer (1985), Eaton and Grossman (1986), and Brander

and Krugman (1983). Global firms can sell in an integrated world market, segmented markets in each country (Dixit 1984; Brander and Krugman 1983), or in some outside country (Brander and Spencer 1985; Eaton and Grossman 1986). The market is integrated if arbitrage keeps prices at home tied to foreign prices. The market is segmented if there is no arbitrage to keep prices in different markets in line. With tariffs and quotas, imperfect markets are best considered segmented.

Probably the most interesting and yet most controversial contribution is the one by Brander and Spencer (1985), which shows that subsidizing the exports from a domestic firm can be beneficial to the economy by a strategic trade policy that transfers oligopoly profits from a foreign firm to the home firm in the same industry. This result was made intuitively clear by Eaton and Grossman (1986), who showed that by a different assumption regarding the behavior of firms it was optimal to tax rather than subsidize the export of the oligopoly. Why the difference? The explanation is extremely simple: if we assume the oligopolist is too conservative toward rivals, the government should subsidize its exports; if the oligopolist is too aggressive, the government should tax its exports. If the economist cannot distinguish between these two cases in practice, then our information does not allow a recommendation. The difference arises in the model as the difference between Cournot and Bertrand competition. Cournot is competition in quantities; Bertrand is competition in prices. Assume a firm in country A and one in country B compete in a third market with goods that are imperfect substitutes. In the case of Cournot competition, the firm assumes that the other firm will maintain its output; in truth, if it expands output, the other will contract its output. Had the firm known this, it would have expanded its output even more. In the case of Bertrand competition, the firm assumes the other firm will maintain its price; in truth, if it lowers the price, the other firm will lower its price. Had the firm known that, it would have lowered its price by a smaller amount. Thus the existence of oligopoly profits does not seem to have raised the likelihood of a beneficial trade policy over and above traditional optimum tariff arguments. Even if strategic trade policies can be identified, they run into the same familiar problems: (1) governments correctly calculating optimizing tariffs or subsidies, (2) foreign retaliation can eliminate the benefits, (3) costly economic rent seeking by industries alerted to the policies, and (4) raising the cost of classifying goods for customs enforcement.

Brander (1981) and Brander and Krugman (1983) examine the role of price discrimination in international trade. In this case, it is assumed that there is an international oligopoly in which each country is a segmented market. Oligopolistic firms can raise profits by cutting prices in the market with a higher elasticity of demand. This implies that the standard theory of price discrimination can be applied, because now firms, regardless of their location, will sell in all markets at the prices prevailing in each segmented market. There now may be cross-hauling, or wasted transportation costs as even identical goods move in both directions (Brander and Krugman 1983). A felicitous mental picture would be two logging trucks going in opposite directions and carrying identical logs.

General Equilibrium and Oligopoly In the general equilibrium approach, it is important to explain the pattern of exports and imports as well as the costs and benefits of trade. The first problem to overcome is how to embed oligopoly in a general equilibrium model that was designed with perfect competition in mind. Some theorists have stressed the difficulties entailed by considering large firms, such as the possibilities of monopsony (or buyer power) in factor markets or considerations about what the large firm should maximize. Following the seminal paper by Lerner (1934) for the case of monopoly, Markusen (1981), Neary (2003), and Ruffin (2003a, 2003b) assume that it is more convenient to consider firms to be large in their industry but small in the economy. In this case, the firm can treat all factor prices and prices in other industries as fixed. Ruffin (2003a) shows that the firm's profit functions are then independent of the numéraire selected, so the problem of what the firm maximizes is avoided. In this case, clear and simple results can be reached.

Both Neary (2003) and Ruffin (2003a, 2003b) also employ the assumption that firms act as Cournot oligopolists; that is, they assume the outputs of their rivals are constant. Neary (2003) takes the assumption literally that firms are small in the economy by considering a continuum of firms, whereas Markusen (1981) and Ruffin (2003a, 2003b) simply consider a finite number of firms acting as if they are small in the economy.

The general equilibrium approach is most easily exhibited in a model in which Cournot oligopolies are selling in an integrated world market. Again, it is oligopoly profits that provide the key. How does oligopoly affect the costs and benefits of international trade? Consider two countries, Home and Foreign, that are the same size, with each having a comparative advantage in a good facing the same demand and costs. Since trade economists already know the impact of different factor intensities across industries, a Ricardian model (Neary 2003; Ruffin 2003a) with only one factor of production is often used. We shall call that factor "labor" but it could be a bundle of resources used in the same proportions in all industries. In this case, if we assume constant returns to scale, the production-possibility frontier for the economy is linear. With these assumptions we can assume that both countries have the same wages under perfect competition. Moreover, if we assume that under oligopoly all industries have the same degree of

competition (same number of firms), it will also be true that both countries will have the same wages with or without trade. Thus if we take wages to be fixed per unit labor (as the unit of measure), we can take dollar costs as given for each country. Thus suppose, as in table 1, that it costs Home $4 to produce a bushel of apples and $6 to produce a bunch of bananas, and it costs Foreign $6 to produce apples and $4 to produce bananas. Note that it is best to take wages as the unit of measure rather than one of the commodities, because in imperfect competition firms are choosing commodity prices to maximize profits.

It will be useful to summarize the Cournot oligopoly model when the product is homogeneous. The key assumption is that firms conjecture that rivals will maintain their output, a conjecture that holds in the Cournot-Nash equilibrium. There is a Cournot-Nash equilibrium if no firm can make an additional profit by changing its strategy, given the strategies of all of the other firms. If $D(P)$ is the demand for the homogeneous product, $D'(P)$ the slope of the demand curve, x_i the output of the ith firm, and c_i the marginal cost of the ith firm, then the Cournot equilibrium is:

$$D'(P)(P - c_i) + x_i = 0 \qquad (1)$$
$$\Sigma x_i = D(P) \qquad (2)$$

If there are N firms, this is a system of $N+1$ equations. The demand functions clearly must reflect all

Table 1
Gains to workers under competition and oligopoly

State	Country	Autarky		Free trade		Gains to workers
		apples	bananas	apples	bananas	
Perfect competition						
	Home	$4	$6	$4	$4	
	Foreign	$6	$4	$4	$4	17%
Tight oligopoly (N 2)						
	Home	$8	$12	$6.67	$6.67	
	Foreign	$12	$8	$6.67	$6.67	31%
Loose oligopoly (N 3)						
	Home	$6	$9	$6	$6	17%
	Foreign	$9	$6	$6	$6	

prices and incomes. Ruffin (2003b) describes the general equilibrium equations, taking account of the incomes of all factors of production and assuming all agents have identical, homothetic utility functions. Equations (1) and (2) replicate rivals holding output constant because when the ith firm adjusts its output, $D'(P)$ is the change in its demand by the resulting change in price. The interpretation of (1) is that if the firm adjusts output by $D'(P)$ by causing price to rise by a dollar, it loses the profit margin on those units but gains x_i on the resulting sales. But this becomes greatly simplified even in the case of nonidentical firms by adding the profit-maximizing equations (1) over the N firms and defining the price elasticity of demand as $\varepsilon = -D'(P)P/D$, resulting in:

$$P = \Sigma c_i/(N - 1/\varepsilon) \qquad (3)$$

For simplicity, suppose that $\varepsilon = 1$, which works for Cournot oligopoly for $2 \leq N$ (Ruffin 1971). Since oligopolists price according to elasticities of demand, this equation can be applied in general equilibrium without worrying about the impact of oligopoly profits on demand as long as we assume world symmetry so that costs can be taken to be independent. In a Ricardian trade model in which both countries have the same income and face the same demand for the good in which they have a comparative advantage, equation (3) works well because we merely have to add the costs of all the firms active in both countries and divide by 1 less than the number of firms in each world industry.

Consider first perfect competition in which prices must equal marginal costs. Table 1 shows both autarky and free trade. Thus in autarky, apples will be $4 and bananas $6 in Home, and the opposite in Foreign. Now if international trade is opened, in a competitive situation only Home would produce apples and only Foreign would produce bananas. Thus people of the world would pay only $4 for both apples and bananas. The gains from trade are simple to measure in this case, since equal amounts of money are spent on apples and bananas: The price of the importable falls by 33 percent, and the gain from trade for the economy as well as workers (the same in

this case) would be roughly one-half of 33 percent, or about 17 percent.

Under oligopoly both workers and oligopolists share in national income. There are two situations: a tight oligopoly in which the oligopoly profits protect high-cost producers from being driven out of business and a loose oligopoly in which oligopoly profits are insufficient for high-cost firms to survive the competition from low-cost rivals. For the moment assume the same degree of oligopoly in both industries, with only 2 or 3 firms in each country producing apples or bananas. With trade, each world industry has the potential of 4 or 6 firms. In the example, a tight oligopoly is when each country has only 2 firms producing apples and bananas, and a loose oligopoly prevails when each country has 3 firms producing both goods. Applying formula 3 to the autarkic state, as illustrated in table 1, we can see that under tight oligopoly Home will sell apples for $8 and bananas for $12. When trade is opened, apples will now be produced by 2 firms with costs of $4 and 2 firms with costs of $6, so according to formula 3 the price of apples (and bananas) will be $6.67 [= {2($4) + 2($6)}/3 = $20/3]. Economic logic tells us that the price must be less than $8, because there are more firms. For Home (and Foreign is symmetrical), the price of apples falls by 1.33/8, or 17 percent, and bananas by 5.33/12, or 44 percent, for a weighted average of 31 percent. Since we can hold worker wages the same (as the numéraire), workers must gain 31 percent from the opening of trade, a substantial improvement over the case of perfect competition. In this case, with equal degrees of competition between the two sectors, the gains from trade to the *economy* will be smaller than in the case of perfect competition because the inefficient banana industry in Home and apple industry in Foreign still operate. Accordingly, since workers gain more than under perfect competition, it follows that trade causes substantial losses to the oligopolists compared with autarky. *Nevertheless, the remaining oligopoly profits of the lower-cost firms serve to protect the higher-cost firms from competition, just as tariffs do.*

If we have looser oligopolies, the situation may be quite different. As shown in table 1 again, suppose

that the number of firms in each industry prior to trade is 3. Then in Home, applying equation (3) once again shows that under autarky apples will sell for $6 and bananas for $9, with the opposite in Foreign. When trade opens, the Foreign apple industry and the Home banana industry will be unable to compete with their low-cost counterparts. Indeed, under Cournot, they will assume that any output will lower price below $6, so that the equilibrium price of each good will be $6. Notice that in this case we get a result similar to perfect competition: trade causes the shutdown of inefficient industries, and both oligopolists and workers gain precisely the same amount as under perfect competition.

The looser oligopoly drives higher-cost firms in the other country out of business simply because price is closer to their marginal costs. This is also a measure of the robustness of a country's comparative advantage. The more robust the comparative advantage, in the sense of the greater the difference in costs between the Home and Foreign countries, more oligopoly power is compatible with driving foreign rivals out of business. Had we assumed $4 costs for apples in Home and $8 costs for apples in Foreign, only two Home firms would have been sufficient to drive the high-cost firms out of business.

In the tight oligopoly case examined in table 1, both high-cost and low-cost firms share the market. With perfect competition or a loose oligopoly, the high-cost firms are driven out of business. In general, this means that oligopoly power can reduce the degree of specialization and so reduce the volume of international trade. This helps to explain one of the most interesting observations about world trade in the last 50 years, namely that it has increased at about twice the rate of world output. People have usually attributed this to reductions in communication costs, transportation costs, and trade barriers. But the deregulation of industry and the rise of domestic competition may be another cause.

The Gains from Trade We assumed in table 1 that there are equal degrees of oligopoly in both sectors of the economy. This implies that the gains from trade in the economy cannot exceed what would prevail under perfect competition, although

workers can clearly gain more because of the procompetitive effects of trade on both export and import prices. But some authors have argued that with oligopoly the trade gains to the economy are greater than under perfect competition! As discussed in Ruffin (2003a, 2003b), this may arise when there are different degrees of competition between sectors. Markusen (1981) considers a two-sector model with perfect competition in one sector and monopoly in the other, and assumes that when international trade opens there is a two-firm Cournot oligopoly of Home and Foreign monopolists. He shows that even in the absence of actual trade, the potential for trade can improve welfare due to the procompetitive effects of the resulting two-firm world oligopoly. Markusen proves the result by making the strong assumption that under perfect competition there are no comparative advantages and, hence, no gains from trade. The existence of monopoly or oligopoly in part of the economy then improves the gains from trade because opening markets reduces those oligopoly powers. But there is no general rule that under oligopoly or monopoly the gains from trade are greater than under perfect competition, as pointed out by Ruffin (2003a). In fact, Ruffin (2003b) gives an example in which the country exporting the good produced by an oligopoly gains more from trade than under perfect competition, but the country importing that good gains less. The reason has to do with the unfavorable terms of trade effects related to exporting goods produced under competition compared with oligopoly.

Oligopoly also has important implications for the effect of trade on income distribution. Standard Heckscher-Ohlin trade theory predicts that abundant factors of production gain from trade while scarce factors lose from trade. The reason for this is that trade shifts resources from industries intensive in scarce factors to industries intensive in abundant factors. The imbalance of supply and demand requires the prices of abundant factors to rise, and those of scarce factors to fall. Thus a key characteristic of Heckscher-Ohlin theory is that the opening of international trade, or the expansion of trade from lower trade barriers, should cause a factor of

production to lose in one country and gain in another country. The existence of oligopoly moderates this effect, and it is possible for oligopoly profits to rise everywhere or fall everywhere. In the case of loose oligopolies, trade can cause profits to soar because low-cost firms drive out high-cost firms and their gain in profits from the world market will offset the loss of profits from the high-cost firms. This can happen everywhere. With tight oligopolies, low-cost firms must compete with high-cost firms and their profits will fall everywhere.

The case of workers is quite different. It is possible to show that, abstracting from Stolper-Samuelson effects arising from different factor intensities, workers must always gain from international trade. This holds under quite general circumstances, regardless of differences in the degree of competition across the economy. The reason is that under all circumstances, prices must fall measured in terms of wage units. Examining equation (3) shows this. Unless the price elasticity of demand falls (an unlikely event in a larger market), an increase in the number of firms (both low- and high-cost) will cause the price of the product to fall for both export goods and import-competing goods. If there is the same number of firms, but the high-cost firms disappear compared with autarky, the prices of imported goods fall while the prices of exported goods remain the same: workers still gain. This, of course, ignores the adjustment costs that workers will suffer moving from high-cost to low-cost industries, as would be the case for perfect competition as well. So oligopoly raises no new issues here except for the possibility of long-term contracts that may be present in concentrated industries that may not be present in more competitive industries. The mobility of workers under oligopoly is an issue that can and should be studied.

The importance of oligopoly in international trade focuses on the role of profits. Trade policy that shifts profit from one country to the other faces informational problems and the possibility of retaliation. Generally speaking, oligopoly makes it more likely that trade will benefit nonprofit factors such as workers. Oligopoly can make trade gains to the economy smaller if oligopoly is widespread, but only if oligopoly is concentrated in the export sectors can trade be more beneficial to the economy.

ROY J. RUFFIN

■ optimum currency area (OCA) theory

Optimum currency area (OCA) theory originates from two seminal articles in the early 1960s by the economists Mundell (1961) and McKinnon (1963). These articles drew on contemporary debates about fixed versus flexible exchange rates, treating a common currency as the extreme case of a fixed exchange rate. At the time, under the Bretton Woods system of fixed exchange rates, the choice of exchange rate was seen as a theoretical rather than practical issue, and applicability of the OCA analysis to the choice of currency domain was limited by the almost universal one country one currency rule (Pomfret 2005). The shift to generalized floating of the major currencies, however, and the move to European Monetary Union (EMU), which began in the early 1970s, generated practical interest in currency areas that has continued to grow.

Despite the huge subsequent literature and increased practical applicability, the theory of currency areas has remained centered on the Mundell-McKinnon approach of identifying the area within which the macroeconomic flexibility gains from having an independent currency are significant. This article focuses on OCA theory and the empirical evidence, while the complementary article on common currency analyzes actual experience with shared currencies.

Variants of OCA Theory In OCA theory the key issue is the extent to which macroeconomic policy can be effective in an open economy. An external shock, such as a recession induced by a drop in export demand, can be countered by cutting interest rates to stimulate investment. An economy with capital mobility and a fixed exchange rate does not have monetary policy independence, however, because the cut in interest rates will lead to capital outflows and an unsustainable balance of payments deficit. Mundell (1961) identified the point at which currency independence becomes worthwhile as the point at which factors cease to be mobile. The boundary of the OCA is set by breaks in factor mobility, that is, points at which the movement of labor or capital becomes more difficult.

The openness of an economy also can determine the effectiveness of exchange rate changes as a macroeconomic policy instrument. In very open economies, currency devaluation is ineffective because prices and wages immediately increase to remove any competitive advantage. Openness undermines the money illusion (or failure to distinguish nominal from real price changes) that permits the exchange rate to be an effective policy instrument. Larger economies have lower ratios of trade to gross domestic product (GDP), and currency devaluation can have a positive impact on output. Thus very open economies are suboptimal currency areas, but for a larger and less open economy the effectiveness of the exchange rate as a policy tool increases;

at some point the currency area becomes optimal (McKinnon 1963).

In the decades following the original contributions of Mundell and McKinnon, subsequent writers lengthened the list of criteria that might be relevant to an assessment of the optimality of a currency area. Recent contributions have argued that the trade-off may be mediated by history and by geography (Alesina and Barro 2002). With multiple criteria a unique ranking of suitability for currency union is unlikely to exist and the theory becomes difficult to test, but the essential structure of OCA theory has remained remarkably robust since 1961.

OCA theory characterizes the choice of currency area as a cost-benefit analysis trading off microeconomic efficiency against macroeconomic flexibility (Krugman 1993). Microeconomic efficiency would be maximized with a global currency. Thus, subglobal OCAs imply the existence of distortions, such as nonclearing labor markets that lead to involuntary unemployment, whose negative effects can be reduced by macroeconomic policy. Another benefit of a larger currency area is that disturbances are likely to be offsetting, so that exchange rate changes are smaller, with less feedback on domestic prices. The greater price stability is usually ascribed to random shocks being offsetting, but other mechanisms include reduction in the impact of outliers in the consumer price index, or CPI (i.e., goods with a particularly large weight in a region's consumption bundle), and reduction in the ratio of trade (or rather transactions denominated in potentially volatile foreign currencies) to GDP.

The cost-benefit perspective suggests an equal role for microeconomic and macroeconomic analysis, but the currency area literature has been dominated by macroeconomists, in part because the micro benefits of reduced transactions costs from a common currency are simple to visualize but difficult to measure. Although the benefit from a common currency (or fixed exchange rate) in terms of lower transactions costs has long been accepted as the overwhelming argument for mini states (such as Luxembourg or Brunei) not to have independent currencies, the argument becomes less potent as the currency area becomes large enough to have well-functioning foreign exchange (including forward) markets. Thus the increasing efficiency of financial markets becomes an argument for OCAs becoming smaller because it reduces the benefits via reduced transactions costs of a common currency. This may explain why it is feasible to have a small currency domain, as in countries such as Iceland or New Zealand, without incurring huge costs, but whether the trade-off between macropolicy flexibility and transactions costs is optimal for these small states is another question, and one which is impossible to answer without a good understanding of the nature and size of the transactions costs associated with independent currencies. Before the beginning of the 21st century little research had been done on the transactions cost benefits of a common currency, but this has changed since the controversial article by the economist Andrew Rose was published in 2000.

Testing OCA Theory The OCA literature has dominated the theoretical explanation of currency areas for almost a half century. There have, however, been few systematic tests of OCA theory and little positive support for OCA theory as a useful way of explaining the composition of existing currency areas or of predicting changes in currency domains. One empirical challenge was the rarity of changes in currency areas during the 1970s and 1980s. In the early 1990s it was argued that the stability of actual currency arrangements may be explained by switching costs (Dowd and Greenaway 1993), but the many changes in currency arrangements in Eastern Europe in the 1990s and the introduction of the euro in Western Europe suggest that the mechanics of changing currency arrangements are neither difficult nor especially costly.

With multiple OCA criteria, the theory becomes difficult to test: a small open economy has the biggest potential gain from joining a larger currency area in order to reduce transactions costs, but it may also be most vulnerable to external shocks and hence has the most to lose from giving up the exchange rate as a macropolicy instrument. The economists Kreinin and Heller (1974) synthesized the various criteria into the single question of whether a country could

better deal with external imbalance through devaluation or through adjustment of domestic demand. Their conclusion was that Italy, Sweden, and Switzerland were the three Organisation for Economic Co-operation and Development countries most likely to abandon their national currencies. Thirty years later only one of the three had done so, while ten of the "less likely" countries had abandoned their national currencies.

If currency areas become "optimal" ex post, then OCA theory may be untestable. A common currency might promote closer trade links and more synchronized cycles, both of which are OCA criteria; closer trade ties increase the benefit from a common currency, and synchronized cycles reduce the cost of giving up independent currencies. This is not a theoretical result but a hypothesis to be tested empirically because more bilateral trade could promote interindustry specialization and less synchronized cycles. Using various measures of bilateral trade intensity and cycle synchronization for 21 developed economies, Frankel and Rose (1998) find a robust relationship between the two variables, which they interpret as evidence that as a common currency promotes bilateral trade it also increases cycle synchronization. Thus actual currency areas fit OCA criteria better than potential currency unions, and the OCA criteria are endogenous.

The impact of currency union on bilateral trade flows has been the subject of a burgeoning literature initiated by the economist Rose (2000). Using a gravity model, Rose found that currency union has a large effect on bilateral trade, which he interpreted as evidence that a common currency substantially reduces transactions costs. Although it is plausible that a common currency reduces transactions costs and stimulates trade, the magnitude of the common currency effect is hotly debated. In Rose's study the countries in currency unions are not from a random draw; several authors have shown that currency union members are smaller and more open than their natural comparators and that history (usually in the form of colonial background) matters.

The debate has been conducted with analysis of currency area changes over time. Analyzing time-series data for correlations between changing currency union status and bilateral trade flows, Glick and Rose (2002) estimated that dissolution of a currency union halves bilateral trade. Currency union breakup is, however, usually associated with other events that disrupt trade; out of some 60 cases of post-1947 currency union dissolutions in the Glick-Rose data set, more than two-thirds broke up within a decade of the end of a colonial relationship, and the end of the ruble zone, which is not in the data set, would increase the percentage still further. In tranquil currency union changes, notably Ireland's secession from its currency union with the United Kingdom in 1979 and subsequent participation in the process leading to the euro, the impact on bilateral trade is unclear. The weaker the link between currency union and bilateral trade, the less convincing is the claim that OCA criteria become self-fulfilling ex post.

In practice, irrespective of whether the criteria may become endogenous, most of the literature on currency domains treats OCA theory as having predictive capability. Yet, the general track record of OCA theory in explaining the monetary history of the post-1945 international economic order has been miserable. Despite the increasing openness of national economies and increasing capital mobility, both unambiguous pressures for larger currency areas according to OCA theory, the number of currencies has increased substantially and the geographical size of currency domains has shrunk correspondingly. The sole significant exception is the introduction of the euro, but in Europe and the former Soviet Union as a whole there were more currencies in 2002 than a decade earlier. Globally, over the last half century, the exogenous increase in the number of countries drove the number and size of currency areas, and the OCA criteria were irrelevant to explaining this pattern. In sum, although OCA theory has dominated the analysis of currency domains, the empirical support for the theory is weak.

RICHARD POMFRET

■ Organisation for Economic Co-operation and Development (OECD)

The Organisation for Economic Co-operation and Development (OECD) is an international organization located in Paris. It was founded in 1960 as the successor to the Organisation for European Economic Co-operation (OEEC), which was established in 1947 to administer American and Canadian aid under the Marshall Plan for reconstruction of Europe after World War II. OECD members are governments of nation-states that meet the criteria of pluralistic democracy and free market economies. The founding members were Austria, Belgium, Canada, Denmark, France, Germany (Federal Republic), Greece, Iceland, Ireland, Italy, Luxembourg, Netherlands, Norway, Portugal, Spain, Sweden, Switzerland, Turkey, the United Kingdom, and the United States. Since then 10 more countries have joined: Australia (1971), Czech Republic (1995), Finland (1969), Hungary (1996), Japan (1964), Korea (1996), Mexico (1994), New Zealand (1973), Poland (1996), and Slovak Republic (2000). The OECD aims to enlarge its membership and to find the means to integrate nonmember governments

into its organization. The secretary-general Angel Gurria said he envisioned the OECD as the "secretariat of the process of globalization."

The basic document of OECD is the Convention of December 1960. It states that the organization shall promote policies (1) to achieve the highest sustainable economic growth and employment and a rising standard of living while maintaining financial stability, (2) to contribute to sound economic expansion, and (3) to expand world trade on a multilateral, nondiscriminatory basis.

Members are obliged to promote the efficient use of their economic, scientific, and technological resources; to pursue policies designed to achieve economic growth without thereby endangering the economies of other countries; to pursue efforts to reduce or abolish obstacles to the international movement of goods, services, payments, and capital; and to contribute to the economic development of member and nonmember countries by appropriate means. In addition, members must furnish the OECD with the information necessary for its tasks, consult together on a continuing basis, cooperate closely, and take coordinated action where appropriate.

The OECD may make decisions that are binding on all members. In addition, it may make recommendations to members and enter into agreements with member and nonmember states. Binding decisions and recommendations have to be made by mutual agreement. Abstention from voting does not invalidate the decision or recommendation, which is applicable to the other members but not to the abstaining member. This consensus method is the standard decision procedure of international organizations.

The OECD is entitled to diplomatic privileges and immunities, as are officials and member country representatives. The OECD is exempt from paying taxes related to its operating revenues and expenses.

Organization, Output, and Analytical Perspectives The supreme body of OECD is the Council, which is composed of all members and one representative of the European Union (EU) commission. It is a permanent intergovernmental conference that meets in sessions of ministers or permanent representatives. Representatives of the members meet in committees to discuss and review policies in various fields. There are about 200 committees, working groups, and experts groups. Each year some 40,000 senior officials from national administrations attend OECD committee meetings, where they request or review work of the secretariat or respond to requests by the secretariat. The OECD budget is financed by the member states. Their contributions are proportional to the size of their economies, with a floor of 0.1 percent and a cap of about 25 percent of total contributions. In 2006, the contributions of the United States, Japan, and Germany made up respectively 25, 17.5, and 9.4 percent of total contributions, while Iceland, Luxembourg, and the Slovak Republic each paid less than 0.25 percent of all contributions. Contributions make up about 80 percent of all operating revenues, which amounted to about U.S. $500 million per annum in 2005.

The secretary-general heads the secretariat. The Council elects him or her for a term of five years. He must neither seek nor receive instructions from any national government. The OECD has had five secretary-generals since its establishment: Thorkil Kristensen of Denmark (1961 69), Emil van Lennep of the Netherlands (1969 84), Jean-Claude Paye from France (1984 96), Donald Johnston of Canada (1996 2006), and Angel Gurria of Mexico (2006). Each secretary-general has had academic training in economics or law, a career in public service as a member of government or senior civil servant, and a political leaning toward economic liberalism.

The OECD has a staff of about 2,000, including about 700 economists, lawyers, and other professionals. The secretariat is structured by departments or directorates, working in parallel to the committees they serve.

Unlike the World Bank or the International Monetary Fund, the OECD does not dispense money to national governments. Instead, it uses its resources for gathering and analyzing data, as well as for publications and conferences. Major products of OECD are statistical data of great quality, analyses of

such data, the development of standards on matters such as corporate governance, and policy reviews. Among the most prominent of these reviews are the economic surveys. An economic survey is published every 1.5 to 2 years for each OECD member and for some large nonmember countries. The surveys analyze national economic policy, discuss policy options, and make recommendations.

The making of an economic survey reflects the political processes and structures within the OECD. The economics department, probably the most important of the 12 departments of the secretariat, organizes the procedure that leads to an economic survey. Within the economics department the Country Studies Branch, with its 15 country desks, is responsible for preparing the review of economic policy in close discussion with senior servants from the country under review. The draft of the economic survey is then submitted to the Economic and Development Review Committee (EDRC), composed of representatives of member countries. Two countries are responsible for the examination. They ask critical questions addressed to the delegation of the country under review. After the interaction of national civil servants, country desks, and examining countries, and after examination in front of the EDRC, the draft is revised and the members of the committee may comment on it. Discussion continues until the committee of representatives of 30 national governments makes a unanimous decision about the publication of the review.

As this example shows, continuous discussion, peer review, and consensual decision making are at the heart of this process, which requires representatives of national governments with very different political leanings to agree on analyses and recommendations for the economic policy of member countries.

The analytical perspectives of OECD have changed over time. When the organization started out it was concerned with core economic variables and had many intellectual affinities to Keynesian thinking. Beginning in the late 1970s it took a more monetarist outlook, and since the 1990s the OECD has broadened its former economic focus to include social and education policies and their different national configurations.

OECD and National Economic and Social Policy One of the major tools that the OECD uses to affect national economic and social policies is its data sets and reports produced by the secretariat in Paris. These reports point to shortcomings in national policy and describe alternative policies that are effective in other countries. The organization also diffuses ideas about good economic governance within an epistemic community of economists, lawyers, and social scientists from the OECD Secretariat and from national governments.

Finally, although the OECD issues standards, recommendations, and decisions, it does not employ sanctions if member countries ignore or violate these norms. "Naming and shaming" of such countries sometimes is taken up by national mass media and politicians. Analyses of the impact of the economic surveys have shown, however, that this is a rare event, especially for large countries. The OECD method of pressure by discussion, peer review, consensual decision taking, and naming and shaming has become a model for other organizations such as the EU, which adopted the OECD method as its "Open Method of Coordination" (OMC) as an alternative to less efficient and more problematic hierarchical methods of political steering. The EU applied OMC for the first time in 1997 and officially endorsed it as an EU method in 2000.

■ Organization of the Petroleum Exporting Countries (OPEC)

The Organization of the Petroleum Exporting Countries (OPEC) is an international cartel of oil-producing states that has attempted, with varied success, to manipulate world oil prices. OPEC was founded in 1960 by Iran, Iraq, Kuwait, Saudi Arabia, and Venezuela, a group of major oil-producing countries that wished to coordinate national petroleum policies and forge a more united front in dealings with the multinational oil companies that were licensed to produce and export petroleum from their lands. Within the next dozen years, eight additional members (Algeria, Ecuador, Gabon, Indonesia, Libya, Nigeria, Qatar, and the United Arab Emirates) joined in, which brought the total membership of OPEC to 13 by 1973. At that time, the combined membership of OPEC accounted for more than half of worldwide crude oil production. Two small producers (Gabon and Ecuador) withdrew during the 1990s and Angola joined in 2007, bringing OPEC membership to its current level of 12 countries.

As with any cartel, OPEC's ability to hold the price of oil above the competitive level is dependent on barriers to entry, which in this case hinge on OPEC's dominant ownership and control of low-cost oil reserves. By accident of nature, some 75 percent of the world's proved reserves of crude oil are located in OPEC nations. Proved reserves constitute that portion of the ultimate resource base that has already been discovered and is commercially producible. Additional reserves can and will be developed through exploration, discovery, and development of new fields, but this process has become increasingly difficult and expensive even more so outside the OPEC nations than within. Thus, while production of crude oil from non-OPEC sources does expand in response to the higher prices that result when cartel members restrict output, the scope for this is limited and will remain so. Moreover, OPEC's coordinated efforts to manipulate the price of oil are protected from antitrust enforcement and legal intervention by the sovereign rights of its members.

Economists have debated and tested various theories about how OPEC actually goes about exerting its influence on the market, whether through the independent initiatives of individual members, actions and strategies undertaken by semiautonomous coalitions working within the larger organization, or concerted plans embraced and executed by the organization as a whole. Some researchers might question whether OPEC has ever managed to operate successfully in the manner of a classic cartel. Whatever one's opinions on those matters, OPEC members have restricted production in ways that are unrelated to the inherent scarcity of crude oil. Although OPEC's proved oil reserves rose steadily between 1973 and 1985, production was cut by nearly half during that 12-year interval, falling from 31 million barrels per day (mbpd) in 1973 to an all-time low of 16 mbpd in 1985. As of late 2007, OPEC continued to hold production below the 1973 level, although the proved oil reserves of OPEC members had doubled in volume since then and total worldwide consumption of crude oil had grown by roughly 50 percent.

Evolution of OPEC The history and development of OPEC can be viewed in three phases. During the first phase (1960 70), OPEC's primary objective was to win for its members a larger *share* of the oil profits that private companies generated within their territory. The stated goal of increasing government take from 50 percent to 80 percent of total profits was pursued largely through the imposition of tax and administrative reforms by individual OPEC

members, including the introduction of fictional "tax reference prices" that boosted the tax base, and therefore government take, without altering the stated tax rate and without much impact on the market price of oil. During this phase, there was no direct attempt by OPEC to raise the overall level of world oil prices, and perhaps there was not even the realization that such a feat would be possible. In those early years, OPEC was concerned with winning for itself a bigger share of the pie, rather than growing the size of the pie.

The second phase (1970 82) saw greater reliance on collective deliberations and coordinated actions designed to reverse a long period of decline in world oil prices (and therefore tax revenues) that had set in after World War II. These efforts began with a series of dictated agreements (the so-called Teheran-Tripoli agreements of 1970 71) by which the OPEC members unilaterally raised posted tax reference prices by 21 percent. The members also announced that further increases could and would be imposed as they saw fit under the doctrine of "changing circumstances," one of which was the declining exchange value of the dollar, the currency in which oil prices were denominated. Indeed, it was during a special OPEC conference convened to review these matters that the October 1973 Arab-Israeli war broke out, which prompted the Arab members of OPEC to declare an embargo on sales to Israel's allies (the United States and the Netherlands). Although the embargo did not have much effect on actual deliveries of oil to those countries, and was soon rescinded, this bold move panicked the markets and fueled a speculative demand for oil inventories, which ultimately drove prices in the spot market to unprecedented levels and taught OPEC ministers something about the value of their oil.

By 1974, the "official" OPEC price had reached $11.25 per barrel, a startling increase from the $2.18 price level that had been established just two years before. By 1975, the posted price was no longer merely a fictional "tax reference" price used by OPEC members to compute their share of company profits. Indeed, the multinational companies were mostly removed from the equation by a wave of nationalizations that began in earnest in 1974, after which OPEC members sold their oil outright to whichever customers were willing to pay the official price. The posted price was successively increased during the 1970s by collective agreement of the OPEC ministers, but the real price of oil actually declined as the decade progressed since the posted price failed to keep pace with accelerating inflation.

Such was the state of affairs at the onset of the Iranian Revolution, when the expulsion of foreign oil field service firms and a series of labor strikes in 1978 and 1979 disrupted Iranian output. Disruptions spread to Iraq in 1980 with the outbreak of the Iran-Iraq war. Again the market panicked, and again the OPEC members were taught something about the value of their oil. By October 1981, the posted price of OPEC oil reached $34 per barrel (which in real terms still represents the all-time high).

A sharp downturn in the oil market led to the third (and current) phase in OPEC's evolution. Already by 1982, individual OPEC members were offering customers large discounts below the "official" OPEC price in order to maintain or even increase their share of what had become a dwindling market. Sluggish OPEC sales and falling prices were the product of reduced consumption and rising non-OPEC oil supplies, both spurred by the price shocks of the 1970s. To deal with the growing surplus of oil in the marketplace, OPEC adopted in March 1983 a formal system of production allocations that imposed for the first time individual ceilings on the output of each member. During this third phase of OPEC's development, OPEC members met at regular intervals (and sometimes more frequently on an emergency basis) to review market conditions and adjust members' quotas as needed to support or "defend" the market price within a desired range. This phase of OPEC's history is the one that most resembles the textbook example of a cartel, at least outwardly.

OPEC's Future Prospects When judging OPEC's past success or contemplating its future course of action, several things must be kept in mind. Foremost is the fact that any system of output restraint is vulnerable to the classic free-rider problem.

OPEC as a whole may benefit from reducing total output, but each member has an incentive to produce beyond its assigned quota. From the individual member's point of view, marginal revenue from incremental sales exceeds the marginal cost of extraction, which creates the temptation to cheat. Cartel membership is most beneficial to a producer when other members are doing the hard work. But if they will not, who will? Without a system to detect and punish cheating, the cartel is hampered by a prisoner's dilemma in which the dominant strategy for most, if not all, members is to ignore their assigned production quotas.

In fact, OPEC lacks an effective means to monitor, detect, and punish members who exceed their quotas. A monthly chart of OPEC's combined crude oil production level relative to the agreed ceiling indicates the scope and persistence of this problem (see figure 1). Compliance has been sporadic. Since the inception of the quota system, total OPEC production of crude oil has exceeded the ceiling by 4 percent on average, but on numerous occasions the excess has run to 15 percent or more. For the most part, compliance has been achieved only during episodes (like 2005 6) when the production ceiling itself pushed the limits of each member's available production capacity.

A second factor that confounds OPEC's attempt to manage the market price is the lack of timely and accurate information about changes in the level of demand for oil and the availability of non-OPEC oil supplies. Several forecasts of demand and supply are available at any given time (including those prepared by the U.S. Energy Information Administration, the International Energy Agency, and by the OPEC Secretariat itself), but the precision of these forecasts is low and surprises are frequent. For example, none anticipated the surge in Asian demand that triggered the sudden tightening of oil markets in 2005. OPEC's forecasting problem is compounded by the fact that several years may elapse, due to rigidities in both supply and demand, before the full impact of a price change can be observed so if a mistake is made, it may go undetected for several years and then take several years more to rectify.

Even if perfect information about future market conditions were available, there is no assurance that the interests of individual OPEC members could be easily aligned around a single "correct" price or production target. OPEC has very limited means by which to redistribute earnings among members. Therefore, any given set of quotas determines not only the overall profit of OPEC, but also the individual revenues that accrue to each member.

If the members were more homogeneous demographically and economically, the problem of misaligned interests would be less severe. As things happen, however, large volumes of low-cost reserves are concentrated in certain countries with small populations and relatively high incomes (e.g., Kuwait, Saudi Arabia, and the United Arab Emirates), while smaller volumes of higher-cost reserves are found in populous and relatively poor countries (e.g., Nigeria, Indonesia, and Venezuela). Table 1 sets forth some of the more salient differences among the members of OPEC. The potential for conflicting interests involves not only the question of which members "deserve" larger quotas, but what is the preferred market price level for OPEC oil.

What price would the respective members of the cartel like to see? Members with low-cost, long-lived reserves will take a long view of the future and may be reluctant to push prices too high given the fear of induced technological innovations that would usher

*Founding member of OPEC

in new forms of energy (or energy conservation) that eventually may compete against OPEC. Members holding fewer reserves and shorter horizons are less vulnerable to this type of risk and therefore perhaps less averse to high prices. Internal divisions between "price hawks" and "price doves" have been observed previously and will likely surface within OPEC again.

A final factor that looms large in the future of OPEC is the role to be played by serendipitous events and geopolitical tensions. A large portion of OPEC's apparent historical impact on the price of oil has come about not as the result of deliberate plans crafted by a purposeful cartel, but as the by-product of clashing national agendas that encompass far more than the petroleum sector. Since the early 1970s, most of the idle capacity held by OPEC members has been involuntary   taken out of production due to military conflict. Much of the hard work that any cartel has to do   commanding the determination and discipline to restrict output   has in OPEC's

case been provided fortuitously. For that reason, the ultimate strength and cohesion of OPEC had perhaps not yet been tested by the end of 2007.

The value of crude oil produced and sold on the world market exceeds $1 billion each day. Even a relatively small impact on the unit price of oil represents an enormous transfer of wealth between consumers and producers. Moreover, the disruptive impact of sudden price "shocks" and heightened volatility threatens the goal of sustained and steady global economic growth. As consumers, investors, and government officials continue to wrestle with these problems, it is no exaggeration to say that OPEC has left an indelible imprint on the world economy through its impact on the price of oil.

■ original sin

The term *original sin*, obviously an allusion to Christian theology, was coined by economists Barry Eichengreen and Ricardo Hausmann to refer to the inability of a particular country (most notably, emerging-market economies) to borrow funds in international capital markets in its own currency. The inability to borrow in domestic currency units necessarily forces the country in question to raise external funds using a foreign convertible currency instead, such as the U.S. dollar, the British pound, the euro, or the Japanese yen. Countries that choose to borrow external funds in this fashion expose themselves to a currency mismatch problem in their balance sheets, as their liabilities are denominated in foreign currency units, while their assets are de-nominated in domestic currency units. If there were no exchange rate movement over time, there would be no balance sheet valuation effects. If the domestic currency were to depreciate or be devalued, however, the country in question would experience a reduction in the market value of its assets, with little or no change in the value of its liabilities. As a result, the likelihood of insolvency and default increases. The risk of currency mismatch affects all sectors exposed to the problem: governments, banks, and even cor-porations.

Economic Impact of Original Sin There is a large and growing theoretical and empirical literature that analyzes the effect of original sin on macroeconomic performance. To be sure, standard models of the open economy do not directly address the issue of original sin. In these models, access to external debt (whether foreign-currency or domestic-currency denominated) is seen as beneficial, as this facilitates the country's ability to smooth out fluctuations in aggregate demand. A country that lacks the ability to borrow funds from the rest of the world is presum-ably worse off than it would otherwise be as it must depend solely on its own savings for financing con-sumption and investment expenditures. If domestic savings is insufficient for funding consumption and investment, access to external capital markets can help to finance the gap, thereby helping to maintain macroeconomic stability and growth. More recent models, however, show that when a large portion of the external debt is foreign-currency denominated, the likelihood of experiencing a balance of payments crisis may increase (e.g., Jeanne and Zettelmeyer 2005). Macroeconomic stability can therefore be seriously compromised when a country is exposed to original sin. In addition, monetary and fiscal policy tools can also be adversely affected by original sin. In particular, original sin could make monetary policy more complex, causing it to lose some of its effec-tiveness in influencing output (Cespedes, Chang, and Velasco 2005; Rajan 2006).

Empirically, many researchers find that original sin actually amplifies macroeconomic volatility. In particular, the higher the level of original sin, the more likely is the country to suffer from instability in output and capital flows. Many researchers see original sin as at least partly responsible for many banking crises in recent decades (Kaminsky and Reinhart 1999). The reasoning behind this belief is that the banking sector in many emerging market economies is often exposed to currency fluctuations: deposits are often denominated in a foreign, convertible currency (in order to attract funds that would otherwise go abroad), while bank assets are primarily loans denominated in domestic currency. When the currency depreciates or is devalued, the market value of bank loans declines; the value of liabilities, on the other hand, remains roughly unchanged, thereby compromising the solvency of the banking sector. The effect of such an event on the rest of the economy can be quite devastating as banks, in an effort to increase liquidity, contract their lending, thereby creating a "credit crunch" that amplifies an economic downturn. Indeed, many researchers argue that original sin is largely responsible for some of the most devastating financial crises in recent history, such as the Asian financial crisis of 1997–98.

Reasons behind Original Sin Given that original sin appears to cause a significant amount of macroeconomic problems, it is natural to ask why countries borrow in foreign currency units. The literature mentions several reasons, including (1) weak economic credibility, (2) weak financial institutions, and (3) structural impediments to domestic currency debt issuance. First, emerging market economies typically lack a strong track record of economic performance. For example, emerging market economies tend to have long-lasting inflation problems. Because of lack of monetary credibility, foreign investors may be reluctant to lend to such countries in domestic currency units, demanding instead that countries issue foreign-currency denominated debt (Jeanne 2005). Second, it is likely that foreign investors are uneasy about holding the debt of countries with weak institutions, such as a poor track record on the enforcement of contracts, and poorly enforced property rights. Facing this constraint, countries may choose to issue debt denominated in foreign currency units as a way to signal to potential investors that they are committed to keep their end of the obligation (Reinhart, Rogoff, and Savastano 2003). Third, the international financial architecture simply does not allow many countries to issue debt in domestic currency units. In particular, some researchers have noted that countries that borrow in international markets using their own currency tend to have large economies and deep financial systems (Flandreau and Sussman 2005). If so, this would imply that issues related to economies of scale, network externalities, or liquidity allow only a handful of currencies to be effectively used in international financial contracts.

FURTHER READING

Calvo, G., and C. Reinhart. 2002. "Fear of Floating." *Quarterly Journal of Economics* 117: 379–408. Investigates whether countries that claim to have a floating exchange rate actually allow their currencies to fluctuate. They find that, for the most part, countries do not. They argue that the "fear of floating" appears to be epidemic.

Cespedes, L. F., R. Chang, and A. Velasco. 2005. "Must Original Sin Cause Macroeconomic Damnation?" In *Other People's Money: Debt Denomination and Financial Instability in Emerging Market Economies*, edited by B. Eichengreen and R. Hausmann. Chicago: University of Chicago Press, 48–67. Presents a theoretical model showing that original sin can undermine the effectiveness of fiscal and monetary policy tools, thereby compromising a country's ability to stabilize output.

Eichengreen, B., and R. Hausmann. 1999. "Exchange Rates and Financial Fragility." NBER Working Paper No. 7418. Cambridge, MA: National Bureau of Economic Research. Introduces for the first time the term *original sin* as one of the avenues through which exchange rate volatility can induce financial fragility.

———. 2005. "Introduction: Debt Denomination and Financial Instability in Emerging Market Economies."

In *Other People's Money: Debt Denomination and Financial Instability in Emerging Market Economies*, edited by B. Eichengreen and R. Hausmann. Chicago: University of Chicago Press, 3–12. Offers an excellent exposition on the issues pertaining to original sin. The introductory chapter summarizes the main contributions of the papers included in the book.

Eichengreen, B., R. Hausmann, and U. Panizza. 2005. "The Pain of Original Sin." In *Other People's Money: Debt Denomination and Financial Instability in Emerging Market Economies*, edited by B. Eichengreen and R. Hausmann. Chicago: University of Chicago Press, 13–47. Presents empirical evidence showing that financial and macroeconomic instability in emerging market economies tends to increase with original sin problems.

Flandreau, M., and N. Sussman. 2005. "Old Sins: Exchange Clauses and European Foreign Lending in the Nineteenth Century." In *Other People's Money: Debt Denomination and Financial Instability in Emerging Market Economies*, edited by B. Eichengreen and R. Hausmann. Chicago: University of Chicago Press, 154–89. Argues that the main cause of original sin is not the lack of credibility and discipline of governments, as others have argued, but rather it is the result of historical path dependence and market liquidity.

Jeanne, O. 2005. "Why Do Emerging Economies Borrow in Foreign Currency?" In *Other People's Money: Debt Denomination and Financial Instability in Emerging Market Economies*, edited by B. Eichengreen and R. Hausmann. Chicago: University of Chicago Press, 190–217. Explores the causes of original sin and argues that original sin in private debt markets is mainly the result of monetary policy.

Jeanne, O., and J. Zettelmeyer. 2005. "Original Sin, Balance Sheet Crises, and the Roles of International Lending." In *Other People's Money: Debt Denomination and Financial Instability in Emerging Market Economies*, edited by B. Eichengreen and R. Hausmann. Chicago: University of Chicago Press, 95–121. Explores two classes of models and finds that in both of them crises can be self fulfilling prophesies. The paper also investigates the role of international lending in ameliorating the effect of financial crises stemming from original sin problems.

Kaminsky, G., and C. Reinhart. 1999. "The Twin Crises: The Causes of Banking and Balance of Payments Problems." *American Economic Review* 89 (3): 473–500. Investigates the links between banking crises and currency crises. Its main finding is that banking problems typically precede currency crises, and once a currency crisis is triggered, it amplifies banking problems, culminating in a banking crisis.

Rajan, R. S. 2006. "Managing New Style Currency Crisis: The Swan Diagram Approach Revisited." *Journal of International Development* 18: 1–24. Presents a model useful for understanding how countries can manage economic disruptions stemming from crises driven by original sin problems.

Reinhart, C., K. Rogoff, and M. Savastano. 2003. "Debt Intolerance." *Brookings Papers on Economic Activity* 1: 1–74. Quantifies a country's vulnerability to a debt crisis as it accumulates external debt. Its main finding is that having experienced debt problems in the past makes a country more susceptible to external debt crises in the future.

CARLOS D. RAMIREZ

■ outsourcing/offshoring

The terms *foreign outsourcing* or *offshoring* apply when the components of a good or service are produced in several countries. The term *offshoring* often refers to a company moving some of its operations overseas, but retaining ownership of those operations. Intel, for example, produces microchips in China and Costa Rica using subsidiaries that it owns, so these production activities have moved offshore. In contrast, *outsourcing* refers to moving activities outside of a firm (which could be to another firm in the same country, as with *domestic* outsourcing, or to another firm in another country, as with *foreign* outsourcing). Mattel, for example, arranges for the production of the Barbie doll in several different countries, so it is engaged in foreign outsourcing. Unlike Intel, however, Mattel does not actually own the firms in those countries. In this entry we will not be concerned with the distinction between foreign outsourcing or offshoring, and use either term to refer to shifting activities to another country.

While there are historical examples of companies doing some of their production in another country, outsourcing is generally thought to be a feature of the modern world economy made possible by improvements in international trade, transportation, and communication. Indeed, the earliest known use of the word *outsourcing* in a published source is from an American auto executive in the *Journal of the Royal Society of Arts*, 1979, who wrote: "We are so short of professional engineers in the motor industry that we are having to outsource design work to Germany" (Safire 2004). This example shows that outsourcing may involve the shifting of service activities (like design work) overseas, in addition to the shifting of production activities (like making the Barbie doll) overseas. In this entry we first concentrate on the shifting of *production activities* to other countries and then discuss *service outsourcing*.

Measures of Outsourcing There are several approaches that can be used to measure the amount of outsourcing. One approach is to look at "processing trade," which is defined by customs offices as the import of intermediate inputs for processing and subsequent reexport of the final product. This activity has grown enormously in China, for which Hong Kong often serves as an intermediary. For example, between 1988 and 1998, processing exports grew from $12.4 billion to $97.2 billion, or from about one-third to over one-half of total Chinese exports (Feenstra and Hanson 2004). This outward processing serves newly industrialized countries in Asia, but also developed countries such as the United States, Japan, and countries in Europe. Between the industrialized countries, too, there has been an increase in processing trade. Görg (2000) reports on the increase in U.S. processing trade with the European Union between 1988 and 1994. He finds that U.S. processing imports into these countries (as a share of their total U.S. imports) increased slightly from 17.7 percent to 19.8 percent, but this same ratio increased more significantly from 13.7 percent to 23.7 percent for U.S. exports into the "periphery" countries of Greece, Ireland, Portugal and Spain.

Another way to measure foreign outsourcing is by the amount of imported intermediate inputs, which can be estimated by using the purchases of each type of input and multiplying it by the economywide import share for that input. Adding overall inputs used within each industry, we obtain estimated imported inputs, which can then be expressed relative to total intermediate input purchases. Feenstra and Hanson (1999) perform this calculation for U.S. manufacturing industries and find that imported inputs increased from 6.5 percent of total intermediate purchases in 1972 to 8.5 percent in 1979, and 11.6 percent in 1990. Campa and Goldberg (1997) make the same calculation for Canada, Japan, the United Kingdom, and the United States. The United States shows a doubling of the share of imported inputs between 1975 and 1995 for all manufacturing, from 4.1 percent to 8.2 percent, though it is still at a low level compared with other countries. Canada shows an increase in the share of intermediate inputs from 15.9 percent to 20.2 percent from 1974 to 1993, and the United Kingdom shows an especially large increase in this share, rising from 13.4 percent to 21.6 percent over the same years. The exception is Japan, where the share of imported inputs in manufacturing fell. With that single exception, the increased use of imported inputs was a characteristic feature of many industrial countries during the 1980s and 1990s.

Effect of Outsourcing on Wages: Evidence from the 1980s Much of the academic and policy interest in outsourcing is due to its potential effect on wages and employment. During the 1980s there was a surprising movement in wages and employment in the United States and other countries. During that decade, the real wage of less-skilled workers (with high-school education or less) fell in the United States, whereas the real wages of the more highly skilled workers (college graduates) rose. Therefore, the ratio of the skilled wage divided by the unskilled wage or the relative wage of skilled/unskilled workers rose. At the same time, the relative employment of skilled/unskilled workers also went up, especially in manufacturing. That pattern is surprising because normally when the relative wage of skilled/unskilled workers rises, we expect that companies will hire fewer skilled employees (since they are more ex-

pensive); instead, the opposite happened and companies hired relatively more skilled workers. The only explanation for this pattern is that the relative *demand* for skilled workers must have increased, especially in the manufacturing sector. What factors can explain this increase in the relative demand for skilled workers?

Two factors that can explain the increase in relative demand for skilled workers are: (1) the increased use of computers and other high-technology equipment, and thus an increase in the skilled workers needed to operate them; and (2) outsourcing. To understand how outsourcing will increase the relative demand for skilled labor, we use the "value chain" of a firm, which includes all the activities involved in the production of a good or service, from research and development (R&D) to assembly to marketing and after-sales service. For the purpose of modeling outsourcing, rather than arranging activities in the order they are actually performed, we instead arrange them in increasing ratio of skilled/unskilled labor used in each activity, as shown in figure 1.

Assembly uses the least amount of skilled labor relative to unskilled labor in figure 1, followed by component production, then marketing and sales, and finally R&D. A firm that is outsourcing to another country with lower relative wages for unskilled labor will want to send those activities using the most unskilled labor. So in figure 1, activities to the left of the line AA will be sent offshore to the foreign country, while activities to the right of the line AA will be performed at home.

Now suppose that the home firm wishes to offshore more activities. The reason for this could be a trade agreement with the foreign country, leading to reduced tariffs; or improvement in the infrastructure in the foreign country, leading to reduced costs there; or an increase in costs at home. When deciding what extra activities to offshore, the firm will look to those activities that were just on the borderline of being outsourced before, that is, those activities just to the right of the line AA, which used to be profitably performed at home but now are shifted abroad. The borderline between the activities performed at home and abroad therefore shifts from the line AA to the line BB.
What is the impact of this increase in outsourcing on the relative demand for skilled labor at home and abroad? Notice that the activities no longer performed at home (i.e., those in between AA and BB) are *less* skill-intensive than the activities still done there (those to the right of BB). This means that the range of activities now done at home is more skilled-labor intensive, on average, than the set of activities formerly done at home. For this reason, the relative demand for skilled labor at home increases, as occurred in the United States during the 1980s. That increase in demand will also increase the relative wage for skilled labor.

What about in the foreign country? The activities that are newly sent offshore (those in between AA and BB) are *more* skill-intensive than the activities that were initially outsourced to the foreign country (those to the left of AA). That means that the range of activities now done abroad is more skilled-labor intensive, on average, than the set of activities formerly done there. For this reason, the relative demand for skilled labor in the foreign country also increases. With this increase in the relative demand for skilled labor, the relative wage of skilled labor also increases in the foreign country. That outcome occurred in Mexico, for example, during the 1980s, as well as in Hong Kong.

Outsourcing versus Technological Change By shifting activities from one country to the other, outsourcing can increase the relative demand for skilled labor in *both* countries, as has actually occurred in a number of industrial and developing countries. However, the same result can occur from skill-biased technological change, such as the

Figure 1

Outsourcing on the value chain

increased use of computers, which can increase the relative demand for skilled labor across countries. Given that outsourcing and skill-biased technological change both predict an increase in the relative wage of skilled labor, it becomes an empirical issue as to which is more important.

A study for the United States (Feenstra and Hanson 1999) seeks to explain the increase in the share of total wage payments going to nonproduction (skilled) versus production (unskilled) labor in U.S. manufacturing industries over the period 1979 90 and analyzes the increase in the relative wage of nonproduction labor over the same period. The study considers two possible explanations for the change in wages: outsourcing and the use of high-tech equipment such as computers. High-technology equipment can itself be measured in two ways: either as a fraction of the total capital equipment installed in each industry or as a fraction of new investment in capital that is devoted to computers and other high-tech devices.

Using the first measure of high-tech equipment (i.e., fraction of the capital stock), 20 23 percent of the increase in the share of wage payments going to nonproduction workers was explained by outsourcing, and 8 12 percent of the increase was explained by the growing use of high-tech capital. Thus, using the first measure of high-tech equipment, it appears that outsourcing was more important than high-tech capital in explaining the change in relative demand for skilled workers. The story is different, however, when the second measure of high-tech equipment (i.e., fraction of new investment) is used. In that case, outsourcing explains only 13 percent of the increase in the nonproduction share of wages, whereas high-tech investment explains 37 percent of that increase. So we see from these results that both outsourcing and high-tech equipment are important explanations for the increase in the relative wage of skilled labor in the United States, but which one is more important depends on how we measure the high-tech equipment.

Moving on to the increase in the relative wage of nonproduction workers, using the first measure of high-tech equipment (fraction of the capital stock),

21 27 percent of the increase in the relative wage of nonproduction workers was explained by outsourcing, and 29 32 percent of the increase was explained by the growing use of high-tech capital. Using the other measure of high-tech equipment (fraction of new investment), the large spending on high-tech equipment in new investment can explain *nearly all* (99 percent) of the increase in the relative wage for nonproduction workers, leaving little room for outsourcing to play much of a role (it explains only 12 percent of the increase in the relative wage). These results are lopsided enough that we might be skeptical of using new investment to measure high-tech equipment and therefore prefer the results using the capital stocks. Summing up, both outsourcing and high-tech equipment are important explanations for the increase in the relative wage of nonproduction/ production labor in U.S. manufacturing, but the relative contributions of the two measures are very sensitive to how we measure the high-tech equipment.

Trade Costs and Outsourcing across Firms The effects of outsourcing described in figure 1 can be thought of as occurring along the value chain of a firm. One natural way to examine these changes is by examining the impact of falling trade costs on manufacturing establishments with different characteristics. It is likely that as firms move production activities offshore, they will outsource the least skilled activities (as depicted in figure 1), or close the plants focusing on these activities.

Bernard, Jensen, and Schott (2006) examine the implications of falling trade costs on U.S. manufacturers, and specifically examine the channels by which trade affects the distribution of economic activity. They find when trade costs in an industry fall, plants are more likely to close. They also find that low productivity, nonexporting plants are more likely to die. This is one channel by which outsourcing can affect the distribution of economic activity. Falling trade costs tend to reduce the amount of economic activity at the low end of the productivity distribution. Because low-productivity plants also tend to be production-worker intensive, this change is likely to reduce the relative demand for unskilled workers.

Bernard, Jensen, and Schott (2006) also find that relatively high-productivity nonexporters in industries with falling trade costs are more likely to start exporting. The magnitude of the effect of falling trade costs on becoming an exporter is substantial. Because higher-productivity plants are more skilled-worker intensive, as these plants expand they will increase the relative demand for skilled workers. They also find that existing exporters increase their shipments abroad as trade costs fall. Because exporters have relatively high-productivity plants, the expansion of the high end of the productivity distribution will tend to raise aggregate productivity (even if no plants changes its productivity). Because exporters are skill- and capital-intensive, this will also tend to increase relative demand for these factor inputs. Finally, these authors find that plants in industries with falling trade costs have faster productivity growth, possibly due to increased outsourcing.

It should be noted that the productivity increase associated with outsourcing means that the real wage of workers (even the less-skilled workers) need not fall due to outsourcing. That result is shown in the model of Feenstra and Hanson (1996), from which figure 1 is drawn. The same result occurs more strongly in the recent model of Grossman and Rossi-Hansberg (2006), where the real wage of less-skilled worker are guaranteed to rise due to the productivity-enhancing effect of outsourcing.

Regional Variation in Wage Inequality in the United States The increase in wage inequality due to outsourcing has not been uniform across the United States. Bernard and Jensen (2000) find that the changing composition of employment in regional economies is strongly correlated with changes in wage inequality in the United States. Somewhat surprisingly, they find that while many regions in the United States experienced increasing wage inequality, some regions experienced *decreasing* wage inequality over the 1970–90 period.

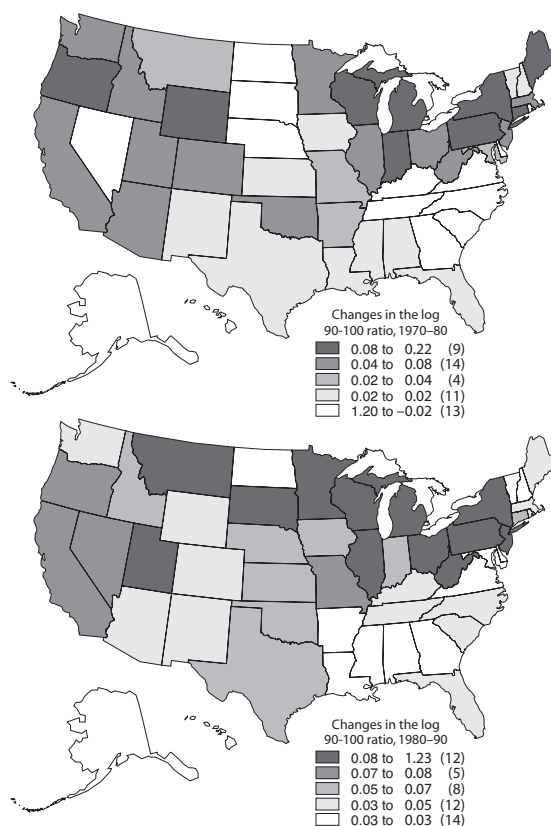
Figure 2 shows the variation across states in changes in residual wage inequality for 1970–80 (upper map) and 1980–90 (lower map). States with large increases in wage inequality are in the traditional "Rust Belt," and states with decreases in wage


Figure 2

Changes in inequality by state. Source: Bernard and Jensen (2000).

inequality are in the Southeast. Bernard and Jensen find that decreases (increases) in the share of manufacturing sector employment in the durable goods sector is strongly correlated with increasing (decreasing) wage inequality.

One specific example of how these heterogeneous responses to trade pressures can affect regions differentially is the case of Appalachian manufacturing. Appalachian manufacturing is concentrated in low-wage, labor-intensive industries, and Appalachian manufacturers within those industries tend to be lower wage and lower productivity than plants in those industries elsewhere in the United States. This combination of industrial mix and plant production technology leaves the region particularly susceptible to import competition from low-wage countries. For

example, low-wage competition shows a more pronounced effect on Appalachian plants in terms of employment growth and plant failure than elsewhere in the United States. Plants in the Appalachian region have higher shutdown probabilities and lower employment growth when facing low-wage imports than do firms in the rest of the United States.

Service Outsourcing in Manufacturing: Evidence from the 1990s The patterns of wages and employment in U.S. manufacturing changed in the 1990s, with rising relative wages and employment for skilled workers. The relative wage of nonproduction/ production labor in U.S. manufacturing continued to increase from 1989 to 2000, but in addition, the relative employment of production workers *decreased*. A likely explanation for this new pattern of wage and employment is that it reflects service outsourcing from U.S. manufacturing. To the extent that the back-office jobs being outsourced from manufacturing use the lower-paid nonproduction workers, then the offshoring of those jobs could very well *raise the average* wage among nonproduction workers, while lowering their employment. So that pattern would be consistent with what has actually occurred in U.S. manufacturing. In the rest of our entry, then, we focus on service outsourcing.

Examples of service outsourcing from the manufacturing sector include the offshoring of services such as communication, finance, insurance, computer, and information services. Amiti and Wei (2006) report that in the United States, the amount of imported service inputs is small but growing. Measured as a share of total inputs purchased, imported services were 0.2 percent in 1992 (i.e., two-tenths of one percent of total inputs), and grew to 0.3 percent in 2000 (i.e., three-tenths of one percent). The fact that imported services are small does not necessarily prevent them from being important for productivity and employment.

In terms of the impact of service outsourcing and high-technology equipment on manufacturing productivity measured by value added per worker, over the eight years 1992 2000, Amiti and Wei find service outsourcing can explain about 11 percent of the total increase in productivity. Despite the small

amount of service imports, they find it explains a significant portion of productivity growth. It may be some of that productivity growth is actually due to domestic outsourcing of service activities, which is confounded in the data with foreign outsourcing of services. The contribution of service outsourcing can be compared to the offshoring of material inputs, which explains a further 5 percent of the total increase in productivity. Adding together these contributions, we see that these two factors explain about 16 percent of the increase in value added per worker, or as much as one-sixth of productivity growth. Since productivity rose by about 4 percent per year in manufacturing, these results show that outsourcing of services together with material inputs during the 1990s can explain two-thirds of a percentage point in productivity growth per year, which is economically important.

Offshoring's Impact on the Service Sector In the previous section we examined the impact of service outsourcing on the manufacturing sector. In this section we consider the potential impact of offshoring on the service sector. While work on trade in services is quite recent and hampered by less detailed information than trade in goods, Jensen and Kletzer (2006) provide evidence on the potential impact that trade in services will have. They use the geographic concentration of service activities within the United States to identify industries and occupations that appear traded across regions within the United States and classify these activities as tradable. They find that a significant share of total employment is in tradable service activities: in fact, more employment is in tradable professional and business services than in manufacturing. They also find that workers in tradable service activities are different than workers in nontradable activities, even in the same sector. Workers in tradable services have more education and significantly higher earnings (after controlling for observable differences). They examine recent trends in employment growth and find little evidence that tradable services have lower employment growth than no-tradable services, though they do find some evidence of higher displacement rates in tradable service activities.

These results suggest that the potential scope for tradable services is large enough to have a significant impact on the U.S. economy. It seems likely that increasing trade in services will have a similar effect as the increased trade in goods. Trade in services is likely to increase productivity through a number of channels, including closure of low-productivity service producers, entry into exporting of relatively high-productivity service providers, and expansion of service firms that already export. Similar to manufacturers, service exporters likely have superior operating characteristics and use a different skill mix than nonexporters. We expect increased trade in services will affect the relative demand for skilled and unskilled labor, though it may affect a different portion of the skill distribution than we witnessed in the manufacturing sector in the 1980s and 1990s.

◼ parallel imports

Parallel imports (also known as gray products) are products imported into a country without the authorization of the intellectual property right owner. They arise when international price differences exceed the costs of transporting the products across borders. No precise data exist on parallel imports, but their volume is considered to be large (up to a market share of 20 percent in some countries and for some products), especially for products such as musical recordings, cosmetics, fragrances, soft drinks, clothing, confectionery, automobiles, motorcycles, consumer electronics, and pharmaceuticals (Maskus 2000).

The international system of intellectual property rights allows each country to establish its own legal regime concerning parallel trade. It is based on the concept of exhaustion of property rights (known as "first-sale" doctrine in the United States), whereby countries choose the geographical area (national, regional, international) within which the owners of intellectual property rights lose (and thus "exhaust") their rights on products after first sales. Most countries have a regime of *national* exhaustion of intellectual property rights allowing the owner of that right to exclude legally parallel imports through trademark, copyright, and/or patent laws. For instance, the United States has national exhaustion on the three property rights fields, but authorized dealers mainly use trademark and copyright laws to block parallel trade (Gallini and Hollis 1999). The other extreme is an *international* exhaustion regime, which makes parallel imports legal. This is the case in Japan (with restrictions) and Australia and New Zealand (for most copyrighted and trademarks goods). A *regional* exhaustion regime, as in the European Union (EU), represents an intermediate case, since it makes parallel imports legal when they originate from EU members but illegal when they originate from non-EU members.

The main economic policy question about parallel imports is whether a property right owner should be entitled to international exclusive distribution territories. The fact that different regimes have been adopted indicates the existence of conflicting views about the motives and economic effects of parallel imports. In a nutshell, views range from banning parallel trade because intellectual property owners should have the right to control the international distribution of their products, to unregulated parallel trade because restrictions are nontariff barriers to trade that are inconsistent with World Trade Organization principles.

Price discrimination is generally considered the primary motive behind a manufacturer's support of a parallel import ban. Income differences, for instance, are typically more important across countries than within them, and they imply different demand elasticities across countries. This provides a strong incentive to manufacturers with market power to set country-specific prices. Because of arbitrage, this strategy would not be sustainable with parallel imports. Allowing international price discrimination (i.e., banning parallel imports) does not imply that international welfare decreases (Malueg and Schwartz 1994). A necessary condition for global

welfare to be higher under international price discrimination is that overall output be greater under discrimination than without it. This is a poor consolation for the high-price country but not for the low-price country, especially if the latter country is not served under a regime allowing parallel imports. This may well arise when income differences are large enough, a case that is relevant in the ongoing dispute about the availability of some critical pharmaceutical products in developing countries. In short, price discrimination does not provide a strong guide about policy prescription concerning parallel trade.

A second important motive behind manufacturers' attitude toward parallel trade is linked to vertical control over intermediaries selling these products to consumers. In particular, banning parallel trade and having exclusive intermediaries may help facilitating collusion among manufacturers or among dealers. It may also provide incentives to these exclusive intermediaries to undertake specific investments in activities such as advertising or after-sales services. If parallel imports were allowed, free riding would take place and, with it, very little incentive to invest in such activities. In other words, whenever exclusive territories are useful to motivate dealers, there are good reasons to ban parallel imports as well. Still, manufacturers who deal with intermediaries may have a strong incentive to let dealers engage in parallel trade. This is particularly the case in markets where production and shipments must take place before demand is really known and for products whose sale value drops at the end of the demand period (Raff and Schmitt 2007). If parallel trade was banned in such markets (for instance, confectionary), intermediaries could be stuck with worthless inventories when the demand in their market turns out to be low. Fearing this possibility, intermediaries would naturally place smaller orders to manufacturers than they would if they were free to resell unsold inventories in high-demand markets. Thus, when seasonality and uncertainty are important market demand features, manufacturers' profits may well be significantly higher when parallel trade is allowed than when it is not.

A third set of motives for banning parallel trade has to do with its dynamic impacts on markets. For instance, banning parallel trade may prevent confusion among consumers when the products have different specifications (whether due to different tastes across locations, safety standards, or packaging). More significantly, parallel imports may reduce manufacturers' incentives to engage in research and development or product innovation. This argument is often made in relation to the pharmaceutical industry (see Li and Maskus 2006).

These possibilities show that parallel trade can have nontrivial implications for the competitive environment of manufacturers and intermediaries. Clearly, a policy about parallel imports, whether at the national or at the international level, can rarely be reduced to a trade policy recommendation but must typically also include strong competition policy considerations.

Empirical evidence shows that the threat of parallel imports does decrease retail prices. In itself, these price effects are not enough to justify a free regime concerning parallel trade. Since a worldwide ban on parallel trade cannot be recommended either, a policy about parallel imports can be designed only on a case-by-case basis, depending on the characteristics of each country or region.

■ partial equilibrium models

Partial equilibrium models are used to analyze trade issues in a single market or, alternatively, in a few closely related markets. They are adaptations of standard supply and demand analysis to the specific features of trade policies. Partial equilibrium models are used in cases where linkages to other sectors of the economy are negligible enough to be ignored. They have the advantage of being relatively easy to construct and lend themselves to transparent application in policy analysis. They are extensively used in the analysis of anti-dumping and countervailing duties, as well as to assess the probable effects of many types of trade policy changes in narrowly defined sectors.

A decision not to use partial equilibrium modeling (or the more involved approach of applied general equilibrium modeling) usually results in the deployment of some sort of trend analysis, which focuses on whether the direction and timing of changes in one set of economic variables are coincident with another set of economic variables. Trend analysis is sometimes implemented in the form of an interpolation based on trend lines before and after a critical event, such as a change in trade policy. Trend analysis has two problems, however. First, the causative links between the two sets of variables are never made explicit, and the relative contribution of one factor to a given set of events is therefore difficult to assess. Second, while the number of necessary parameter estimates is minimal, this is simply a consequence of the implicit assumptions embedded in

the approach. Partial equilibrium analysis is a superior approach in almost all circumstances.

To construct a partial equilibrium trade policy model, the analyst first needs to determine whether the imported and domestic competing goods are perfect or imperfect substitutes and then needs to determine whether the country is "small" with reference to the rest of the world (in which case the import supply curve is horizontal or perfectly elastic) or "large" with reference to the rest of the world (in which case the import supply curve is upward sloping or less than perfectly elastic). These fundamental choices, which ideally should reflect the empirical reality of the situation being modeled, determine the appropriate modeling framework. If imports and domestic competing goods are best modeled as imperfect substitutes (following Armington 1969), the transmission of shocks from the market for the imported good to the market for domestic goods relies on the cross-price elasticity of demand or, alternatively, the elasticity of substitution. This measure affects the extent to which changes in the price of an imported good affect demand for the domestic competing good. Partial equilibrium models, whether perfect or imperfect substitutes, are typically implemented using spreadsheet software, examples of which are included in Francois and Hall (1997) and Roningen (1997).

A Perfect Substitutes Model We will first consider a perfect substitutes model with "second-best" effects in the "small" country case. This model proceeds as indicated in the supply and demand diagram of figure 1. The supply curve S represents the behavior of domestic firms, and the demand curve D represents the behavior of domestic households. Imports are available from the world market at a constant price P^w. It is the constant nature of this price that puts us in the "small" country case. The domestic government has imposed a specific tariff on imports of amount T_1. At the resulting domestic price of $P^w + T_1$, imports are of an amount equal to Z_1. The policy change we are to consider here is an increase in this tariff of up to level T_2.

The supply and demand curves in figure 1 are linear, that is, they can be expressed in the form of
Figure 1
A small country, perfect substitutes model

$Q = a + bP$. However, it is also common to use a constant elasticity functional form, in which case the curves are expressed as $\ln Q = c + d \ln P$, where "ln" denotes the natural logarithm. In the former case, the price elasticities of demand and supply vary along the curves, while in the latter case, they are constant and equal to d.

The increase in the tariff level raises the domestic price to $P^w + T_2$ and reduces imports to Z_2. Consumer surplus (a measure of household welfare) falls by area $A + B + C + D$, and producer surplus (a measure of firm welfare) increases by area A. The government gains tariff revenue due to the increase of the tariff of area C but also loses tariff revenue due to the reduction in imports of areas E and G. Area F is collected as tariff revenue both before and after the increase in the tariff. The net result of all these changes is that welfare as conventionally measured declines by $B + D + E + G$. Note also that the increase in domestic output from Q_1 along the supply curve can be easily translated into an increase in employment using a fixed employment-output ratio and that this change is often of key political interest.

Calibrating this simple model involves the same three elements that are used in more complex mod-

els: functional forms, initial values, and elasticities. In the present context, the functional forms are those of the supply and demand curves (either linear or constant elasticity) and the elasticities are those related to these functions. The elasticities are estimated prior to applying the model. With regard to initial values, the calibration can be made easier by defining the initial domestic price ($P^w + T_1$) to be unity. Then the sum of the border value of the initial imports plus the initial tariff revenue gives the quantity Z_1, and the value of domestic output give the quantity Q_1. Q_1 determines the calibration point along the supply curve, and $Q_1 + Z_1$ determines the calibration point along the demand curve. This way of defining units is typical of applied trade policy models.

Imperfect Substitutes Model We next consider an imperfect substitutes model in the "large" country case, allowing for terms of trade effects. This model is presented in figure 2. The important difference between figures 1 and 2 is that, in the imperfect substitutes framework of the latter, there are now *two* closely related markets, one for the imported good Z and another for the domestic competing good D. The demand curves in these two markets are related through the cross-price elasticity of demand (or alternatively the elasticity of substitution) between the two goods. The initial equilibrium in the absence of a tariff results in the two prices P_{Z1} and P_{D1}. The imposition of a specific tariff T on imports of good Z causes the supply curve of this good to shift upward by the amount of the tariff, raising the domestic price of the imported good along the demand curve. The increase in the price of good Z affects the demand for good D, shifting the curve out as households substitute toward the domestic good. This increases the domestic price of good D and in turn causes a substitution toward good Z and a shift out of the demand curve for imports. These two substitution effects are simultaneous, and the resulting, new prices are P_{Z2} and P_{D2}.

We next consider the welfare effects of the tariff in this imperfect substitutes framework. In the market for the domestic good, there is an increase in producer surplus along the supply curve equal to trapezoid H (extending from the vertical price axis all the
Figure 2
A large country, imperfect substitutes model

way to the supply curve). This entire area, however, comes as a cost to the consumers, with the producer gain and the consumer loss exactly offsetting each other. In the market of the imported good, there are no domestic producers to account for. However, the estimation of the consumer welfare effect is troubled by the fact that both the supply curve and the demand curve in the market for good Z have shifted. The standard approach to this, introduced by analysts such as Morkre and Tarr (1980), is to measure the change in consumer surplus along the presumed path between the initial and final equilibria points. The resulting consumer surplus loss is the trapezoid $I+J$. Rectangle I represents an increase in tariff revenue, so the net welfare effect in figure 2 is just triangle J.

One important aspect of figure 2 is that, discounting for the effect of the shift of the demand curve, the rise in the domestic price of the imported good is less than the tariff. This is because there is a movement in world quantity supplied down S_Z and a resulting decline in the border price of the imported good. This terms-of-trade effect of the tariff is missing in figure 1. The terms-of-trade effect has the property of reducing the height of the net welfare triangle J and is present unless the import supply

curve S_Z is horizontal or infinitely elastic, putting us back into a "small" country case.

As in the perfect substitutes model, the increase in domestic output along S_D can be easily translated into an increase in employment using a fixed employment-output ratio, and calibration to the initial equilibria points can be made easier by defining the initial domestic prices of the imported and domestic goods to be unity.

Partial equilibrium modeling of trade policy changes will continue to be an important analytical tool for situations where the linkages of the trade policy change to the broader economy under consideration are weak. Despite some complications in the imperfect substitutes case, the models are relatively easy to implement in spreadsheet form and are widely used by trade policy analysts.

peso problem

The term *peso problem* generically refers to situations in which the possibility of a significant change in the distribution of future shocks to the economy influences the expectations of economic agents. The interaction of expectations and shifts in the distribution of economic shocks can lead to behavior in the prices of assets such as stocks and foreign exchange that is not in accord with the predictions of standard economic theory.

The precise origin of the term is uncertain, but is often attributed to comments made by Milton Friedman regarding the Mexican peso in the early 1970s. At that time, the Mexican peso traded at a fixed rate against the U.S. dollar while the interest rate on Mexican bank deposits exceeded that on comparable U.S. deposits. The existence of such an opportunity to earn a profit with little or no risk might appear to present a problem for rational-agent-based models of financial markets. Such an interest differential would fail to be arbitraged away, however, if investors thought that the peso would be devalued in the future. Indeed, in August 1976, the peso was allowed to float against the dollar and subsequently declined in value.

Peso Problems and Forecasts The peso problem is intimately related to economic forecasting. Good forecasts of future events have two important properties: they are unbiased, meaning that forecast errors are zero on average, and forecast errors are themselves unpredictable. Forecasting models are typically constructed and tested with historical data that are assumed to accurately represent the statistical distribution of the variables under consideration. When the statistical distribution is invariant over time, historical data can be used to assess the likelihood of future outcomes and generate forecasts with good properties. If the distribution of outcomes is shifting over time, however, then forecasts that are

conditioned on historical data may be biased or have predictable forecast errors because the historical data may not give an accurate representation of the changing statistical distribution.

Peso problems may occur when an economy faces this sort of instability. The use of historical data to predict the future becomes more difficult if the likelihood of future outcomes differs significantly from what was observed in the past. For example, wars and severe political turmoil are extremely hard to predict and may lead to significant changes in the economic environment. If economic agents believe there is a large enough possibility that such infrequent events might occur, there can be a significant impact on forecasts and forecast errors. To an outside observer, it may then appear that forecasters are making persistent errors, even though forecasters are using best practices in conditioning on such infrequent and hard-to-predict events.

Technically, peso problems can be interpreted as a failure of the methodology of rational expectations econometrics (Evans 1996). Rational expectations econometrics requires that the actual, or objective, distribution of economic variables be equal to the distribution expected by economic agents when they make decisions. The expected distribution may put weight on events that subsequently fail to be realized, and so may not be accurately represented in the ex post distribution. Under such circumstances, the predictions of rational expectations models may appear to be at variance with the data.

The Forward Premium Puzzle The forward premium puzzle is an asset-pricing anomaly that has lent itself to a peso problem interpretation. The foreign exchange market allows individuals to purchase forward contracts on currencies. A forward contract is an agreement to buy or sell a currency on a future date for a specified price called the forward rate. Consequently, the forward rate embodies investors' beliefs about the future value of the spot rate, which is the price at which a currency can be bought or sold for immediate delivery. The forward rate would thus seem to be a good predictor of the future spot rate on the date that the forward contract matures. A large amount of evidence indicates that the forward rate is not an unbiased predictor of the future spot rate, however. Under a peso problem interpretation, the bias, which is a tendency for the forward rate to stay above or below the spot rate for extended periods of time, could be due to investors' perceptions that there is a chance that the exchange rate will change substantially. If so, and until the exchange rate actually does shift, the forward rate will remain persistently above or below the spot exchange rate. Such a peso problem explanation of the forward premium puzzle has some validity in the data (Evans and Lewis 1995).

Stock Market Returns and Peso Problems Historically, the U.S. stock market has performed well relative to the stock markets of other industrialized nations. The historical, real return on U.S. equities is about 4.7 percent compared with a median return of about 1.5 percent for a sample of 39 countries (see Jorion and Goetzmann 1999). Peso problems offer one potential explanation for the large relative return. Investors must be rewarded for taking risks. Risk-averse stock market investors will demand a high return on equities in normal times to compensate them for the risk of extreme losses in bad times. But for the United States, extreme bad outcomes have largely bypassed the stock market. For example, unlike the stock markets of France, Russia, Germany, and Japan, the operation of the U.S. stock market was not interrupted for significant stretches of time by war. Nonetheless, stock market investors presumably attached some positive probability to a severe market disruption and factored that in to the returns they require to make their investments worthwhile. Since such a U.S. market disruption has not occurred, actual historical returns on equities have not reflected it. Thus the large realized U.S. equity return may be tied to investors' assessment of the possibility of extreme outcomes that never actually materialized for the U.S. economy.

Models Peso problems clearly present a difficulty for estimating and evaluating economic models. Good models require that events are realized often enough in historical data samples that researchers can accurately determine their probabilities of

occurrence. In the context of peso problems, this requires that infrequent events be observed often enough in the data for scholars to accurately assess the likelihood of repeated occurrence. One methodology that has been applied with some success to cases in which the distribution of outcomes shifts over time is the Markov regime-switching model (see Hamilton 1989). This model assumes that the economy can be in one of several distinct regimes and that regime switches are stochastic. That is, they change in a random fashion over time. If regime switches are observed to occur often enough in the historical data, researchers can estimate the probability of being in a particular regime and incorporate that information into the structure of economic models. This framework has had some success in modeling expectations of a possible future change in the economic environment that can in turn have implications for the behavior of asset prices.

■ petrodollars, recycling of

Recycling of petrodollars refers to what becomes of revenues earned by oil-exporting countries, particularly after major oil price shocks. Countries may spend some portion on foreign goods and services, but typically the increases in oil revenues following price shocks have been so large that oil exporters have been unable to absorb these petrodollars into their domestic economies either through consumption or through investment. Instead, petrodollars usually get recycled in the form of foreign asset savings held abroad. Such foreign assets may range from deposits held in foreign banks to bonds and private equity.

The most significant oil price shock followed the 1973 oil embargo imposed on the United States by the Organization of the Petroleum Exporting Countries (OPEC), but petrodollar recycling was one result of a steady increase in oil prices from 2002 to 2005. Oil prices reached an average $53 per barrel in 2005, more than twice their level just three years before. As a result, for a significant group of oil-exporting countries, oil export revenue rose from $262 billion in 2002 to an estimated $614 billion in 2005. These revenues in turn were invested in foreign assets, making oil exporters important counterparts to the United States in the ownership of foreign savings. In 2005 their current account surplus represented nearly 40 percent of the U.S. current account deficit.

What has the impact been and what is the impact likely to be of petrodollar recycling on global financial imbalances? If energy exporters spend their oil revenue, part of the petrodollar inflows would flow

out again to pay for imports of goods and services, boosting the economies of the industrialized oil-importing countries from which the petrodollars originated. This process would serve as a countervailing force to the oil price shock, rebalancing some portion of global imbalances. If, on the other hand, oil exporters save their revenue, this would exacerbate global imbalances by draining resources away from investment or consumption in the oil-importing world, in turn reducing growth and employment. To the extent that oil-exporting countries deposit their petrodollars in U.S. banks, however, this would mitigate the dampening effect. This is precisely what happened in the aftermath of 1973. But as we shall see, the real legacy of petrodollar recycling in the 1970s was not global financial imbalance but a third-world debt crisis.

Oil Shock of 1973 The oil shock of 1973 74 scaled up the size of postwar global economic imbalances by an order of magnitude and gave rise to widespread fears of a depression similar to the Great Depression of the 1930s. This episode gives important insights into issues of collective action problems, the resilience of international financial markets, and the uses and limitations of exchange rate adjustments.

The shock was generated by the large rise in oil prices following the oil embargo imposed against the United States in retaliation for its support of Israel in the Yom Kippur War of 1973. Because of the low price sensitivity of the demand for oil over the short and medium terms, this resulted in a significant increase in revenues for the oil-exporting countries. Combined with limitations on the speed with which the oil-exporting countries could increase their expenditures on imports (limitations of the capacities of their ports was a major initial bottleneck) and the fact that oil bills were paid primarily in dollars, this resulted in massive inflows of dollar reserves to oil-exporting countries, particularly in the Middle East.

The economies of the oil-importing countries were subject to three sets of pressures. Consumer prices rose while purchasing power drained away. For many oil-importing economies, the resulting stagflationary effects rising inflation combined with

reduced growth and employment were on the order of several percentage points of gross domestic product. On top of this, large current account deficits could cause severe balance of payments problems.

It soon became clear that in the aggregate there would not be a balance of payments problem corresponding to the huge current account imbalances. Had the world still been on a gold standard the situation would indeed have been dire since these imbalances would have drained gold out of the oil-importing countries, forcing monetary contraction and magnifying the initial recessionary effects of the oil price increases. Indeed, under the rules of the gold standard, the oil shock would have generated a new Great Depression.

Gold convertibility no longer existed, however, so the oil-exporting countries had to hold non-interest-bearing foreign currencies or, more reasonably, invest the surplus back into oil-importing countries through banks that accepted dollar deposits, primarily in Europe. Thus, in the aggregate, the oil surpluses created a financing glut instead of a financing shortage. In effect, the oil exporters recycled the funds by making very large deposits, which swelled the supply of loanable funds, forcing banks to offer extremely low-interest loans to any reasonable taker.

This in turn caused serious problems. Oil-importing countries with strong financial markets, such as the United Kingdom and the United States, began to run overall payment surpluses as the oil-related investment inflows exceeded their increased oil payments. As a result, there was an urgent need for secondary recycling of the petrodollars (as these surplus investment funds were called) more in line with the patterns of current account deficits.

Some of this alignment was accomplished by foreign aid from the oil exporters and some from a special recycling facility set up by the International Monetary Fund (IMF) in cooperation with oil-exporting nations. The oil exporters placed funds directly with the IMF that the IMF, in turn, then re-lent to oil-importing countries. The bulk of recycling took place through the international banking and financial sectors, however: a substantial amount of

the funds placed in the major financial centers (including the Eurodollar market) were re-lent mostly to newly industrializing countries (NICs) in Latin America and Asia.

Global Savings Glut Because of the sudden deposit glut, banks were eager to re-lend funds. The demand for loans within advanced industrial countries had slowed considerably due to recessionary conditions following the oil crisis. Banks saw the opportunity for big profits in loans to oil-exporting NICs, however, as oil prices had nearly quadrupled, making these countries appear to be good risks. Moreover, banks were attracted to the Latin American market, where authoritarian governments were standing ready to accept and guarantee repayment of private bank loans. Banks operated on the principle that sovereign loans carried very little risk of default compared with private sector loans. This was assumed true even for the oil-importing NICs, which also benefited from large loan packages.

Of course, Latin American countries exhibited considerable eagerness to borrow. Having reached the end of what scholars have referred to as "the easy phase" of import-substituting industrialization, Latin American NICs required new infusions of capital to maintain high growth rates. This process of borrowing to maintain high growth rates became known as debt-led growth. Moreover, the majority of Latin American NICs were governed by bureaucratic authoritarian regimes whose legitimacy hinged on their ability to continue delivering rapid industrial growth. To these regimes, the ability to borrow from private banks and thus bypass IMF conditionality was simply a bonus. But perhaps Latin American NICs' greatest incentive to borrow grew out of financial market conditions. Inflation had skyrocketed after the 1973 oil price hikes while nominal interest rates had leveled off and even fallen in some cases due to the credit glut. Together these phenomena resulted in extremely low and even negative real interest rates. Quite literally, for a time, banks were paying Latin American governments to take their money.

Another concern with respect to global financial imbalances after the oil shock was that instead of borrowing to finance their current account deficits,

countries would want to adjust their payments imbalances. But in the aggregate this was not possible in the short and medium term. Devaluations by all oil-importing countries would in effect raise the real price of oil, and because of the short-term inelasticity of demand for oil such actions would increase rather than reduce the aggregate current account imbalances.

For individual countries, however, devaluation would work by increasing their exports to, and reducing their imports from, other oil-importing countries. This process could work only if it were not practiced by too many other countries. This collective action problem was quite similar to the one countries faced during the Great Depression. Any one country could stimulate its domestic economy by increasing exports and reducing imports, but if all countries followed this strategy, the result would worsen the economic situation for everyone. In the 1930s, the combination of understanding of this problem and willingness to cooperate internationally was insufficient to avoid economic catastrophe.

Avoiding Beggar-Thy-Neighbor Policies Another Great Depression, therefore, was a realistic concern in the 1970s. Fortunately both the economic understanding of government officials and willingness to pay some attention to the international repercussions of national actions had developed sufficiently so that with valiant efforts from international organizations such as the IMF and the Organisation for Economic Co-operation and Development a repeat of the widespread beggar-thy-neighbor problems of the 1930s was avoided. Of course, cooperation was far from complete and many countries were criticized for not taking what was considered by others to be their fair share of the collective oil deficits (numerous calculations of "fair shares" were undertaken by various economists and organizations), but overall the initial handling of the oil shock was much better than could have been realistically hoped for.

Indeed, the international pressure to avoid overadjustments in the form of reduced spending and economic contraction following the oil shocks was so successful that over the medium term many developing countries did not adjust enough, continuing to

rely for too long on heavy amounts of borrowing. This, in turn, was one of the major contributing factors to the Latin American debt crisis of the 1980s. Nevertheless, the overall success in avoiding a repeat of the economic catastrophes of the 1930s was a major tribute to the growth of international cooperation and set the basis for dealing with several subsequent major run-ups in oil prices.

■ petroleum

The world petroleum sector includes the exploration, extraction, and transportation of crude oil, and the refining of crude oil into finished products. Participants in the world petroleum sector include fully integrated oil companies, national oil companies, independent oil and gas producers, refiners and marketers, pipeline operators, and others. The fully integrated companies explore for and produce oil and gas around the world, own pipelines and tankers to transport oil and gas, process the crude oil into refined products, and sell finished products through a global network of wholesale and retail outlets. Typical fully integrated companies are often international oil companies (IOC) such as Exxon Mobil Corporation, BP, Chevron Texaco, ConocoPhillips, and Royal Dutch/Shell. In contrast to IOCs, national oil companies are owned by national governments and are typically found in major oil-producing nations. Independent oil and gas producers only explore and/or produce crude oil and natural gas. Independent refiners purchase crude oil and process it into finished products. These companies may also own wholesale and retail marketing outlets or sell their products to marketing companies. Independent marketers purchase refined products, usually gasoline, and sell them at retail outlets. Pipeline companies transport crude oil, refined products, natural gas and natural gas liquids using networks of pipes and pumping or compressor stations.

Oil and natural gas provide nearly 60 percent of the world's primary energy and will remain indispensible in meeting the projected growth in energy demand during the early decades of the 21st century. The rapidly growing world economy will require large increases in oil, which will come from a variety of sources, including existing production capacities, development of existing reserves, new discoveries, and development of nonconventional liquids. Yet there is uncertainty about the industry's ability to overcome the multiple increasing risks of meeting the growing demand for oil. Such risks include gaining access to promising resources, making investment in infrastructure, and determining how much oil is recoverable.

Oil Demand Between 1960 and 1972, world consumption of oil increased by one and one-half times, about 7 percent on average per year. In turn, the world's industries, including transportation and commerce, and individual households became increasingly dependent on oil. In the years immediately following the Arab oil embargo in 1973 and the subsequent shock in 1979, world demand for oil greatly diminished. From 1980 to 2000, the annual growth in world oil demand averaged 0.9 percent.

The average growth in world oil demand for the future is expected to be much greater than in the past. Between 2000 and 2030, oil demand is projected to increase at an annual rate of from 1 percent to 1.9 percent. World demand for oil is expected to grow from about 76 million barrels per day in 2000 to between 98 and 138 million barrels per day in 2030. On a global basis, the transportation sector accounts for 68 percent of the total projected increase in oil consumption between 2004 and 2030, followed by the industrial sector, which accounts for another 27 percent of the increased consumption (Energy Information Administration, *International Energy Outlook, 2007*).

The largest increases in oil consumption from 2004 to 2030 are projected to be 7 million barrels per day in North America and 15 million barrels per day in Asian countries that do not belong to the Organisation for Economic Co-operation and Development (OECD). It is projected that non-OECD countries' oil consumption will continue to grow, driven by strong economic and industrial growth and rapidly expanding transportation use. It is further estimated that the fastest growth in oil consumption will occur in non-OECD Asia, averaging 2.7 percent per year from 2004 to 2030. Non-OECD Asia accounts for 43 percent of the overall increase in world liquids consumption (Energy Information Administration, *International Energy Outlook 2007*).

Prices Historically, world oil prices were low and stable in the 1950s and 1960s, driven by new discoveries in the Middle East, the North Sea, Alaska, and Nigeria. Cheap oil thus contributed to strong worldwide economic growth, which in turn stimulated greater consumption. With the first oil shock in 1973, prices increased fourfold, and in 1979, prices increased by another threefold. Prices thereafter declined haltingly and gradually until 1986 and then collapsed until late 1992. From 1992 to the beginning of 2007, oil prices increased fivefold.

Future projections of world oil prices, in constant 2006 dollars, have been projected by the U.S. Energy Information Administration (EIA) to decline from $68 per barrel in 2006 to $49 per barrel in 2014, then rise to $59 per barrel in 2030 ($95 per barrel on a nominal, noninflation-adjusted basis). The EIA low- and high-price cases suggest great uncertainties in the reference case projections, however. In the low-price case, world oil prices are projected to be $36 per barrel in 2030 ($58 per barrel on a nominal basis), while in the high-price case, oil prices are estimated to be $100 per barrel in 2030 ($157 per barrel on a nominal basis).

Production Oil production is projected to increase by 35 million barrels per day in 2030 over 2004 levels. To meet the demand for oil, production is expected to increase in both the Organization of the Petroleum Exporting Countries (OPEC) and non-OPEC producers, with most (65 percent) of the total increase coming from OPEC countries.

It is generally acknowledged that OPEC members with large reserves and relatively low costs for expanding production capacity can accommodate sizable increases in the world's petroleum consumption. Geopolitical issues in a number of the OPEC countries, including Iraq, Iran, Venezuela, and Nigeria, lead to great uncertainty in making projections of future production levels. Projections of Iraq's future oil production are well below its prewar production.

Reserves and Resources As of January 1, 2007, "proved" world oil reserves were estimated at 1,208 billion barrels. Proved reserves are estimates of the amount of oil recoverable from known reservoirs under current economic and operating conditions. Proved reserves reflect only a fraction of the oil that a reservoir may hold. "Recoverable" oil includes proved reserves and undiscovered oil that is economically extractable.

Reserves are concentrated in the Middle East and North Africa (MENA), together accounting for 62 percent of the world total. Saudi Arabia, with the largest reserves of any country, holds about a fifth of the world's total reserves. Of the twenty countries with the largest reserves, seven are in the MENA region. Iranian oil reserves have increased by 46.6 billion barrels, or 52 percent, since 2000. Kazakhstan has had the third-largest increase, 24.6 billion barrels, since 2000. Among the top 20 reserve holders in

2007, 11 are OPEC member countries that, together, account for 65 percent of the world's total reserves.

The United States Geological Survey (USGS) mean estimate of ultimately recoverable global conventional oil plus natural gas liquids (NGL) was 3.345 trillion barrels at the beginning of 1996. The estimates range from 2.5 to 4.4 trillion barrels, expressed in statistical terms, where 2.5 trillion barrels represents a 95 percent probability that the quantity size will exceed the estimate, and 4.4 trillion barrels indicates a 5 percent probability that the quantity will exceed the estimate. By comparison, IOCs project an average of 3.5 trillion barrels. The IOC most-likely estimates for ultimately recoverable global conventional oil range from 2.8 to 4.0 trillion barrels.

The uncertainty of ultimate recoverable oil and NGL has led to a continuing debate about the prospect of a future oil production peak and eventual decline. The timing of a peak and subsequent decline is subject to interpretation because of a number of variables, such as lack of transparent reporting of producing fields, conflicting estimates of recoverable oil, the increased costs of producing oil from conventional and nonconventional sources, and the timing and scale of development of alternative fuels.

Oil Companies State-owned, or national, oil companies control most of the global proved oil reserves. As of 2005, the global proved oil reserves were 1.148 trillion barrels, with national oil companies (NOCs) in control of 77 percent of the total (886 billion barrels) and allowing no private equity ownership. According to an 2005 annual survey published by *Petroleum Intelligence Weekly*, 12 of the top 20 oil companies are traditional (100 percent state-owned) national oil companies (NOCs) or hybrid, partly state-owned NOCs. *Petroleum Intelligence Weekly*'s ranking shows that Saudi Aramco, Iran's NIOC, Iraq's INOC, Kuwait's KPC, Venezuela's PDVSA, United Arab Emirates' Adnoc, Libya's NOC, and Nigeria's NNPC hold the largest reserves in the world.

National oil companies' objectives often differ greatly from those of the privately owned international oil companies. The NOC objectives go beyond maximizing returns on investments, and often include redistribution of wealth in society, foreign policy objectives, energy security, wealth creation, and economic development. The NOCs' noncommercial objectives tend to interfere with decisions regarding investments in oil production expansion. However, not all NOCs have the same interests. In more mature NOCs, such as Statoil (Norway) and Petronas (Malaysia), the focus is on returns on investment, and the companies exhibit more familiar corporate behavior. At the opposite extreme, the business practices of PDVSA (Venezuela) and NNPC (Nigeria) are heavily influenced by domestic policies. These firms are focused squarely on increasing the revenues to the government. Saudi Arabia has used its oil reserves in its foreign policy strategy, given its role as the world's oil swing producer. In its role as having the largest spare crude oil production capacity in the world, Saudi Arabia has the ability to replace the exports of any small- or medium-sized oil-producing country with days or weeks.

Investment The International Energy Agency estimates that over the period of 2005–2030 $4.3 trillion in new investments will be needed in the global oil sector to meet rising world demand for oil. The largest investment projections are in the Middle East and developing Asia, where most of the upstream (exploration and production) and downstream (refineries, pipelines, tankers) investments will be needed. The upstream sector accounts for the bulk of this investment requirement, with required investments averaging $125 billion per year. Almost three-quarters of the upstream investments will be required to maintain existing production capacity in the face of declining capacity of existing oil wells as reserves are depleted. Downstream investment requirements are projected to be about $700 billion from 2005 to 2030. This projection includes the addition of new refineries to meet the rising demand and additional investments on existing refineries.

There is no guarantee that the projected levels of investment will actually occur, as several barriers exist to upstream and downstream investments. First, most privately owned IOCs have large cash reserves and are able to borrow at reasonable rates from

petroleum

capital markets when necessary for new projects. Because of restrictions on access to oil reserves in many resource-rich countries, however, many IOCs may not be able to invest in upstream development. A large portion of oil reserves are found in countries where there are restrictions on foreign investment. Kuwait, Mexico, and Saudi Arabia, for example, remain totally closed to upstream oil investment by foreign companies. Other major oil-producing countries, such as Venezuela, Russia, Iran, Algeria, and Qatar, have effectively restricted foreign investment as well. Second, even in those cases where IOCs are willing to invest, other barriers such as licensing and fiscal terms, or the investment climate, may discourage them from doing so. Stability of the political regime, war or civil conflict, or other geopolitical tensions act to dissuade inward investment in the development of countries' resources.

■ pharmaceuticals

The pharmaceutical industry provides an important part of fundamental health care to the citizens of any given nation. Besides its social value, the industry is also important in economic terms its innovative capabilities contribute significantly to the knowledge and skills-based economy of advanced industrialized nations. Since the 1970s, the pharmaceutical industry has experienced considerable structural change. Government regulation continues to play a significant role in the industry, as does the drug discovery process and the cost of bringing a new drug to market.

Government Regulation The majority of new drugs are developed within the United States, the European Union (EU), and Japan, where the agencies responsible for their approval are the Food and Drug Administration; the European Medicines Agency (EMEA); and the Ministry of Health, Labor, and Welfare, respectively. Within the EU, marketing authorizations can be granted by either the EMEA or individual member states. If the product is derived from biotechnology, a firm must use the centralized system of the EMEA. Otherwise, if the firm chooses the national route, the procedure of mutual recognition, in which a product that has been judged safe for sale in one member state will be sold in all other member states, is adopted.

Although government regulation has increased to ensure the efficacy and safety of new drugs, important steps have also been taken toward increased international harmonization. The EU, for example, developed a single market for pharmaceuticals, culminating in the formation of the EMEA. In addition, the International Conference on Harmonization (ICH) was set up in 1990 to bring together regulatory authorities and drug developers from the EU, the United States, and Japan to attempt to eliminate duplicative requirements for drug development and approval. Since its inception, ICH has achieved the harmonization of technical guidelines and, more recently, of the format and content of registration applications.

Variations in pharmaceutical pricing, however, remain extreme due to the many differences in national health care systems. In Japan and the EU member states, the government is the main purchaser, and indeed, parallel trade (estimated at 4.2 billion euros in 2005) is allowed under the single-market rules. Thus third parties exploit price differences by buying pharmaceuticals in markets where low prices are enforced and selling them to governments and other purchasers in markets where higher prices have been agreed. In the United States, although the government is not the main purchaser, the rapid expansion of health care maintenance organizations has led to a concentration of purchasing power.

The only major national markets in which firms are free to set the price of new drugs are the United States, the United Kingdom, and Germany (since 2005), but soaring health care costs in advanced industrialized nations have led to tougher price competition. Governments and other purchasers have reduced reimbursement rates, increased the use of "limited lists" (which define drugs that may be prescribed and/or reimbursed for different diseases), and placed pressure on prescribers to substitute generics for branded drugs wherever possible. For example, the generic market grew by 13 percent in the eight largest national markets in 2005, compared to around 5 percent for "branded" pharmaceuticals, and generic prescription volume was greater than branded volume for the first time ever in the United States.

Drug Discovery Process At the end of World War II, the pharmaceutical industry experienced a radical shift from very little new drug development toward a research-oriented environment in which firms essentially screened thousands of chemical compounds for efficacy against a given disease (so-called random screening). Serendipity mattered: the mechanisms of how drugs worked were not well understood, and firms correspondingly maintained huge libraries of chemical compounds. As basic biomedical knowledge increased in the 1970s, a second technological shift occurred: "rational drug design" was adopted, which involved more precise models of how particular diseases function and the design of molecules that target particular cells or cause particular biological interactions. Since the 1980s, biologics (derived from biotechnologies) constitute the third shift and provide a crucial arena for the development of new drugs in the 21st century. Approximately 20 percent of new drugs launched on the world market are biotechnology derived, and biologic sales were $52.7 billion in 2005. The United States was the single most important national market in 2005 in terms of research and development (R&D) expenditure (78 percent) and turnover (76 percent), with approximately 140,000 employees as compared with Europe's 33,000.

Over time, the average cost of developing a new drug has increased substantially. The cost was estimated at $897 million in 2003, compared with $500 million in the 1990s and $231 million in 1987. This compares with the first ever estimate of the average cost of developing a new biologic, which was estimated to be $1.2 billion in 2006, reflecting both the cost of time and the drugs that fail (Tufts Center for the Study of Drug Development). This increased cost is primarily due to the increasing focus on chronic rather than acute illnesses as populations age (i.e., targeted diseases such as Alzheimer's are more "complex," and the cost of R&D varies across therapeutic groups), tougher governmental regulations that have lengthened development times and increased the number of clinical trials, and finally, the need to convince prescribers that the new drug has significant benefits as compared with rival pharmaceuticals on the market.

Source: Firms' Annual Reports, *Pharmaceutical Executive* (May 2006).

Note: Where merger/acquisition has occurred, the market shares in 1998 and 1992 represent the larger of the two previously separate entries. Thus, for GlaxoSmithKline, the 1998 and 1992 market share data represent Glaxo's only.

[a] The data for Roche include Genentech's sales (as they own a majority holding). Genentech's sales in 2005 = $5.5 billion, with $1.3 billion on R&D.

[b] Astellas was incorporated on April 1, 2005, through the merger of Yamanouchi (Jap) and Fujisawa (Jap).

X: outside the Top Twenty

On average, it takes 12 years from a scientific discovery to bring the drug to market. The shorter effective patent life (reflecting the longer development period, which leaves a shorter period for sales of the pharmaceutical before it goes off patent), the increased ability by rival firms to use rational drug design to produce close substitutes, and the increase in generic competition due to changes in regulations have all eroded the length of market protection once enjoyed by the pioneer developer of a pharmaceutical. As the competitive environment has moved from the national to the global level, firms currently attempt to launch a new drug in as many major national markets as possible, as well as design various (incrementally innovative) formulations of the drug, license promising new compounds, and advertise directly to consumers where government regulations allow.

Industry Structure The pharmaceutical industry is best characterized as a global oligopoly in which large multinational firms dominate. Moreover within these firms, "blockbusters" (defined as drugs that

generate more than $1 billion in worldwide sales annually) dominate the product range, as shown in table 1. A good descriptive measure of success is the proportion of leading global medicines that national firms (in terms of the location of company headquarters) account for. In 2004, Germany owned 0 of the top 75 (as measured by worldwide sales), France owned 5, Japan owned 5, Switzerland owned 8, the United Kingdom owned 17, and the United States owned 40.

Total global pharmaceutical sales in 2005 were $602 billion, with the United States accounting for 44 percent, the EU for 30 percent, and Japan for 11 percent. Table 2 highlights the substantial increase in merger and acquisition activity in the 1990s, where a significant proportion was cross-border activity. Table 1 also gives the market shares of the 20 leading firms in the period 1992 2005, showing that the ranking of the leading companies changed significantly even in this rather short time period. Note also the relatively high increase in industry concentration. In 1992, the top five firms accounted for 12.9 percent of the global market. By 1998 this had increased to

Table 2

Merger and acquisition activity in the pharmaceutical industry

	Abbott Laboratories (US) and BASF Knoll (Ger)
2001	Bristol Myers Squibb (US) and DuPont Pharmaceuticals (US)
2003	Pfizer (US) and Pharmacia Upjohn (US/Sweden)
2004	Aventis (Fr) and Sanofi (Fr)
2006	Bayer (Ger) and Schering (Ger)

20.4 percent and to 26.8 percent by the end of 2005. The leading firms also rapidly increased their proportion of industry R&D: in 2005, for example, although the 10 top firms accounted for only 41.6 percent of the market by sales, they accounted for 65.9 percent of total R&D expenditure. Moreover it must be noted that an increasing proportion of firm-level R&D was spent in the United States, at the expense of Europe and Japan. In 1990, the respective R&D expenditures were $6.8 billion, $9.9 billion, and $3.6 billion, compared with $29.6 billion, $26.3 billion and $8.4 billion, respectively, by 2004.

Outlook Health care costs have increased steadily in advanced industrialized nations, due mainly to aging populations. In turn, this has led to the increased substitution of drugs for more expensive alternatives such as surgery and hospitalization. Moreover rapidly rising health care costs have led to more intense pressure on how pharmaceuticals are priced. National governments have tried various containment measures, such as allowing increased

competition from generics. In addition, R&D costs have risen due to the increasing costs of clinical trials and other regulatory hurdles, as well as the focus on chronic rather than acute diseases and the movement toward new drug discovery through biotechnology. In response, the industry experienced unprecedented mergers and acquisitions during the 1990s.

Overall the pharmaceutical industry plays a vital role in the modern world economy. Health care is one of the major issues when thinking about what welfare means in the 21st century. The industry is an enormous generator of innovation, investment, and highskilled employment. Given the high cost of innovation, notwithstanding the significant public funding in basic medical research, however, there remains a relative lack of research into rare (genetic) diseases that afflict the few and diseases that primarily affect developing countries. Other major issues for the industry include the protection of intellectual property and the improvement of access to medicines in developing countries.

CATHERINE MATRAVES

■ Plaza Accord

The Plaza Accord was an agreement reached on September 22, 1985, at the Plaza Hotel in New York, among the G5 countries (the United States, Japan, Germany, France, and the United Kingdom) to push down the value of the dollar in order to reduce large U.S. trade deficits. On the day that the Plaza Accord was announced, the trade-weighted or effective value

of the dollar fell 4 percent. The dollar fell 17 percent against the Japanese yen and 15 percent against the German mark between September 1985 and the end of the year.

Background In the 1970s, the United States had frequently sought to push down the value of the dollar to reduce its trade deficit. In 1976 and 1977 expansionary monetary and fiscal policies, together with attempts by Treasury secretary Michael Blumenthal to "talk down" the dollar, caused the exchange rate to depreciate (Frankel 1994). The fall of the dollar, aggravated by inflationary pressures, subsequently led to consternation among policymakers.

In October 1979 Fed chairman Paul Volcker initiated a change in monetary policy operating procedures designed to fight inflation and strengthen the dollar. The new strategy allowed interest rates to reach very high levels if necessary in order to defeat inflation. Over the next two years the overnight interbank interest rate (the federal funds rate) increased 800 basis points and the 10-year Treasury bond rate increased 600 basis points. Long-term real interest rate differentials between the United States and its trading partners increased 4 percentage points between September 1979 and the end of 1982, contributing to an appreciation of more than 21 percent in the Federal Reserve's real trade-weighted value of the dollar.

Although the Volcker disinflation succeeded by the end of 1982 in breaking the back of inflation, interest rates in the United States remained stubbornly high. The real interest rate differential between the United States and its trading partners increased another 100 basis points in 1983 84 as compared with 1981 82. The real exchange rate also appreciated another 20 percent over this period (Frankel 1994). The most likely explanation for the continued increase in U.S. interest rates and the dollar over this period was the large increase in the U.S. structural budget deficit.

The dollar continued appreciating between June 1984 and February 1985 even though real interest rate differentials, trade imbalances, and other fundamental factors were moving against the dollar

(Boughton 2001). Many argued that the appreciation at this time was due to a speculative bubble. The Reagan administration, however, maintained a position of benign neglect toward the exchange rate. The strong dollar made U.S. exports, measured in foreign currencies, more expensive and U.S. imports measured in dollars cheaper. It thus led to a burgeoning trade deficit. Between 1980 and 1985, the trade deficit increased by $87 billion, reaching $112 billion in 1984. The automobile, steel, textile, agriculture, and capital goods sectors were particularly hard hit. Firms responded to these pressures by seeking tariffs and other protectionist restrictions on free trade. In 1985, for example, more than 300 trade bills were introduced in Congress; of these, 99 were directly and seriously protectionist and 77 were potentially so (Destler 1986).

Coordinated Action to Correct the Global Imbalances These protectionist pressures jolted the Reagan administration and foreign leaders into action. They saw the world trading system that had been carefully built up over 40 years in danger of collapsing. Foreign leaders were also concerned because the strong dollar was raising import prices and generating inflationary pressures.

In January 1985, the incoming treasury secretary James Baker suggested that the Reagan administration should reconsider its policy of benign neglect toward the exchange rate. In February 1985, the G5 countries engaged in coordinated interventions in foreign exchange markets to lower the value of the dollar. The dollar began falling in February 1985 and fell 15 percent against the German mark and 10 percent against the Japanese yen before the signing of the Plaza Accord in September of that year. It is unclear whether these currency realignments were due to market forces correcting the overvaluation of the dollar (Feldstein 1988) or to foreign exchange intervention by G5 countries in February (Frankel 1994; Funabashi 1989).

The actual agreement sought to correct trade imbalances not only through exchange rate changes but also through expenditure-reducing policies in the United States and expenditure-increasing policies in the other countries. The agreement stipulated:

1. The U.S. would reduce its budget deficit by more than 1 percent of gross domestic product (GDP) in fiscal year 1986 and reduce it further in the future;
2. Japan would liberalize financial markets to ease up on consumer credit and would take into account the yen exchange rate when conducting monetary policy;
3. Germany would cut taxes;
4. All the countries would cooperate closely in foreign exchange markets to encourage further depreciation of the dollar; and
5. All trading partners would resist protectionist pressures (Meyer et al. 2002).

The U.S. current account balance improved over the next several years and returned to balance in 1991. Although several factors, including a recession in the United States, were responsible for this improvement, the orderly exchange rate adjustments following the Plaza Accord were important factors as well. In the first decade of the 21st century, as U.S. trade deficits as a percentage of GDP have reached levels twice as large as the imbalances of the 1980s, there have been calls for a new Plaza Accord (see, e.g., Cline 2005). Since the United States is running trade deficits with many countries, a new agreement to reduce the value of the dollar would probably involve many more countries than the five that took part in the original accord.

WILLEM THORBECKE

■ **political economy of policy reform**

Policy reforms create winners and losers. Hence, implementation of policy reforms requires attention to political economy. Even when reforms are efficient in the aggregate, the absence of compensation means that reforms create losers who may oppose reforms. Thus many reforms that may be efficient will not be implemented. Even reforms that will benefit a broad

swath of society are often delayed for long periods of time. The political economy of policy reform studies the implementation of reforms and why they are often delayed.

The political economy of reform can be viewed as an issue of how to get reforms enacted, and then how to keep them from being reversed. The first problem involves relaxing ex ante political constraints. The latter problem is to relax the ex post political constraints (Roland 2002).

An important aspect of implementation is the design of reforms. How reforms are designed may affect both the likelihood of implementation and the sustainability of reforms. The major distinction in this area is between "big bang" and gradual reforms. Big bang reforms are attempts at comprehensive reforms, the idea being that unless a slate of reforms is undertaken simultaneously the policy will be unaffected. Gradual reform focuses on sequencing and the benefits of trial and error in policymaking. The argument is that reform on too broad a front is too difficult to implement. Getting the sequence of reforms right can build momentum for reform; thus the argument is also one of political acceptability. This controversy has been most discussed in the literature on economic transition, though it has more general application. Often Russia is taken (incorrectly) to be an example of big bang reforms and China is taken as the premier example of gradual reforms.

To fix ideas, consider a policy of tariff liberalization in a small economy. Implementation of the reform will raise national income. But it will cause losses among factors in the import-competing sector while leading to gains in those sectors that consume the imports and in the export sector. Assuming the gains exceed the losses the potential for compensation could lead to a Pareto-improvement and thus no problem with implementing the policy. But as compensation is problematic, the potential losers may oppose the policy or at least cause significant delay. This is the problem that is the focus of the political economy of policy reform.

Implementing Reforms Fernandez and Rodrik (1991) developed a model of status quo bias in re-

form that has become classic in the literature. The idea is that when individuals are uncertain over the benefits of reform potentially beneficial programs may not be implemented. Even if everyone knows that in the aggregate the policy will be beneficial (i.e., there is no aggregate uncertainty), if individuals are uncertain over their own situations a status quo bias may still arise. Individual specific uncertainty implies that agents do not know whether or not they will win from reforms. Even if they know that a majority will benefit they may vote against reforms if they believe that they may be losers.

One may suspect that compensation packages may be useful in alleviating this problem, but there is a credibility problem at work. Ex post a majority of voters benefit; hence the losers have little power to enforce a promise for compensation. And with a majority in favor, there will be little chance to reverse the reform. Hence, potential losers know that a promise of compensation is not credible, and this may cause them to oppose reforms. Moreover in practice, it is very difficult to identify who the losers are. This demonstrates that the potential losers have a strong incentive to prevent implementation   their bargaining power drops dramatically after the policy is passed.

The Fernandez-Rodrik model explains why reform may not be implemented, but reforms do take place. To explain why suboptimal policies are reversed requires a dynamic analysis. Alesina and Drazen (1991) developed a model in which interest groups differ over the net benefits of reform. They consider a reform that has public good aspects   a fiscal reform, for example. The problem is that there is a distributional conflict over who wins most from the reform. Each group prefers that the other group pay a higher share of the costs. Delay in reform is modeled as a war of attrition. Reform occurs when one of the groups realizes that it has more to lose from delay than from reform. When one side capitulates, the reform occurs. This also implies that reform will take place sooner the greater the crisis, since this makes delay more problematic. The problem of reform is then to overcome distributional concerns to create consensus over reform.

While the Fernandez-Rodrik model emphasizes winners and losers (and is applicable to reforms that need not have public good aspects) the Alesina-Drazen model emphasizes the need to form consensus for reform to eventually occur. What is common to both, however, is the emphasis on heterogeneity and the conflict of interests that this implies. The models are essentially complementary.

Another mechanism that may lead to blockage of beneficial reforms reflects the influence of special interest groups. Grossman and Helpman (1994) analyzed how such interest can have influence on political decision making (through monetary contributions or information transmission) and used their model to explain the structure of trade protection. Politicians care about social welfare and campaign contributions that can be used to get votes in future elections. They show how even if politicians care about social welfare, the campaign contributions that can be raised by running on a platform of trade protection, for instance, may cause them to place greater weight on workers and capital owners in some sectors of the economy than on others (Grossman and Helpman 1994).

Big Bang versus Gradualism An important debate in the literature on policy reform concerns the *dimensionality* of reform: Shall reform be piecemeal or comprehensive? In the literature on economic transition, the debate has centered on two dimensions: speed and comprehensiveness. The form this debate has taken is often characterized as shock therapy (or big bang) versus gradualism. Related is the issue of whether there is a single blueprint sometimes called the Washington consensus that suits all reforming countries. It is important to note that this debate often conflates two dimensions of reform: timing and scope. This is perhaps inevitable, as big bang reforms typically push for rapid, comprehensive reform. But it must be noted that gradual reforms can be comprehensive as well, but over time.

Big bang reform packages are obviously comprehensive in intent. It is crucial to emphasize, however, that gradual reform is not at all the same thing as partial reform. The primary debate is over pace and sequencing. In the case of emerging market reforms,

the debate centers on whether financial institutions and the rule of law must be implemented before capital markets are liberalized. This argument has been made most forcefully by McKinnon (1993), for example. The broader issue is whether markets can operate before the institutions that support them are established, or whether broad-brush market reform creates an environment where the institutions will develop.

Especially in the transition context, the goal is eliminating the command principle and moving to a private property based market economy. Hence, *eventually* the same steps must be taken. The question is how many steps to take at once and whether they must be taken in a precise order or not. For example, do you need to establish institutions of a private property economy before privatization, or will privatization create the *demand* for private property institutions? There is little debate over the importance of institutions for the success of the market economy, but there is still debate over how to induce their development.

The competing principles are easy to understand. The need for a big bang seems almost implied by the lessons from partial reform (e.g., Murphy, Shleifer, and Vishny 1992). Partial reforms for example, enterprise autonomy without price liberalization lead to supply diversion and inferior outcomes. If reforms are complementary, then partial implementation may lead to outcomes inferior to the status quo. When reforms are complementary, implementation of the whole package may be necessary for the reforms to succeed. Moreover partial reforms in this context create rents for insiders who then may oppose further reforms. And if there is a window of opportunity for reform, it may be advantageous to implement a far-reaching reform before the window is shut.

For example, in the case of transition there is a question of how much of the infrastructure of a market economy is needed for markets to be effective. Privatization cannot work without price liberalization, and neither policy can work without stabilization and the elimination of the soft budget constraint. If the command system is not dismantled the private sector will not be able to compete. The big

bang view thus argues for reform on a broad front so that complementarities across reforms can be utilized.

The case for a big bang approach often builds on the argument that it takes some time for people to realize whether they are going to win or lose from reform, and to form a powerful opposition against reform if they expect to lose, so by moving quickly, the politician prevents emergence of opposition powerful enough to actually stop or reverse reforms. This is often referred to as the "window of opportunity." It was a prime consideration of reformers in Poland and the architects of privatization in Russia.

A related argument for the big bang stems from the problem of state capture (Hellman 1998; Sonin 2008). Suppose that a complete set of reforms must be implemented and that reforms imply short-term costs. Then *if* the reform package gets stuck partway, voters may fear they will reap only costs and no benefits and hence they will oppose reforms all together. This may happen when the reform process is likely to be captured by winners from partial reform. Hence when the political environment is such that this may occur, big bang policies may be the only way to implement reforms. Forward-looking agents that would be willing to bear the short-term costs if they were sure to reap the long-run benefits may withdraw their support for reform if the realization of the long-run benefits becomes uncertain because of the risk of getting stuck in a partial reform equilibrium.

Another potential argument for the big bang approach (noted by Olofsgård 2003) can be derived from the recent literature on self-control problems. The idea is that voters may not have the self-control to stick with a schedule of partial reforms. The urge for immediate gratification may induce voters to delay reforms or to support the nonreformer in order to avoid the short-term cost of reforms. This may occur even though voters' lifetime expected utility as calculated *in the very beginning of the reform process* is higher with continuation of reform. The big bang approach may thus serve as a commitment device in this case, because it restricts the choice set of the voters if reform reversal is unlikely or very costly.

The alternative view — dubbed the "evolutionary-institutional view" by Roland (2002) — is motivated,

first of all, by the recognition that one cannot do all at once. There are limited skills and limited amounts of time available to policymakers. This alternative conception gradualism sees the trial-and-error method as a virtue. Gradualists often accuse proponents of the big bang approach of hubris. McMillan (2004, 35), for example, argues: "Reform is hard to do because we cannot predict its effects. The big bang approach presumes we know where we are going and we know how to get there. But we don't." This argument, also put forward by Easterly (2006) and Rodrik (2008), emphasizes humility and a menu of approaches rather than a unique program applicable in all countries.

This argument is extended to the issue of complementarities in reform. Although the necessity for implementing a package of reforms would seem to argue against gradualism, McMillan (2004, 36) argues to the contrary: "The systemic interactions are hard to predict. We know little about how the pieces of the market system fit together. Some interactions may be complex and indirect, and so we may not even be able to anticipate their existence. Others are straightforward . . . but we have little data on their magnitude."

Opponents of big bang reforms point out that if they are designed incorrectly they can lead to a lock-in of bad reforms. Sonin (2003) argues that mass privatization in Russia created a lock-in of power among early winners. These oligarchs could afford their own property rights protection and thus were opposed to the development of the rule of law, government reform, tax reform, and other policies that would threaten their own incumbent position. Indeed this argument has been made in a more general way by Rajan and Zingales (2004), who argue that the biggest threat to capitalist economies often comes from incumbents. It is not clear, however, to what extent this is an argument against big bang so much as against bad sequencing of reform. It is certainly the case that bad reform will lead to bad effects.

The classic example pointed to by proponents of gradualism is the dual track system in China. This system liberalized at the margins: enterprises were

required to continue fulfilling the central plan but could use the market to sell above-plan-level production. Li (1999) provides an interesting analysis contrasting the big bang and dual track reforms with special emphasis on the Chinese experience. The success of Chinese reforms is frequently attributed to the dual track. This makes it all the more ironic that the dual track closely resembles Soviet partial reforms   the "law of state enterprises" of 1987   which performed so poorly. This suggests that the success of reforms may be attributable to the specific conditions of the case rather than to general principles. What worked in China did not work in the Soviet case, most likely because state authority remained strong in China but was deteriorating rapidly when these reforms were implemented in the Soviet Union.

To some extent, gradualism may require that political control, à la China, remains. This seems to be the lesson of the comparison of Gorbachev's reforms regarding the Law on State Enterprises with the dual track system in China. Both allowed enterprises to use markets to allocate above-plan-levels of production. In China the system has been a success, as enterprises continued to produce for the plan, although significant corruption occurred as well. In the Soviet Union, on the other hand, plan fulfillment fell dramatically as supplies were diverted to take advantage of higher market prices, and as a result, planners increased targets continually. The lack of enforcement power of the government made it hard to utilize this mechanism in the Soviet Union. Without such control it may be difficult to control the pace of transition. And democracy may work against more gradual mechanisms. This suggests that often the difference between the relative successes of the two approaches may be due to a third, independent, factor: the nature of the political equilibrium in a reforming country.

A related argument in favor of gradualism stems from the notion of an incubation period. In the late Soviet period there was the idea of the "500-days" plan. This was a blueprint for reform, written by leading reformers and accepted by Yeltsin that was eventually rejected by Gorbachev. The essence of the plan was to move in a steady way to a market economy. Enterprises would be broken up before being privatized to reduce monopoly power. Apartments would be privatized before price liberalization to soak up the monetary overhang. The key idea was to prepare the system for the transformation.

The opposite view is that crisis prevents an incubation period. This is certainly true in the Polish case and also in the Russian case. The problem is that the urge to undertake radical reform did not take hold until a crisis emerged, at which point there was no time left for incubation. This argument is less important in the case of Czechoslovakia and Hungary, where in fact some incubation did take place. These considerations point to the fact that the amount of hemorrhage in the fiscal budget may be a critical factor in deciding the outcome of reform.

Sequencing is also important for the continuation of reform. If early reforms lead to an improved situation for the median voter, this may create support for future reforms. The success of agricultural reform in China is often seen as creating a favorable environment for reforms of industry. This suggests that starting with a reform that increases the welfare of a majority runs a smaller risk of reversal. In contrast, incorrect sequencing (starting transition with the more painful reforms) undermines popular support and may unnecessarily lead to reform reversal. The case for gradualism thus crucially hinges on correct reform sequencing (Dewatripont and Roland 1995, 1209).

One way to cope with the status quo bias is to provide compensation. This need may also argue for partial reform as it reduces the fiscal cost of compensation. For example, unemployment is very likely to increase during transition. To avoid opposition to a reform by the unemployed, the government needs to provide unemployment benefits. In these conditions, Dewatripont and Roland (1995) point out that a slower, feasible speed of transition may be preferable because the pressure on the fiscal sector is lessened. Of course fiscal costs are not the only costs that should be considered, but imperfect reforms that are actually implemented may be preferable to perfect reforms that cannot be implemented.

The importance of political constraints may thus alter the balance between big bang and gradual reforms.

Reversal Costs A big bang strategy involves high reversal costs, which are often considered to be an advantage ex post since they reduce the reversibility of enacted reforms, which is a constant concern for reformers. Thus Anatoly Chubais, the architect of Russian privatization, spoke of the irreversibility of mass privatization as one of its most important benefits. If reforms are irreversible, then a concerted effort can achieve a permanent impact on performance. The problem with this view, however, is that it ignores the ex ante problem. If reversal costs are high, then it may be harder to implement reforms in the first place. After all, if reversal costs are high and reforms have unexpected consequences, any learning cannot be acted on. Hence if there is significant uncertainty about the consequences of reform that is, if there is significant probability of learning then high reversal costs make it harder to enact reforms in the first place. From the ex ante point of view, however, high reversal costs in the case of a negative aggregate outcome may make a big bang approach politically unfeasible. Gradualism makes reforms easier to start because it gives an additional option of early reversal at a lower cost after some learning has taken place (Dewatripont and Roland 1995).

If partial reform is less costly to reverse than full reform, gradual reforms may be more politically acceptable than full reforms because they provide an option of early reversal (Dewatripont and Roland 1995). If after partial reform is implemented, a continuation of reform toward full reform seems unattractive to a majority because the signals given by partial reform about the future are not promising enough, then it is always possible to come back to the status quo. On the other hand, if the signals given by early reform are promising enough, then the reforms can continue with greater support. Gradualism thus lowers the cost of experimenting with reform and makes a move away from the status quo more acceptable to a majority.

Note that this argument for partial reform is intimately connected with learning. If reforms are complementary, then one may learn from partial reform. Suppose that one can decompose a reform package into two parts. A gradual reform would implement one part first price liberalization in agriculture before industry, for example. One may then learn about the consequences of the package from experiencing the first part. Informativeness is the key necessary condition for gradualism to dominate the big bang strategy in the sense that learning about the first reform tells whether to try the second reform or not, depending on the realization of the state after the first reform is implemented. If there is no complementarity, there is nothing to learn and hence you might as well do all at once.

Costs and Benefits of Gradual Reform We can summarize this discussion by considering the costs and benefits of gradual reform. The most important cost is simply the delay in improved performance. If some important reforms are only implemented later, then the full benefits of reform are delayed. An equally important cost may be that delayed reforms continue the hemorrhaging that is taking place. This is especially true when reforms are undertaken in economies suffering crisis. When the IMF is called to provide support for an economy it is already in an economic crisis. Similarly, in the case of transition economies, the status quo may not be feasible. The economy is in crisis and gradual reform may not be possible. A third important cost of gradual reform is that it may dissipate the credibility of reformers, given that partial reform was a frequent failed policy in planned economies.

The benefits of gradual reform are also straightforward. Most important, perhaps, is that if it is carried out successfully, momentum for further reforms can be built. Building constituencies that support reform may enhance the sustainability of reform. Gradual reforms also allow for learning and may be easier to implement when reversal costs are high. They allow for experimentation. Finally, gradual reforms may involve a lower level of transfers, and hence, a more feasible fiscal burden.

On balance, the choice between big bang and gradual reforms may come down to the extent of current crisis and the strength of the state. If there

is significant political legitimacy or control, gradual reforms may be feasible. If reforms are taking place in a period of extraordinary politics, however, big bang reforms may be the only choice.

Empirical Evidence Given the experiences of emerging and transition economies what has been the experience of big bang versus gradualism? The question is not easy to answer, though advocates of each approach have plenty of cases to point to. The experience of Russia and China are often contrasted and used to illustrate the relative success of big bang and gradual reform policies, respectively. The problem, however, is that policies are not implemented in isolation. The success of policies will depend on external circumstances. Russian reforms took place during a period of very low oil prices. When the economy deteriorated, it was natural to blame reforms. But this may miss the essential point. For an economy that is the second largest exporter of oil and whose economy is heavily resource-dependent, this fact accounts for economic performance far more than any reform packages.

A related problem is that the choices between the two programs are not chosen randomly. The choice is endogenous, and the political equilibrium in the country is often decisive. In more stable societies gradual reform may be chosen, but if the society has a stable political system even big bang reforms may be successful. In contrast, most economies in crisis choose big bang approaches, and performance is frequently less than stellar. But there is a reason these economies were in crisis, and it is not clear that a gradual program would succeed in these countries.

Another fundamental problem with empirical work focusing on this question is how to identify whether a country chose a big bang or gradual approach. Often, this judgment is made ex post via expert surveys. The identification is thus influenced by how successful reform was thought to be. But this just ensures that one's prior assumptions are confirmed. If a country announces a big bang reform but is only partially successful at implementing the various parts of the program, should this country be classified as big bang or gradual? This is a knotty problem that has plagued this literature and is a major reason for a lack of consensus about outcomes.

BARRY W. ICKES

■ **political economy of trade policy**

After the provision of internal order and external security (and bound up with both as a source of revenue), the regulation of international trade is one of the oldest known activities undertaken by states. Thus it is not surprising that we have records of an alytical comment on commercial policy from the earliest writings on economics and political econ omy. Most of this early writing is "political econ omy" in the sense of practical policy advice, but this is not unrelated to the term's more modern meaning as positive accounts of policy choice. Policy advice is given under an implicit model of government (sometimes called the Weberian model after Max Weber) that the government is willing and able to act on advice intended to improve aggregate social wel fare. Given its focus on explaining welfare-worsening policy, contemporary political economy research generally rejects this model (even when, as in the case of very low levels of protection, it would seem to be a more accurate model than the obvious alternatives). Instead, we take the obvious fact that trade policy deviates from virtually any straightforward model of welfare maximization as a warrant to consider alter native accounts of policy determination. The great majority of this work begins with an attempt to link policy preferences of the relevant agents to their material self-interests, defined in terms of the prim itives (axiomatic assumptions) of some underly ing model of the economy, and then seeks to map these policy preferences into policy outcomes via some (usually extremely spare) model of policy determination.

Early Steps in the Political-Economy Analysis of Trade Policy The most immediate predecessors of modern research on the political economy of trade policy are three works by political scientists that still repay close study and that contain most of the themes that still motivate contemporary research:

Schattschneider's *Politics, Pressure, and the Tariff* (1935); Bauer, Pool, and Dexter's *American Business and Public Policy* (1963); and Lowi's "American Business, Public Policy, Case Studies, and Political Theory" (1964). The first of these treats trade policy (in this case the Hawley-Smoot tariff) as the outcome of an asymmetric lobbying process in which protection seekers dominate and certain sectors are more effective than others. Bauer, Pool and Dexter saw their work as a rejection of Schattschneider's. Looking at omnibus trade legislation in the period 1953 62, they found (among other things) members of Congress to be relatively free from lobbying constraint and saw lobbying primarily as information transmission. Lowi's brilliant review and reconciliation argued that a fundamental institutional change had resulted in a redefinition of trade policy such that the politics had changed between the periods studied in these two classic works. Although the great bulk of contemporary research on the political economy of trade is rooted in the asymmetric group theoretic tradition presented in Lowi, a growing body of work emphasizes institutional features and, while not much applied to trade policy, the dominant strand of research on lobbying in political science now emphasizes informational issues.

The first wave of research by economists on the political economy of trade protection was actually less concerned with developing a coherent and, at least in principle, testable positive theory than with finding a way to increase the costs of protection. In the first paper of this sort, Tullock (1967) argued that the standard welfare analyses (focused on what economists call "deadweight loss" or "welfare triangles") were sizable underestimates of the actual welfare costs of protection (and monopolies). Specifically, potentially productive resources were spent seeking the rents implied by the presence of the tariff. Accounting for these would permit us to count the rent rectangle, as well as the deadweight loss triangles, as costs. The empirical application of this logic by Krueger (1974) to the case of Turkey, in which rent seeking clearly added to the costs of protection, moved political economy analysis to the center of trade policy analysis, at least in developing countries.

This approach reached its most sophisticated form in the work of Bhagwati and his coauthors on directly unproductive profit-seeking activities (e.g., Bhagwati and Srinivasan 1980). As applied to pathological situations (e.g., Turkey) this approach makes a lot of sense, but as a general extension of the normative analysis of trade policy, it is deeply problematic: adding the economic costs of political action to the costs of protection without a systematic normative analysis of political action makes little sense. After all, in a nonpathological situation, lobbying or directly unproductive political activities are just other terms for citizens approaching their government. The ability of citizens to do this is an essential component of the democratic political process, something most of us would consider highly positive.

The other precursor to current work grows out of Olson's *Logic of Collective Action* (1965) and the closely related earlier work by political scientists on the foundations of group theoretic models of political action. Olson's key insight, relative to much of the earlier research on the political activity of groups in the determination of policy outcomes (called "pluralist theory" by political scientists), was that the decision to invest real resources (e.g., time and effort, as well as money) in group membership was a rational decision, constrained by the expected impact of those resources on the goals of the group. Because groups, especially political groups, seek goals that benefit all members, regardless of their level of investment, the decision to invest has the form of a decision to provide a public good (i.e., it has a prisoners' dilemma structure). In addition, asymmetries in group effort can be expected to emerge based on group size. That is, large groups will find it hard to provide the optimal level of the public good, while small groups with concentrated benefits from political action will find it relatively easier to organize. Thus small groups expecting concentrated benefits can be expected to be more politically successful than large groups with diffuse benefits.

In the case of trade policy, the most common form of this argument is that producers of an import-competing good will expect concentrated benefits (not only supporting higher factor returns, but

protecting jobs and immobile capital from unemployment) and will find it in their interest to organize to support protection, while a large number of consumers, each of whom bears only a small additional cost as a result of the protection, will not find it in their interest to organize. Thus we will observe protection even if it is welfare-reducing in aggregate. Although this may well explain why we do not observe much in the way of consumer activity on trade policy, it does not explain why large retail intermediaries (e.g., Wal-Mart) or industrial users of intermediate goods are not more active on trade, or why what little consumer activism we do observe tends to support protection (e.g., Public Citizen, a U.S. consumer rights organization founded by Ralph Nader).

A sizable empirical literature developed to account for tariff structure in terms of a number of more or less ad hoc variables in a linear regression framework. Sign patterns in these variables were suggested in terms of a number of loose explanatory frameworks. This work increasingly focused on variables seen to be associated with effective group formation and then used loosely construed models linked to early Chicago school political economy as an interpretive framework. Overall this work provides quite strong evidence that political-economic factors must be part of any coherent account of systematic patterns in the tariff structure.

Political Preference and Minimally Institutional Political Economy The core of virtually all political economy models developed by economists is a formal derivation of preferences over policy from primitives of the underlying model of the economy. More formally, endogenous policy models build some form of explicit political structure into some form of neoclassical general equilibrium model. That is, the underlying economy is made up of households, characterized by preferences over final goods and portfolios of productive factors, and firms, which transform factors of production into final goods. We can denote a neoclassical economy with the set: $E = \{\mathbf{Z}, \mathbf{F}, \mathbf{R}\}$, where $\mathbf{Z}$ is a matrix allocating factors of production among households, $\mathbf{F}$ a vector of technologies, and $\mathbf{R}$ a vector of household prefer-

ences over final commodities. To this economy we attach a vector of possible interventions ($\mathbf{t}$) and a political mechanism ($\mathbf{M}$) yielding a political economy: $\Pi = \{\mathbf{Z}, \mathbf{F}, \mathbf{R}; \mathbf{t}, \mathbf{M}\}$. The easiest part of the analysis of a system like Π involves the derivation of citizen preferences over policy. For a given household, $h(R_h \in \mathbf{R}, \mathbf{z}_h \in \mathbf{Z})$, for a fixed E, we simply ask how any relevant state of the policy variable (t) affects household welfare. By answering this question for every feasible state of the policy variable, we trace out household political preferences over that policy.

It is now well known that the most general version of this model (usually called the Arrow-Debreu-McKenzie model) does not yield comparative static results of the sort necessary for this exercise. As a result, most work in this area builds on either a Heckscher-Ohlin-Samuelson (HOS) model (i.e., a model in which all factors are fully mobile between sectors) or a Ricardo-Viner model (i.e., a model in which every sector is characterized by a specific-factor and a single mobile factor is used by all sectors). The former yields conflict based on factor ownership (i.e., class conflict), while the latter yields conflict based on industry attachment. Recently, a specialized form of the latter has been widely used, in which n-1 sectors are characterized by a specific factors structure and the nth sector (the *numeraire* sector) is a freely traded Ricardian good (Grossman and Helpman 1994). This is usually combined with quasilinear preferences to produce an economy in which virtually all general equilibrium linkages have been severed. This makes for an extremely tractable, if somewhat implausible, framework for political economy modeling of contemporary trade policy. If we think of the HOS model (and its dimensional generalizations) as a model of the long run and the Ricardo-Viner model as representing a relatively short run, it is probably clearest to treat their use in political economy models as reflecting the period of political calculation. That is, if political agents make their calculations over a relatively short time period, the most appropriate model would be some form of specific-factors model; while, if the time horizon of political calculation is long, the HOS model is more appropriate.

The evidence is somewhat mixed, but the bulk of it would seem to suggest that, for most agents, the time horizon of political calculation is relatively short. The most compelling evidence comes from actual political activity. Starting with Magee's (1978) classic study of testimony on trade legislation, most work has found strong evidence of sector-based political activity. This is consistent with studies of capital and labor mobility that suggest relative immobility over politically plausible time horizons (i.e., two to six years in the United States). Research on policy preferences revealed by public opinion polls is generally interpreted as more consistent with factor-based calculation, but the implications of these results for either factor mobility or the time horizon of political calculation are currently a matter of considerable dispute.

Just as knowing preferences over final goods is not sufficient for a theory of market equilibrium, knowledge of political preferences is not sufficient to determine political-economic equilibrium. In principle, a model of political action must be combined with a model of policy determination to determine a full political-economic equilibrium. Here there are many possibilities. One convenient way of distinguishing among the basic models is in terms of what is assumed about the activity permitted of demanders of policy and suppliers of policy. If we consider that each type of agent (demander and supplier) may be active or passive, we get the simple typology shown in table 1.

The simplest approach is to assume that policy is determined by a referendum on the tariff. Under the

assumption that voting is costless (and the assumption that preferences are single-peaked over a one-dimensional t), this approach simply determines the policy outcome at the most preferred point of the median voter. No resources are used up in the political process, there are no gains from misrepresentation of preferences, so once citizen policy preferences have been determined, the step to final policy determination is straightforward (Mayer 1984). The virtue of this approach is its simplicity, but it has at least two major drawbacks as a framework for empirical work: there have been almost no actual referenda on trade policy, and at the level for which general equilibrium analysis is appropriate, trade policy is inherently multidimensional. As a public issue, trade policy usually is discussed in terms of the overall level of protection offered in the country as a whole (not in terms of tariffs on specific line items in a tariff schedule). Seen in this way, there have been times and places in which "The Tariff" was sufficiently important to public partisan competition that a given election could be seen as a referendum on the tariff (e.g., the Canadian election of 1911 and the British elections of 1906 and 1914).

An extension of this approach implicitly assumes that representatives are elected to represent their constituencies *on trade policy*, so that their votes on trade policy can be treated as determined by the material interests of their constituents. However, as Bauer, Pool, and Dexter argued, and as implied by theoretical work on voting in high dimensional issue spaces, given the dimensionality and complexity of the issue environment in which representatives operate, they will generally be free to vote on virtually any issue as they prefer. Thus, especially for issues such as trade, which are not major reelection issues, inference based on this constraint seems less than well grounded. Given that, at least until recently, trade policy has not been a major public issue, some form of lobbying model would seem to be a more solid basis for framing the analysis of the political economy of trade policy.

The simplest approach is to follow Peltzman (1976) in doing away with the attempt to model demanders and focusing on the behavior of suppliers

Table 1
Political economic equilibrium

	Groups are

The state is		
Passive	Referendum	"t" formation function
Active	Political response function	Menu auction

who face an untheorized (but completely plausible) function of implicit group demands and a concern with the general welfare consequences of their actions. Hillman (1982) develops a model of this sort applied to trade policy. The *political response function* reflects the trade-off facing a politician who seeks to favor one group (say, producers) at the expense of another (consumers). While Hillman motivates his analysis by loose reference to lobbying in the context of an election constraint, neither the lobbying nor electoral competition are explicitly modeled. The general pattern of signs could emerge from a variety of institutional environments. Thus it seems sensible to characterize this approach as "active state/passive groups." The essentially ad hoc form of the political support function makes for a natural match with the ad hoc empirical analysis referred to in the previous section.

Where the political support function approach abstracts from the political activity of groups, lobbying models, with a passive register state, introduce an explicit analysis of costs of political action and rational strategic behavior by groups, but abstract from active decision making by the state. Findlay and Wellisz (1982) develop a model of this sort for the case of trade policy. The core institutional assumptions of this model are: (1) effective political demand is represented by the lobbying activity of entrepreneurial political action committees (PACs); (2) political activity involves no fixed costs, and there are no collective action problems in the organization of group activity; and (3) the state is a passive register of effective citizen demand. That is, politically active sectors hire labor to engage in lobbying, and the state is represented by a *tariff-formation function*: $t = \tau(\boldsymbol{L})$ where $\boldsymbol{L} = \{L_1, \ldots, L_n\}$ is a vector of quantities of labor hired for lobbying. The outcome is determined as the Nash equilibrium in lobbying, where PACs take into account the direct cost of lobbying (i.e., wL_i), the indirect costs (i.e., the effect on the market wage of withdrawing labor from production for use in lobbying), and the return on lobbying via $\tau(\boldsymbol{L})$.

A major advance in the formal theory of lobbying was made by Grossman and Helpman (1994), who developed a model in which the state and economic agents are politically active, thus rendering both the political support function and the tariff-formation function approaches essentially irrelevant. Grossman and Helpman's essential insight was that the relationship between lobby groups and the state could be effectively modeled as one of common agency (with politically organized sectors as the principals and the state as the common agent) and that the menu auction model of common agency was a tractable framework for developing a broader model of political-economic equilibrium than had previously been presented. Each active PAC offers the state a menu associating a payment with every possible tariff *schedule* and the state then chooses a tariff schedule that maximizes its welfare. Unlike the passive register state, the Grossman-Helpman state is explicitly concerned with overall welfare as well as bribes. Specifically, their state's objective function is a linear combination of bribes and aggregate welfare:

$$G = \sum_{i \in I} C_i(\mathbf{p}) + aW(\mathbf{p})$$

where the C_i are the bribes ("contributions"), W is the aggregate welfare, both conditional on the state's choice of $\mathbf{p}$ (the price vector determined via the small country assumption by the tariff), and a is the weight the government attaches to aggregate welfare. Note how this structure embeds both the Weberian state and the passive register state as special cases.

Given the menu auction structure as a characterization of politics, and the claim that truthful equilibria are focal among the continuum of equilibria that generally result, and the Grossman-Helpman economy characterized by quasilinear preferences, n-1 sectors characterized by a specific factors structure, and a freely traded Ricardian numeraire sector, Grossman and Helpman show (proposition 2) that equilibrium trade taxes and subsidies must satisfy a *modified Ramsey rule*:

$$\frac{t_i^\circ}{1 + t_i^\circ} = \frac{I_i - \alpha_L}{a + \alpha_L} \left(\frac{z_i^\circ}{e_i^\circ} \right),$$

where I_i is an indicator variable that takes a value of 1 if the sector is organized and 0 otherwise, α_L is the fraction of the total population that is organized by some lobby, z_i° is the ratio of domestic output to

imports, and e_i° is the elasticity of import demand. This form has been widely taken to be a framework for structural estimation. Overall, there seems to be considerable econometric support for lobbying as a key determinant of the cross-section pattern of protection.

For all the success of the basic models reviewed in this section, primarily in providing a general account of deviations from welfare optimal policies in terms of political pressure and in providing a specific account of the cross-section pattern of protection, it is hard to escape the conclusion that, more than other branches of research on political economy (in particular, local public finance and macroeconomic policy), the gap between the models and their object (either as formal empirics or as a framework for understanding) is large. The next section considers several avenues of current research that seek to extend the scope of research on the political economy of protection, but we conclude this section with one problem fundamental to lobbying models: exogeneity of group organization.

All of the research on lobbying we have considered to this point treats group organization as exogenous: there is no formal analysis of groups at all in the political response function literature; tariff-formation function and menu auction models treat active groups as fully organized and completely efficient in extracting resources to pursue political goals (the menu auction models explicitly treat organization as primitive reflected in I_i in the modified Ramsey rule). This was a sensible strategy in the early development of lobbying models, but before they can be treated seriously as frameworks for empirical analysis, group formation needs to be systematically integrated into the analysis. The few attempts that have been made to construct such an analysis build, sensibly, on Olson's (1965) theory of collective action. Two approaches seem to have been pursued, both of which treat lobbying as an example of voluntary provision of a collective good. The approach that matches the lobbying models most directly focuses on the decision to join under the assumption that agents joining a PAC will be taxed optimally by the PAC organizer (Mitra 1999). While this is a good

match to the theory of lobbying, it is a poor match to the empirical reality in which groups seem not to be either perfectly organized or perfectly unorganized, but rather to be more-or-less well organized. The alternative is to assume that all groups are potentially active and consider contributions from zero to some maximal (or optimal) level. While there is no shortage of work that considers contributions to a single lobby (treated as a public good), there is very little work that considers those contributions in a strategic context. The problem with this latter approach is that "groups" are not really organized but simply exist as a function of a common pattern of individual contributions. One of the early fundamental criticisms of Olson's work was the lack of attention to political entrepreneurship in the formation of groups, and it seems like an explicit introduction of political entrepreneurs might be a route to linking these two approaches.

Frontiers of Research on the Political Economy of Protection The essentially context-free theoretical environment of the models we have considered to this point is a feature, not a detriment. As with virtually all good modeling programs, the endogenous policy approach to political economy modeling achieves its cutting power by abstracting from details that interfere with the main line of the story in this case, the contest of material self-interest projected from the economy to the political system. Models serve a number of purposes:

1. *Cautionary tales*: most people think X, but in my model X does not occur;
2. *"Just So" stories*: here is a fact, and I can construct a model rationalizing that fact;
3. *Loose frameworks for thinking about issues*; and
4. *Generators of structural frameworks for econometric analysis.*

The Tullock-Krueger-Bhagwati work discussed earlier was essentially of the first sort (protection is more costly than you might think as a result of rent-seeking costs); most of the work discussed after that is of the second and third sort (it is plausible to think about "bad policy" as the outcome of a political process and the empirical work is loosely consistent

with those accounts). Grossman and Helpman's modified Ramsey rule has been treated as a structural form, but the results of that work do little more than underwrite the use of the model for purposes 2 and 3. Making these models more operationally relevant means introducing more of the relevant context into the models. Current work focuses on both political and economic context.

In terms of political context, one approach that is receiving attention is the attempt to explicitly model the link between contributions, elections, and policy outcomes (rather than burying the link in a political response function or the government's objective function). The focus on the role of partisan competition opens the door to both theoretical and empirical work of a comparative nature, as well as cross-sectional work on the foundations of partisan support. This work is interesting, but given that protection is now rarely set by legislatures, it seems unlikely that this line of work will be much help in extending the applicability of current models. By contrast, the sizable body of work that builds on detailed knowledge of the GATT/WTO-legal administered protection mechanisms has already begun to provide a rich body of theoretical and empirical work consistent with the more general models discussed above (see Blonigen and Prusa 2003; and Nelson 2006 for surveys).

An alternative direction of generalization abstracts from the assumption that markets are complete and perfect. One of the standard results of time-series work on the correlates of protection is that demand for protection, and protectionist outcomes, are positively related to unemployment. This is loosely consistent with public opinion data suggesting that support for protection increases if questions are "framed" in terms of unemployment. This suggests that modeling the economy, on which the political economy is based, as characterized by equilibrium involuntary unemployment, could make a major contribution to our understanding of the political economy of trade policy. Recent work by Bradford (2006) and Matschke and Sherlund (2006) make a start in this direction, but there is room for much more. Similarly, standard models assume that po-

litical preferences are strictly self-regarding. Experimental results and public opinion data suggest, however, that political preferences are more complex. In particular, it seems clear that widely held notions of fairness strongly affect expressed preferences over trade policy. To the extent that public politics constrain trade policy, it would seem to be important to try to incorporate such considerations in our models.

Thinking about "Good" Trade Policy Virtually all of the work we have considered to this point has attempted to account for "bad" (i.e., welfare-reducing) trade policy. Given that the single most important fact of trade policy in the era since World War II is the historically striking trend toward greater trade liberalism and, by the mid-1980s, the truly extraordinary low level of overall protection (aside from agriculture) in the world's major trading nations, this focus seems a bit peculiar. If we believe, as surely we must, that political economy forces help explain the structure of protection, it seems equally clear that political economy forces must help explain this liberality. These forces need not be the same and, in fact, are unlikely to be the same. Thus the gains from new work on the domestic political economy of liberalization would seem to be sizable. One approach to this question might be to study the link between liberalization and protection. Whereas in the era of tariff politics, liberalization and protection were simply directions in a relatively unidimensional scale, in an era in which omnibus trade legislation endorses the power to liberalize at the same time it changes the terms of administered protection, it is not only difficult to say whether a piece of such legislation is protectionist or liberalizing, it seems likely that the two are related. Nevertheless, the extant models have brought us some distance in understanding the political economy of trade policy.

■ pollution haven hypothesis

A pollution haven is a country or region that attracts
pollution-intensive industry because its environ-
mental policy is less stringent than that of its trading
partners. A key issue in the debate over the effects of
trade on the environment is whether globalization
leads to the emergence of pollution havens: that is,
does trade and investment liberalization cause pol-
lution-intensive production to relocate from (mostly
high-income) countries with stringent environmen-
tal policy to (mostly low-income) countries with
weak or loosely enforced environmental regulations?
The pollution haven hypothesis posits that the an-
swer is yes.

If this hypothesis is correct, there is reason for
concern about the effects of trade on global envi-
ronmental quality. If production shifts from a region
with stringent environmental policy to one with
weak policy, the average pollution intensity of global
production rises, increasing global environmental
degradation. Moreover the shift in the incidence of
environmental harm from rich to poor countries
could increase human suffering, both because poorer
countries are less able to afford to respond to the
health effects of environmental damage and be-
cause poor countries are much more reliant on
natural capital (which is vulnerable to environmen-
tal damage) to sustain their income. Finally, an
exodus of pollution-intensive production from rich

to poor countries could lead to a political back-lash against stringent environmental policy. This possibility is sometimes referred to as a "race to the bottom" governments may weaken or fail to en-force environmental policies due to fear of job loss as firms threaten to leave for countries with weaker policy.

Discussions of the pollution haven hypothesis often confuse two different questions. One question is whether tightening environmental policy in a country (holding all else constant, including the trade regime) reduces net exports and/or net inward for-eign direct investment in pollution-intensive indus-tries. This question is simply whether environmental policy is one of the many factors that affect interna-tional competitiveness in pollution-intensive in-dustries. I will refer to this as the *competitiveness hypothesis*.

A second question is whether changing the trade regime by liberalizing trade or investment leads to a systematic reallocation of pollution-intensive pro-duction from countries with stringent environmen-tal policy to countries with weak environmental policy. For this to be true, something much stronger than the competitiveness hypothesis must be satis-fied: the effect of environmental policy on competi-tiveness has to be strong enough to be the key de-terminant of the overall pattern of trade and investment. I will refer to this as the *pollution haven hypothesis*.

Some authors distinguish between the two ques-tions by defining a pollution haven *effect* to exist if the competitiveness hypothesis is satisfied. The stronger pollution haven *hypothesis* then requires both that a pollution haven effect exists and that it be strong enough to determine the direction of trade and in-vestment flows.

Competitiveness and the Pollution Haven Ef-fect: Theory The prediction that tighter environ-mental policy will reduce competitiveness is quite robust and requires only one key assumption that more stringent environmental policy raises produc-tion costs. The most prominent alternative hypoth-esis is the Porter hypothesis. Porter and van der Linde (1995) argued that more stringent environmental

policy may actually increase productivity, for exam-ple by stimulating innovation. However most stan-dard economic models predict that placing increased constraints on firms (such as via tighter environ-mental policy) will raise costs and hence reduce competitiveness.

Competitiveness and the Pollution Haven Ef-fect: Empirical Evidence Testing the competitive-ness hypothesis has been very challenging (see Cope-land and Taylor 2004; and Copeland and Gulati 2006 for more detailed reviews). The most signifi-cant difficulty has been a lack of good data on the stringency of environmental policy. Pollution taxes are rarely used by governments, and other forms of environmental policy are difficult to quantify. A number of researchers have used county-level com-pliance with the Clean Air Act as a proxy for the stringency of environmental policy in the United States. The idea here is that states are required to have a plan to improve air quality in counties not in compliance with the act; consequently, noncompli-ance is taken to be a measure of relatively stringent environmental policy. Measures of abatement costs at the firm level have also been used; however, they are not available for very many countries, they are based on survey data, and they are problematic be-cause they are endogenous: if the pollution haven hypothesis is correct, the most polluting firms will have been driven away by tight pollution regulation, which would lead to lower measured average abate-ment costs in jurisdictions with stringent environ-mental policy (Keller and Levinson 2002).

A second set of difficulties arises from unobserved heterogeneity across jurisdictions. Trade and invest-ment are affected by many factors, and if some of these factors are correlated with the stringency of pollution policy, but not controlled for, then results will be affected by omitted variable bias. Recent work has used panel data techniques to deal with this type of issue; however the availability of such data is limited.

Endogeneity problems have also been a challenge. Pollution policy may respond directly to trade flows and investment and to variables correlated with trade and investment. As an example, suppose that

the competitiveness hypothesis is true but countries facing significant import pressure in pollution-intensive industries respond to trade liberalization by weakening environmental policy to help protect local firms from foreign competition. Then we could find that high imports are correlated with weak environmental policy, which is opposite to what the competitiveness hypothesis predicts. This type of problem has been dealt with by using techniques such as instrumental variables.

Early work testing the competitiveness hypothesis mainly used cross-sectional data to investigate how cross-industry differences in abatement costs affected trade or investment flows (for a survey, see Jaffe et al. 1995). Most of this work found that environmental policy had little or no effect. In some cases the estimated sign was opposite to what the competitiveness hypothesis predicted more stringent environmental policy was correlated with increased net exports. Some interpreted this finding as support for the Porter hypothesis; however, recent work has emphasized the role of omitted variable bias in affecting the results obtained from cross-sectional studies.

More recent work using panel data, mostly from the United States, has found support for the competitiveness hypothesis. A number of researchers have found that pollution regulations arising from the Clean Air Act had a significant effect on the location of new plants in pollution-intensive industries. Becker and Henderson (2000) found that new plant births in polluting industries in counties not in compliance with the Clean Air Act (and therefore subject to more stringent environmental policy) were 26 45 percent below levels in counties that were in compliance. There is also evidence that environmental policy affects trade flows. Levinson (1999) found that (all else being equal) high taxes on the disposal and processing of hazardous waste deter shipments of such waste from other states. Levinson and Taylor (2008) found that U.S. net imports are higher in industries with high abatement costs (once they accounted for the endogeneity of pollution policy using instrumental variables). This finding is consistent with the competitiveness hypothesis. The

results on foreign direct investment have been mixed. Keller and Levinson (2002) used a panel of U.S. state level data and found that states with relatively more stringent environmental policy (measured with an index of abatement costs per unit output) were less likely to attract foreign direct investment. So far, however, there is little evidence on whether the stringency of environmental policy affects the decisions of foreign firms to locate in developing countries.

Overall, a growing body of evidence supports the competitiveness hypothesis. Almost all of this work is based on U.S. data, however. More work, especially with data from developing countries, is still needed.

It is important to note that evidence that more stringent environmental policy reduces competitiveness in polluting industries does not imply that such policy is welfare decreasing. Weak environmental policy is an implicit subsidy for pollution-intensive production. Increased efficiency (and improvements in environmental quality) requires removal of this implicit subsidy, and this change will result in a shift from pollution-intensive production toward other cleaner production.

Pollution Haven Hypothesis: Theory The first pollution haven model was developed by Pethig (1976). He considered two countries that are completely identical except that one (North) has a higher pollution tax than the other (South). North's high pollution tax gives it a comparative advantage in the clean good. When trade is liberalized, trade shifts pollution-intensive production to the low-regulation country (South).

Copeland and Taylor (1994) showed how pollution havens could develop in poor countries even if all governments were free to choose whatever pollution policy best suited their countries. In the Copeland and Taylor model, countries are completely identical except in income levels. Northern countries are richer than Southern countries. The key assumption is that environmental quality is a normal good as income increases, consumers demand higher environmental quality. If government policy is responsive to consumer demand, then the model

predicts that richer countries will have more stringent environmental policy than poorer countries. Consequently, poor countries will have a comparative advantage in pollution-intensive production. When trade is liberalized, North exports clean goods, and South exports pollution-intensive goods: poor countries will become pollution havens.

This result is only part of the story. In reality, there are many reasons for trade, and the actual pattern of trade depends on the interaction among all such motives. Antweiler, Copeland, and Taylor (2001) developed a pollution haven model suitable for empirical testing by allowing for more than one motive for trade. In this model, countries differ in capital abundance as well as in income levels. Suppose that pollution-intensive industry is also capital intensive and that North is capital abundant. North's capital abundance tends to give it a comparative advantage in the pollution-intensive industry, but its stringent pollution policy tends to give it a comparative advantage in the clean industry. If the effects of North's capital abundance on the trade pattern are more important than the cost-increasing effect of its stricter environmental policy, then North will have a comparative advantage in the pollution-intensive good and trade liberalization will shift pollution-intensive production from the low-income South to the high-income North. In short, theory predicts that pollution policy is but one of many factors that affect trade. Whether or not trade liberalization leads to pollution havens depends on whether the effects of differences in environmental policy on production costs are more or less important than all of the other motives for trade.

Pollution Haven Hypothesis: Empirical Evidence Surprisingly, there is relatively little work that directly tests the pollution haven hypothesis. Several studies have found that the share of pollution-intensive goods in exports from developing countries has risen over time and the share of pollution-intensive goods in exports from members of the Organisation for Economic Co-operation and Development (OECD) has fallen over time. These trends are also consistent, however, with economic growth and capital accumulation in developing

countries and are not a full test of the pollution haven hypothesis.

Ederington, Levinson, and Minier (2004) looked at the pollution content of U.S. exports and imports during the period 1972 94 and found that U.S. imports from non OECD countries have become less pollution intensive over time relative to U.S. exports. This finding is opposite to what the pollution haven hypothesis predicts. Antweiler et al. (2001) estimate the effects of increased openness to trade on sulfur dioxide pollution, controlling for scale and other factors. They found that, all else equal, increased openness tended to increase SO_2 pollution in rich countries and reduce it in poor countries. Again this is opposite to what the pollution haven hypothesis predicts. Both Ederington et al. and Antweiler et al. argue that the evidence suggests that other factors (such as capital abundance or agglomeration) are more important than environmental policy in explaining trade flows.

In summary, there is a growing body of evidence that more stringent environmental policy does reduce a country's competitiveness in pollution-intensive industry, but there is little or no evidence to support the strong version of the pollution haven hypothesis: other factors are more important (on average) for affecting trade patterns. These are, however, the results of studies that look at broad patterns. There will be cases where poor countries have a comparative advantage in polluting industry for reasons unconnected with environmental policy (such as in polluting industries intensive in the use of unskilled labor). In cases such as this, weak pollution policy will reinforce the preexisting comparative advantage and increase the tendency for such industry to locate in a poor country.

Consumption-Generated Pollution Much analysis of the pollution haven hypothesis has focused on production-generated pollution. However, much pollution is generated by consumption (such as home heating, automobile transportation, and sewage). The effects of environmental policy on competitiveness are very different when regulations target consumption-generated pollution. For example, stringent automobile emission standards are applied

to all automobiles sold within a country, regardless of whether they are produced locally or imported. Consequently, tighter emission standards need not reduce domestic competitiveness. In fact, if it is easier for domestic producers than foreign producers to comply with stringent emission standards, then tighter environmental policy aimed at consumption-generated pollution may favor domestic producers over foreign producers. Hence the scope for trade-induced pollution haven effects is reduced when environmental policy affects consumption-generated pollution.

Natural Capital and Pollution Havens The effects of environmental policy on natural capital can be critically important for trade patterns. Consider the example of fisheries (where the fish stock is natural capital). Conservation requires that harvest rates be held below open access levels to ensure that the fish stock is sustainable. Hence in the short run, a country with weak conservation policy may harvest fish at a much greater rate than countries with good conservation policy. This can lead to a result analogous to pollution havens—trade liberalization would increase pressure on fish stocks in countries with weak conservation policy and exacerbate resource depletion in those countries.

However, it is possible for trade to have the opposite effect, especially in cases where resources are severely depleted. If a country has severely depleted its fish stock, then its potential supply of fish will be low. On the other hand, countries with relatively stringent conservation policies will have a much larger fish stock and hence a greater sustainable supply of fish. Hence when trade is liberalized, it is quite possible that countries with good conservation policies will be net exporters of fish and countries with poor conservation policies will be net importers of fish (Brander and Taylor 1997). Again, this is opposite to what the pollution haven hypothesis would predict.

BRIAN R. COPELAND

■ poverty, global

The most commonly used definition of poverty is a lack of income; more specifically, having an income below an amount (the poverty line) deemed necessary for a minimum acceptable level of material well-being. Income is just a means to an end, however. There are more direct measures of the quality of life, such as health, education, and possibly freedom of expression. Poverty estimates also regularly make reference to mortality rates, schooling, and literacy.

Poverty may be defined and measured in either a relative sense (deprivation compared to societal norms) or an absolute sense (deprivation compared to being able to afford "objective" basic needs of food, clothing, and shelter). Discussions of global poverty have settled on an absolute definition of poverty, implicitly relegating concerns about income distribution to secondary importance. Doing so has deflected attention from redistribution and the role it can play in poverty reduction. Since the World Bank's 1990 *World Development Report*, "a dollar a day" has become the standard international poverty line a level based on an average of the poverty line being used in 10 developing countries at the time, although more recent estimates also use two dollars a day, which is a more relevant poverty line for middle-income countries such as those in Latin America.

Poverty estimates using the dollar-a-day line are made using "purchasing power parity," meaning they allow for differences in purchasing power as many items cost less in developing countries than in developed ones. The most commonly reported measure is the poverty headcount (the percentage of the population below the poverty line), but the same data can be used to calculate the poverty gap, which is a summary measure of the average distance of the poor below the poverty line, and the poverty severity index, which gives greater weight to the poorest. The poverty measures used in health and education are also absolute; that is, they do not base well-being on a comparison of the same indicators for the better off at either the national or international level.

Patterns of Poverty Estimates of dollar-a-day poverty are calculated only for the developing world. The proportion of absolutely poor in developed countries by this measure is nil or negligible. Figure 1 shows the evolution of dollar-a-day poverty since the early 1980s. The most striking trend is the dramatic fall in poverty in East Asia, powered largely by reductions in the number of poor in the world's most populous country, China, but assisted by more recent declines in neighboring Vietnam. There has been a slower, but still marked, decline in the poverty headcount in South Asia, including in the world's second largest country, India. By the mid-1990s the rate of decline was sufficient for the absolute number of poor people in South Asia to start falling. Asia thus makes up the vast bulk of poverty reduction in the closing decades of the last century. During the 1990s global poverty fell from 27.9 percent in 1990 to 21.1 percent in 2001, but excluding China these figures were 26.1 and 22.2 percent, respectively. That is, more than half the decrease in poverty came from China alone. Indeed sub-Saharan Africa, which has suffered economic hardship since the 1970s, saw a rise in income poverty, with close to half the people

on the subcontinent now living on less than a dollar a day. Africa's poor performance lies behind the low overall decrease in the number of poor from 1.20 billion in 1987 to 1.03 billion in 2002. Africa's share in this total rose from 12 percent to 30 percent over this period (whereas Asia's fell from 80 percent to 64 percent). The final trend of note is the resurgence of poverty in the formerly centrally planned economies following the collapse of the communist governments, though there has been some remission since the beginning of the 21st century.

The Africanization of poverty is also evident when considering other poverty measures. Health is commonly measured by infant mortality (the number of children who die before their first birthday per 1,000 live births) and child mortality (deaths between first and fifth birthdays per 1,000 children); these two indicators are combined to make under-five mortality. The United Nations Population Division reports population data, including mortality, from 1950, with projections to 2050, though only those to 2010 are shown here. The positive news is that mortality rates have been falling across the world (figure 2), although some African countries experienced a reversal in the 1990s as a result of HIV/AIDS and worsening health systems after three decades of economic decline. At the extreme, life expectancy in

Botswana has fallen by 29 years since 1990, from 64 to just 34 years. In Africa as a whole the decline in mortality rates has been insufficient to keep up with population growth, so the number of deaths has continued to increase. A turnaround is expected, but another expectation is that the situation in Africa will improve less than that elsewhere, so the continent will account for close to two-thirds of the world's under-five deaths in the coming decades.

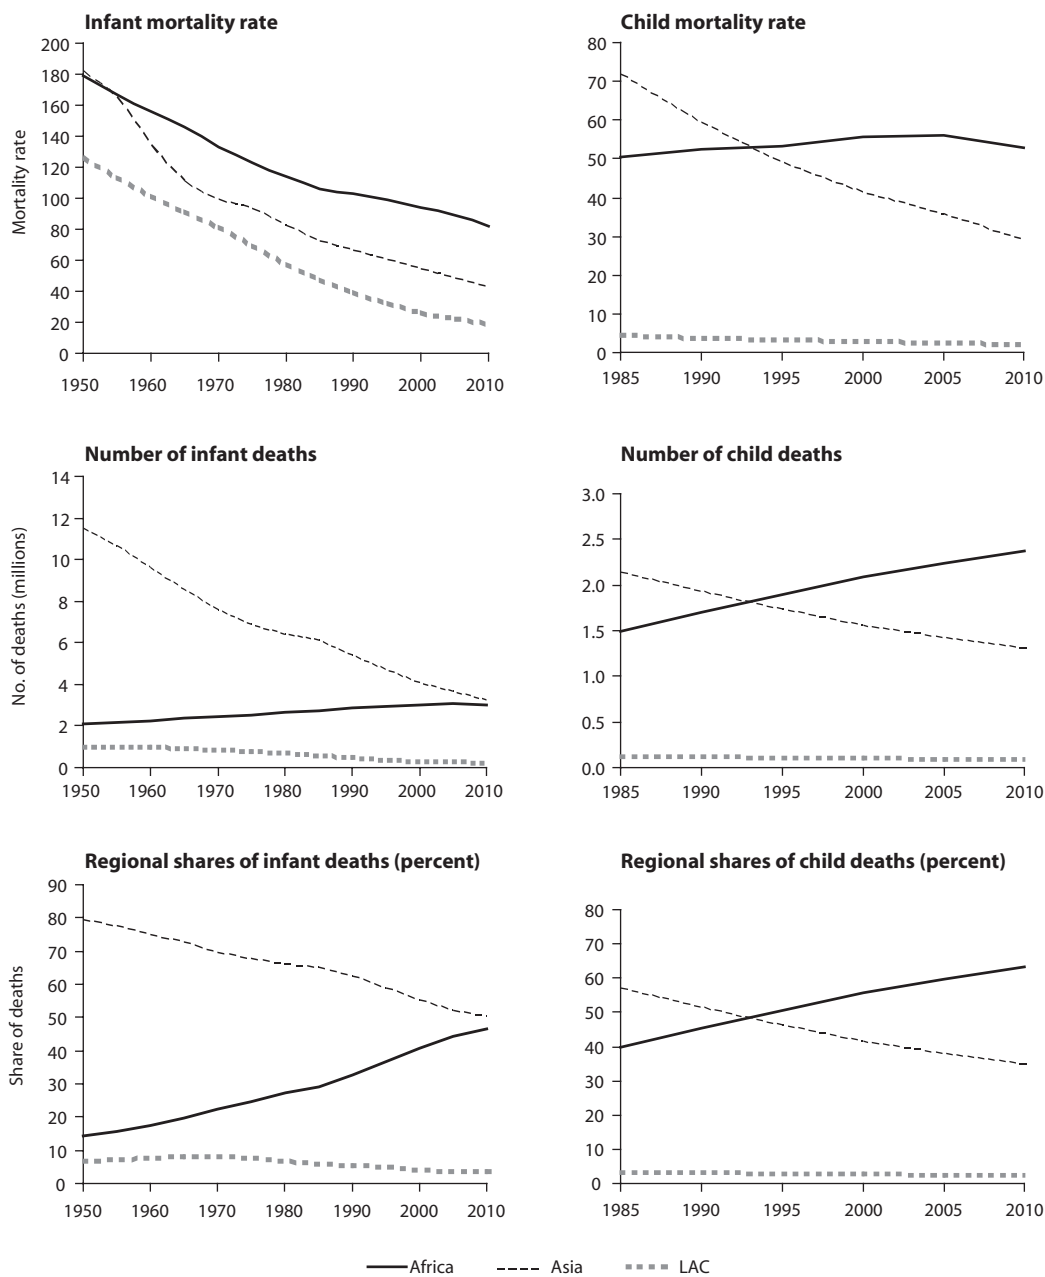
Progress in education has gone in stops and starts. During the colonial period there was little formal education for most of the population in much of the developing world other than that provided by mission schools. Newly independent governments undertook substantial expansions of the education sector at all levels, though enrollments remained well below half of all children, especially in rural areas. Since 2002 there has been a renewed emphasis on raising primary education levels with the international Fast Track Initiative. Many countries, notably in Africa, have pushed for higher enrollments, scrapping school fees at the primary level, resulting in rapid increases in student numbers, although across the subcontinent as whole about 30 percent of children do not attend school, and many of those who do learn little. In Asia also large strides have been made in moving toward full enrollment in recent years so


Figure 2

Trends in infant and child mortality. Source: UN Population Division database, http://esa.un.org/unpp/.

that primary enrollments exceeded 90 percent as of 2007, and the focus has shifted to secondary education with international agencies financing stipend schemes for girls in rural areas.

These aggregates hide systematic patterns in poverty at the national level. Poverty is nearly always higher in rural areas than urban ones: at least 80 percent of Africa's poor live in rural areas, where income opportunities are fewer and service provision lower. There are usually disadvantaged regions where poverty is higher: for example, infant and child mortality rates may be twice the national average. In Bangladesh, for instance, neonatal mortality (death in the first month) is 32 per 1,000 live births in Barisal Division, but 63 per 1,000 in the more conservative Sylhet Division, where tradition prevents women from seeking medical assistance even in the case of birth complications. These variations may reflect ethnic or racial biases and are not confined to developing countries: African Americans have a higher rate of under-five mortality than do white South Africans (indeed, the United States as a whole has a higher under-five mortality rate than does Cuba).

Gender also plays an important role in poverty. Girls are less likely than boys to be in school, and women continue to earn less than men for their labor. In rural India a woman's daily agricultural wage is typically half that of a man's. Female-headed households are typically poorer than those that are male-headed, although this is not the case when there is an absent male sending remittances back to the household. And families in most of Asia prefer sons to the extent that female infants are often neglected, with food and health care given preferentially to male children.

Globalization of Poverty The globalization of poverty is the view that we are today affected by the poverty of those in other nations in ways we were not in the past. In the words of the former German premier Willy Brandt, who led the team responsible for the 1980 report *North-South*, "Ignoring the problems of the South is like a person on a sinking ship saying 'I'm all right, my end's not sinking.'" Brandt's view was one of global Keynesianism: growth in the developing world will power growth at home through increased demand for our exports, whereas decline overseas will cause eventual decline at home. Other aspects of global poverty are also thought to spill over to affect the West in ways that did not happen before, such as disease and the increased flow of refugees fleeing from conflict or disasters.

These views overstate the extent to which global interdependence is a new phenomenon. One-quarter of the Irish population emigrated to the United States during the potato famine of the 1840s, and a similar percentage of the Scottish population did so as a result of Highland clearances in the same century (landlords turning land cultivated by smallholding tenants over to sheep grazing). Earlier settlers brought with them illnesses that wiped out a large part of the indigenous population. Centuries earlier the Black Death spread from Asia to Europe, killing up to two-thirds of the European population.

Strategies to Tackle Global Poverty Two broad approaches may be identified in the dominant discourses on development. Official agencies emphasize the role that growth can play and believe that growth is best brought about through liberalization of markets. Others, including most nongovernmental organizations, place greater emphasis on the need for development aid.

According to the first view, the best support the West can give to reduce poverty is to encourage developing countries to deepen their engagement with the global economy and to open up to private sector capital flows. But critics point to the apparent hypocrisy of developed countries, which continue to practice protective policies, notably subsidies to agriculture, that are harmful to the welfare of developing countries. For example, U.S. subsidies to domestic cotton producers reduce the prices received by farmers growing cotton in countries such as Brazil and Zambia. Furthermore, although there can be benefits from capital inflows, short-term speculative flows can be destabilizing, as shown by the East Asian crisis of the late 1990s. Others point out that an increased global flow of labor, rather than capital, would probably do most to reduce poverty but is restricted by the developed countries. On balance,

however, one can say that many developing countries engaged in excessive degrees of state intervention following independence and that dismantling these controls has freed up resources to be used more productively in growth. But this argument does not support the view that full liberalization of all markets is the most conducive means to sustained growth and certainly not the fastest route to poverty reduction.

Aid's impact on poverty has been muted since poverty reduction has not always been the explicit focus of foreign aid. This is partly because donor countries also use aid to pursue their own political and commercial objectives. But it is also because aid has focused on other issues, such as the development of infrastructure in the 1950s and 1960s and on restoring economic growth, albeit with mixed success, in the 1980s. There was a clearer poverty focus in the 1970s, under the banner of Basic Needs, and it reemerged more strongly in the 1990s. Reviews of aid's poverty impact provide a mixed picture there are undoubted success stories of aid improving the lives of poor people, but a lot of aid at best leaves them unaffected and at worst harms them. Efforts to ensure that aid indeed benefits the poor are being made but can run into political opposition in both developed and developing countries.

The latest stage in efforts to focus aid on poverty are the Millennium Development Goals (MDGS), formerly the International Development Targets. These are a set of targets based on various UN resolutions, such as the halving of income poverty by 2015, a two-thirds reduction in infant and child mortality by the same date, and the already missed target of equality in girls' education by 2005. Aid donors have responded to this increased poverty focus by concentrating aid on poorer countries and reorientating it toward basic services, such as providing money for rural health clinics rather than urban hospitals and the stipend schemes for girls to attend secondary school in Asia mentioned earlier.

In most low-income countries aid is given in the context of Poverty Reduction Strategy Papers (PRSP), which are a formal requirement for countries receiving debt relief from the Highly Indebted Poor Country Initiative. Central to these strategies, promoted by the World Bank and the International Monetary Fund, is the notion that economic growth is the key to poverty reduction and that growth is best brought about by liberalized markets: hence critics argue that PRSPs are just "business as usual." A contrary view of development comes from the United Nations Development Program (UNDP) through its *Human Development Reports*, which argues that there is a larger role of government through direct investments in social infrastructure, which can bring about reductions in poverty faster than is possible by growth alone.

Future Poverty Trends Analysis of likely future trends shows a continuation of the patterns discussed here, most notably the continuing Africanization of poverty as poverty levels fall in Asia but with at best slow progress in Africa. The MDG for a halving of income poverty will be met in most of Asia, but not in Africa or in the former communist countries of Eastern Europe; poverty in these regions began to rise after the MDG base year of 1990 and is unlikely to meet its former low levels by 2015, let alone fall to half the 1990 levels.

These forecasts assume "business as usual." But it is likely that things will be worse than that on account of both manmade and natural disasters. Poor countries and poor people are least able to withstand these shocks; households do not have insurance and the country is less able to afford reconstruction as shown comparing the amounts spent on reconstruction after Hurricane Katrina in 2005 and after the far worse Indian Ocean tsunami in 2004. Conflict destroys livelihoods, disrupts education, allows the reemergence of disease, and can set growth back by years. Civil wars and regional conflicts continue to have these adverse effects around the world. A larger shock from a global conflict is not an impossibility, which would render all projections meaningless.

■ primary products trade

Primary products are unprocessed raw materials. They include agricultural, forestry, fishing, and mining products, including minerals and fuels. Unlike the processing of these raw materials into manufactured goods, the ability to produce primary products is limited by natural endowments: some regions have the deposits of oil or minerals, the soil and climate, or the natural fisheries that make it possible to obtain these products, while other regions do not. As a consequence, human beings have engaged in primary product trade from time immemorial. Today, primary products account for around 25 percent of global merchandise trade. The ability to exchange agricultural and fisheries products has enriched diets, while access to forestry and mining products has enhanced the consumption possibilities of communities located far from the sources of these products.

Despite the advantages of primary product trade to consumers, it has been the subject of intense criticism. Do the countries producing these products gain equivalent benefits? Does concentrating a country's resources in the production of primary products enhance the welfare of its citizens? Does it provide a sound basis for a country's long-term growth and development? These questions are of more than academic concern for developing countries, many of whose exports are heavily concentrated in primary products. Indeed, today primary products account for only 19 percent of the merchandise exports of high-income countries, but 36 percent of the exports of middle-income countries and 50 percent of the exports of low-income countries. For many developing regions, this figure is even higher: 69 percent in sub-Saharan Africa and fully 80 percent in the Middle East and North Africa.

Classical and Neoclassical Trade Theory Classical economists were the first to systematically address whether primary exports were good for welfare, which they answered in the affirmative. Based on differences in techniques of production, the Ricardian trade model showed that there were potential gains for each country engaging in comparative advantage trade. In such trade, each country specializes in those products it can produce at lower relative labor cost than other countries. The Heckscher-Ohlin trade model of the 1920s assumed countries could choose from the same array of technologies to produce any product, but they still faced differences in their factor endowments and therefore in relative factor prices. These differences resulted in different choices of technology and in different relative product costs. If each country chose to specialize in the products in which it had a lower opportunity cost, global production would be carried out by the most efficient producers, and global output would increase. Trade would allow consumers in all countries to increase their consumption beyond the limits imposed by their own capabilities.

Prebisch-Singer Critique The Heckscher-Ohlin model and its variants, generally referred to as the neoclassical trade model, showed that every country gains from comparative advantage trade, no matter what specific product a country exports. This conclusion was based, however, on the assumption that

markets are perfectly competitive and that relative prices therefore reflect relative costs. The first serious critique of the neoclassical model came in the 1930s and 1940s, from the economists Raúl Prebisch and Hans Singer, who challenged this fundamental assumption. They argued that the benefits for primary exporters were limited. Primary exporters faced both fluctuating prices for their products and declining terms of trade, resulting in volatile and diminishing gains over time.

The most commonly cited elements of their critique have to do with the elasticities involved. First, price inelastic demand for agricultural products combines with frequent weather- or pest-induced shifts in supply to create considerable volatility in agricultural prices. Second, income inelastic demand for many primary products, especially agricultural products (Engel's Law), combined with considerably higher income elasticities for manufactures, contributes to declining relative prices or commodity terms of trade for many primary exporting countries. In addition, the development of synthetic substitutes can contribute to sharp declines in primary product prices. Synthetic dyes, chemical fertilizers, and synthetic fibers, for example, have caused collapses in the markets for natural dyes, for organic and mineral fertilizers, and for natural fibers, while plastics have affected the markets for a broad range of forestry and mineral products. Critics of primary export specialization point to numerous episodes of economic collapse in primary-exporting countries resulting from these developments.

In addition, Prebisch and Singer first advanced the argument that markets were not perfectly competitive and that international market prices might in fact not reflect relative costs of production. Although the production of many primary products could be said to occur under competitive conditions, producers faced a limited number of buyers (oligopsony or monopsony) when they sold their raw materials. These buyers had the market power to drive producer prices below their competitive level. On the other hand, manufactured goods purchased by developing countries tended to be produced in oligopolistic markets, where suppliers had the market power to

potentially raise prices above competitive levels. Put together, these market characteristics suggested that primary-exporting developing countries got paid too little for their exports, while paying too much for their imports. A corollary is that technological progress would be encouraged in the industrial countries but discouraged in the primary exporting developing countries. More recent trade models have included elements of noncompetitive markets, especially increasing returns to scale, which capture these aspects of international pricing that disadvantage primary exporters (e.g., Greenaway 1991).

The experience of the Latin American region in the century following independence in the 1820s provided Prebisch with clear evidence of the volatility of primary product export earnings, as countries experienced related boom-and-bust cycles with alarming frequency. More recently, commodity crises have affected producers of coffee, cocoa, tin, and cotton, to name but a few. Prebisch also found evidence for his arguments in the data collected by the United Nations, which showed a steady decline in the prices of primary products compared with manufactures in international markets from 1876 to 1938. More recent studies have found similar declines over the 20th century for non-oil-exporting developing countries.

This original empirical evidence was critiqued, however, because it did not take account of changes in the costs of production. Productivity gains in primary production could have accounted for the relative decline in primary product prices. Given the difficulty of calculating the "double-factoral" terms of trade that take account of productivity changes, the debate over the empirical evidence continues today.

Agricultural Subsidies and Developed-Country Trade Barriers What is not subject to debate is the effect that agricultural subsidies have had on global prices for many products. For decades, the advanced industrial countries have provided large subsidies to their agricultural producers, especially producers of grains, dairy, cotton, and tobacco. These subsidies have given developed-country agricultural products a price advantage that has lowered global prices of these products and undercut less subsidized producers in developing countries (Oxfam 2002). The

decline in international prices for these products has also been encouraged by persistent protectionist policies in the industrial countries, as well as by efforts to encourage increased production of agricultural exports in developing countries under structural adjustment programs. Developing country protests regarding these pricing issues led to the breakdown of the World Trade Organization's Doha Round of negotiations.

Distribution of Gains from Trade Another element of the critique of primary product exports is the question of the distribution of any gains within the producing country. The Stolper-Samuelson extension of the neoclassical model predicts that trade will raise the price of the factor utilized intensively in the exported product. Many observers assumed that for developing countries this factor would be labor, since capital was scarce, and that as a result international trade would benefit the poor through increased wages. Primary products exports increase the demand for natural resources much more than for labor, however, so most of the benefits of such trade accrue to landowners, often an already wealthy elite. It is no surprise, then, to find that the century of primary export specialization and trade in Latin America, from the 1820s to the 1920s, created a region with the most unequal income distribution in the world, a legacy that persists to this day. The increasing concentration of natural resource ownership over this period ensured that most of the benefits from primary export trade went to a small land-owning elite. In more recent times, many developing countries have found that much of the wealth from exploitation of natural resources has accrued to foreign investors.

If there are overall gains from trade, it is possible to distribute the gains broadly, although whether this occurs in practice depends on the social and political institutions that influence access to natural resources. One approach is to maintain public ownership of key natural resources and to use the revenues for public expenditures that provide widespread benefits to the population. Unfortunately, this is not always the way these revenues are actually used. Another approach is to allow private development of natural resources but tax resource owners in order to spread the benefits

of trade. These efforts have met with mixed success due to the ability of foreign investors to influence political outcomes. In Guatemala, for example, the United Fruit Company, a large landowner and the country's main banana exporter, was able to avoid all but minimal taxes for more than 50 years.

Dynamic Trade Benefits Beyond these issues regarding the static gains from trade, perhaps of even greater significance for the developing countries is the effect of primary product specialization and trade on the long-term growth of the economy: the "dynamic" trade effect. Proponents of comparative advantage trade argue that it can serve as an "engine of growth" for the overall economy. This will occur through expanded factor endowments and spillovers or linkages.

Expanded factor endowments will occur if the export sector is able to attract foreign investment and the capital, skilled labor, and technological know-how that it can bring into the country. Human capital may expand as a result of the "learning-by-doing" effect. These effects will increase productivity and incomes in the export industries, creating profits that can be reinvested into continued productivity gains and expansion of the sector.

At the same time, spillovers and linkages may develop to other productive activities in the economy. The income from primary exports increases consumer demand and may finance investment in new industries. Backward linkages may develop to domestic suppliers of inputs for the export industry, as demand for those inputs grows and allows suppliers to produce at efficient levels. Forward linkages may develop to the processing, transportation, storage, and marketing of the export products, with spillovers to services for other domestic products. Infrastructure constructed to facilitate the production and trade of the export products may also serve other productive sectors. Exports can therefore serve as a growth pole, stimulating other economic activities in an ever-expanding process of economic diversification.

Limited Dynamic Benefits for Primary Product Exporters While advocates of comparative advantage trade predict that dynamic benefits will accrue to

any country, regardless of the specific products they export, critics argue that the extent of these benefits can be limited for countries whose comparative advantage lies in primary products. Indeed, some have gone so far as to posit a "resource curse" effect, whereby abundant natural resources reduce a country's growth rate.

There are numerous theories as to why this may be the case. Factor endowments will not expand if declining terms of trade reduce profitability of primary exports. The same negative impact on investment can occur if extraction of nonrenewable resources raises production costs or if renewable resources are overtaxed, so that the country's comparative advantage gradually declines.

Even if investment in the primary sector continues to be robust, critics argue that spillovers and linkages are unlikely to develop, for many reasons. Some arguments focus on the employment and income effects of resource wealth. Rural wealth and employment may raise industrial real wages and therefore reduce incentives to invest in manufacturing. At the same time, primary products may generate fewer learning effects than manufactures, so that the country's labor force skills remain underdeveloped.

On the other hand, some primary products may be land- and capital-intensive, generating limited employment and therefore limited consumption multiplier effects. This is most likely with mining activities, but can also occur with large-scale, mechanized agricultural production. While these activities can create considerable wealth for investors and landowners, this wealth may not remain in the developing country, especially in the case of multinational investment. Profits, dividends, royalties, and the earnings of skilled expatriate employees may be remitted rather than entering into domestic financial institutions.

One reason for this capital flight may be the continued low profitability of manufacturing investment in the country, as spillovers fail to materialize. Economies of scale in manufacturing, especially in the case of technologically complex production processes, can make it difficult for developing countries to produce on a profitable scale. This can limit

backward linkages to capital and intermediate goods, forward linkages to processing, or consumption linkages to consumer durables, especially for smaller countries. These cost disadvantages can be compounded by the limited technological capabilities of the labor force and the underdeveloped state of the country's institutions and infrastructure. While there may be spillovers from infrastructure developed to support primary production, these extractive activities are often geographically isolated from main population centers, their infrastructure therefore conferring few external benefits.

Geographic isolation is not the only reason why centers of primary production may become "enclaves." The very success of primary exports can, paradoxically, have this effect, in a process that has been dubbed the "Dutch disease." A booming export sector can act as a black hole, pulling resources into itself and thereby raising production costs for domestic manufacturers, while the inflow of foreign currency causes the prices of competing manufactured imports to fall. Rather than creating positive spillovers, the booming export sector creates negative externalities for other tradables sectors. Resource windfalls have also been found to have a negative effect on overall savings and investment and to stimulate rent-seeking behavior.

There is evidence to support the contention that primary exporters do not gain dynamic trade benefits. Sachs and Warner (2001), for example, found that countries with a higher percentage of natural resource based exports in 1970 grew more slowly from 1970 to 1990. There are, nevertheless, exceptions to this general rule, as proponents of the "staples theory" argue (Lewis 1989). Malaysia and Thailand, for example, are resource-rich countries that have experienced exceptionally high growth rates since the 1970s (Reinhardt 2000). Recent literature suggests that the impact of resource abundance on growth is not immutable but rather depends on institutions, educational and industrial policy, and the nature of the learning process (Mehlum, Moene, and Torvik 2006). On the other hand, there is evidence that these variables are themselves influenced by natural resource abundance, being indirect channels through

which resource wealth inhibits economic growth (Papyrakis and Gerlagh 2004).

While the debate over primary exports continues, trade liberalization in the past several decades has increased the importance of this issue for many developing countries, who find their short-term welfare and long-term prospects tied to the fortunes of their primary products. Although commodity price booms such as those of recent years have created windfall gains for many developing countries, they still face the difficult task of turning those primary export gains into a sound basis for growth and development.

■ proximity-concentration hypothesis

The proximity-concentration hypothesis or trade-off is a way to explain why firms undertake horizontal foreign direct investment (FDI), in which firms produce the same product at plants in multiple countries. Firms do so when the benefits of avoiding high trade costs outweigh the costs incurred when producing in multiple markets. Firms are more likely to undertake horizontal FDI as transport costs and trade barriers become higher and as investment barriers and scale economies at the plant level become lower.

Horizontal FDI models are motivated by a large and increasing share of FDI, especially two-way FDI, which takes place between economies with similar factor proportions. Models of vertical FDI (in which different parts of the production process are done in different countries), by contrast, suggest that FDI should arise between economies with different factor proportions (and in only one direction). The proximity-concentration hypothesis also draws from the literature on ownership, location, and internalization advantages as drivers of FDI (mostly ownership and location advantages).

Understanding why multinationals often establish multiple plants in various countries is important because it highlights factors that affect these decisions and informs businesses and policymakers on appropriate policy measures that could influence such investments.

Theoretical Framework A firm has several modes of servicing an overseas market: exports, FDI, or licensing. In deciding on its overseas expansion strategy, a firm faces trade-offs between proximity and concentration advantages. Proximity advantages could arise from savings on transportation, tariff, and warehousing costs, superior customer services, better understanding of the local market conditions, and access to specialized inputs. The concentration advantage arises from any scale economies at the firm or plant level. Economies of scale at the firm level are associated with activities such as research and development, marketing, advertising, and management services, while economies of scale at the plant level result in lower per unit cost as the scale of production increases. Brainard (1997) states, "The proximity-concentration hypothesis predicts that firms should expand horizontally across borders whenever the advantages of access to the destination market outweigh the advantages from production scale economies."

Among the many models of horizontal FDI, Markusen (1984) pioneered one in which multiplant economies are a driver for multinational investment. Multiplant economies are the result of a joint input that can be shared across multiple production facilities and whose productivity is not affected by the number of facilities at which it is used. In this scenario, multinational production avoids costly duplication of the joint input that would arise with independent national firms.

Brainard (1993) coined the term *proximity-concentration trade-off hypothesis*. She uses a model in which firms chose between exports and FDI based on scale economies at the firm and plant level, and transportation costs that increase with distance. Absent factor price differences, firms compare the additional variable cost of exporting with the additional fixed cost of setting up a plant overseas. This model has three possible equilibria: a multinational equilibrium where all firms are multinationals with plants in both countries; a trade equilibrium where all firms are national with a single plant and export to foreign countries; and a mixed equilibrium where multinational and national firms coexist.

With a two-stage production structure, two-way horizontal intraindustry FDI completely crowds out trade in goods even without differences in factor proportions, as long as proximity advantages are strong relative to concentration advantages. For intermediate ranges of transportation costs and scale economies at the firm level relative to plant-level scale economies, there is a mixed equilibrium in which national and multinational firms coexist in this sector: there is two-way trade in final goods and two-way FDI. For a fixed number of firms, the proportion of firms that export is greater the larger the plant-level fixed costs and the smaller the transportation and other trade costs and the size of each market.

If concentration advantages dominate in upstream activities (activities that take place at the initial stages of production, e.g., production of intermediate inputs) and proximity advantages dominate downstream activities (activities that take place after the final stage of production through the consumption stage, e.g., transportation, distribution, and marketing activities), the incorporation of a third stage of production, such as sales, results in two-way intrafirm, intraindustry trade in intermediate goods replacing trade in final goods; here multinational activity is complementary to trade in goods. When both factor proportions differences and proximity-concentration trade-off are combined, firms decide whether to export or undertake overseas production based on the relative strength of these considerations.

In the knowledge capital model (see Markusen 1997; Markusen and Maskus 2001; Carr et al. 2001) both horizontal and vertical multinationals can arise depending on country characteristics such as size, size differences, relative differences in endowments, trade costs, and investment costs. Horizontal multinational firms are associated with similarities between countries in both size and relative factor endowments. The model suggests that affiliate production and trade tend to be substitutes for similar countries and complements for countries with substantially different relative factor endowments.

An extension of the horizontal model introduces intraindustry firm heterogeneity in the proximity-concentration framework to examine the trade-off between exporting and FDI (Helpman et al. 2003). Exporting involves lower sunk costs but higher per-unit costs relative to FDI. Every industry has heterogeneous firms that differ in productivity. Firms with higher productivity are more profitable in all three activities: production for the domestic market, exports, and FDI.

The least productive firms are not profitable and exit the market. Low-productivity firms serve only the domestic market as they expect to incur losses from exports or FDI. We then have a range of higher productivity firms that can serve both domestic and foreign markets. The less productive among these

expect to be profitable through exporting, but anticipate losses from FDI. Hence they undertake exports but not FDI. The most productive firms, on the other hand, chose FDI over exports as they expect greater operating profits from FDI than from exporting. Thus, while proximity-concentration variables determine the level of firm productivity needed to make international expansion attractive, the intraindustry distribution of firm productivity plays an important role in explaining the composition of trade and the firm's choice between exports and FDI.

Empirical Validation In empirical tests of the proximity-concentration hypothesis, we expect to find the share of affiliate sales in total foreign sales to be positively related to distance/trade costs, local market size, and firm-level economies of scale, and negatively related to plant-level economies of scale. Several papers provide some empirical support for this hypothesis. Using industry-level data from U.S. multinationals, Brainard (1997) finds that the proximity-concentration hypothesis is fairly robust in explaining the share of total sales accounted for by exports as compared with affiliate sales. The share of affiliate sales increases as income similarities between trading partners, transportation costs, foreign trade barriers, and firm-level scale economies increase, and decreases as foreign investment barriers, foreign taxes, and scale economies at the plant level increase.

Ekholm's (1998) analysis, using Swedish firm-level multinational data, finds some support for the proximity-concentration hypothesis: concentration advantage negatively affects the likelihood of affiliate production, while an increase in transportation costs/ geographic distance increases the share of affiliate sales in total foreign sales. Carr et al. (2001) find results consistent with Brainard (1997): outward investment increases with the sum of the economic sizes of the source and host countries, their similarity in size, the relative skilled-labor abundance of the parent nation, and the interaction between size and relative endowment differences. Using firm-level U.S. multinational data, Helpman et al. (2004) find

firms substitute FDI for exports where transportation/tariff costs are high and plant-level returns to scale are relatively weak. When firm-level heterogeneity is introduced, however, greater firm-level heterogeneity in productivity leads to significantly more subsidiary sales relative to exports and the size of this effect is the same order of magnitude as that of trade frictions/costs.

Policy Implications The proximity-concentration hypothesis provides explanations for FDI between countries with very similar factor proportions, cross-border multiplant configurations, intraindustry trade, and complementarities between trade and investment. Several policy implications arise from proximity-concentration models. Local governments can undertake policy initiatives such as tariffs, subsidies, or taxes to influence the type of multinational activity undertaken in their country. Brainard (1993) suggests that the relative structure of tariffs on intermediate and final goods influences firms' decision regarding what to produce at home and what to produce overseas. Where there are relatively large proximity advantages and scale economies at the firm level, restrictions on investments may have more damaging welfare effects than restrictions on trade.

The proximity-concentration hypothesis suggests some factors that influence whether a firm decides to establish plants in both countries or to serve the foreign market by exports. There is broad empirical support for the theory that firms do indeed weigh the benefits of proximity against the costs of forgoing the economies of scale that would be enjoyed by concentrating production.

■ purchasing power parity

The notion of purchasing power parity (PPP) has a long intellectual history and can be traced to the 16th-century writings of scholars from the University of Salamanca in Spain. The modern definition of PPP, usually credited to Gustav Cassel (1918), is quite intuitive: when measured in the same unit, the monies of different countries should have the same purchasing power and command the same basket of goods. Otherwise, international arbitrage should bring about adjustments in prices, exchange rates, or both, which will ultimately restore parity. Another way to interpret the parity condition is that the exchange rate between two currencies should equal the ratio of the countries' price levels.

Despite its simplicity, the parity condition is the subject of many empirical studies, driven mainly by its significant implications for the global economy. For instance, PPP is a major building block of most models in international economics. The relevance of these models and their policy implications thus depends critically on the validity of PPP. Another application of PPP is the comparison of national income levels. Some economists believe that a meaningful comparison of income across countries should be based on, instead of market exchange rates, PPP exchange rates that control for price differentials of same goods across countries.

The use of PPP goes beyond academic interest, however. In the context of the global economy, exchange rate misalignment is a main source of imbalances in trade and capital accounts. These imbalances, if left unchecked, can create intense stresses for both individual economies and the global system. The PPP condition describes the relationship between exchange rates and national price levels and is commonly used as a benchmark for evaluating exchange rate misalignment.

The absolute and the relative PPP conditions are the two commonly discussed versions of PPP. The absolute PPP is given by

$$s = p - p*$$

where s is the exchange rate expressed as the domestic price of the foreign currency, p is the domestic price index, and p* is the corresponding foreign price index. All the variables are in logs. The relative version is given by

$$s = c + p - p*$$

where c is constant.

Under the absolute PPP, movements in the relative price, p p*, and in the exchange rate offset each other to maintain the parity. On the other hand, the relative PPP is a less stringent condition and requires only that the proportion of exchange rate variations is the same as the proportion of variations in the relative price.

Law of One Price and PPP The law of one price (LOP) states that prices of identical goods from different locations are the same after adjusting for exchange rates. International arbitrage is the main argument behind the LOP. The difference between LOP and PPP is that the former concept refers to the actual price level of a good while the latter refers to an index of prices for different goods. LOP is a main building block of PPP. For instance, it can be shown that the PPP condition can be derived when only one good satisfies LOP (Niehans 1984). The requirement of only one good, instead of all the goods, satisfying LOP is an interesting result and it implies a high likelihood that PPP holds.

Most studies that evaluate the LOP condition find that, in general, the condition does not hold and deviations from the LOP vary substantially across product types. These studies, however, usually employ price subindexes, such as the price of chemical products. Thus they are examining the relative rather than the absolute LOP. Studies that use actual individual prices are far less common. The documented price convergence in the European car market during the integration process is one of the few pieces of evidence that are in favor of LOP (Goldberg and Verboven 2005). Overall, while one is hard pressed to find favorable evidence among the empirical studies, a casual look at, say, the global precious metal market suggests that the presence of one good satisfying the LOP may not be an extremely stringent condition.

Basics of Evaluating PPP Arguably, the PPP is the most intensely examined parity condition in international economics. Constrained by data limita-

tions, empirical studies usually examine the validity of relative instead of absolute PPP. Specifically, price indexes do not allow an easy comparison of absolute price levels across countries.

The choice of price indexes is an issue in evaluating PPP. The common choice is between consumer price and producer (wholesale) price indexes. Some researchers use the former index as a proxy for the price index of nontradable goods and the latter one as a proxy for tradable goods. In general, the use of producer price index yields stronger evidence in favor of PPP than the use of consumer price index does. Other candidates include price indexes of imports and exports, the GDP deflator, and components of the GDP deflator.

The sample period used in PPP studies ranges from the post-1973 floating period to historical samples that cover 100 years or more. There is a trade-off between short and long samples. An advantage of long historical samples is that they are better suited for studying long-term trends and thus for evaluating the long-run PPP. A drawback, however, is that these samples cover periods of different exchange regime arrangements and significant economic changes that may complicate the analysis. Compared with long historical samples, the post-1973 period may not have enough observations to reveal reversion to the PPP. Nonetheless, results from the post-1973 period are derived from a more homogenous setting and are likely to be more relevant for current policy considerations.

Real Exchange Rate Persistence The persistence of real exchange rates is commonly used to infer the validity of PPP. If PPP holds continuously, the real exchange rate is constant. It is not difficult to verify that the instantaneous PPP does not hold since a constant real exchange rate is typically not observed in reality. This is why most empirical exercises focus on long-run PPP. Under the long-run PPP regime, deviations from parity are possible but short-lived. Over time, the relative price and the exchange rate adjust to restore the parity condition and the corresponding real exchange converges to its equilibrium value. Thus an operational interpretation of long-run PPP is that real exchange rates are mean-reverting,

and the test for the validity of PPP can be translated to a test for mean-reverting behavior of real exchange rates.

The mean-reverting behavior of real exchange rates and, hence the PPP condition, is commonly assessed using unit root test procedures. Indeed, the evolution of these empirical studies closely tracks the development of unit root test procedures. In the 1980s, the introduction of the Dickey-Fuller test revolutionized the assessment of economic data persistence in general and real exchange rate persistence in particular. Since then, a flurry of studies have used various versions of unit root tests, including the original augment Dickey-Fuller (ADF) tests, improved versions of ADF tests, Bayesian unit root tests, the fractional integration test, panel data unit root tests, and procedures allowing for alternative adjustment mechanisms to evaluate real exchange rate persistence.

Traditionally, real exchange rate persistence is evaluated in a linear time-series framework. If the real exchange rate follows a nonlinear path, then the use of a linear model can overstate its degree of persistence. A few nonlinear models, including models with structural breaks, fractional integration models, Markov switching models, and threshold autoregressive models, have been applied to real exchange rate data. In general, allowance for nonlinear dynamics enhances the ability to reveal the reversion to the PPP and lowers the empirical estimate of real exchange rate persistence (Michael, Nobay, and Peel 1997).

On balance, the empirical evidence suggests that PPP tends to hold in the long run but not in the short run. Complementing academic empirical findings, foreign exchange dealers, who jointly determine exchange rates in the global market, also indicate that PPP provides a good gauge of exchange rate movements only in the long run (Cheung and Chinn 2001).

Of particular importance is the survivorship bias in PPP analysis (Froot and Rogoff 1995). This bias refers to the common practice of investigating long historical data from developed countries. The practice mainly reflects data availability rather than

research interest. One implication of the bias is that results from developed countries may overstate the empirical support for PPP. A related issue is whether developed and developing countries have similar real exchange rate behavior. Cheung and Lai (2000a) conduct a large-scale analysis and find substantial cross-country heterogeneity in the persistence of deviations from parity, and it is more likely, rather than less likely, to find parity reversion for developing countries than developed countries.
