The presence of administratively set prices is by definition a deviation from a competitive environment. Although administratively set prices may limit physicians' ability to exploit their market power through price discrimination (and thus, may in fact be welfare enhancing), it does not necessarily prevent physicians from exploiting the heterogeneity and nontradability of their services or the presence of switching costs (and this even in the presence of perfect information). By simply giving patients a 'take-it-or-leave-it' offer on the quantity of care to be provided, the physician may convince the patient to consume excessive amounts of care (i.e., yield higher profits for the physician and lower patient welfare; McGuire, 2000). For example, consider a patient who can consume care at p dollars per unit q. Further suppose that the patient's net benefit from consuming the utility maximizing amount of care is given by $B(q) - pq$. Now suppose that the patient faces a switching cost k if they decide to leave their current physician for an alternative who would be willing to provide q units (also at p). Switching costs could be monetary if tests or procedures need to be redone, or psychic in the sense of building a relationship with a new physician. If the patient leaves their current physician for an alternative one, they then receive a net benefit of $B(q) - pq - k$. Thus, the current physician can persuade the patient to consume q' units of care (greater than q) as long as $B(q') - pq' > B(q) - pq - k$. Thus, in the presence of administratively set prices, nontradable goods, and switching costs, physicians may hold important market power even in the presence of full information. The above suggests that increasing the patient's ability to move from one physician to another (i.e., decreasing the switching costs) is likely to yield important implications on physicians' market power and patient welfare (which is consistent with previous work (Allard *et al.*, 2009)). As a result, one could imagine that the presence of portable medical records and increased patient education may have important benefits in encouraging an efficient provision of care.

How the fees are actually set and how closely they reflect marginal cost pricing is also an important issue. In several systems, payment rates are primarily based on relative weights that reflect the costs of inputs used to provide physician services and a conversion factor which translates these weights into dollar amounts. The weights reflect factors such as physician work (time, effort, skill, etc.), practice expenses (rent, equipment, and staff), and professional liability insurance expenses and the medical profession often exerts significant control in determining them. Governments can use (or attempt to use) adjustments to conversion factors to limit spending on physician services and to constrain spending growth (e.g., US Medicare's Sustainable Growth Rate system).

In many jurisdictions, physicians have played an important role in setting these rates. In Canadian provinces, provincial physician associations negotiate directly with their respective governments to set the fees – fees which then apply to all physicians. In Germany, decisions made both by a government committee at the federal level and by regional physicians' associations affect the amounts physicians are paid for the services they provide to patients. In the US, however, reimbursement rates paid to the same physician can vary between insurance providers. For example, a physician might receive different reimbursement rates for the same procedure depending on the patient's (governmental or nongovernmental) insurer (from Medicare, to Medicaid, to private insurers). Furthermore, physicians are prohibited of collectively bargaining when negotiating reimbursement fees.

One of the ways that insurers have reduced the fees paid to physicians is through Managed Care Organizations (MCO). MCOs control costs through a variety of tools including selective contracting. Selective contracting refers to limits imposed on the pool of physicians that enrolled patients can consult with (i.e., a network of providers). By limiting their enrolees' access to providers, MCOs gain bargaining power relative to physicians. Although very strict forms of restrictive contracting were popular in the early years of managed care, less restrictive contracts such as Preferred Provider Organizations are more common now. These forms of managed care contracting also coexist with 'any willing provider' laws, which require managed care plans to explicitly state their evaluation criteria and to accept any qualified provider who is willing to accept the plan's terms and conditions. Selective contracting and 'any willing provider' laws are clearly designed to have opposing effects on competition in the physician market.

In response to the potential negative effects of MCOs on physician earnings, physicians have introduced different organizational structures in order to reduce costs or increase their bargaining power. Independent Practice Associations are networks of independent physicians that contract with MCOs and employers. Physician-Hospital Organizations, however, are joint ventures between hospitals and physicians. Emerging Accountable Care Organizations are networks of physicians or physicians and hospitals that contract with insurers. Although such networks may provide important efficiency gains, they run the risk of antitrust violations. Accordingly, 2010 legislation in the US prevents new physician-owned hospitals from being built and puts strict limits on already existing ones given the physician's obvious conflict of interest (and corresponding evidence that they may cherry-pick customers, avoid costly services and provide low quality of care).

Insurance

In many markets, consumers face a price that reflects the cost of production when making purchasing decisions. This is usually not the case in the medical services market however because of the presence of insurance. With insurance, consumers face a partially or fully subsidized price and they will wish to consume care until the marginal benefit of care is equal to their subsidized cost (i.e., their out-of-pocket cost) and not the actual marginal cost of production – a phenomenon known as *ex post* moral hazard. As a result, insurance can cause important deviations from the Pareto efficient outcome. To reduce this problem of *ex post* moral hazard (and thus, limit also its perverse effect) one can simply increase the share of the expense the patient pays for (i.e., increase the copayment). By doing so, however, one reduces the risk-spreading benefits of insurance.

Limits to Supply and Barriers to Entry

The condition of free entry is clearly not met in the case of the physician market, with significant barriers existing in training, licensure, and migration across jurisdictions. Nearly all OECD countries exercise some form of control over the number of medical school students – often in the form of a numerus clausus, or limit on the number of medical school slots – or residency positions. This is motivated by a variety of factors including restricting medical school entry to the most able applicants, controlling the total number of physicians for cost-containment reasons, and limiting the direct cost of training. Although countries vary in their approaches to these limits (i.e., ministerial decisionmaking vs. financial incentives) and the extent to which control is devolved to subnational governments (state/provincial/canton) or medical schools themselves, the net result is that the number of physicians is largely determined by policy.

Beyond the total number of physicians, the mix of physicians in different specialties is a function of the number of residency slots, which is largely determined by organized medicine. In the US, Residency Review Committees, consisting primarily of physicians from a particular specialty, control the number of residents who train in, and therefore the number of physicians who flow into, each specialty. Nicholson (2003) showed that these committees could set the flow of residents in order to achieve their desired combination of licensed physicians and physician rents and that minimum wage regulation and scarcity of teaching material (i.e., patients) could also result in the observed persistent excess rates of return to specialization.

After medical education and residency training are completed, entry into the market for both physicians and AHPs is restricted via licensing and practice regulations that can limit competition geographically and in terms of specific services provided. Three primary mechanisms are used to regulate physicians and AHPs, licensure, certification, and registration, and in the US this occurs at the state level. Licensure involves a

mandatory system of state-imposed standards that practitioners must meet to legally practice within the state. Nongovernmental boards, dominated by members of the regulated profession but often also including political appointees or members of the public, determine applicants' eligibility requirements, develop standards of practice, and enforce disciplinary actions. Certification refers to a voluntary system of standards, usually set by nongovernmental agencies or associations. Physicians may become board certified within a specialty to establish they have the appropriate level of knowledge and skills in that area. Registration is the least restrictive mechanism, requiring practitioners to file their name, address, and qualifications with a government agency in order to practice, but not to meet any additional educational or experience requirements.

As discussed in Section Who Competes against Whom?, competition in the market for physician services is also affected by nonphysician providers, the extent to which they are complements to or substitutes for physicians, and the laws and regulations that govern the range of services they provide and how they are remunerated. Feldstein (1988) describes how organized medicine has influenced the demand for, and supply of, physician services, notably by encouraging insurance coverage for their services, disallowing price competition among members, and restricting (expanding) the scope of practice of substitute (complementary) providers allowed under state practice acts. He also describes similar efforts by the American Dental Association, American Nurses Association, and American Hospital Association on behalf of their memberships. For example, the American Medical Association has favored the use of foreign medical graduates to serve as interns and residents (complements, because the physician bills for services provided) and also their return to their home country once their residencies are completed and they become substitutes. Similar tensions are seen between physicians and PA, NP, and chiropractors. Beyond limiting the legal scope of practice of substitute providers, efforts to exclude their payment by a third party has often occurred in the context of public insurance programs (US Medicare, Canadian provincial plans, etc.).

The last barrier to entry considered here is migration, or physical entry into the physician market. Internationally, OECD countries have adopted specific policies designed to stimulate immigration of foreign physicians although respecting the constraints of licensing requirements, protection of vested interests by domestic physicians, and minimization of any negative impacts on the home country. Even within countries, state, or provincial-level licensing requirements mean that physicians may face considerable barriers to practicing in another jurisdiction.

Conclusion

In this article the authors provided an overview of the physicians' market and the role of competition within it. Specifically, the authors noted that although the idea of competition is relevant in all contexts, the observed level and form of competition in any market for physician services will depend on the institutional context and the economic environment. Although the authors empirically observe indicators of the degree of competition in the physician market to vary across contexts, whether a lack of competition decreases social welfare remains an open question. The uncertainty regarding competition's impact on welfare in this market stems from the numerous market failures discussed in Section The Competitive Model. Although some of these deviations from the competitive model are likely inherent to markets for 'expert' services (information asymmetries, search and switching costs), others are more amenable to change via health policy and regulation (insurance, limits on entry, price competition, and provision of services by other providers).

In this second-best environment, the value of competition as a tool to increase welfare is unclear. Whether competition is welfare decreasing depends on the context, specifically how many market imperfections exist and how big are they? Put another way, how far are we from the first best? Competition may be a positive if it encourages the provision of high-quality care (e.g., heterogeneous physicians provide an appropriate mix and levels of care in the presence of information asymmetry and insurance). Competition may be undesirable if it encourages the wasteful use of resources in attracting and treating patients or increases the quantity of services without corresponding reductions in administered prices. For example, Kessler and McClellan (2000) empirically examined the impacts of competition in US hospital markets and found that, in that specific context and time, competition improved welfare. The authors expect that similar work to better understand the implications of physician competition, taking into account the specific institutional and economic contexts, will also be valuable.

Physician-Induced Demand

EM Johnson, Massachusetts Institute of Technology, Cambridge, MA, USA

Introduction

Physicians are often blamed for the high cost of healthcare in the US. Physicians dupe patients into consuming too much care, the story goes, driving up costs without producing commensurate gains in health.

This line of reasoning derives from the physician-induced demand (PID) hypothesis, which is a long-debated topic in health economics. Under the PID hypothesis, physicians influence patient demand to suit their own interests. They are able to do this because their patients know relatively little about the type or quantity of treatment they need. Faced with payment systems that reward quantity of care on the margin, the inducing physician provides care beyond the level that objective clinical judgment and patient preferences would dictate. In short, inducing physicians create their own demand rather than reacting to market demand.

The idea that doctors create their own demand is often used to make the case for healthcare reform, particularly changes to provider payment systems. Peter S. Orszag, the director of the Office of Management and Budget from 2009–10, was paraphrased by the New York Times as saying, 'the supply of hospitals, medical specialists, and high-tech equipment appears to generate its own demand' in June of 2009 (Pear, 2009). Induced demand is also a leading explanation for the geographic variation in utilization that has been documented across the US (Fisher *et al.*, 2003a, b). Atul Gawande has argued in the New Yorker magazine that induced demand combined with differences in the 'culture of money' across areas explains regional variation in Medicare costs per capita (Gawande, 2009). Although there has been no rigorous test of this relationship (as noted in Fuchs (2004)), policymakers have latched onto the idea that altering physician incentives in high cost areas can reduce costs without sacrificing quality of care. 'The Economic Case for Health Care Reform' of the White House states, "large variations in spending suggest that up to 30 percent of health care costs (or about 5 percent of GDP) could be saved without compromising health outcomes" (http://www.whitehouse.gov/administration/eop/cea/The Economic Case for Healthcare Reform).

This article reviews the empirical evidence on PID from the health economics literature. In the next section, induced demand is defined and the evidence on the topic reviewed. The following section brings evidence to bear from related literatures. Finally, the concluding section discusses policy implications and areas for future research.

Empirical Evidence

The concept of induced demand is first attributed to Evans (1974). The precise definition of McGuire (2000) follows:

> Physician-induced demand exists when the physician influences a patient's demand for care against the physician's interpretation of the best interests of the patient.

Under induced demand, a physician takes an action to shift the patient's demand curve in the direction of the physician's own interests. Physicians can affect such a shift, because they have more information regarding the patient's condition and treatment options than the patient, an example of the market failure known as asymmetric information. In theoretical models of induced demand, the action taken by the physician is unobserved and is limited at the margin by its costs. Typically inducement is itself costly for the physician, but in some models inducement negatively impacts patient flows (e.g., Pauly, 1980; Rochaix, 1989) or physician reputation (e.g., Dranove, 1988).

Two aspects of this definition merit clarification. First, induced demand does not include actions that influence demand in the best interest of the patient. Indeed, moving demand toward the patient's optimum is a responsibility of physicians. Second, the definition leaves room for treatment to vary across patients and providers. The benefits and risks of treatments vary with patient characteristics, and it is the job of the physician to tailor care to individual patients. Moreover, differences in physician practice styles, practice environments, and experience mean the true costs and benefits of treatments vary across physicians.

In the researcher's ideal world, the quantity of care the physician views as being optimal from the patient's perspective would be observable. The econometrician could then compare actual treatment with this benchmark, taking any difference as evidence of inducement. By comparing inducement across incentive environments, she could then estimate the physician's objective function. However, many of the characteristics of patients and doctors that determine appropriate treatment are unobserved. For this reason, empirical work on induced demand has used alternative identification strategies. This review groups papers according to the empirical approach and reviews each group sequentially. First are studies that use shocks to physician incomes, and especially physician-to-population ratios, to test for induced demand. Next are studies that use changes in physician fees or variation in patient information to identify inducement.

Before turning to empirical results, it is helpful to briefly clarify the predictions of PID models and compare them with alternative models of physician behavior (see McGuire (2000), for more detail). Under PID quantity is determined in equilibrium by physicians equating the marginal cost of induction with its marginal benefit. Physician incomes, fees, and patient information are all predicted to affect the quantity of care. Physician incomes affect the quantity of care through the income effect. A negative (positive) income shock increases (decreases) the marginal utility of income and increases (decreases) the returns to induction. If quantity of care is reimbursed at the margin, physicians then respond by increasing the quantity of care. An important caveat is that this prediction applies only when there is an income effect; otherwise inducing doctors induce equally at different levels of income (McGuire, 2000).

Changes in physician fees also affect quantities under PID. As in the case of an income shock, a fee reduction increases care quantities through the income effect. In addition, if the fee reduction differentially affects one area of the physician's practice (e.g., certain treatments or patients) relative to others, then there is a substitution effect (McGuire and Pauly, 1991). The relative returns to inducing decrease in the more affected area, and quantities are shifted to less affected areas. Thus, in response to own-fee reductions quantity can either increase or decrease, depending on the relative strength of the income and substitution effects. The prediction for less affected areas is unambiguous: quantity will increase. A final prediction that has been tested empirically is that physicians should have less ability to induce demand among more informed patients, where the asymmetry of information is lessened. This arises as long as the costs of inducement to informed patients are higher.

All of these predictions are in contrast with the perfect agent benchmark, in which only patient preferences and clinical factors matter for treatment, but it is more interesting to contrast the predictions of PID with models of physicians under symmetric information. When patients are informed, profit-maximizing physicians cannot shift demand, but they can affect healthcare quantities by making take-it-or-leave-it offers of nonretradeable services or by altering their choice of quality or effort (McGuire, 2000). This means observing quantities that depart from the patient's optimum is not sufficient evidence of PID. More relevant for evaluating the existing empirical work on PID, observing substitution in response to a fee change is not informative on PID, as physicians with informed patients can also be expected to shift quantities in this manner (McGuire, 2000).

However, profit-maximizing suppliers differ from inducers in that they do not adjust quantity in response to income shocks. This explains the focus of the empirical literature on using shocks to physician incomes and large fee changes to test for PID, though this approach amounts to jointly testing PID and the income effect. Because profit-maximizing physicians have no reason to treat informed and uninformed patients differently, studies using variation in patient information are also informative as to the underlying model of physician behavior. With this in mind, for some policy questions, one only needs to understand the reduced form relationship between physician incentives and utilization, so evidence in this category is considered as well.

Income Shocks

Many empirical studies of induced demand use variation in physician incomes to test for inducing behavior. The earliest studies of induced demand fall into this category. For the most part, these studies examined the relationship between market-level physician-to-population ratios and utilization. This approach is rooted in the idea that an exogenous increase in the number of physicians in a local practice area should spread patients more thinly, lowering physician incomes. Healthcare utilization is then increased if inducing physicians respond through the income effect and treat patients more intensively. Termed the 'availability effect' by Pauly (1980), these studies come the closest to directly testing the proposition that healthcare supply creates its own demand.

The first paper in this vein, Fuchs (1978), runs cross-sectional two-stage least squares (TSLS) regressions of surgeries on the number of surgeons per capita at the market level. To identify supply shifts, Fuchs instruments for the number of surgeons using characteristics of metropolitan areas that should affect surgeons' location decisions, but not local demand (e.g., metropolitan status, hotel receipts, and percent white). He finds a 10% increase in the surgeon-to-population ratio increases surgery by 3%, which he interprets as evidence of induced demand. Cromwell and Mitchell (1986) use a similar methodology with more data and finer geographic markets and find a 1.3% increase in elective surgery. Rossiter and Willensky (1983, 1984) relate healthcare utilization to physicians-per-capita using physician-level data and find even smaller effects.

These studies were highly influential, but there is concern that the instruments employed to isolate supply shocks do not satisfy the exclusion restriction. For example, Gruber and Owings (1996) suggest that results are biased toward inducement, because the average coinsurance rate, which is unobserved, is likely correlated with demand and with the included measures of attractiveness of an area to physicians. An additional concern is that supply shocks may reduce the price or time cost of services, causing patients to move down a static demand curve. Omitting these factors would bias the results toward finding inducement. Dranove and Wehner (1994) provide a powerful critique of the empirical methodology. Employing a method similar to Cromwell and Mitchell (1986), they show that increasing the number of obstetricians increases utilization on a dimension clearly out of the physician's control: the number of births.

Gruber and Owings (1996) avoid many of these problems and provide some of the best evidence to date on PID. In this paper, the authors instrument for state-level changes to the physician-to-population ratio, using the secular decline in the fertility rate from 1970 to 1982. They then look for evidence that physicians respond to the income shock by increasingly performing highly reimbursed Cesarean sections (C-sections) in lieu of less profitable vaginal deliveries, and they find a modest effect: obstetricians replaced approximately 10% of their income by increasing C-sections. By studying a plausibly exogenous shock to income, this approach is not subject to the criticisms of the previous literature. There are also fewer concerns about changes in time–cost in this context. However, it is difficult to compare the size of the estimated effect with previous studies, as obstetricians may have also recovered income on other margins.

Changes in Physician Fees

There is also a large empirical literature that uses changes in physician fees to identify inducement. The main advantage of this approach is the availability of large, exogenous fee changes for study, and most studies have used Medicare fee changes. Medicare fee changes are also appealing for testing PID because Medicare patients make up a significant fraction of physicians' practices. This is important because only fee changes that affect physician incomes have differential

predictions for utilization under PID and models with symmetric information (McGuire and Pauly, 1991).

Rice (1983) studies a large fee change enacted by Medicare in Colorado in 1976. Consistent with an income effect, Rice finds increases in Medicare volume in the Denver metropolitan area, where fees are lowered, relative to the surrounding areas where fees are raised. Point estimates suggest that a 10% decline in reimbursement led to a 6.1% increase in medical services and a 2.7% increase in surgery. However, it is possible that patient demand was affected by changes in patient responsibility over the time period. The short panel also prevents the author from assessing whether urban and rural areas were affected by differential trends over the period of study.

Nguyen and Derrick (1997) also study the impact of a Medicare fee change on Medicare volumes. They study the 1990 Medicare fee change, legislated in the Omnibus Budget Reconciliation Act of 1989, which reduced reimbursement for procedures deemed to be 'overpriced.' Using physician-level data, the authors find physicians experiencing fee reductions increase Medicare volumes. The volume response is similar in magnitude to Rice (1983), but it is significant only for the 20% of physicians who experienced the largest price reductions. While results are again consistent with PID, the study suffers from limitations similar to Rice (1983).

Yip (1998) also studies the 1990 reform, additionally considering the effect of Medicare fee changes on non-Medicare volumes. The paper focuses on thoracic surgeons, whose reimbursement rates were significantly reduced by the 1990 Medicare fee change. In this context, fee cuts led to increased volumes to both Medicare and private payers, with providers recouping, on average, 70% of income lost due to price reductions. The paper also convincingly demonstrates that the income effect is driving results by showing that physicians whose incomes were hit hardest by the reform have the largest volume responses. Jacobson *et al.* (2011) exploit a more recent Medicare fee change. The authors study the 2005 change in Medicare's reimbursement of outpatient chemotherapy drugs, and they find that physicians responded to reduced fees by increasingly administering chemotherapy. They also show that physicians substituted toward drugs that were lesss affected by the fee reduction in their prescribing behavior.

Gruber *et al.* (1999) is another important paper on fee changes and quantities. This paper studies Medicaid fee changes, specifically changes in Medicaid's reimbursement for C-sections. The authors expect the policy to have only a small income effect since Medicaid patients are a small fraction of providers' practices, and in fact, they find that the substitution effect dominates in this context: a 10% increase in the Medicaid fee led to an 8.4% rise in C-sections in the Medicaid population. While this result is consistent with models of PID, it is also consistent with physicians setting quantity under symmetric information.

Variation in Patient Information

There is also a long-established literature that uses variation in patient information to test for induced demand. These studies are motivated by the idea that informed patients should resist doctors' attempts at moving them away from their optimum consumption level. When inducing physicians are reimbursed for treatment on the margin, one expects utilization to be lower among more informed groups. The first study in this vein, Bunker and Brown (1974), compares rates of surgery for lawyers, businessmen, and ministers with those of physicians, who they view as informed consumers of medical services. Contrary to the prediction, they find self-reported surgery rates to be equal or higher among physician families when compared with other professional families in the same county. They conclude that physicians must have unobservably higher demand for medical services.

The conclusion of Bunker and Brown (1974) highlights the main weakness of the approach. When comparing utilization across patient groups, any omitted factors that are correlated with utilization will bias results. For example, prices, care quality, and health status may all differ across the professionals considered in this study. Hay and Leahy (1982) adopt the same approach using survey data with more extensive controls, including income, insurance coverage, and self-reported health status, but they also find higher use among physicians.

Domenighetti *et al.* (1993), in a more recent survey in Switzerland, find that the average person's probability of receiving one of seven major surgical interventions is one-third above that of a physician or a member of a physician's family. Ubel *et al.* (2011) survey physicians and find they want less intensive treatment for themselves than they would recommend to patients in two fatal disease scenarios. Again, results are difficult to interpret as patient characteristics influencing demand may differ across groups. Currie *et al.* (2010) address this weakness by conducting a patient audit study, which allows them to ensure comparability across informed and uninformed groups. Fake patients visited physician offices in China, where physicians have a financial incentive to prescribe medication. They then compare prescription rates of patients who verbally signal their understanding of appropriate prescription behavior with those who do not. It is found that prescription rates for the uninformed patient are higher by 25%. However, the physician could also have interpreted the information signal as a signal of patient preferences.

Related Literature

In this section, evidence on PID from related empirical literatures is considered. First, the empirical literatures on medical malpractice and defensive medicine are reviewed briefly, and results from the growing literature on physician incentives in managed care are summarized. The literature on physician self-referral, which considers whether physicians respond to the private incentive to use resources they partially own more intensively, is also reviewed. Finally, the literatures on pay-for-performance programs and studies of physician convenience factors are discussed.

First consider the literature on medical malpractice. So far, it has been assumed that the incentive physicians respond to in inducing demand is financial, but physician response to private liability risk is also consistent with the definition of

induced demand. Kessler and McClellan (1996, 2002) show that tort reform reduces medical expenditures on Medicare heart patients without affecting patient outcomes. They interpret this as evidence that doctors practice 'defensive medicine,' providing care that does not benefit patients in order to reduce their liability risk. More recently, Currie and MacLeod (2008) show that malpractice pressures increase the utilization of procedures that reduce liability risk, such as diagnostic testing, but decrease the use of risky treatments, such as the performance of C-sections in delivery. More research is needed to explore the relationship between financial and malpractice incentive systems.

The discussion has so far presupposed that it is financially rewarding for physicians to provide more healthcare to patients. Although this is true in fee-for-service payment systems, physicians paid by capitation have incentives to provide less treatment (Ellis and McGuire, 1986; McGuire, 2000). In fact, researchers have shown that physicians paid by capitation spend less time with patients (Mechanic *et al.*, 2001; Tai Seale *et al.*, 2007; Glied and Zivin, 2002; Melichar, 2005) and provide less care to each patient (Epstein *et al.*, 1986; Safran *et al.*, 2002; Stearns *et al.*, 1992; Greenfield *et al.*, 1992). Salaried doctors and doctors with bonuses tied to utilization measures also appear to respond to incentives for providing less care (see e.g., Hickson *et al.* (1997), Barro and Beaulieu (2003), Gaynor *et al.* (2004), and Hemenway *et al.* (1990)). These results cannot be interpreted as conclusive evidence of PID, however, as symmetric information models also predict this behavior. Further complicating interpretation is the fact that even perfect agents may reduce care if resources are rationed under managed care.

There is also a large empirical literature on self-referral practices by physicians. This literature studies treatment decisions when physicians have an ownership stake in some part of their practice. Reimbursement is typically higher when resources are owned by the physician, and studies find that physicians respond to this incentive by increasingly recommending patients for treatment. Mitchell (1992) and Hillman *et al.* (1992) study ownership incentives and referrals to diagnostic testing facilities, Yee (2011) studies ambulatory surgery centers, Barro *et al.* (2005) study specialty hospitals, and Baker (2010) studies the utilization of imaging devices. Iizuka (2012) also contributes evidence by showing that physician prescription behavior responds to pharmaceutical markups in Japan, where physicians dispense as well as prescribe drugs. Afendulis and Kessler (2007) studies a related conflict of interest. They observe that integrated cardiologists, who can both diagnose and perform interventional procedures to treat heart disease, have stronger incentives to recommend patients for intervention compared with non-integrated cardiologists, who must refer patients for treatment. They find that patients of integrated cardiologists are, in fact, more likely to receive percutaneous interventions.

Finally, the recent literature on pay-for-performance programs, which tie physician reimbursement to observable quality measures, suggests that performance incentives can affect care (Campbell *et al.*, 2007; Rosenthal and Frank, 2006; Mullen *et al.*, 2010). Studies of labor and delivery also suggest that obstetricians sometimes perform C-sections for their own convenience (Burns *et al.*, 1995; Spetz *et al.*, 2001). These results are inconsistent with the perfect-agent model. However, symmetric information models also predict substitution toward more highly reimbursed and away from more costly treatments. Therefore, it is again difficult to disentangle distortions due to financial incentives from those due to principal-agent concerns.

Suggestions for Future Research and Policy Implications

There is a large and growing body of empirical evidence that physicians' treatment decisions are influenced by factors beyond their patients' needs. Convincingly identified studies have shown that obstetricians do more C-sections in response to declining fertility, cardiac surgeons treat more intensively when their incomes are impacted by fee reductions, and physicians in China prescribe more medication to 'uninformed' patients. This evidence is inconsistent with the model of physicians as perfect agents, and it supports PID as one avenue through which physicians affect quantities of healthcare. In addition to this direct evidence of PID, physicians respond to private malpractice incentives and financial incentives for self-referral. Physicians also appear to respond to the incentives in managed care plans. Finally, there is some evidence that pay-for-performance programs and physician convenience factors affect healthcare choices. Taken together, these studies suggest that physician incentives, broadly defined, are important determinants of both healthcare costs and the distribution of health resources in the United States.

However, more work is needed before one can make statements about the economic importance of PID. Although empirical research has provided estimates in several contexts, there is reason to believe that the effect will differ across incentive environments, physician specialties, patient groups, and even across treatment categories within physician–patient pairs. Future research exploring this heterogeneity should also aim to bridge our current understanding of PID with claims made in the health policy arena. How much of the variation in utilization across geographic areas can be explained by demand inducement? Have physician incentives or constraints on inducement changed, such that PID has contributed to growth in health spending over time?

More theoretical work is also needed. Exploring the impact of competition on physician behavior is a promising area for research (and one that may produce new testable implications for PID), though this first requires refining our understanding of the sources of physician market power. It would also be interesting to theoretically explore the interplay of the various incentive systems that physicians face, for example, by studying physicians who are contracted with both HMOs and PPOs.

The PID research agenda is important for policy. The general direction of health policy in the US and other countries is to push some financial risk to physician groups, as accountable care organizations (ACOs) do in Medicare. If PID is pervasive and powerful, creating an interest among physicians in providing less care may work well to reduce healthcare costs, but not without raising concerns about access and quality. The extent of induced demand also has implications for physician workforce and training policies; and gaining

clarity into induced demand behavior has implications for health insurance design – inducement affects the interpretation of parameters that are central in the optimal insurance literature. Finally, the literature on PID can help us to understand the impacts of patient empowerment policies, for example, patient ownership of their own medical information.

Physicians' Simultaneous Practice in the Public and Private Sectors

P González, Universidad Pablo de Olavide, Sevilla, Spain

Glossary

Access The degree to which individuals are inhibited or facilitated in their ability to receive care and services from the healthcare system. Factors influencing this ability include geographic location, architectural features, availability of transport and financial considerations.

Asymmetry of information A situation in which the parties to a transaction have different amounts or kinds of information as when, for example, physicians have a greater knowledge than patients of the likely effectiveness of drugs while the patients have greater knowledge of the likely impact of drugs on their family circumstances.

Cost sharing An arrangement whereby the cost of healthcare is shared, typically between the patient and insurer.

Cream skimming A form of selection in private health insurance markets by which the insurer obtains a higher proportion of good risks (people with a low probability of needing care or who are likely to need only low-cost care – or both) in their portfolio of clients than is assumed in the calculation of the insurance premiums. Also called 'cherry-picking' and 'creaming'.

Dual practice A combination of public and private practice by doctors, sometimes even within the same hospital.

Efficiency A resource allocation is efficient if it is not possible to reallocate resources so as to increase one person's utility (or health or output) without decreasing another person's utility (or health or output). In health economics the entity maximized is generally assumed to be utility, health, or welfare.

Incentives Any factor (financial or nonfinancial) that influences providers' or consumers' behavior. In the health market, it often refers to financial or psychological rewards designed to motivate physicians to perform at or better than an established standard.

Physician-induced demand The effect that providers of services may have in creating more patient demand than there would be if they were to act entirely in the interests of their patients. Also called supplier-induced demand.

Prospective payment A method of reimbursing health service providers (especially hospitals) by establishing rates of payment in advance, which are paid regardless of the costs in actual individual cases.

Quality of healthcare It can refer variously to clinical process, hotel services, health outcomes, frequency of adverse events, or conformity with clinical guidelines and other authoritative standards of care.

Rationing Allocating resources according to their prices, a planning procedure, a set of rules, or other administrative arrangements.

Introduction/Background

Dual practice among doctors, which the literature often refers to as dual (or multiple) job-holding among health workers, is a phenomenon that can be observed in most countries with both public and private health care systems.

The term 'multiple job-holding' is defined as working simultaneously in more than one paid job. Any worker can hold several jobs at one time, and health professionals are no exception. Multiple job-holding in the health sector can take various forms. Doctors may combine medical practice with other related activities, such as research or teaching, for example, or with a totally unrelated activity, as in many developing countries. They may also hold more than one job within the public (or private) sector, or in both sectors simultaneously. This article focuses on the last option, that is, dual practice among doctors whose main job is in the public sector but who also do clinical work in the private sector.

Despite the prevalence of multiple job-holding among health workers, the phenomenon is largely undocumented. It is nevertheless allowed in most countries with mixed health systems, with two main exceptions, Canada and China, where it is forbidden by law. As a result, dual practice among doctors is widespread in European countries, prominent examples being Ireland, where 90% of the doctors employed in state hospitals also work in the private sector; and the UK, where 60% of state-employed doctors do so. Data also exist for countries outside Europe, for example, Australia and New Zealand, wherein according to the Royal Australasian College of Physicians, 79% and 43% of public sector doctors, respectively, hold some jobs in the private sector. In less developed countries, the exclusively state-employed doctor is a fading figure, due to low public-sector salaries. Dual practice is therefore widespread in Asian countries (Thailand, Vietnam, India, among others), Africa (Egypt, Zambia, Mozambique, etc.), Latin America (in Peru, almost 100% of doctors are dual practitioners), and also in Eastern Europe, wherein despite a rapidly growing private health market, doctors are reluctant to give up their public sector jobs entirely.

Just like many others, doctors may have various reasons for holding more than one job. Possibly, the most powerful being economic motivation. The intuition is that, what with overtime restrictions in the main job, people will be willing to earn extra income by taking on a second job, if it is sufficiently well paid. A recent empirical study for Norway by Godager and Luras, provides the evidence that, after a decrease in income due to shortage of patients, general practitioners have reacted by increasing the hours devoted to community health service.

Other reasons leading doctors to hold more than one job include: (1) complementarities between jobs, either in terms of income (public sector stability combined with private sector earnings that are higher on average, albeit more variable) or nonmonetary advantages (opportunities to expand professional contacts or obtain recognition and prestige within the profession), and also technological and training complementarities (a second job can enable doctors to widen their experience and/or learn new techniques); (2) professional and institutional factors relating to workload and work satisfaction, or ineffective organization, structural deficiencies, and unsatisfactory working conditions in the public health sector; and (3) personal characteristics (age, gender, household structure, etc.).

The economic theory underlying dual practice is still scant and relatively recent. Few theoretical models have been developed to analyze the issue (see Table 1 for a summary of the theoretical literature), and there is a notable lack of empirical studies on the subject.

Dual Practice: A Context for Discussion

Despite the prevalence of dual practice among doctors in the majority of mixed health systems, there is a surprising lack of evidence regarding the potential impact on the efficiency of health care resource management. Although allowing health professionals to hold more than one job may have some positive consequences, it may also give rise to a degree of opportunistic behavior that could compromise the efficiency and quality of public health provision. This is why dual practice among doctors is subject to social controversy. Detailed below are some of the arguments for and against dual practice, together with their theoretical underpinnings.

Costs of Dual Practice

It is generally acknowledged that dual practice may have three potentially negative consequences for public health provision: (1) poorer care quality, (2) longer waiting times and waiting lists, and (3) higher costs. Although these three problems are directly interlinked (e.g., longer waiting times can lead to poor quality of care), in the remaining part of this article they are presented as independent issues, along with the related, but limited, scientific literature.

The problem of the deterioration of the quality of care in public health services due to dual practice on the part of doctors is directly linked to incentives. Dual practice doctors may have incentives to dedicate as much time and effort as possible to their private work, and therefore fail to complete their hours effectively in their public jobs either by making less effort or by taking on a lower work load. Unjustified absenteeism and shirking by health professionals are quite common in many developing countries, although there is evidence, albeit anecdotic, that these are not unknown phenomena in western economies. However, the empirical studies that report this behavior are unable to separate the effect of dual practice from that of poor organization and general lack of motivation toward effort.

Potential shirking of professional responsibilities has been widely studied in the economic literature. Inherent in these research models is the notion of asymmetric information, relating to the fact that employers cannot observe the efforts of their workers (or the result of that effort) and supervision is costly. As contracts cannot be contingent on effort, doctors may have other incentives attributing to their less than the socially desirable level of effort into diagnosing and treating patients, with negative repercussions for health care quality.

When doctors are dual providers, the reduction in their care quality may result not from lack of dedication to the public job, but from their strategic undermining of patients' perception of public health care (a more subtle kind of physician-induced demand) so that more patients opt for private treatment. The motives for this are mainly economic, driven by the fact that the public sector pays a fixed salary, whereas in the private sector incentive schemes are more common. In a paper by Brekke and Sørgard (2007), dual practice leads doctors to skimp on their effort in the public sector in order to process fewer public sector patients and thus increase the demand for private treatment. In Biglaiser and Ma (2007), it is shown that only a fraction of doctors, who are classified as 'moonlighters', provide minimal service quality in the public sector and have incentives to refer patients out of the public system. Although the quality of public health care could still diminish, the authors show that this need not be the case, given that health authorities can utilize the savings in public health costs resulting from the diversion of patients to the private sector to improve the quality of service from 'dedicated' doctors working exclusively in the public health sector. Finally, Delfgaauw (2007) suggests that average public health care quality (interpreted in their model as the probability of receiving high quality care from an altruistic doctor) suffers because of dual practice, thus penalizing the poor who cannot afford private treatment.

A large part of the literature focuses on the design of contracts incorporating incentives to encourage desirable behavior. It is generally agreed that, for doctors working exclusively in one sector, to strike the optimum balance between cost and performance, it is necessary to combine a purely prospective payment system with partial cost reimbursement (i.e., adopting a mixed payment system). If doctors are dual providers, the effectiveness of incentives to discourage opportunistic behavior on the part of doctors does not depend entirely on the type of payment system used in the public sector. It also depends on how they would be paid in a potential second job. It has been suggested that a mixed payment system is also the best alternative for dual practitioners, although the cost reimbursement rule is likely to be more complicated. Depending on whether the relationship between public and private practice is one of substitution or complementarity, the optimal rule will yield a higher or lower return on costs than when doctors do not hold two jobs at the same time (Rickman and McGuire, 1999).

Another issue being closely linked to the deterioration of the quality of public health care is the fact that health care delivery by dual practitioners is sometimes associated with longer waiting times and longer waiting lists in the public sector. The origin of this problem may also be twofold. Firstly, it may be the result of incentives for doctors to shirk in the public sector and save their efforts for the private sector. Secondly, dual practitioners

Table 1 Overview of different theoretical models on physicians' dual practice

Authors	*Research question*	*Model description*	*Main results*	*Policy recommendations on dual practice*	*Reference*
Barros and Olivella (2005)	Cream skimming of patients when public treatment is rationed.	There are three groups of players: (1) a health authority which runs a public hospital and chooses a rationing policy; (2) a representative physician that treat patients in public sector, chooses the maximum level of severity he is willing to treat in his private practice, and offers those patients the possibility of resorting to a private treatment; (3) a set of patients that differ in their severity and choose whether to wait for free public treatment or pay for immediate private treatment.	Although doctors might have incentive to select highly profitable (low cost) patients for treatment in the private sector, full cream skimming is only compatible with intermediate rationing policies. If, on the contrary, rationing is either very lax or very stringent, then cream skimming is always partial.	None	*Journal of Economics and Management Strategy* **14**, 623–646.
Biglaiser and Ma (2007)	Welfare implications of dual practice when some public-service physicians may refer patients to their private practices.	There are three groups of players: (1) a regulator that decides physicians' payment in the public sector and whether dual practice is allowed or not; (2) two sets of doctors: dedicated (working only in the public sector) and moonlighters who choose a quality level to provide to their patients in the public system. Moonlighters decide also whether to refer their public patients to their private practices; (3) a set of patients that differ in income and who may be offered a private option by a moonlighter.	Allowing dual practice increases social welfare. But public care quality may decrease as a result of adverse behavioral reactions, such as moonlighters shirking more and dedicated doctors abandoning their sincere behavior.	Limiting private income through price ceilings limits adverse behaviors in the public system and improves consumer welfare.	*RAND Journal of Economics* **38** (Winter), 1113–1133.
Brekke and Sørgard (2007)	Interaction between public and private health provision in a National Health Service.	There are three different agents: (1) a health authority, which decides whether or not to allow private (out of plan) provision of health care alongside the National Health Service (NHS), and the public sector remuneration (wage level); (2) a set of physicians determining their labor supply in the public sector and, if allowed, in the private sector; (3) a set of individuals demanding medical treatment from the NHS and private (out of plan) providers, if this is an option.	Allowing physicians' dual practice 'crowds out' public provision and results in lower overall health care provision.	A ban on dual practice is desirable if private sector competition is weak and public and private cares are sufficiently close substitutes.	*Health Economics* **16**(6), 579–601.

(*Continued*)

Table 1 Continued

Authors	*Research question*	*Model description*	*Main results*	*Policy recommendations on dual practice*	*Reference*
Delfgaauw (2007)	Allocation of patients to physicians under different systems of health provision.	There are three agents: (1) the health authority, which enforces a minimum public treatment quality; (2) two groups of physicians (regular and altruistic), who are identical except for their attitude toward patients; (3) a population of patients who differ in income. In a purely public system, treatment is provided (free of charge) within the public sector, and patients and physicians are randomly matched. In a mixed system, there is also private provision of health care, and each physician chooses whether to work for the public or in the private sector, and each patient decides where to obtain treatment.	Allowing for private provision of health care, parallel to free treatment in a National Health Service, benefits all patients. But allowing dual practice is detrimental for the poorest patients.	None	Tinbergen Institute, Discussion Papers 07-010/1.
González (2004)	Design of contracts for dual providers who use their public practice as a source of reputation for their private activity.	There are three agents: (1) a health authority, which decides the physicians' payment contract aimed at providing incentives for an accurate diagnosis and treatment decision; (2) a representative patient who suffers from an illness whose severity is unclear and requires medical attention; (3) a representative physician in charge of diagnosing the illness and its severity, and deciding whether to treat or refer the patient to a specialist.	Physicians have incentives to overdo medical services when they use their public performance as a way of increasing their prestige as private doctors.	Exclusive contracts are the 'second best' choice. The desirability of limiting policies is ambiguous. On the one hand, they can help to mitigate the physicians' tendency to over-provide services. But, at the same time, they increase the cost for the health authority of inducing an accurate diagnosis on the part of the physician.	*Health Economics* **13**, 505–524.
González (2005)	Cream skimming of patients when health authorities reach agreements with private hospitals to have some of their public patients treated there.	There are three agents: (1) the health authority, which decides the payment to public physicians and the amount of patients that are referred to private hospitals to alleviate public sector congestion; (2) a set of patients differing in their degree of severity; (3) a representative physician, who selects the patients he wants to treat in the public sector. The remaining patients will be transferred to the private hospital.	Dual providers refer the most profitable (low cost) patients from public sector to private practice.	None	*Health Economics* **14**, 513–527.

González and Macho-Stadler (2013)	Optimal regulations on dual practice in developed and developing countries	There is a health authority that contracts physicians to provide public health and designs the regulatory regime regarding dual practice. Physicians have different skills and decide whether to work solely for the public sector, be dual practitioners, or work in the private sector exclusively. Private market rewards quality. The production technology of health differs for developed and developing countries, being more dependent on physicians' skills in the latter.	Banning dual practice increases the cost of retaining high skilled physicians in the public sector. Limiting dedication to private practice is more efficient than limiting dual practitioners' earnings. Whenever enforceable, a policy of limits is always more efficient than one of offering exclusive contracts.	In developing countries, the scope for regulation is generally limited due to the high health costs because of a brain drain of health professionals. In developed countries, when regulation is needed, limits to dedication emerge as the best policy.	*Journal of Health Economics* **32**(1), 66–87.
Iversen (1997)	Effect of a private sector on the waiting time associated with treatment in the public sector.	The model is a two-stage game. In a first stage, the hospital (physician) decides on hospital admissions and waiting time. Patients choose, then, between private treatment (costly) and public treatment (free but with rationing and waiting). In a second stage, the health authority decides the budget allocated to the hospital. When physicians are dual suppliers, part of their income coming from private practice is increasing in the public sector waiting time.	When waiting-lists admissions are rationed, the waiting time increases if public sector consultants are allowed to work in the private sector in their spare time.	None	*Journal of Health Economics* **16**, 381–396.
Rickman and McGuire (1999)	Optimal public sector reimbursement rule when physicians are dual providers.	A representative patient receives treatment from his/her physician in the public sector (e.g., the NHS) and the private sector. These treatments can be either substitutes or complements. Treatment in the public sector is free of charge but private treatment is costly. The physician derives utility from his/her private income and public sector work, and also from patient's welfare. The health authority designs the payment contract for the public sector in order to maximize social welfare.	Public sector cost-sharing remains socially efficient, but it is generally nonlinear. The precise details depend on whether public and private services are substitutes or complements and on the degree of social efficiency achieved in the private sector.	None	*Scottish Journal of Political Economy* **46**, 53–71.

may have strategic incentives for enabling public sector waiting times and waiting lists grow. Along these lines, Iversen (1997) shows that if admissions to public sector waiting lists are rationed, the waiting time for patients will increase when their doctors are allowed to work in the private sector in their free time. Doctors will be motivated by the desire to increase their private earnings, in this case by maintaining long waiting lists in the public sector so that more patients are willing to pay for private treatment.

Finally, dual practice by doctors can increase public sector direct costs in various ways. These include opportunistic behavior, such as the appropriation of material paid by the public sector or the use of public sector equipment to treat private patients. Although this kind of behavior is more frequent in developing countries, there is anecdotic evidence to show that it also takes place in western economies.

The cost of public health care may also increase if doctors have incentives to practice 'cream skimming.' This means selecting patients for treatment on the basis of either seriousness of their condition or their likelihood of recovery. In an environment of asymmetric information, cream skimming can often be the result of a prospective payment system, which encourages overtreatment of patients with minor ailments and undertreatment of serious cases. In a context with dual practitioners, cream-skimming may be explained as the result of doctors having incentives to refer less serious cases to their private practices, and leave more serious cases to the public sector. Barros and Olivella (2005) and González (2005) studied this phenomenon in a context of public sector waiting lists. The second of these studies shows that doctors holding more than one job have (purely economic) incentives to divert less serious (thus, less costly) cases to the private sector when the health authority decides to use private hospitals to alleviate congestion in the public sector, a policy that has recently been applied in many EU countries. Barros and Olivella (2005) stress that, when public treatment is rationed, the actual scope for cream skimming depends on the waiting list admission criteria used by the health authority. In fact, the scope for cream skimming is limited both by laxity, which results in a waiting list with a higher proportion of mild cases who will be less willing to pay for private treatment, and by extreme strictness, which reduces waiting times. Therefore, according to these authors, only an 'intermediate' policy will allow dual providers to divert less serious patients to their private practices, thus affecting public health costs.

Finally, it could be argued that dual practice is sometimes accompanied not by shirking but by precisely the opposite kind of behavior. Doctors may try to build their professional reputation and prestige through their work in the public sector and thus increase their private sector earnings. In this case, public health care would not suffer, but treatment costs might increase through doctors prescribing stronger (and more expensive) treatments (González, 2004).

Benefits of Dual Practice

Allowing doctors to work in the public and private sectors at the same time also carries some benefits for public health care provision.

In many countries, by allowing dual practice, governments are able to retain their best health professionals at less cost. If a high percentage of doctors abandon the public sector, care quality will be badly affected. This is potentially a serious problem in developing countries, where low salaries imply there is often a shortage of doctors in the public sector. An article by González and Macho-Stadler (2013) illustrates this possibility using a theoretical model where doctors differ in their levels of skill, which is understood as their capacity to deliver adequate health care. A ban on dual practice reduces the number of doctors working in the public sector. The impact this causes on the total amount of public health provision is particularly significant if the private market rewards quality and thus draws the more skilled doctors away from the public sector.

Also, allowing doctors to work in the private sector to supplement their public sector salaries can have the positive effect of reducing the prevalence of informal payments, which are so widespread in developing and transitional economies. Informal payments constitute an informal market for health care within the confines of public health care networks, and, compromises governmental efforts to improve efficiency and equity in the delivery of health services. It was to reduce this problem that Greece legalized dual practice by doctors in 2003.

When there are complementarities between the tasks performed in different jobs, working in different working environments can enrich the professional experience of dual practitioners. Sometimes, working in the private sector allows doctors to access new technologies and improve their knowledge and technical expertise. This benefits both their private and public sector patients. The latter could benefit not only directly, if the new techniques or technology are introduced in public hospitals, but also indirectly, through improvements in professional skill and experience.

Finally, the incentives of dual providers to direct their public sector patients into the private sector can be potentially beneficial in aggregate welfare terms. This is the case if the diversion involves higher income patients who are able to afford private treatment. Thus, the more altruistic kind of doctor may advise poor patients to seek free treatment in a public hospital, and refer only those who can afford it to their private practice. This is precisely the conclusion reached in the paper by Biglaiser and Ma (2007) mentioned earlier, in which allowing dual practice is found to result in welfare gains. The motivation is twofold. Firstly, there is a saving in public sector costs, where the numbers of patients being treated will decrease as some are diverted to the private sector. Secondly, efficiency will improve because patients in the private sector will receive medical treatment of quality for which they are willing to pay. This type of argument must be treated with some caution, however, because only if there are real differences in quality between public and private health provisions, will there be patients willing to pay for private treatment. This could mean that the rich and the poor would receive unequal medical treatment, that is, a clear two-tier system. There is also some empirical evidence to show that people from low income, poorly educated groups are often the most likely to respond to inducement, to use private services and pay for private treatment instead of using the subsidized public health service.

An Overview of Dual Practice Interventions

Whether physicians' dual practice should be regulated in some way, and how health authorities should best intervene are two difficult questions for which the literature has not yet found unanimous answers. As mentioned already, previous theoretical studies are rather ambiguous when it comes to identifying the ultimate impact of dual practice on the efficiency and quality of public health care provision. More importantly, there has been no solid empirical research to enable us to quantify the costs and benefits of allowing (or banning) dual practice.

The reality is that dual practice by doctors is regulated in a fair number of countries, although regulations differ enormously from one country to another. Canada and China are two examples of the very few countries where dual practice is prohibited. There is disagreement in the literature as to the effectiveness of prohibition. Brekke and Sørgard (2007) find that the banning of dual practice is an efficient policy in cases where the private health sector is not highly competitive, or patients perceive public and private health care as substitutes. In both these situations, the crowding-out effect of physicians' dual practice on public health care is so strong that dual practice is welfare-reducing and banning is desirable. González and Macho-Stadler (2013) nevertheless stress that a ban on dual practice does not appear to be a good strategy. In developed countries, professional ethics and self-regulation are well established and can reduce the incidence of unacceptable behavior. At the same time, dual practice enables governments to retain highly qualified professionals at a relatively low cost. In these countries, therefore, the gains from banning dual practice would not offset the costs. In less developed countries, although the institutional environment is weak and the work environment permissive, prohibition still appears undesirable. These countries often suffer from a heavy 'brain-drain' of doctors from the public sector in search of better job opportunities. If the prohibition of dual practice means that even fewer doctors are attracted to the public sector, the poorest patients, who cannot afford private treatment, will find quality health care frankly difficult to access. Finally, prohibition is not found to be a good strategy in Biglaiser and Ma (2007) because it cancels out the efficiency gains being generated by dual practitioners diverting those patients who are willing to the private sector where they can obtain better quality treatment in return for payment.

If prohibition is not the best solution, what other options are available? Governments worldwide have tackled this issue in a wide variety of ways. Some countries, such as Italy, Portugal, or Spain, among others, have taken the alternative of offering doctors some kind of premium (a salary bonus or promotion points) in exchange for voluntarily restricting their professional activity to the public sector. The limited theoretical literature on the subject suggests that this kind of policy is optimal only in certain circumstances: (1) when it is not possible to design incentive contracts to encourage desirable behavior for health professionals (González, 2005) and (2) when other regulations – particularly, dual practice restrictions – are difficult to implement (González and Macho-Stadler, 2013).

In developing countries, exclusive contracts are a still less desirable option. Leaving aside the financial constraints affecting these countries, exclusive contracts will inevitably attract more poorly skilled doctors with less chance of making money in the private sector. Poor countries sometimes lack sufficient clinical technology and clearly defined treatment protocols, and doctors often work in isolation. As a result, the quality of treatment in the public sector largely depends on the skill of the doctor. Thus, the efficiency gains from this policy will tend to be minimal (González and Macho-Stadler, 2013).

Another measure adopted by some countries is to place restrictions on dual practice. For instance, the UK has placed an upper limit on the amount of money dual practitioners are allowed to earn in the private sector. Biglaiser and Ma (2007) examined this option and show that, when the probability of doctors' shirking depends on their earning potential in the private sector, it is socially optimal to allow dual practice but cap doctors' private earnings, by means of price-ceilings. This enables the health authority to compensate for the loss in public sector health care quality due to dishonest doctors' shirking, with efficiency gains derived from dual practice, as mentioned above. González and Macho-Stadler (2013) show that it will always be more efficient to limit doctors' dedication to private practice rather than the earnings they make from it, because the latter will only affect highly skilled doctors, who will have to reduce their dedication to private practice to comply with earning constraints. Although this may be the case, it is also no less true that limits on dedication to private practice are much harder to implement and enforce than the ceiling on earnings.

Finally, regulations in countries such as Austria, France, Germany, Ireland, and Italy are oriented toward offering doctors incentives to enable their private practice from public hospitals, while specifying the maximum amount of private work that can be provided within public facilities. This kind of policy has the advantage of facilitating supervision, reducing opportunistic behavior, and easing the enforcement of restrictions.

Most dual practice control policies have been introduced in developed countries, wherein theoretically speaking, professional ethics and existing control mechanisms provide a guarantee against serious side effects. In the developing world, however, there is little control over dual practice, despite growing interest in the problem among public decision-makers in such areas. González and Macho-Stadler (2013) show that despite the risk of opportunistic behavior among dual practitioners in developing countries, direct regulation of dual practice is unlikely to be desirable because it carries the risk of pushing away the best doctors and thus reducing the population's access to quality health care. Furthermore, the implementation of any of these policies will require credible contracting institutions, which developing economies mostly lack. Therefore, in contexts such as these, regulations will only work subject to improvements in the contractual and institutional framework.

Policy Responses to Uncertainty in Healthcare Resource Allocation Decision Processes

C McCabe, University of Alberta, Edmonton, AB, Canada

Background

The past two decades have seen a revolution in the science that underpins new health technologies. Many new technologies offer hope for previously untreatable conditions and potential step changes in the outcomes of care for many others. Regulators committed to supporting the translation of the breakthroughs in biomedical knowledge into the clinic often approve new medicines on the basis of immature evidence, in terms of both the quantity and the quality of evidence for effectiveness and safety.

At the same time, the processes for manufacturing many of these new technologies are considerably more expensive than for conventional therapies such as small molecule pharmaceuticals. This, along with factors driving up research and development costs, means that many of these new technologies arrive at market with prices that are of magnitudes greater than previously encountered.

Improvements in population health status and the effectiveness of healthcare are also leading to increasing demand for treatment, as people live long enough to develop conditions associated with aging. As a result, not only the price but also the budget impact of introducing new technologies is much larger than was historically the case, with some technologies representing a genuine threat to the financial viability of smaller healthcare payers.

For reimbursement authorities charged with making protecting and promoting the health of the population they serve, the tension between the promise of these new technologies and the relative paucity of evidence that the promise will be fulfilled inevitably gives rise to the question 'What if the resources are consumed but the promise is not fulfilled?' The risk of making the wrong decision, the decision uncertainty, and how policy makers have responded are the focus of this article. The remainder of this article is constructed as follows. The Decision Uncertainty in Healthcare Resource Allocation section briefly reviews the concept of decision uncertainty and then outlines the factors that contribute to decision uncertainty in the context of value-based healthcare resource allocation decision processes. The Designing Patient Access Schemes section reviews the literature on their design and implementation, proposing a typology for differentiating them according to their objective and the mechanism for managing the decision uncertainty. The Evidence for the Success or Otherwise of Patient Access Schemes section considers the evidence for the success or otherwise of different types of scheme. The Linking Research and Reimbursement Decisions section considers recent developments linking research and reimbursement decisions, whereas Section Value-Based Pricing and Decision Uncertainty considers the degree to which a value-based pricing reimbursement framework might meet the needs of policy makers to manage the decision uncertainty around new and potentially innovative technologies. Eventually, Opportunities and Challenges in Emerging Decision Uncertainty Management Frameworks section considers emerging risk management frameworks from the perspective of health systems, manufacturers, and patients.

Decision Uncertainty in Healthcare Resource Allocation

Decision uncertainty can be thought of as the risk of making the wrong decision, the probability that the observed costs and outcomes will be sufficiently different from the expected costs and outcomes, that the option not chosen would have been better than the one chosen. Given that this is an unknown and one-off event, such probability is inherently a Bayesian rather than a frequentist concept. In the context of healthcare resource allocation decisions, the decision uncertainty is an accumulation of the uncertainty in the characterization of parameters in the decision problem, the characterization of the objectives of the decision process and the decision rules that flow from those objectives.

The extent to which decision makers need to take account of decision uncertainty is largely determined by the expected cost of making the wrong decision. The expected cost of making the wrong decision is determined by the probability of making the wrong decision given the currently available evidence and the expected health gains foregone and additional costs incurred due to making that decision. This is also known as the expected value of information (VoI). Where the expected cost of making the wrong decision is small, it is unlikely that investing in measures to reduce it will be justified, even when the decision uncertainty is high. Similarly, if the health gains foregone and costs incurred if the decision proves wrong are high, but the decision uncertainty is low, then investing in ameliorating mechanisms is unlikely to be efficient. However, with innovative technologies, healthcare systems are often facing a combination of high levels of decision uncertainty combined with high expected cost of uncertainty. In these circumstances, explicit consideration of mechanisms to reduce the expected cost of uncertainty is almost required for good stewardship of limited resources.

The simplest mechanism for reducing the cost of uncertainty is to reduce the cost of the technology; historically this has arguably been the most frequently used strategy. However, there are constraints on when this can be used and the degree of discount that is feasible. In pharmaceuticals, parallel imports, where drugs are bought in a low-price market and then sold in a higher price market, with the intermediary receiving the price premium rather than the manufacturer, are often cited as a reason for not using price discounts to manage risk. In some cases such as biologics, the cost of production of the technologies may mean that the scale of discount required

to reduce the cost of uncertainty to an acceptable level may be such that it would threaten its commercial viability.

If the expected cost of uncertainty cannot be reduced to acceptable levels through discounts, then there are a number of alternative drivers of the cost of uncertainty that can be addressed within the reimbursement decision process, some of which relate to the evidence for the technology, some to its clinical application, and some to the decision criteria used. Still others relate to the manner in which the technology is paid for by the health system.

Evidence and the Expected Cost of Uncertainty

The uncertainty in the evidence base for a new technology is the type of uncertainty that people consider most readily. It is recognized that for most new treatments, the evidence is provided by studies whose participants are very different from the patients who will be treated in everyday clinical practice; the length of follow-up in the studies is typically too short to provide any insight into the long-term effectiveness of the technology, and the number of participants is likely to be too small to uncover any rare but severe safety problems with the treatment. For technologies that treat previously untreatable conditions, it may even be the case that the health system will be substantially uncertain about how many patients have the condition of interest. To some degree the only way to be confident about how valuable a technology is, is to use it in a large number of 'typical' patients in routine clinical practice, and to do so for a reasonably long time. However, to do this simplistically entails the health system taking on the expected cost of the uncertainty. The development of Access with Evidence Development schemes, which are discussed in more detail in the section Decision Uncertainty and Innovative Payment Mechanisms, are an attempt to square the circle of generating real-world evidence on the value of a new technology while reducing a health system's exposure to the expected cost of the uncertainty.

Decision Uncertainty and the Clinical Application of a New Technology

Frequently the indications for the application of a new technology, as described in the license or the summary of product characteristics, tend to inclusivity. Where the value of the new technology is uncertain, reimbursement authorities will frequently seek patient subgroups within the licensed indication for whom there is evidence of a greater expected benefit than for the whole population. Even though, by definition, the uncertainty in the estimate for the effectiveness of this group is greater because the estimate is based on less data, the expected cost of uncertainty is reduced because the smaller number of patients reduces the budget impact and the expected value for the subgroup is more clearly below the decision threshold.

When reimbursement authorities are not in a position to identify a patient subgroup for whom to approve reimbursement, they may choose to impose a cap on the total budget impact of the technology. This strategy addresses the expected cost of uncertainty first by limiting the total expenditure directly and second by creating an indirect incentive for clinical practice to focus the utilization of the technology on those patients for whom it will be most beneficial. This strategy is particularly attractive where there is a significant risk of off-label use of the technology. In some cases, reimbursement authorities have linked manufacturers' payments to the achievement of predicted cost offsets in other areas of the budget, a form of financial risk sharing scheme that is distinct from the more widely known effectiveness-based risk sharing schemes. The advantage of this approach is that it creates an incentive for the manufacturers to discourage off-label usage as such use is less likely to generate the targeted cost offsets.

Decision Uncertainty and Reimbursement Decision Criteria

Healthcare resource allocation decisions are rightly subject to challenge by the patients, clinicians, and manufacturers who are affected by them. Arguably the most frequent challenge made to these decisions is that the value of the benefits of the technology has not been adequately captured in the evidence considered. Decision processes that assume the value of health gains are independent of the characteristics of the recipient, and are frequently challenged to take account of special factors such as the (lack of) alternative treatments, the severity of the condition, the imminence of death, the rarity of the condition, the age of the people affected, and even whether the health gain is produced in an innovative manner. All of these special factors attempt to shift the decision threshold and in doing so reduce the probability that the technology will prove not to be of good value, and thereby drive down the expected cost of uncertainty. The evidence base to specify decision criteria is both sparse and of variable quality. What evidence there is does not speak strongly to value premia for many of the proposed factors, but neither do they support a pure health gain maximization strategy. As a result the social legitimacy of these amendments to decision criteria frequently rests on the democratic legitimacy of the decision makers.

Decision Uncertainty and Innovative Payment Mechanisms

A final group of responses to decision uncertainty in reimbursement decision processes has been the development of new payment strategies. Conventionally, healthcare systems have paid for technologies in full prior at the time of their consumption, with the exception of large capital equipment such as magnetic resonance imaging (MRI) machines and surgical robots where leasing arrangements have been deployed. The effect of this is that all the risk associated with the uncertainty of the technology is transferred from the manufacturer to the health system before the outcome of treatment is known. Two distinct types of payment mechanism responses to this problem have been observed; the first operates at the individual patient level, whereas the second operates at the group level. Such schemes attempt to address decision uncertainty by reducing the expected budget impact and reducing the risk that payment will not produce the anticipated results.

Individual-level schemes – often referred to as payment by results, risk sharing, or Patient Access Schemes – link payment to outcomes for the individual patient. Beyond this basic shared characteristic, the specifics of the schemes vary. In

some, initial treatment is provided free of charge but only patients who respond to treatment continue with treatment that is paid for. With extremely expensive treatments, such as those for very rare diseases, the monitoring of response to treatment is sometimes a continuous process, so that if a patient stops responding, the funding can be stopped. In other schemes, patient treatments are funded up to a maximum number of administrations, after which the manufacturer provides the technology free of charge, the presumption being that only patients who are responding to treatment will remain on treatment beyond the maximum number of administrations.

Group- or population-level schemes tend to be referred to as Access with Evidence Development, Coverage with Evidence Development, or risk-sharing schemes. Under such schemes patients receiving the treatments will provide data on response to therapy as part of the scheme. These data are then used to inform a review of the reimbursement decision at a specified point in time. The review may lead to a change in the price or indeed a change in the reimbursement status. In principle, these group-level schemes offer a limit on the budget impact if the technology does not prove to be as valuable as hoped, and produces additional data to reduce the decision uncertainty.

Designing Patient Access Schemes

The range of policy responses to decision uncertainty in healthcare resource allocation has given rise to a relatively large number of labels in a remarkably short period of time: including risk sharing, coverage with evidence development, access with evidence development, patient access, and only with research (OWR). Behind all of these labels is a shared intention of achieving prompt patient access to the technology under consideration while attempting to ameliorate the expected cost of uncertainty associated with the reimbursement decision. Although the number of Patient Access Schemes is large, and the literature that comments around individual schemes is notable, substantial research on the principals that should inform their design and implementation is scarce.

The National Institute for Health and Clinical Excellence (NICE) has described the principals that will guide their assessment of a Patient Access Scheme, and the Commission for Medicaid and Medicare Services in the US is developing on guidance on the design of Coverage with Evidence Development schemes. In a similar vein, the International Society for Pharmacoeconomics and Outcomes Research is developing good practice guidance on the design of performance-based risk-sharing schemes. A Canadian group produced a consensus statement on the design of access with evidence development schemes in 2010, although this was based on a review of schemes that had worked well or not so well, rather than any clear theoretical framework.

Work on a theoretical framework for Patient Access Schemes is anchored in Decision Science, more specifically the VoI framework. Claxton and colleagues have focused on developing criteria to identify the efficient choice, for decision makers, between open and conditional reimbursement for a technology, and when the choice is for conditional reimbursement, to identify whether reimbursement should be only in research (OIR), i.e., only patients involved in the research have access to the technology, or OWR, which provides access for all patients as long as the research goes forward. Importantly, they have demonstrated that awaiting further research can be the correct decision even when the expected incremental cost effectiveness ratio is below the cost effectiveness threshold. It is the magnitude of the uncertainty, the budgetary impact of reimbursement, the feasibility undertaking the necessary research while the technology is generally available, and the reversibility of the investment that drive the value of further OIR or OWR Patient Access Schemes.

The work of Claxton and colleagues has tended to consider the burden of the uncertainty associated with specific parameters in a decision problem and not the details of the research that would be required to address that uncertainty. Their work is complemented by a series of publications from Willan and colleagues, who have developed methods for establishing the value of clinical trial research, taking due account of the time it takes for the research to report, costs incurred, and the value of any health gain foregone while the research is completed. More recently, Hall and colleagues placed this type of analysis in the decision framework used by Claxton, showing how to assess the expected value of an OIR and OWR Patient Access Scheme from the perspective of the healthcare payer. It is noteworthy that the work of Hall and colleagues indicates that OWR strategies are only likely to be an efficient use of health system resources when the expected cost of uncertainty is relatively low. These developments proffer real benefits to agencies interested in Patient Access Schemes as a means to reduce the expected costs of uncertainty by improving the evidence base for future decisions. However, this is only one component of the cost of uncertainty and only one of a number of possible objectives for a Patient Access Scheme.

Strictly, the VoI framework is not focused on Patient Access Schemes; rather it considers the most efficient means for generating additional evidence to inform a reimbursement decision. Achieving prompt patient access may be the result of such analyses, but it is not the primary concern. The primary concern is the risk that uncertainty in the evidence base may lead to the inappropriate reimbursement of an inefficient technology or the inappropriate rejection of an efficient one. The results of a well-designed and well-implemented VoI study may expedite or delay general patient access to a treatment. However, VoI does provide a framework for designing policy responses to uncertainty in the evidence base.

It may be useful, therefore, to differentiate between policy responses that have the reduction of uncertainty in the evidence base as their primary aim and policy responses whose primary aim is patient access to therapy. Within the former category, there are schemes that allow patient access to therapy while additional evidence is developed and schemes that constrain patient access in order to enable collection of additional evidence. In the latter category there are a range of schemes and they differ according to their secondary objective: (1) Patient Access Schemes that seek to reduce the cost per treated patient – in essence price discount schemes, (2) Patient Access Schemes that seek to limit the budget impact of the technology, (3) schemes that seek to target expenditure on those patients who respond to therapy, and (4) schemes that seek to develop evidence to inform future reimbursement decisions.

If policy responses that focus on the reduction of uncertainty are labeled Type 1, and responses that focus on patient access Type 2, six distinct categories of policy response to uncertainty in the evidence base can be defined: Type 1 OIR, Type 1 OWR, Type 2a, Type 2b, Type 2c, and Type 2d.

Understanding the specific type of scheme may help predict or explain observed policy responses to additional evidence. For example, Type 2d schemes may appear to be equivalent to Type 1 OWR schemes. However, the difference in the primary objective – reduced uncertainty versus patient access – is likely to lead to different policy responses to the same evidence. The UK multiple sclerosis risk sharing scheme is likely a Type 2d scheme. It was explicitly established to enable patient access to therapies that were not considered good value while at the same time collecting further evidence on the effectiveness of the therapies. Thus, accumulated evidence that might support changing the reimbursement status has received a very cautious policy response.

Evidence for the Success or Otherwise of Patient Access Schemes

The volume of Patient Access Schemes reported in the literature may well be the best evidence of their success. Decision makers keep returning to the schemes as a means of breaking the deadlock between patients and manufacturers on the one side and the limited resources of the healthcare system on the other. However, evidence that Patient Access Schemes have delivered affordable population health gain, or information to inform subsequent research decisions, is notable by its absence. Very few schemes have published reports of any data that have been collected and even fewer have reported estimates of the population health gain attributable to a scheme. By contrast, there is a substantial literature reporting problems with the process characteristics of Patient Access Schemes.

The Banff Workshop in 2010 identified problems with the process as one of the major impediments to success, where success was defined as observable changes in reimbursement and/or clinical practice in response to the evidence accumulated by the scheme. The same workshop, having reviewed published evidence and heard from experts involved in a number of different health systems, produced a consensus statement that emphasized the importance of governance in the establishment of schemes, if the intended objectives were to be achieved.

Linking Research and Reimbursement Decisions

Once a technology is licensed for use in a healthcare system, the typology of policy responses described in Section Designing Patient Access Schemes provides a useful framework for considering the linkages between further research and reimbursement. However, the reimbursement decision is also the mechanism that a healthcare payer has for signaling their willingness to pay for new technologies, and hence there is, conceptually at least, a link between reimbursement decision making and prelicensing research.

Considering postlicensing research and how it relates to reimbursement, the value of any research is dependent on the willingness of decision makers to change the reimbursement status in response to additional evidence. There is little, if any, convincing evidence that data collected as part of Type 2 Patient Access Schemes lead to changes in reimbursement status. The trial of lung volume reduction surgery, which many consider the first example of a Medicare Patient Access Scheme, produced strong evidence that the intervention was not effective and yet coverage of the procedure was not revoked. Similarly, the UK multiple sclerosis risk sharing scheme changed the rules in response to the first release of data, which indicated that the treatments were not effective, thereby avoiding a review of its reimbursement status.

There is an emerging interest in postlicensing trials of extremely expensive technologies such as Herceptin, rituximab, avastin, and lucentis (Table 1). Often these studies are at least partly funded by the healthcare payers and can often be cost saving in their own right, irrespective of the results that they provide, due to the cost of the technologies. However, there remains the challenge for decision makers of changing the reimbursement status when the studies report. In the absence of a commitment from decision makers to act on the evidence generated by such research, there must be questions about the ethics of enrolling patients to trials with a view to benefiting others, if the link to future reimbursement is fractured by the healthcare payers' reluctance to reverse a previous positive reimbursement decision. The recent decision by the UK NICE to reverse its positive recommendation for denosumab for prostate cancer is an encouraging development in this area.

Although postlicensing responses to uncertainty in the evidence base for new technologies are useful, they are a response to the problem that new technologies arrive at market that is often ill-suited to the needs of reimbursement decision makers. As market access is increasingly dependent on reimbursement rather than licensing and clinical use decisions, commercial considerations should lead companies engaged in developing new healthcare technologies to link their prelicensing research and development activities to the evidence needs of reimbursement decision makers. The VoI framework

Table 1 Examples of postlicensing trials of high-cost technologies

Study	*Technology*
FinHER study	Herceptin in early-stage breast cancer
PHARE trial	
Persephone study	
ARCTIC trial	Rituximab in CLL and in rheumatoid arthritis
SWITCH trial	
PARAMEDIC study	LUCAS CPR device
STAR trial	Sunitinib in locally advanced/metastatic renal cancer
IVAN trial	Ranibizumab in age-related macular degeneration
CATT trial	
OPTIMA study	Oncotype Dx for test-guided chemotherapy in early-stage breast cancer
RATPAC study	Point-of-care cardiac biomarkers
ELUCIDATE trial	Enhanced liver fibrosis test

that Claxton and colleagues have developed relatively fully for quantifying the value of research from the perspective of healthcare systems is increasingly being considered as a mechanism for evaluating prelicensing research investments.

The central observation that additional research, through reducing decision uncertainty, impacts on the probability of a positive or negative reimbursement decision is pertinent to both health systems and technology developers. However, the costs and benefits of positive and negative reimbursement decisions are very different. Specifying the cost and payoff functions for technology developers is arguably more complex than for healthcare systems, but it is likely to be at least as valuable. In a prelicensing context, additional research delays the time to licensing and thus the start of an income stream from the technology. It also 'burns' patent life and thus reduces the expected time from licensing to the onset of generic competition. These are costs that need to be captured in the evaluation of the investment. The characterization of benefit is also more complicated as evidence will inform decisions in a portfolio of healthcare systems. Each system is likely to operate different decision criteria and will differ in terms of the revenue stream to be expected conditional on a positive decision, reflecting different epidemiology and pricing policies. Willan and colleagues have started to examine these issues, but it remains a very immature literature. That said, it arguably has the greatest potential for matching research and development investment to technologies that will produce effects that patients and health systems will value and hence pay for.

A specific policy barrier to the wider utilization of these methods in the development of new technologies is the role of licensing authorities such as the Federal Drug Administration in the USA and the European Medicines Agency in Europe. Conventionally these organizations have focused on evidence of safety and efficacy rather than incremental value. Although the licensing authorities retain this focus and their approval continues to be a necessary but not sufficient condition for market access, technology developers will be understandably reluctant to adopt new strategies for designing and prioritizing prelicensing research and development. Although there are increasing communications between licensing and reimbursement authorities, the two communities appear to be still getting acquainted rather than developing coherent and complementary strategies focused on aligning research and the evidence needs of those who must decide whether and how much to pay for new technologies.

Value-Based Pricing and Decision Uncertainty

The concept of value-based pricing for health technologies is a relatively new one, but interest in it has grown rapidly. Initially, value-based pricing was thought of as a change in the mechanism for establishing the price of a treatment. Many healthcare systems are price takers. Reimbursement authorities consider whether a technology is of good value using the price that the manufacturer stipulates. The idea of value-based pricing is a simple one – why don't reimbursement authorities consider a technology and then specify the price at which it would represent good value. However, as consideration of how to operationalize this concept for real-world decisions has gathered pace, the debate about how to assess the value of a technology has intensified. In large part these discussions have covered the same arguments as the literature regarding the adequacy of the quality-adjusted life-year, as a measure of the effect of a technology, for use in cost effectiveness analysis. Equity arguments for value premia reflecting *inter alia* severity of ill-health, rarity, availability of alternative therapies, extensions of life at the end of life, and cause of disease have all been proposed as components of the assessment of value. The use of formal multicriterion decision-making processes has been proposed as a mechanism for capturing these disparate components of value. Although there is uncertainty if not outright ignorance about the relative and absolute value weights for these components of value, a multicriteria approach to resource allocation decisions is not a policy response to uncertainty.

Value-based pricing can be considered a policy response to uncertainty in that it allows decision makers to identify the price at which the expected cost of uncertainty does not support delaying reimbursement while further research takes place, or limiting reimbursed patient access during the research. However, in the context of the high cost and high levels of uncertainty associated with biologic, metabolomic, and genomic technologies, it is possible, even likely, that the price at which these conditions are met could have significant implications for the sustainability of private investment in health technology development and even the production of the technologies. In response to this concern, health policy makers are being encouraged to consider a premium for innovation and to allow prices to be revised upward if data from use of the technology in practice either reduce the uncertainty relating to its expected value or indicate that its actual value is greater than previously thought. The latter would represent a significant departure from current practice, where the price charged for a technology at launch is the highest price point, and subsequent developments will at best maintain the price and likely lead to price reductions. The data capture infrastructure required for the routine application of price adjustments based on observed effectiveness would be substantial, and it would be interesting to see whether there would be a symmetrical reluctance to increase price in the face of reduced uncertainty, reluctance to reduce price when evidence has suggested a technology has been less valuable than claimed. The incentives for gaming the system when the evidence of value is not derived from well-conducted randomized controlled trials will likely be significant, especially for therapies for common disorders.

The innovation premium is the added value attributed to a technology that does something that current technologies do not do, over and above the value attached to its effectiveness compared to currently available technologies. The justification for such a premium would likely rest in either the option value of subsequent alternative applications of the technology to meet other currently unmet needs or, when there is no evidence to support such an expectation, the value of the hope for such application. What is clear is that the innovation premium is a reward for 'newness' and thus likely to be highly and positively correlated with uncertainty. As such, the innovation premium works in the opposite direction to the expected cost of uncertainty and increases the likelihood of a positive reimbursement decision at any given level of decision

uncertainty. In the context of population health promotion, the magnitude of the innovation premium should depend on the option value of future potential applications. However, when healthcare organizations have implicit or explicit industrial policy objectives, such as the National Health Service in the UK and the Commission for Medicare and Medicaid Service in the USA, the magnitude of premium may partially reflect these considerations also.

A further potentially problematic characteristic of value-based pricing as a mechanism for addressing uncertainty is the creation of different prices for the same technology in different markets. Manufacturers are understandably concerned about differential pricing creating opportunities for parallel imports of their technologies acting as a downward pressure on their global revenue. Consumers in high-price environments such as the US, Germany, or France might procure their therapies in lower price markets such as Canada, Poland, and Spain. However, there are additional challenges associated with value-based pricing schemes for manufacturers. First, because knowledge is essentially a public good, health systems that are not engaged in a value-based pricing schemes may be able to free ride, even if the specifics of the additional evidence generated is kept confidential, as any change in price will be informative. Second, because healthcare systems differ in terms of budgets and the epidemiology of disease in the populations served, there will likely be much larger variation in prices between health systems than is currently observed, with an associated increase in the uncertainty in the expected return for investors.

Although value-based pricing is intuitively appealing as a response to uncertainty that will not require the reengineering of existing research and development processes, its operationalization for highly uncertain high-cost technologies may not be consistent with the sustainability of research and development investment. Further, its implementation may introduce new parameters into the decision problem about which there is substantial uncertainty from the healthcare payer perspective. At the same time, it may generate additional uncertainty regarding revenue flows for the manufacturers and investors, as prices arrived at through value-based pricing processes may differ markedly between healthcare markets even when the value criteria used are shared. New evidence generated through a value-based pricing mechanism in one system will likely influence prices in other systems; this may not be symmetrical; i.e., health systems may be more likely to 'free ride' on knowledge that supports a price cut than knowledge that supports a price rise. It may be that manufacturers would be more attracted to lower but more certain returns on their investment, compared to opening this Pandora's box.

Opportunities and Challenges in Emerging Decision Uncertainty Management Frameworks

Broadly there are four strategies for addressing the decision uncertainty facing reimbursement authorities driven by the mismatch between the evidence produced by conventional health technology development processes and the evidence required to inform efficient and equitable use of limited healthcare budgets: (1) Patient Access Schemes, which focus on achieving patient access alongside one or more secondary objectives such as per patient cost containment, total cost containment, and targeted use or evidence development; (2) research, which has the reduction of decision uncertainty as its primary objective. This may require that the technology is not available to patients except as part of the research (OIR) or may allow access to the treatment if that does not confound the required research study or is required for the research to proceed (OWR); (3) value-based pricing, which sets the price of the technology at a level that reduces the expected cost of uncertainty associated with reimbursement below the cost of requiring further research; and (4) reengineering the pre-licensing research and development process to meet the needs of reimbursement decision makers.

The first three strategies treat the focus of current research and development processes on the requirements of licensing authorities as immutable. They are more or less focused on the needs of the identified patients who will benefit from the newly licensed technology (1 and 3), or the needs of the unidentified patients who will bear the opportunity cost of reimbursing the new technology (2 and 3). The fourth strategy perhaps naively assumes that the structures within which technologies are developed can be redesigned and considers how it might be redesigned to match technology development investments to the objectives of healthcare systems.

The time it takes for investments in research and development to pay off means that policies that address problems with the conventional evidence development processes will be required for many years to come. However, this does not mean that work on developing a more efficient research and development process, focused on developing high-value technologies with 'reimbursable' evidence dossiers at the time of licensing, is not worth investment. That said, there are significant challenges to be addressed in developing the VoI framework to inform the design of research and investment processes.

VoI is predicated on a clearly specified payoff function – whether it be population health benefit or revenue from sales. For investors in mid- to late-stage clinical trials, the payoff function of interest is conditional on the objectives of the portfolio of healthcare systems that are the clients for the technologies they are seeking to develop. The methods for representing and combining these functions in assessing the value of alternative investments may not be intellectually trivial challenges.

Skeptics are likely to argue that much of the information that is pertinent to the decision problem cannot be known with any confidence so far in advance of the decision, and therefore early-stage VoI analyses are likely to involve as much guess work as knowledge. Although this is true, to use it as the basis for rejecting changes in the approach for designing research and development processes is to assume that a similar degree of guess work is not implicitly or even explicitly involved in the current processes. Given the high failure rate in the research and development process, and the problem with licensed technologies struggling to achieve reimbursement, it seems likely that the current process is based on at least an equally flawed assessment of the values and needs of future healthcare systems.

There are short-, medium-, and long-term challenges facing healthcare systems seeking to take a systematic approach to

managing the uncertainty in reimbursement decisions. In the short term, Patient Access Schemes are likely to be more not less prevalent and thus the total value of resources invested is likely to increase. Experience to date does not provide confidence that these schemes are automatically of good value to the health systems that enter into them. Careful design and governance may reduce the cost of uncertainty associated with these schemes. In the medium term, all these schemes rely to a substantial degree on capturing reliable evidence on the impact of therapies on patients in the typical clinical setting. Few health systems currently have routine data capture infrastructure fit for this purpose. The capacity for establishing successful Patient Access Schemes may well be among the more valuable, if less noticed, returns on investing in such infrastructure. On a longer term, all reimbursement authorities in healthcare – innovators, investors, regulators, clinicians, patients, and health systems – need to find mechanisms to align the research and development processes with the needs of all patients, signaling societies' willingness and ability to pay for health gain, so that the current incentives to invest large sums in high-risk candidates that may produce only marginal health gains are removed, leading to fewer marginal value and highly uncertain technologies being launched.

Pollution and Health

J Graff Zivin, University of California, San Diego, La Jolla, CA, USA
M Neidell, Columbia University, New York, NY, USA

Glossary

Ambient pollution Harmful contamination within a surrounding area, generally expressed as a concentration per unit of volume of air, for example, micrograms per cubic meter of air.

Avoidance behavior Actions an individual takes to reduce exposure to a pollutant.

Willingness to pay (WTP) The maximum amount of income a person would be willing to pay to reduce exposure to a certain amount of pollution.

Introduction

A primary objective of environmental policies worldwide is to protect human health. Optimal policy design, however, is typically hampered by limited information regarding both the benefits and the costs associated with regulation. Benefits assessments frequently rely on translating laboratory findings to uncontrolled settings, extrapolating from high- to low-concentration exposures within and across societies, and drawing inferences from observational analyses that do not account for the endogeneity of pollution. Economic assessments have typically focused on the costs of compliance to firms. Efforts to improve societal welfare clearly depend on a strong understanding of both elements. Although the health-pollution relationship largely remains the pursuit of epidemiologists, the focus of economics on casual identification along with valuation techniques consistent with utility maximization has helped to reframe these relationships in a manner that facilitates policy choice and environmental rule setting.

Early epidemiological investigations of the impacts of extreme pollution events were some of the first compelling studies to suggest a causal relationship, with one of the most famous focused on the 'killer fog' in London, England in December, 1952. A temperature inversion combined with windless conditions led to a sudden and dramatic increase in air pollution. Because residents were used to winter fogs, there was little, if any, changes in behavior, leading to a rather clean measure of pollution impacts in this case. The dramatic rise in mortality that precisely coincided with the timing of the fog had been a driving force behind the federal regulations aimed at air pollution control.

The pollution levels experienced under this and similarly studied extreme events, however, had been dramatically higher than those that nearly all people in developed countries face today. Moreover, most exposures do not conveniently arrive as a 'surprise' under which causal impacts can be easily assessed, and it is on this front that economists have made their most significant contributions. In particular, economic studies have typically focused on quasi-experimental settings in order to synthesize the 'surprise' of pollution. Besides improving the causal understanding of these relationships by minimizing threats from confounding, it has also identified important compensatory behaviors undertaken by individuals to mitigate exposure.

These behavioral responses are often nontrivial because many pollutants are observable, and even those that are not easily detectable by the public, such as ozone and particulate matter, are forecast and publicized through a broad range of media outlets. If optimizing individuals compensate for changes in ambient pollution levels by reducing their exposure, estimates that do not account for these responses will understate the biologic relationship between ambient pollution levels and health. This problem is potentially severe because the more an individual is likely to suffer under pollution, the more they have to gain from reduced exposure. Indeed, emerging empirical evidence finds that behavioral responses are largest for more vulnerable individuals (Neidell, 2009; Graff Zivin and Neidell, 2009; Graff Zivin *et al.*, 2011) and that individuals are more responsive to higher levels of pollution (Neidell, 2009; Mansfield *et al.*, 2006). Equally important, these behavioral responses are costly and thus ignoring them will also understate the welfare effects of pollution (or the regulation thereof). Although the costs of spending additional time indoors, rescheduling activities, or even relocating to areas with better environmental quality are often difficult to enumerate, they can represent a substantial fraction of the total costs of pollution.

In the remainder of this article, a basic economic framework for evaluating environmental health impacts is presented, followed by a discussion of the core empirical challenges that researchers face in estimating the relationship between pollution and health. A selective review of significant contributions from the literature that focus on the effects of air pollution is then provided, concluding with some suggestions for fruitful lines of future research.

Conceptual Framework

Estimation of the relationship between pollution and health is typically focused on the following health production function:

$$h = f(\mathrm{P}, \mathrm{A}, \mathrm{E}, \mathrm{S}) \quad [1]$$

where h is a measure of an individual's health, P is pollution levels assigned to the individual, and A is avoidance behavior. E are other environmental factors that directly affect health, such as weather and allergens, and S are all other behavioral, socioeconomic, and genetic factors affecting health. Given that

 doi:10.1016/B978-0-12-375678-7.00306-0

meteorological elements can play an important role in pollution formation and can also affect health (e.g., cold weather increases asthma exacerbation), E is defined separately because it represents an important source of environmental confounding.

Two main approaches are taken to eqn [1], with the difference stemming from the treatment of avoidance behavior. The first, or 'reduced-form' approach does not directly control for avoidance behavior. As health impacts will depend on ambient pollution levels and avoidance behavior that determines exposure to those pollution levels, the health relationship can be expressed as the following total derivative: $dh/dP = \delta h/\delta P + \delta h/\delta A * \delta A/\delta P$. The second, or 'production function' approach directly controls for avoidance behavior to obtain the partial derivative: $\delta h/\delta P$.

The importance in separating these two approaches is to relate each to the benefit calculation, or willingness to pay (WTP) for a reduction in pollution (Harrington and Portney, 1987; Cropper and Freeman, 1991; Deschenes and Greenstone, 2011). In the reduced-form approach, welfare is typically expressed as: $WTP = dh/dP * C_h + p_A * \delta A/\delta P$, where C_h is the 'full' cost associated with a change in health, and p_A is the price of avoidance behavior. In the production function approach, welfare is typically expressed as: $WTP = p_A * [(\delta h/\delta P)/(\delta h/\delta A)]$. Although the production function approach appears more data hungry because of the need to control for avoidance behavior when estimating eqn [1], the reduced-form approach must also control for avoidance behavior in order to estimate $\delta A/\delta P$, although this can be done separately from estimating eqn [1]. Furthermore, as these expressions demonstrate, all forms of avoidance behavior must be accounted for at some point in order to obtain a proper estimate of WTP.

One advantage of the reduced-form approach is that the econometrician does not need to properly specify the functional form of eqn [1] with respect to P and A. This is particularly helpful because data limitations often necessitate the use of proxy measures for avoidance behavior, and economic theory provides little guidance on how these proxy measures should enter into eqn [1].

The value of the production function approach is that it provides estimates of the biological effect of pollution. Because avoidance behavior is likely to vary across socioeconomic and cultural environments, but the biology is considerably less context specific, it facilitates generalizations across settings. Moreover, focusing on the biological effect enables one to potentially identify important nonlinear effects, such as threshold effects, and heterogeneous effects based on individual susceptibility, both of which can play an important role in defining the feasible set of policy interventions. Interested readers should consult Graff Zivin and Neidell (2013) for more elaboration on this framework.

Empirical Challenges

In this section, three primary challenges confronted by empiricists when estimating the relationship between pollution and health are outlined. Although weather is a potential confounder, this is not discussed at length because it is directly observable (often at a finer scale than pollution data), so that any threat can be obviated through the careful control of relevant variables.

Measurement of Health

The measurement of health outcomes and how to place monetary values on them is a persistent challenge. A frequently used measure is mortality, which is objectively measured and can be readily monetized using estimates of the value of a statistical life (VSL). One concern with using mortality is that it is an extreme outcome that misses more subtle outcomes that may be more commonplace. Furthermore, using VSL to monetize these impacts may be misleading if the loss only represents short-term mortality displacement, commonly referred to as 'harvesting.'

Measures of morbidity have also been examined using data on hospitalizations for various conditions, largely respiratory related. Although hospitalizations clearly capture events less severe than death, they may introduce sample selection. Those who have a relationship with a primary care physician (PCP) and receive regular care may never experience a hospitalization, and access to a PCP is clearly endogenous. Furthermore, the economic valuation of hospitalizations is particularly difficult as hospital charges (which are all that is typically available) do not capture the costs associated with the pain and suffering experienced by sickened individuals or their family members.

Birth outcomes are another metric that has some of the desirable properties of both mortality and morbidity endpoints, albeit for a select population. Like mortality and hospitalizations, birth outcomes are a census and not a sample, hence offering large sample sizes for analysis. Unlike mortality, birth outcomes can capture more subtle impacts, and unlike hospitalizations, they do not introduce sample selection because any birth that files for a birth certificate is reported. Valuation approaches can be used when the birth outcome studied has been linked to monetizable events – for example, birth weight has been linked with education and earnings (Black *et al.* 2007) – although these links may not capture all relevant costs.

An emerging area of focus is on indirect 'health' outcomes at school or the workplace, principally absenteeism and performance. Such outcomes offer terrific promise for capturing rather subtle health impacts that might be broadly disseminated throughout society. They are also generally straightforward to monetize, particularly for performance. Limited data availability, especially for representative samples, is a formidable obstacle to the conduct of credible empirical work in this area.

Assignment of Local Pollution Levels

Most studies focus on air pollution because of the availability of data from ambient air pollution monitors, which typically measure air concentrations at an hourly scale at a fixed location. Although this frequency of measurement generates data at a fine temporal scale, the limited number of monitor locations relative to the size of a country and the geographic distribution of the population leads to data that are rather

coarse on a spatial scale. As a result, studies often approximate contemporaneous pollution levels based on an individual's general location and the location of the monitor. This crude approach leads to measurement error that increases with an individual's distance from the monitor and the degree to which pollutants disperse nonuniformly. This measurement error will typically bias estimates downward, but with a large enough dataset, researchers can use data from multiple monitors and various weighting techniques to obtain more precise assignments of localized pollution levels. A finer level of geographic disaggregation for individuals, such as a residential address, also allows for better assignment of relevant pollution levels and hence is more likely to provide precise estimates.

The usual mobility of individuals in their everyday life (not in response to pollution, discussed below), both within a day and over time, can also present a measurement issue. Individuals spend their time not only at home, but at work, school, and other possible locations that are not typically recorded. Although the use of personal monitors is designed to overcome this, two issues remain: (1) the high costs of personal monitoring often result in the use of a small, unrepresentative sample without a clearly defined control group; and (2) the link to policy is less clear because indoor sources also contribute to pollution but are subject to different regulatory rules. Mobility over time also presents a significant measurement issue in assigning cumulative exposure over longer periods of time. Focusing on children, and in particular infants, whose parents are typically less mobile, can greatly limit this concern (Joyce *et al.* 1989; Chay and Greenstone, 2003).

Behavioral Responses to Pollution

Optimizing individuals may respond to pollution with permanent changes, such as relocating (i.e., sorting), and temporary changes, such as spending less time outside. As argued above, it is crucial to understand the role of these behavioral responses both to allow generalizations from one setting to another and to account for the full welfare costs of pollution. Although careful quasi-experimental designs can address permanent behavioral changes by exploiting exogenous shocks to pollution levels, short-run changes pose greater challenges because many of these responses involve nonmarket behaviors that are difficult to observe. For example, simply spending less time outside on a polluted day is a highly effective means for reducing exposure, but such an activity is rarely recorded. Clearly, the degree to which such short-run behavioral responses will be important depends on the 'visibility' of pollution, either literally, through information dissemination, or through health feedbacks that allow individuals to infer it on the basis of physiological responses.

Evidence

Rather than provide an exhaustive review of the economic literature examining the relationship between pollution and health, this section limits its attention to a selection of studies that offer key insights or introduce important methodological advances.

Primary Impacts

One of the earliest examples of a quasi-experimental approach to estimate an environmental health relationship in relatively recent times is found in a series of studies by Pope *et al.* (1992); Ransom and Pope (1992); Ransom and Pope (1995). The authors used changes in pollution that had resulted from the opening and closing of a steel mill, which was a major source of particulate matter, in the central Valley of Utah due to a labor strike. As the steel mill had closed due to a labor strike, the temporary changes in pollution were credibly exogenous and unlikely to lead to any immediate residential sorting. Furthermore, the authors selected a neighboring, unaffected community as a control group to account for time trends by estimating difference-in-differences models. When the steel mill was closed, the authors found significant declines in school absences, respiratory-related hospital admissions, and mortality. One potential concern with this study is that the steel mill closure has also led to a temporary change in income, which may affect one's use of time and services. This does not seem likely to be an issue for school absences, hence at least some of the findings are credibly causal. A more significant concern with the design is that, as an 'event study,' the pollution variable is common to all members in a group for a given time period (despite the availability of individual level health outcomes as dependent variables). As a result, their standard errors are likely to be nontrivially understated, making the appropriate statistical inference in this setting particularly challenging (Donald and Lang, 2007).

One important study by Chay and Greenstone (2003) overcame this problem by focusing on the recession of the early 1980s. The dramatic change in manufacturing that had resulted from this recession induced considerable spatial variation in total suspended particulates (TSPs) throughout the US in a short period of time, with some areas experiencing as large as a 35% decline in 3 years. These changes in TSPs are unlikely to be related to other factors affecting health. Importantly, although income changed considerably at the same time, it did not show comparable spatial patterns as with TSP. Using this exogenous variation in levels of pollution at the county-year level to identify environmental health effects, they estimate that a one-unit decline in TSPs associated with the recession yields benefits of roughly US$14 billion, recognizing that this captures only one health outcome and only for a specific group.

Although the Chay and Greenstone results are nontrivial, the continued improvements in air quality since then suggest that the results also apply to a time period when pollution levels in the US are considerably higher. Currie and Neidell (2005) turn their attention to infant mortality in California during the 1990s, a period that is much more reflective of contemporary pollution levels across much of the developed world. They use zip code fixed effects to account for residential sorting, thereby exploiting the strong temporal variations in pollution levels in the short-run due to changes in plausibly exogenous ambient conditions (rather than anthropogenic sources) to identify health impacts. They find that reductions in carbon monoxide over the 1990s saved approximately 1000 infant lives in California, which translates into benefits of roughly US$4.8 billion.

Currie *et al.* (2009), like Currie and Neidell (2005), focus on infant outcomes in a more recent time period, but use the exact address of the mother to improve pollution assignment and estimate sibling fixed effect models to control for differences in family background and genetics. They find that a one-unit change in mean carbon monoxide (CO) during the last trimester of pregnancy increases the risk of low birth weight by 8%, and a one-unit change in mean CO during the first two weeks after birth also increases the risk of infant mortality by 2.5% relative to baseline levels. The authors calculate that the 15-year decline in CO from 1989–2003 translates into US$720 million in lifetime earnings from improvements in birth weight and US$2.2 billion from the reduction in infant mortality for the 2003 birth cohort. The use of sibling fixed effects increases estimates, suggesting the importance of accounting for maternal characteristics within neighborhoods. And the better assignment of pollution by using the mother's exact address rather than zip code also increases point estimates, consistent with measurement error inducing a downward bias.

In a novel design, Lleras-Muney (2010) uses the relocation of military personnel to estimate the effect of various pollutants on children's health. The relocation of personnel is entirely based on 'the needs of the army', which explicitly rules out the possibility of sorting and offers a plausibly exogenous source of variation in pollution. Using this design, Lleras-Muney finds that a one standard deviation decrease in ground-level ozone exposure decreases the probability of a respiratory hospitalization for children by 8–23%. Her estimates suggest that lowering pollution levels nationwide to the levels experienced in 'low' pollution areas would save approximately US$928 million (US$1994) in direct medical expenditures alone.

All of the previously mentioned studies exploit 'natural' experiments that generate exogenous changes in ambient pollution in order to minimize concerns regarding residential sorting and other long-run behavioral responses to poor environmental quality. They generally ignore potential short-run adjustments that could also impact the environment-health relationship, and hence provide estimates of a reduced-form relationship between pollution and health. The key challenge in capturing these short-run behavioral responses is clearly the availability of data suited for the task, and researchers often follow creative paths for obtaining such data. One example is Neidell (2009), who uses attendance data from several outdoor facilities in Los Angeles to uncover significant behavioral responses to high ozone levels that are forecasted through smog alerts. As smog alerts are issued only when ozone is forecasted to exceed a particular threshold, he employs a regression discontinuity design to compare attendance on days just above the threshold to that just below. Although this paper does not provide estimates of the costs of avoidance behavior, in a closely related paper Graff Zivin and Neidell (2009) examine successive days of smog alerts to show that the costs of avoidance behavior, due to limited opportunities for intertemporal substitution, are increasing over time. Graff Zivin *et al.* (2011) identify substantial increases in the purchase of bottled water when local municipalities violate drinking water standards. As this type of avoidance behavioral is market-based, the authors have calculated the costs associated with it, and have found that water quality violations in 2005 induced roughly US$60 million worth of bottled water purchases nationwide.

Two notable studies attempt to produce estimates of the biological effect of ozone on health. In the paper discussed earlier, Neidell (2009) controls for smog alerts and ozone forecasts as a proxy for avoidance behavior when estimating the relationship between ozone and respiratory-related hospitalizations. Using zip code fixed effects and exploiting the strong daily temporal variation in ozone, he finds that including these proxies significantly increases the estimated impact of ozone on health. Moretti and Neidell (2011) use daily boat arrivals and departures into the port of Los Angeles as an instrumental variable (IV) for ozone levels, which deals with both avoidance behavior and measurement error in pollution assignment. Boat traffic represents a major source of pollution for the Los Angeles region and, because of the extended length of travel and unpredictable conditions at sea, daily variation in boat traffic is arguably uncorrelated with other short-run determinants of health and is not included in the ozone forecasts used to encourage avoidance behavior. Similar to Neidell (2009), they find that using boat traffic as an IV leads to significantly larger estimates for the impacts of pollution on health.

Although the short-run behavior literature has generally assessed the costs associated with avoiding exposure, this again represents a partial characterization of social welfare; a complete calculation requires an assessment of both avoidance costs as well as the costs of those adverse health effects that are not avoided. To our knowledge, the only attempt to bring both pieces together in a quasi-experimental setting is from Deschenes and Greenstone (2011), who focus on the health effects of extreme temperatures, which are forecast to increase under climate change. They construct a WTP estimate to avoid extreme heat that includes the costs due to excess mortality as well as expenditure on energy consumption as a proxy for air conditioning usage to buffer individuals from exposure to that heat. Using county fixed effects to exploit the plausibly exogenous variation in temperatures in an area within a given year, they find that the avoidance costs are roughly 25% of the mortality costs.

Secondary Impacts

Although most of the literature has focused on primary health endpoints, for example, mortality and hospitalizations, an emerging literature has begun to examine the manifestation of less visible health assaults on nonhealth outcomes. Although these impacts are referred to as secondary, it remains possible for them to exceed the costs of primary impacts depending on their prevalence. Almond *et al.* (2009) examine the impact from prenatal exposure to radioactive fallout from the 1986 Chernobyl accident on both birth and schooling outcomes for children in Sweden. Although Sweden is more than 500 miles away from Chernobyl, weather conditions forced some of the plume over Sweden, and local variation in rainfall levels led to stark geographic variation in the levels of fallout throughout the country. Their study reveals that radiation exposure exhibits latent effects that affect human capital development

later in life. Although they find little evidence of health effects as measured by birth outcomes and childhood hospitalizations, they find significant decreases in several schooling outcomes that correspond to roughly US$510 million in lost annual earnings.

Graff Zivin and Neidell (2012) also follow a nontraditional approach by examining the impact of ozone on worker productivity. They use a unique dataset on agricultural workers who are paid by piece rate and whose labor supply is highly inelastic in the short run, hence limiting the scope for avoidance behavior and the need to value it. Using models with worker fixed effects to exploit plausibly exogenous daily variation in ozone levels, they find that a 10 ppb decrease in ozone concentrations increases worker productivity by 5.5%, which translates into productivity benefits to the agricultural industry of approximately US$700 million.

Conclusion

Pollution affects a wide range of health outcomes, and these effects are nontrivial even at current emissions levels in the developed world. The optimal level of these pollutants is highly contested. For example, a proposed ozone standard issued by the EPA in 1997 was finally upheld by the Supreme Court in 2002, but only after endless appeals and lengthy lawsuits initiated by states and industry (Bergman, 2004). Better estimates of the relationship between pollution and health and society's WTP for improvements in pollution through the use of quasi-experimental research designs offers an important tool for informing this debate. Additional work on the measurement of avoidance behavior and its costs remains a critical piece of the puzzle.

Despite the growth of quality evidence on this topic, one area in need of more evidence is on the long-run effects from cumulative exposure to various pollutants. Although it is clear that pollution has shortrun impacts, the potential impacts from exposure over a lifetime may be considerably larger, as hinted at by the results from Almond *et al.* (2009). These impacts may also affect people's investment decisions throughout their life course, suggesting a wide range of potential economic outcomes that may be affected. The empirical issues are more daunting given the challenges in appropriately measuring health outcomes and pollution exposure, and the ability to isolate exogenous variation in pollution, but nonetheless deserve more attention.

The impact of pollution on human capital formation and its deployment in school as well as labor markets also represents a particularly fruitful area for additional exploration. The use of these indirect outcomes can capture a broader range of economic impacts, and they also have the ability to capture subtle, but likely more pervasive health impacts than those captured through standard measures of mortality and hospitalizations. As the improvement in biomedical understanding of the etiology of disease continues, this area of study is likely to rise in frequency and importance.

Preferred Provider Market

X Martinez-Giralt, Universitat Autònoma de Barcelona and MOVE, Barcelona, Spain

Glossary

Antitrust The legislation and processes in the USA by which a more competitive environment is created through the prohibition of certain practices deemed illegal by antitrust laws, such as price fixing, welfare-reducing mergers, and monopolization.

Bundled discounts A multiproduct seller which has market power over at least one of its products (i.e., the ability to charge an above-cost price for that product) and offers a bundle of several of its products at an above-cost price, attempting to exclude an equally efficient, but less diversified, rival.

Copayment An arrangement whereby an insured person pays a particular percentage of any bills for health services received, the insurer paying the remainder.

Deductible The amount of expenses in an insurance policy that must be paid out-of-pocket before the insurer will pay any expenses.

Downstream competition Capacity of a monopolist to control prices to force competing downstream buyers to sign tying contracts that will lever its monopoly into another market.

Duplicate coverage insurance (double coverage) Situation where an individual contracts two different insurance policies providing coverage for the same events.

First-mover advantage The advantage gained by the initial ('first moving') occupant of a market segment yielding a control of resources that followers may not be able to match.

Idle capacity Production facilities that remain unused because of lack of business. Also, a provider may hold strategic idle capacity to deter entry of a potential competitor by investing in capacity beyond the optimal level.

Indemnity Amount paid by the insurer to the insured by way of compensation for a particular loss. Typically, the insurance policy contemplates a ceiling to this compensation.

Joint ventures Agreement between two (or more) parties to take on a project. The participating parties contribute in money, time, and effort.

Mixed oligopoly Oligopolistic market structure where the objective of at least one firm differs from that of other firms. A particular instance contemplates a public firm aiming at maximizing some notion of social welfare competing with profit maximizing private firms.

Premium competition Insurers' strategic setting of the premium in insurance policies to attract individuals.

Strategic effects Study of the effects of the interrelation among competitors in oligopolistic markets on the decision making and outcome for each participant in the market.

Vertical integration Degree to which a firm owns its upstream suppliers and downstream buyers.

Introduction

In most countries, private health care insurance is provided by managed care organizations (MCOs). They appeared in the late 1990s as an alternative to the traditional fee-for-service health insurance contract. Their main role is to administer and manage the provision of health care services to their clients within a general objective of cost containment in the health care sector. In this sense, an MCO is a middleman contracting with health care providers on the one side and with enrollees on the other. The latter obtain advantageous fees when visiting in-plan providers and the former guarantee a larger base of clients. The most common types of these organizations are preferred provider organizations (PPOs) and health maintenance organizations (HMOs).

An HMO offers health care insurance to individuals as a liaison with providers (hospitals, doctors, etc.) on a prepaid basis. HMOs require members to select a primary care physician, a doctor who acts as a gatekeeper to direct access to specialized medical services whenever the guidelines of the HMO recommend it.

A PPO offers private health insurance to its members (health benefits and medical coverage) from a network of health care providers contracted by the PPO. The main characteristics of a PPO are:

1. health care providers contracted with the PPO are reimbursed on a fee-for-service basis;
2. enrollees in a PPO do not require referral from a primary care physician to access specialized care;
3. enrollees sign a contract defined by a fixed premium, a copayment on the health care services received, and possibly, a deductible;
4. enrollees have freedom to visit out-of-plan providers (with a possible penalty in the form of the payment of a greater share of the provider's fees);
5. drug prescription may be covered as well when enrollees patronize participating pharmacies; and
6. preventive care procedures (check ups, cancer screenings, prenatal care, and other services) may also be available.

To summarize, a PPO is a particular instance of integration between upstream providers and downstream third-party

payers. The aim of this article is to describe how providers compete to become preferred providers.

The PPOs Market Place

Competition in the health care market takes place at different levels. MCOs (and in particular, PPOs) compete to attract enrollees and providers compete for patients and compete to be selected by PPOs. Often, this competition develops in the framework of a regulated market by some public agency aiming at achieving some social welfare goal.

Most of the literature on PPOs deals with the selection of providers, with competition among providers (hospitals and physicians), and with the effects of the design of the insurance contracts on competition. Usually, it is assumed that individuals have already chosen an insurance contract. Some of these individuals may become ill and seek health care services. Sick individuals are referred to as patients. They are the focus of attention of the demand side of the market. Generically, individuals are supposed to make their choices to maximize their level of satisfaction. Focusing the attention on the choice of a PPO, an individual compares on the one hand the premium, co-payment, and deductibles of alternative insurance contracts and on the other hand, the set of in-plan providers. Also, the individual will try to guess how transparent is the information provided by the PPO on medical costs and its negotiation capacity as these are elements characterizing an insurance contract. Also, the individual may consider the plans of the PPOs to enlarge the present set of enrolled providers. All in all, the best plan for an individual reflects the balance between (expected) health care needs, the freedom to choose providers, and his(her) budget constraint. Finally, enrollees should have proper incentives to use the in-plan providers so that the PPOs fulfill their role in the health care system.

In the supply side of the market, one of the reasons for the appearance of MCOs is the need for cost containment in the health care system. As a consequence, managed care has transformed the way hospitals compete for patients and physicians. From competing in quality and provision of services and amenities, managed care introduces the so-called 'selective contracting' of providers. This means that not all available providers in a community are able to contract with the managed care plan. Accordingly, hospitals and physicians compete to be selected as in-plan providers. An issue appears on the size of the PPOs. The negotiation between a provider and a PPO to become in-plan determines the discounts that in turn, are linked to expected utilization. Therefore, the PPO faces a dilemma. Limiting the number of providers in-plan favors achieving the utilization levels, and thus the capacity to offer better deals to enrollees. But a too short list of in-plan providers may discourage individuals to contract with the PPO because it limits the freedom to choose. Empirical evidence seems to point to the prevalence of the obtention of lower prices associated with this selective contracting due to the capacity of the managed care plan to control the number of providers and idle capacity. Also, the size of the managed care plan may be an additional element toward lower prices. The selective contracting mechanism has induced a process of integration between providers and insurers. In this integration, we find upstream health providers deciding first the prices charged to the insurers for a bundle of services, and next insurers deciding the premiums of the (menu of) contracts offered to individuals. The interesting finding is that net revenues, upstream or downstream, result from the combination of a competition effect and a coordination effect. The former reflects the impact of downstream competition on upstream providers; the latter captures the efficiency gains from integration. A PPO, by maintaining some separation between providers and insurers, softens premium competition with respect to the other more integrated structures like HMOs. Accordingly, PPOs emerge as more profitable than HMOs, adding an argument to the popularity of PPOs.

Surprisingly enough, there is very little literature on the process of selecting providers and on competition among providers when different reimbursement rules apply, according to the provider chosen by the patient. Generally, patients have to bear part of the cost of the treatment provided by an in-plan care provider. If an out-of-plan care provider is visited instead, the patient pays the full price and obtains the indemnity from the insurer specified in the insurance contract. It should be clear that the setting of the indemnity associated with the out-of-plan provider is a crucial element in the choice of an insurance contract. Three alternatives can be envisaged, capturing three organizations of the health care systems.

The first one simply does not provide coverage for choices outside the preferred provider set. This is called a pure preferred provider system that captures a pure public system of health provision, such as the Spanish one, where a patient visiting a private provider (instead of a public one) has to bear the full cost of the treatment (unless the patient has some duplicate private insurance). The second alternative, labeled fixed co-payment rule, defines an indemnity equal to what the patient would have obtained had she(he) visited a preferred provider (that is the price of the in-plan provider is used as reference price to determine the indemnity). This alternative captures the idea of indemnity based on a reference price inspired by some features of the French system. Also, it captures some important features of the pharmaceutical sector. Finally, the third alternative, the so-called fixed reimbursement rate rule, considers the same co-payment rate on all providers. It is equivalent to the scenario where all providers have been selected by the insurer. This captures some features of the German system, where, together with the public providers, there is a fringe of private providers regulated through bilateral agreements.

There is also an alternative way to endogenously form the PPO. This is the so-called any willing provider mechanism. Under this approach a third-party payer announces a reimbursement rate and the set of health plan conditions. Any provider finding these acceptable is allowed to join the network.

When providers make simultaneous decisions on prices and qualities, this set-up approaches the primary care sector, whereas when decisions are sequential, first (high-cost, long-run decision on) qualities and then (low-cost, short-run decisions on) prices, the set-up approaches the specialized health care sector. When the market is organized around profit-maximizer providers, the fixed-co-payment rule on the primary health care sector is enough to make providers choose the optimal (welfare-maximizing) price and quality levels. In

contrast, there is no way to attain such an outcome in the specialized health care sector, unless some regulation is introduced. This issue is discussed next.

Alternatively, the mixed public–private provision of health care and the regulation of the market by a public health authority can also be considered. Two scenarios are envisaged. In the first one, an agency regulates both price and quality of the public provider and acts as a Stackelberg leader whereas private providers are followers. It turns out that the first-mover advantage of the public provider coupled with a fixed co-payment rule are sufficient instruments to achieve the first-best allocation. In the second scenario, regulation takes the form of a three-stage game where the regulator sets the level of quality to maximize welfare, then the private providers decide their quality levels, and finally providers compete in prices in a mixed oligopoly fashion. Now, leadership by direct operation of one provider does not ensure achievement of the social optimum, due to the strategic effects resulting from the sequential nature of the decisions. Comparison of these two ways of modeling the role of a public regulator allows to derive some normative conclusions on the implementation of price controls in the health care systems of some European Union member states. All governments have looked at ways to contain health expenditures. Direct and indirect controls over health care providers have been imposed in some countries where co-payments play an important role. In several countries, controls on prices (pharmaceuticals, per-day treatment in hospitals) exist, whereas in others, no such controls exist. Co-payment changes have been frequent in the European countries, mostly limited to the value of the co-payment, whereas maintaining its structure (fixed reimbursement rates). Moreover, co-payments are designed with insurance coverage in mind (typically, they have an upper limit). No role as a market mechanism underlies the choice of the structure and the value of co-payments. Thus, the relative unsuccessful episodes of cost containment through co-payments is not totally surprising. The structure of the co-payment has been kept constant, although the results reported highlight the fact that changing its structure would have a greater impact.

Anticompetitive Scrutiny of PPOs

It has been mentioned in the Section Introduction that a PPO can be seen as the vertical integration between upstream providers and downstream third-party payers. As it is well-known in the economics of regulation, vertical relations may jeopardize market competition. This is so in the private health care market as well.

In the UK, concerns on limits to competition in the provision of private health care, has prompted the Office of Fair Trading (OFT) to its scrutiny. In particular, attention is focused on the level of concentration among providers of private health care, barriers to entry, restrictions on the ability of medical professionals to practice, and consumers' access to providers. The report appeared in December 2011 (the report can be downloaded at http://www.oft.gov.uk/shared_oft/market-studies/OFT1396_Private_healthcare.pdf) led the OFT to undertake a public consultation on its findings which closed in January 2012 (see the associated press release in http://www.oft.gov.uk/news-and-updates/press/2012/26-12). A special report on this study has been published by Health Insurance in January 2011 (issue 158, pp. 14–15, see http://content.yudu.com/A1r4do/HIJan2011/resources/index.htmreferrerUrl=), assessing the viewpoints of private hospitals and doctors, and insurers. They share aims but also face difficult trade-offs. Although insurers agree with hospitals and doctors on the need to guarantee prices and patient flows, they disagree on the patients' capacity to choose among a variety of providers. Finally, hospitals and doctors align with insurers on preventing shortfalls but disagree on the meaning of 'keeping costs at a reasonable level.'

The European Union antitrust authorities are virtually silent on anticompetitive issues around PPOs.

In the USA, the Federal Trade Commission (FTC) acknowledges the changes occurring in the health care market place, so that antitrust enforcement is essential to guarantee the performance of a health care system based on the systems of delivery of health care competing for consumer acceptance. In its report of 2004, the FTC remarks that its activity addresses two basic questions. One refers to the current role of competition in health care and how it can be enhanced to increase consumer welfare. The second one deals with the way antitrust enforcement protects existing and potential competition in health care. Regarding the PPOs, two areas of activity of the FTC are highlighted: bundled discounts and network joint ventures. Bundled discounts refer to the combined sale of two or more products and services at a lower price than the sum of the prices of those goods and services when bought separately. An instance of bundled discount would be proposing discounts to insurers in tertiary services if the insurers made a PPO the sole provider for primary, secondary, and tertiary services. The proper test to prove the existence of bundling requires to show that the price of the bundle is lower than the seller's incremental cost. This is not simple because antitrust laws do not provide clear guidelines.

Physician network joint ventures are under the scrutiny of the FTC because they may reduce and even eliminate competition among the participants in the venture, and they may rise impediments to effective competition among different networks or health plans operating in the same market. Some providers excluded from the network joint ventures have filed complaints of monopolization of the market. However, evidence to support such complaints is difficult to obtain.

A different phenomenon widely studied is hospital mergers. Besides the traditional arguments of enhance efficiency and market power, another motive behind hospital mergers is the improvement of the bargaining position against MCOs. Some empirical evidence suggests that most consolidation of competing hospitals favor price increases in their markets, so that the market power motive seems to offset the efficiency argument.

Silent PPOs

In the early 1990s in the USA, a practice started by which one health plan was selling or renting its provider network (and the network discount rates) to another insurer without the provider's knowledge. This practice has been labeled as 'silent PPO.'

To illustrate, remember first that a physician's reimbursement, when providing out-of-network services, is higher than the in-network fee. Now, consider a physician member of a certain PPO who receives the visit of a patient whose insurance company has no agreement with this physician's practice. Typically, these insurers are organizations without networks of their own. Accordingly, the physician expects to receive the full bill charge from the patient's insurer. The patient's insurer when receiving the bill (and without the knowledge of the patient) assesses whether the physician belongs to a network with a negotiated discount. Then, it enquires about the possibility of the physician's PPO allowing the patient's insurer to use its negotiated discount (this is called the secondary discount market). If so, the physician receives a discounted reimbursement instead of the full payment for the treatment provider, so that even though the patient's insurer does not belong to the PPO, it reimburses the health care services as if the physician would be an in-plan provider. In short, out-of-network services are reimbursed at in-network prices. Figure 1 illustrates the discussion considering a scenario with two PPOs. Physician 1 in PPO1 receives a fee f when treating an in-network patient, and expects a fee $F > f$ when treating an out-of-network patient.

In principle, this need not be an illegal practice. It depends on the terms of the agreement between the insurer and the provider. Such agreements may contain an assignment provision allowing the health plan to offer the contract conditions to anyone willing to pay the agreed fees. Sometimes, there is written consent for the assignment to occur, sometimes there is no express consent or advance knowledge of the provider of such extension of the benefits to other health plans.

Initially, the term 'silent' PPO referred to a PPO where the contract was silent with regard to the commitment of the PPO to direct and encourage its patients to visit the in-plan providers. In the early 2000s however, the term changed to refer to improper and illegal practices. The American Medical Association (AMA), the American Hospital Association (AHA), and the American Association of Preferred Provider Organizations (AAPPO) have taken stance against these practices, and actively tried to encourage legislative actions against them. The problem arises because the providers (physicians and hospitals) realize the situation ex-post, once the treatment has been provided and billed. Accordingly, it falls in the hands of the providers to ensure that only patients enrolled in the PPO receive the discounted fees, whereas outside patients are billed the full price of the treatment received.

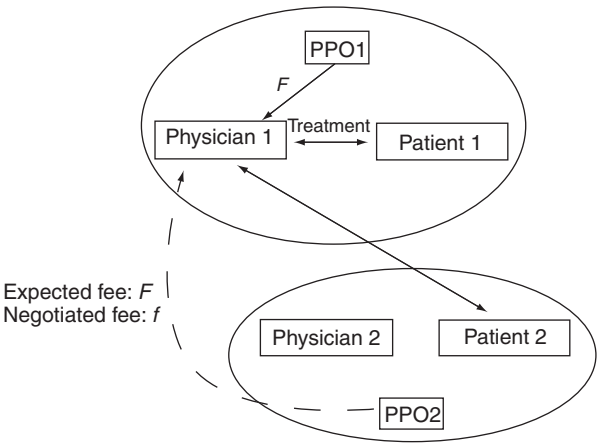

Figure 1 Silent PPOs.

Final Remarks

Preferred provider organizations are the most popular forms of private provision of health care. It balances in the best way the trade-off between insurers and individuals on the one hand, and between insurers and providers on the other. That is, the freedom of individuals to choose providers and the terms of the insurance contract on the one hand, and the base of patients and the discounted fees on the other, with respect to other forms of managed care.

All these agents meet in the market place, where two features are of particular concern. The first one, the structure of PPOs vertically integrating upstream providers and downstream third-party payers, raises the inquiry from the antitrust authorities. The second refers to the degree of transparency of the terms of the contracts between insurers and providers that have promoted legislative initiatives to prevent the better informed party from taking advantage of imperfect information.

Preschool Education Programs

LA Karoly, RAND Corporation, Arlington, VA, USA

Introduction

In recent years, it has become increasingly common for children to be enrolled in preschool education programs for one or more years before the traditional starting age for primary school. According to data from the World Bank, during 2010, 48.3% of preprimary-age children were enrolled in school, a rate that was just 34.1% a decade earlier. Although preprimary enrollment rates in high-income countries far exceed those of low-income ones (82.2% on average vs. 14.9% on average), enrollment rates have been rising since a decade in countries across the development spectrum. Preschool participation rates are not strictly related to the level of economic development, however. Even among high-income countries such as those in the Organization for Economic Cooperation and Development (OECD), there is considerable variation in the share of 3- and 4-year olds enrolled in preschool programs (see Figure 1). Although the preschool enrollment rate during 2009 exceeded 90% in Belgium, Denmark, France, Germany, Iceland, Italy, Norway, Spain, and Sweden, it was not even half that rate in Greece, Ireland, Korea, Switzerland, Turkey, and the US.

The high and rising rates of preschool enrollment across most countries reflect a growing demand among parents for early learning opportunities before the age at which school traditionally begins, as well as enthusiasm on the part of governments across the globe for supporting such programs with public funds. Interest in early childhood investments have been bolstered by research in early childhood development, which has advanced toward a more in-depth understanding of the importance of the early years for lifelong health and development. Emerging evidence from neuroscience, molecular biology, genomics, psychology, and social sciences have converged to provide a new paradigm pointing to the role of both genes and the environment for shaping physical and mental health from the point of conception through to adulthood. Early adversity from nutritional deprivation to insufficient emotional support, or limited cognitive stimulation can trigger the human body's stress management systems in ways that can be protective or harmful, depending on the available supports. These scientific findings serve as a foundation for the theoretical framework put forth by the Nobel Laureate of 2000 in Economics, James Heckman along with his colleagues, which views skill formation as a life-cycle process wherein abilities are both inherited and developed. In this framework, the development of human capital at one stage in life boosts skill attainment at later stages, and early investment improves the productivity of later investments, resulting in a high rate of return to early investment, as skill begets skill.

In the light of these trends and scientific foundations, the goal of this article is to highlight the specific research base that provides support for early education investments. In particular, two strands of research put together strengthen the support on the part of policymakers, practitioners, and parents for preschool education. First, a growing body of evaluation evidence has demonstrated that high-quality early learning programs can boost school readiness and provide long-term benefits in multiple domains. Second, benefit–cost calculations by economists have confirmed that effective programs can more than pay back their costs. Although there are some important caveats and knowledge gaps in each of these research areas, the case for preschool investments rests on a solid research foundation.

Throughout this discussion, it is important to bear in mind that preschool programs defined herein serve children 1 or 2 years before formal primary schooling begins, taking on various forms depending on the country, time period, source of funding, and provider (an even broader array of early childhood intervention models, not being considered here, begin as early as pregnancy and offer services to parents and children in home and center settings in the first 3 years of life, sometimes beyond). Preschool programs may focus on one or more developmental domains including language and cognitive development; behavioral, social, and emotional competencies; and mental and physical health including nutrition. Programs may be delivered in a group setting, such as a child care center or an elementary school; in some countries, home-based providers also offer formal early learning programs. Program intensity can vary, with offerings over 1 year or multiple years that range from part-day programs delivered during the academic year to full-time year-round programming. In addition to programs centered on the child, some programs also engage the child's parents in the learning process through home visits, parenting classes, and other activities. Finally, programs may be fully or partially subsidized by the public sector, with parents or other private sources of support (e.g., employers or philanthropies) filling any gaps.

Evidence from Program Evaluations

For many, the findings from brain research and other developmental science is sufficient justification for providing children – particularly those with disadvantaged backgrounds – with various developmental supports, including formal early learning programs. Yet, preschool programs can take many forms, with considerations for features such as the number of children in a group setting, the ratio of adults to children, the education and training background of the caregivers or teachers, and the choice of an early learning curriculum. With uncertainty over what constitutes an effective program – one that will achieve the goal of supporting children's developmental progress – a body of evaluation research has accumulated to assess the effectiveness of particular program models or specific program features.

The gold standard for evaluation evidence is an experimental design. If outcomes of children who are enrolled in a

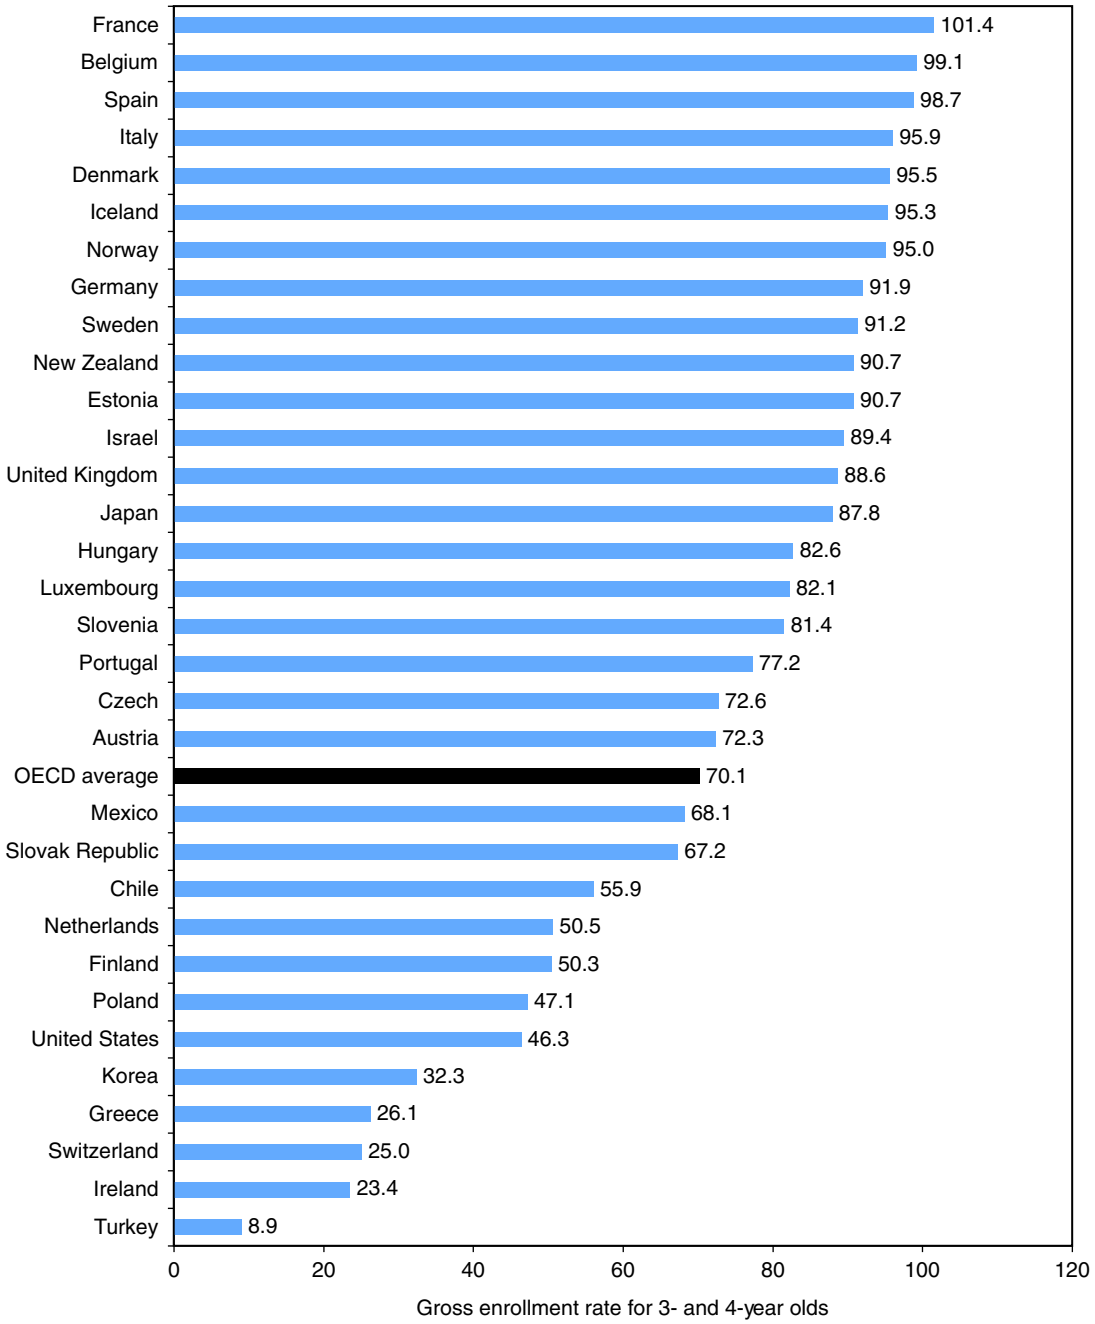

Figure 1 Gross enrollment rates for 3- and 4-year olds in OECD Countries: 2009. Reproduced from OECD (2011). *Health at a Glance 2011: OECD Indicators*. OECD Publishing. http://dx.doi.org/10.1787/health_glance-2011-en. The rate for Canada was not available.

preschool program are compared with those of children not enrolled, the observed differences may arise from the program itself, or from other factors that influence parental choice regarding preschool enrollment as well as child development. This issue of selection bias is avoided with a well-designed experimental study. Random assignment to the treatment group (program participation) versus the control group (no participation) ensures that all other possible determinants of child outcomes are controlled for, so that any observed differences in outcomes between treatment and control children are the result of the intervention.

Of course, experimental studies may be unethical and impractical, or too costly to launch. In such cases, quasi-experimental methods that closely replicate experimental conditions may be feasible. For example, one common method used in the US to evaluate a number of state-funded preschool programs for 4-year olds is a regression discontinuity (RD) design. This approach exploits the strict age-cutoff used to determine when children can enroll in a state preschool program. Effectively, this method uses the accidental birth to compare a child whose birthday occurs just before the enrollment cutoff (and is therefore able to enroll

and experience the preschool treatment) to a child who just misses the birthdate cutoff (and therefore does not experience the program being unable to enroll until next year).

Rigorous Evidence from the USA and Other Countries

In the US, rigorous evaluations of voluntary preschool programs serving 3- and 4-year olds have been conducted for small-scale demonstration programs implemented during the 1960s and targeted to very disadvantaged children, such as the High/Scope Perry Preschool Program and the Early Training Project, and for programs implemented on a large scale and evaluated for more recent cohorts of low-income children such as the Chicago Child–Parent Centers (CPC) program by the Chicago public school system and the federally funded Head Start program. More recently, the RD quasi-experimental method has been used to assess the impact of several state-funded preschool programs targeting children from low-income families as well as Oklahoma's preschool program, which is one of the few programs for 4-year-old children in the US.

Taken together, the evidence from the US evaluation research – synthesized in studies by Barnett, Burchinal, Gormley, Pianta, Shonkoff, and others – has demonstrated that well-designed preschool programs can improve child developmental outcomes on both short- and long-term bases. Based on an assessment of the literature from the US by Karoly and colleagues, Table 1 lists the specific outcomes that have been significantly affected by at least one rigorous (i.e., experimental or well-designed quasi-experimental) evaluation of a preschool program serving children for 1 or 2 years before kindergarten entry. The bulk of the evidence base is in the first tier of Table 1, as all preschool evaluations measure some early childhood outcomes. Most evaluations, for example, find significant favorable effects on one or more developmental measures that are assessed during the program or soon after. Such outcomes in early childhood include measures of general intelligence or intelligence quotient (IQ), assessments of school readiness such as specific prereading and premath skills, as well as gains in socioemotional or behavioral competencies. Meta-analyses across multiple studies being conducted in the US tend to show larger average treatment effect sizes for impacts on cognitive outcomes – in the range of 0.2–0.3, when compared with impacts on socioemotional or behavioral outcomes. Larger impact estimates have been found for specific studies and these indicate that intentional design can boost program impacts beyond those measured for typical programs. The magnitudes found for the most effective programs are large enough to close half or more of the achievement gap between disadvantaged children and their more advantaged peers.

Table 1 Outcomes with favorable impacts from preschool interventions

Lifecourse stage	*Specific outcomes for participating child*
Outcomes in early childhood	IQ behavior, social competence developmental milestones, general health status, immunization abuse and neglect, school readiness
Outcomes in school-age years	Achievement tests, grade repetition, special education use, grades high school completion, college attendance, teen pregnancy
Outcomes in adulthood	Employment earnings, use of social welfare programs, criminal activity, use of tobacco, alcohol, and drugs

A more limited evidence base supports the second and third tiers in Table 1, with confirmation of the benefits from preschool programs continuing into the school-age years and persisting beyond. Studies with follow-up intervals, pertaining to elementary school and later grades – such as the Perry Preschool and Chicago CPC evaluations – demonstrate higher achievement scores, reduced rates of grade repetition and special education use, and higher high school graduation rates. These two studies, with continued follow-up into adulthood (age 40 for Perry Preschool and age 26 for Chicago CPC), also find favorable impacts in other domains like employment and earnings, social welfare program use, criminal activity, and health behaviors. Many of these same impacts are found for other targeted intensive early intervention programs such as the Carolina Abecedarian Project, which provides full-time year-round center-based educational programming till kindergarten entry, starting just few weeks after birth.

In many European countries, where preschool participation rates are almost universal, fewer experimental or quasi-experimental studies have been conducted. Longitudinal studies such as the 1958 British Cohort Study and the 1997 Effective Provision of Preschool Education Project in England provide observational evidence of the favorable effects of preschool participation on child development both in the short and long runs. In developing countries such as Argentina, Jamaica, Mauritius, the Philippines, Turkey, Uganda, Uruguay, and Vietnam, a number of experimental and quasi-experimental evaluations of preschool programs have been implemented, often in combination with other services pertaining to child health and nutrition. Recent syntheses or formal meta-analyses of the evaluations of non-US programs, conducted by Nores and Barnett and by Vegas and Santibañez, among others, document that the favorable impacts found in US studies across multiple developmental domains are replicated throughout the range of low-income to high-income countries. At the same time, there is also considerable variation in the magnitude of the impacts across program models. Such differences may be attributable to program design or the populations served.

Limitations of the Knowledge Base

Although the cumulative evidence from rigorous evaluation studies is very compelling, it is important to recognize the limitations of the research to date. First, much of the evidence of preschool program benefits have stemmed from studies of programs targeting disadvantaged children. This is especially true for the kind of research in the US where both small-scale demonstration programs and large-scale models like Chicago CPC or Head Start serve children in families with limited

resources or other disadvantages. One exception for the US is the evaluation of Oklahoma's universal preschool program, which has demonstrated significant favorable impacts across income and race-ethnic groups, although the evidence suggests that the benefits from preschool participation are greater for the more disadvantaged children. Nevertheless, even children from families with income above poverty are likely to face various stressors that can comprise their healthy development and readiness for school. The Oklahoma results suggest that the benefits from participation in a high-quality preschool program may be broadly shared.

Second, evaluations of specific preschool programs demonstrate proof of the principle that high-quality early learning programs can improve child developmental outcomes on both short- and long-term bases. However, such evidence does not confirm that every program will necessarily have favorable impacts or effects that are equal in magnitude to those found in specific evaluations. In most cases, existing evaluations quantify the impact of specific combinations of preschool inputs as a bundle: group size, staff–child ratio, curriculum, teacher education and training, teacher–child interactions, total hours spent in the program, and so on. The evaluation can neither tease apart the effect of specific inputs nor identify the impacts that would result with some different combination of factors. Essentially, the research to date largely treats each evaluated preschool program as a 'black box' sans the ability to identify which program factors account for the measured impacts. Implementing programs with different combinations of inputs or with different levels of intensity may well produce different impacts, but how much different remains largely unknown. Given these limitations, ongoing research is seeking to understand issues such as whether there are minimum levels of quality required for programs to be effective and how program impacts vary with program dosage (e.g., annual hours in the program).

Third, as participation in some form of early care and education has become more common over time, especially in high-income countries, it has become challenging to measure the impact of preschool program participation against a true 'no program' control group. For example, in the national Head Start experimental evaluation conducted during the early 2000s in the US by Westat and others for the US Department of Health and Human Services, 48% of the 4-year olds in the control group participated in some form of center-based program and 13% attended some other Head Start program than the one they were randomized out of. Thus, the experimental evaluation had measured the effect of participation in Head Start against the status quo where nearly half of 4-year-old children living in poverty were already in some form of early education program. In contrast, when programs like Perry Preschool were evaluated in the 1960s, US children in the control group did not have access to other early learning programs, and were thus in a control condition of parental care only. In other countries with very high preschool enrollment rates, the opportunities for measuring program impacts against a 'no program' control group are very limited. For this reason, ongoing research is centered on assessing the impact on child developmental outcomes from different preschool program designs so as to identify which program models are most effective, rather than trying to assess whether programs have an impact when compared with the alternative of no program participation.

Economic Case for Preschool Investments

In an era of result-based accountability, there has been a growing interest in the US and other countries in demonstrating that the investments in public sector programs generate a favorable economic return to the public sector or at least to society as a whole. This has prompted increased application of benefit–cost analysis (BCA) methods to social policies, including early childhood programs.

The BCA methodology requires (1) a comprehensive measure of program costs relative to the baseline without the program; (2) evidence of the causal impact of the program relative to the same baseline; and (3) the ability to value all the program impacts in a common monetary value, often called 'shadow prices.' The method then compares the present value of the stream of program costs with that of the stream of lifetime program impacts (whether favorable or unfavorable) to determine whether net benefits are greater than zero or alternatively the ratio of benefits to costs is greater than one. This accounting of benefits and costs can be conducted from the perspective of different stakeholders. Most common is to calculate the economic returns for the public sector – accounting for the costs or benefits to taxpayers of a given intervention. The most comprehensive perspective is for the society as a whole, accounting for benefits and costs that accrue to the public sector as well as private benefits and costs that accrue to program participants and non-participants.

The Application of Benefit–Cost Analysis to Preschool Programs

For both preschool programs and other early childhood interventions, one of the challenges in applying BCA is that many of the outcomes affected by these programs are neither easily valued in dollars nor in some other monetary unit. The early childhood outcomes listed in the first tier in **Table 1** including those related to child health are ones where ready shadow prices do not exist for the most part. Consequently, BCA has not been employed for many preschool interventions. When the tool is used, the lack of ready shadow prices means that the economic returns tend to be understated because benefits are undercounted relative to costs.

Given the challenge of placing an economic value on early childhood outcomes, the application of BCA to preschool programs has mostly been limited to those programs with long-term follow-up into the school-age years and beyond, because more of such outcomes can be valued. For example, if a preschool program leads to reductions in the use of special education services, then that represents a savings to the public sector because children will be enrolled in regular education classes instead of the more costly special education programs. Likewise, if a preschool program boosts high school graduation rates, then that can lead to an increase in lifetime earnings for the children when they reach adulthood, and those higher earnings can generate more tax revenue to the

government. Achieving higher educational attainment is also likely to reduce the use of social welfare programs and lower the incidence of crime. Therefore, benefits in these areas may be projected based on any measured educational gains; or these outcomes may be directly observed as they have been in the long-term follow-ups of the Perry Preschool and Chicago CPC evaluations.

As two of the preschool programs with long-term follow-up, the Perry Preschool and Chicago CPC programs have been the focus of a series of BCAs. As shown in Table 2, Perry Preschool has been the subject of at least five different BCAs, three are conducted by the High/Scope evaluation team using updated information at each adult follow-up stage (studies (a), (b), and (c), using follow-up data at ages 19, 27, and 40, respectively) and two are conducted by other research teams using somewhat different methods (studies (d) and (e) based on follow-up data at ages 27 and 40, respectively). The Chicago CPC program has been the subject of two BCAs by the evaluation team using follow-up data at ages 21 and 26 (studies (f) and (g), respectively). Table 2 also shows the benefit–cost ratio for a study by the Washington State Institute of Public Policy, which is based on a meta-analysis of early childhood education programs serving 3- and 4-year-old children in low-income families (study (h)). Thus, rather than a BCA for a specific preschool program, this analysis represents the likely return for high-quality preschool programs on average when implemented at scale.

These results demonstrate several patterns. First, in all cases, the analyses show that the programs generate positive economic benefits with benefit–cost ratios ranging from $2.36–1 to $16.14–1. As Heckman notes, the findings for these programs and other early childhood interventions demonstrate that early childhood investments offer a rare policy option that can promote both economic efficiency, as well as fairness and social justice. Second, as more follow-up data becomes available, the calculated economic returns tend to increase. This is because, the methods of both the Perry Preschool and CPC BCAs to project future benefits are typically too conservative when compared with the actual experiences from later follow-ups. Third, methodological choices matter in the calculated returns. For example, unlike the evaluation teams, the independent estimates for the Perry Preschool program (studies (d) and (e)) made different choices like excluding the value of intangible crime victim costs or using different values for the cost of crime. As the available estimates of crime costs vary widely, these choices can have a considerable impact on the estimated returns. Fourth, the estimates of returns for specific programs will not necessarily generalize those for more generic preschool programs. The lowest benefit–cost ratio in Table 2 is for the more generalized targeted preschool program where the estimated program impacts are assumed to be attenuated because of program scale-up. Thus, this estimate may be closer to what the typical 'real world' program would generate.

Limits on the Generalizability of Existing Economic Analyses

The issue of the generalizability of the findings in Table 2 for either the small-scale Perry Preschool program or the large-scale Chicago CPC program is an important one. Both programs have been designed to serve particularly disadvantaged groups of children, and the estimated program impacts and the associated benefit–cost ratios thereof may not be replicated in other programs or for other populations of children. Programs that are less effective due to lower quality would not be expected to generate the same economic return. Likewise, programs serving more advantaged groups of children would not necessarily have impacts across the same range of outcomes or of the same magnitude. To the extent that impacts are attenuated when quality declines or the population served varies, the economic returns would be lowered accordingly. However, the attenuation of program impacts when programs serve a broader base of children does not necessarily mean that the economic returns will no longer be positive. For example, several studies have estimated the returns to universal preschool programs while assuming that the favorable impacts

Table 2 Reported benefit–cost ratios for preschool programs in the USA

Program/program type	*Source*	*Benefit–cost ratio*
Estimates for specific programs

Note: The benefit–cost ratios are the ratio of the present discounted value of total benefits to society as a whole (participants and the rest of society) divided by present discounted value of program costs. The discount rate is 3% unless otherwise noted. The value of reducing intangible crime victim costs are excluded unless otherwise noted.

are concentrated among the most disadvantaged children. Even so, the total economic benefits to society as a whole can remain positive, so long as the returns for the disadvantaged groups are sufficiently large.

The economic returns to preschool programs implemented in other countries is also an issue that remains largely unexplored, and the magnitudes of the economic returns demonstrated for programs in the US may not be relevant for other developed or developing countries. Economic returns may be higher or lower depending on how the magnitude of program impacts can vary in other countries and also depending on the variation in the economic values attached to the realized program impacts. For example, the high economic returns to Perry Preschool stem, in part, from the high cost of juvenile and adult crime in the US, costs that are likely to be lower in most other countries in the world. For this reason, rigorous program evaluations in all countries need to be accompanied by careful estimates of program costs and benefits. In addition, in the absence of long-term follow-up data from interventions in both high- and low-income countries, there is a need to develop estimates of the economic value associated with changes in child health and development in the early years.

Prescription Drug Cost Sharing, Effects of

JA Doshi, University of Pennsylvania, Philadelphia, PA, USA

Introduction

Pharmaceuticals play an increasingly important role in health care. New discoveries of prescription drugs and biologics have transformed the medical management of several diseases. Pharmaceutical expenditures have also dramatically grown over time in part due to increases in the quantity demanded and the high prices of these new medications. An ongoing challenge for third-party payers in countries with public or private insurance coverage for prescription drugs, has been how best to balance the competing goals of affording access and financial risk protection versus avoiding overconsumption of prescription drugs and controlling costs. To contain pharmaceutical spending, various cost-containment policies have been implemented by payers across countries. One such policy, cost sharing between patients and insurers, is common in many developed countries, particularly the US. Cost sharing, as referred to in this article, is the portion of the drug's cost to be paid for by the patient at point-of-service, although the insurer (or payer) covers the remainder of the cost. Other terms used for cost sharing in some countries include user fees, user charges, consumer charges, or prescription drug charges.

The goals of this article are to present an economic framework for the effects of prescription cost sharing, provide an overview of the different forms of prescription cost sharing, and summarize the empirical evidence related to their effects on prescription and medical service use, expenditures, and outcomes.

Economic Framework

Insurance involves a tradeoff between the gains from risk protection and the losses from the incentives to use more medical care caused by the presence of insurance. Patients who have no insurance coverage for prescription drugs, as is the case in many developing countries, face full price (i.e., 100% cost sharing) for all drugs, and are fully at risk for any and all drug expenses. However, patients with full insurance coverage for prescription drugs, pay no costs (i.e., 0% cost sharing) and this may raise potential for moral hazard i.e., additional insurance-induced utilization of drugs. To mitigate the potential problem of moral hazard, insurers in most countries with private or public drug coverage require some cost sharing for prescription drugs, i.e., patients pay some portion of the costs associated with the drugs used as opposed to receiving full coverage. As pharmaceutical expenditures have continued to rise over time, insurers across many countries have increased the levels of prescription cost sharing and/or experimented with alternative forms of cost sharing to control pharmaceutical spending. In many countries, however, the increase in the drug cost sharing amounts has more likely been related to the payer's budgetary burden or deficit problems rather than the recognition of or change in moral hazard of the covered population.

Prescription drug cost sharing may reduce payer drug expenditures through several mechanisms. First and most directly, an increase in patient drug cost sharing reduces payer drug spending by shifting responsibility of a portion of the drug costs from the payer to the patient. Hence, even if drug demand was perfectly inelastic cost sharing would still result in reductions in payer drug expenditures.

The second mechanism through which prescription cost sharing may reduce drug expenditures is through reductions in the price of prescription drugs, either directly by causing pharmaceutical manufacturers to lower drug prices or offer rebates/discounts (as is the case with reference pricing or tiered copayments discussed in the next section) or indirectly via encouraging patients to shift to lower priced (perfect or imperfect) drug substitutes. Examples of the latter include switches from brand name to generic drugs, nonpreferred to preferred brand drugs, and drugs above the reference price to those at the reference price.

Third, assuming that demand for drugs is not inelastic additional reductions in payer expenditures may be obtained by reductions in the overall quantity of drugs demanded with an increase in patient cost sharing. This decrease in quantity, however, can result from either a reduction in the probability of drug use among potential new users (i.e., noninitiation of newly prescribed medications) and/or a reduction in the number of prescriptions refilled among current users (i.e., nonadherence to or discontinuation of ongoing medications). The question then arises with regard to what types of drugs do the patients forego or delay taking and what other services they might substitute for the foregone drugs.

There are several ways that prescription drug cost sharing may affect nondrug health care expenditures. Firstly, certain medical services are direct complements to drugs (as, e.g., physician visits or laboratory tests) and their quantity demanded may also decrease with an increase in prescription cost sharing. For instance, physician office visits are an example of a complement given that the disease diagnosis is made and a prescription is written during a physician visit. Furthermore, certain newly prescribed medications or those prescribed for chronic illnesses require ongoing laboratory monitoring and follow-up visits with the physicians. Hence, if an increase in prescription drug cost sharing reduces the quantity of drugs demanded then it may also reduce the number of physician visits and lab tests required and associated health care expenditures.

However, for many conditions, particularly chronic illnesses, medical treatments may be substitutes for drug treatment in the short term (as, e.g., surgery rather than drug treatment for gastroesophageal reflux disease) or longer term (as, e.g., inpatient and outpatient care associated with coronary artery bypass surgery after a heart attack or kidney dialysis in diabetes patients which could have been prevented by use

 doi:10.1016/B978-0-12-375678-7.01211-6

of long term drug treatment). This substitutability between drugs and other medical services is often the basis of one of the arguments raised against policies intended to increase prescription cost sharing.

Economic theory suggests that when patient cost sharing rises, rational patients will reduce the consumption of drugs whose costs exceed the marginal benefits and continue to consume drugs whose marginal benefit exceeds the costs to the patient. The primary assumption underlying this is that patients are fully informed of the marginal benefits of the drugs to make such evaluations and rational choices. However, critics argue that patients (and providers) often have imperfect information about the marginal benefits from drugs and other treatments, and hence may forego, delay, or decrease adherence to beneficial drugs, which in turn may adversely affect health outcomes and lead to increases in use of other medical services. If the increases in the spending due to the resultant medical service use offset the savings in prescription drug expenditures, then the prescription cost sharing policy will fail in its intended goal of cost containment and improving efficiency.

These considerations have implications for both the design and evaluation of prescription cost sharing by private and public insurers who provide coverage for both drugs and medical services. To the extent that medical services are complements or substitutes for drugs then the drug demand elasticity alone may not determine optimal cost sharing levels; both the own price elasticity of demand and cross-price elasticities of demand need to be factored in (Goldman and Philipson, 2007). For example, even though the own price elasticity of drug demand is high, the optimal cost sharing for the drug may be lower (or even zero) if hospitalizations and emergency room visits are substitutes for the drug, as lower drug cost sharing itself will result in a lower use of these other more expensive services. Similarly, evaluations of the effects of prescription cost sharing policies should not take a siloed view of the impact of cost sharing on only pharmaceutical use and spending but should also examine the effects on patient health outcomes, other medical service use and spending, and more importantly the cost offsets and net effects on total spending.

Types of Cost Sharing

Copayments, Coinsurance, and Tiered Formularies

The two most common types of prescription cost sharing used by payers across countries are copayments and coinsurance. Copayment is a fixed monetary amount per prescription to be paid by the patient (e.g., $10), and coinsurance is a fixed percentage of the total cost of the prescription to be paid by the patient (e.g., 20%). Copayments provide better financial risk protection than coinsurance, because they better cover higher-priced drugs. Under coinsurance patient out-of-pocket payments vary directly with the price of the drugs; hence, it provides stronger incentives for the patient to choose lower priced drugs than copayments.

Payers in several ex-US countries in Europe and Australasia typically require modest drug cost sharing with several protections such as an annual out-of-pocket maximum or stop-loss, sometimes related to income and exemptions for vulnerable groups (e.g., low-income, elderly, disabled, children, pregnant women). Unlike US payers, some of these countries also impose the same level of cost sharing (copayment or coinsurance) for all drugs, regardless of the cost or type of medication This is partly explained by the fact that payers in these countries rely less on patient cost sharing and more heavily on other forms of supply-side cost containment (i.e., reimbursement and price controls). By contrast, most payers in the US use patient cost sharing as a primary tool to control costs and hence have moved away from requiring such flat cost sharing levels. Instead, they have adopted tiered formularies which require differential levels (or tiers) of cost sharing for different types of drugs based on factors such as the cost of the drug to the insurer, relative to the cost of close alternatives. Most private plans in the US have adopted three-tiered formularies that require the lowest cost sharing for Tier 1 drugs (typically generics), a second and higher level of cost sharing for Tier 2 drugs (typically preferred brand-name drugs), and a third and highest level of cost sharing for Tier 3 drugs (typically nonpreferred brand name drugs). Private plans are now increasingly imposing a fourth tier requiring even higher cost sharing (often coinsurance rates) for very expensive specialty biologic medications (see Section Specialty Tier Cost Sharing for more detail). Tiered or differential cost sharing creates financial incentives for patients to use less expensive drug substitutes such as generics and preferred brands. Insurers are also often able to negotiate discounts and/or rebates with brand-name drug manufacturers in exchange for placement on the preferred brand tier, as opposed to the nonpreferred tier.

Reference Pricing Surcharges

Reference pricing leads to another form of cost sharing wherein the incentives are set up for patients to use less expensive drug substitutes. The insurer sets the maximum ('reference') price it will cover (based on prices of low-cost benchmark drugs) for a group of therapeutically similar drugs that are deemed to be close substitutes for one another in the treatment of specific diseases. Patients who want to use a higher-priced drug must pay out-of-pocket for the entire difference between the retail price of that drug and the reference price covered by the insurer. Reference pricing is commonly used in European countries (e.g., Germany and Netherlands), Canada (e.g., British Columbia), and New Zealand. However, its use is rare in the US.

Deductibles

A deductible is the expense that must be paid 100% out of pocket by patients before an insurer will start paying for any drug expenses. They are generally used in combination with other forms of cost sharing such as copayments or coinsurance. Except for certain private plans in the US Medicare Part D program (which offers voluntary prescription insurance to the elderly and disabled), most other payers in the US typically do not subject medications to deductibles. Drug deductibles are also rarely used in European countries,

except for Denmark and Sweden. Some Canadian provinces such as Manitoba and British Columbia also use drug deductibles, the levels of which vary based on patient income.

Benefit Caps

Benefit caps include cost sharing features which require 100% out-of-pocket payments for all prescriptions filled either after the patient's total drug spending reaches a predefined amount (i.e., annual benefit caps or coverage gap) or after a patient fills a predefined number of prescriptions in a month (i.e., prescription limits). These somewhat extreme forms of cost sharing are only seen in the US For example, the standard benefit design under Medicare Part D implemented in 2006 included a coverage gap (i.e., 'doughnut hole') wherein beneficiaries were required to pay 100% of drug costs after total drug spending exceeded a predefined amount ($2250 in 2006) until they reached the catastrophic cap amount ($5100 in 2006) and were then required to pay only 5% of all drug costs. Before the availability of Medicare Part D, drug benefits available through private Medicare managed care plans typically included such annual benefit caps (but without catastrophic coverage). Similarly, some US state Medicaid programs that cover low-income Americans impose a limit on the number of prescriptions covered per patient in each month. Such policies may reduce prescription drug spending by shifting the entire financial responsibility for drugs to the patient after the benefit cap is reached as well as reducing overall drug use if patients try to avoid exceeding the benefit cap. Heavy medication users such as the elderly and the chronically ill are most likely to face the brunt of these policies.

Specialty Tier Cost Sharing

Specialty drugs include high-cost self-injectables, infusions, and certain inhalations and oral agents; they are typically biologically derived and/or require cold-chain distribution. As compared to the 'traditional' chemically synthesized medications (i.e., small-molecules), specialty biologic medications (i.e., large-molecules) are manufactured in more complex, highly involved processes and often represent significant advances in treatments for complex, chronic conditions such as cancer, rheumatoid arthritis, and multiple sclerosis. At the same time they are priced 10 to 20 times higher than traditional drugs which means patients needing such medications are at financial risk for high out-of-pocket expenditures in the absence of insurance coverage. Initially, US insurers covered specialty biologics in a manner similar to other traditional pharmaceuticals, particularly given that a very small proportion of members were users of these medications. However, as the specialty biologic market has expanded significantly over the past two decades and spending growth for these medications has far outpaced the growth for traditional drugs insurers have begun to alter the coverage structure for specialty biologics.

In the US, insurers have created additional, higher cost sharing tiers, often called specialty tiers, on which these drugs are placed. The intent of these tiers is to isolate specialty drugs from lower cost small-molecule entities and to assign specific cost sharing and utilization management tools to these types of medications. Although even the standard three tiers (generics, preferred brands, and nonpreferred brands) require a copayment, the specialty tier often carries a percent coinsurance as opposed to a copayment. This means that beneficiaries are responsible for a far greater proportion of the costs of these expensive medications than they would if the insurer had imposed a copayment. The creation and utilization of specialty tiers was originally most noticeable in the US Medicare Part D program, in which drug plans were allowed to place drugs with monthly costs exceeding a certain threshold (e.g., $600 in 2012) on a specialty tier and require as high as a 33% coinsurance. Today, virtually all Part D plans that use tiered cost sharing structures have created a specialty tier. Although specialty tiers are less commonly used by US employers or private insurers, their adoption has been increasing rapidly in recent years especially as new specialty medications for more common conditions such as osteoporosis and rheumatoid arthritis have begun to enter the market.

Empirical Evidence on the Effects of Drug Cost Sharing

This section summarizes the empirical evidence on the effects of drug cost sharing for traditional drugs and specialty biologics.

Effects of Cost Sharing for Traditional Drugs

A substantial number of studies examining the effects of cost sharing on traditional small-molecule medications have been published in the literature. Numerous reviews with varying scopes and objectives have attempted to qualitatively summarize these studies which are highly heterogeneous in terms of the study design, study population, study outcomes and disease group/drug classes examined, type of data source, and statistical methods; hence, often resulting in mixed findings (Gibson *et al.*, 2005; Goldman *et al.*, 2007; Gemmill *et al.*, 2008; Austvoll-Dahlgren *et al.*, 2008; Eaddy *et al.*, 2012). The vast majority of these studies have been conducted in the US followed by Canada. A few studies have examined the impact of cost sharing increases in Europe (UK, Sweden, Netherlands, Italy, Germany, and Denmark), Australasia (Australia and New Zealand), and Asia and the Middle East (Taiwan, Nepal, and Israel).

Except for the RAND Health Insurance Experiment (HIE) which was a randomized trial in the US (Newhouse, 1994), all the remaining studies are observational in nature. Unfortunately, the coinsurance rate for drugs was made identical to and varied at the same time as the coinsurance rate for other medical services in the RAND HIE; hence, it does not provide an unbiased estimate of the demand elasticity for drugs alone. It is important to note that the methodology used in many of the remaining observational studies has also been reported to be of low to moderate quality (Austvoll-Dahlgren *et al.*, 2008; Soumerai *et al.*, 1993). In particular, several studies are cross-sectional in design whereas others have evaluated outcomes

before and after the cost sharing change without including a control group to account for biases arising due to contemporaneous trends. The latter was often the case in studies from ex-US countries wherein the government increased cost sharing for the entire population (Goldman *et al.*, 2007; Austvoll-Dahlgren *et al.*, 2008).

Prescription drug use and expenditures

Majority of the evidence indicates that higher levels of drug cost sharing are associated with lower total prescription expenditures (Gibson *et al.*, 2005; Goldman *et al.*, 2007; Gemmill *et al.*, 2008). There is also consistent evidence to indicate that the payer's prescription expenditures decrease and not surprisingly, patient out-of-pocket expenditures increase. As noted earlier, the magnitude of the reductions in drug expenditures varies based on factors such as the type and magnitude of change in cost sharing, therapeutic drug class being studied, and the type of study population subject to cost sharing. Some studies report price elasticity estimates reflecting the percentage change in drug spending that would be associated with a 1% increase in cost sharing. If studies that lacked a control group or had very small changes in cost sharing are excluded, price elasticity estimates have been reported to range from -0.2 to -0.6 (that is, 10% increases in cost sharing via copayments or coinsurance are associated with a 2–6% reduction in prescription drug expenditures) (Goldman *et al.*, 2007).

A few studies from the US, Canada, and Taiwan have examined the effect of coinsurance rates rather than fixed dollar copayments. Overall, the effect of coinsurance is at the low end of the price elasticity range of -0.2 to -0.6 (Goldman *et al.*, 2007). Although surprising, this is primarily explained by the fact that in most of the study settings the coinsurance was accompanied by an out-of-pocket maximum per prescription or per year which likely subdued the effect of the coinsurance (Goldman *et al.*, 2007). However, a recent study of US adults with employer sponsored coverage examined coinsurance versus copayments of equal dollar amounts and reported that the use of (adherence to) diabetes medications was lower under coinsurance, perhaps due to the additional uncertainty generated for patients in their out-of-pocket spending depending on changes in the price of drugs (Dor and Encinosa 2010).

As opposed to the relatively modest effects of low (and often flat) levels of cost sharing reported in some of the earliest studies published in the literature, a majority of the recent studies of tiered cost sharing suggest larger effects (Goldman *et al.*, 2007). For example, results from a study of privately insured US adults suggest that doubling drug copayments was associated with 60% reductions in drug spending in the first year (i.e., 'short run' elasticity of -0.6) and a further 20% in the second year (i.e., 'long run' elasticity of -0.8) (Gaynor *et al.*, 2007). A majority of the evidence from studies examining reference pricing also suggests that it lowers prescription drug spending, at least in the first one or two years after implementation (Gemmill *et al.*, 2008).

Very few studies have examined the effect of deductibles. In particular, evidence on deductibles in private plans within the Netherlands suggests price elasticity estimates to be only -0.06 to -0.08 (Gemmill *et al.*, 2008). However, a sizeable number of studies have examined the impact of benefit caps such as annual caps on drug spending, monthly prescription limits, and the coverage gap in Medicare Part D (Goldman *et al.*, 2007; Gemmill *et al.*, 2008; Polinski *et al.*, 2011). As one would expect, prescription drug spending is significantly lower with these extreme forms of cost sharing. For instance, one of the studies of an annual cap of $1000 on total drug spending reported 28% lower prescription drug spending in US elderly patients in a Medicare managed care plan with the cap compared to those not subject to the cap.(Hsu *et al.*, 2006) Similar levels of reductions in prescription drug spending have been reported during the coverage gap in Medicare Part D (Polinski *et al.*, 2011).

There is also consistent evidence to indicate that the payer's prescription expenditures decrease with most forms of cost sharing; not surprisingly, increases in patient out-of-pocket expenditures have also been well documented in the literature (Gibson *et al.*, 2005; Gemmill *et al.*, 2008; Polinski *et al.*, 2011). Although clearly some of the reductions in payer spending on drugs arise from cost-shifting to patients, part of them also arise due to decreases in the overall quantity demanded and/or the price of the prescription drug expenditures (Gibson *et al.*, 2005; Goldman *et al.*, 2007; Gemmill *et al.*, 2008; Eaddy *et al.*, 2012).

The existing evidence largely suggests that the decrease in quantity of drugs demanded occurs through both a reduction in the probability of drug use or initiation (Gibson *et al.*, 2005; Gemmill *et al.*, 2008; Solomon *et al.*, 2009) and a reduction in the number of prescriptions refilled among current users via nonadherence to or discontinuation of ongoing medications; however, the results vary by type of cost sharing change, study population, and drug class studied (Gibson *et al.*, 2005; Eaddy *et al.*, 2012). For instance, a US study of elderly patients with employer sponsored retiree coverage reported that higher cost sharing significantly delayed the initiation of drug therapy within 1 year and 5 years in patients newly diagnosed with hypertension, hypercholesterolemia, and diabetes (Solomon *et al.*, 2009). In a recent review of US and Canadian studies examining the relationship between patient cost sharing and medication adherence, 56 (85%) of the 66 included studies demonstrated a statistically significant negative relationship (Eaddy *et al.*, 2012). The remaining studies demonstrated either limited or nonsignificant findings. Extrapolating across the studies, the authors reported that for each dollar increase in patient copayments, adherence would be expected to decrease by 0.4% (that is, a $10 increase would be associated with a 3.8% drop in overall adherence); however, they note that the actual decline may be larger or smaller depending on the study population and type of cost sharing change given the wide range in the study results. The evidence tends to be more mixed for tiered formularies wherein some studies report decreased adherence and increased discontinuation and others find no changes depending on the drug class and population studied (Gibson *et al.*, 2005). However, majority of the evidence indicates that reference pricing is generally not linked to worsened adherence with drugs at the therapeutic class level (patients may switch from a drug above the reference price to one at the reference price but rarely completely discontinue taking any drug within the therapeutic class) (Goldman *et al.*, 2007). The evidence on

benefit caps (annual caps on drug spending, monthly prescription limits, or the coverage gap in Medicare Part D), however, consistently suggests a reduction in the probability of use of medications and higher rates of discontinuation across common therapeutic classes (Goldman *et al.*, 2007).

Several studies indicate that the reductions in the medication use with higher cost sharing occur for both drugs considered less 'essential' (e.g., antihistamines) as well as more 'essential' (e.g., medications for hypertension, diabetes, and asthma) for stabilizing or improving health (Gibson *et al.*, 2005; Goldman *et al.*, 2007). Although economic theory predicts that reductions in use should be larger for 'less' essential medications relative to 'more' essential medications, the empirical evidence is quite mixed and inconsistent with some studies reporting evidence of such differences and others reporting no such differences (Gibson *et al.*, 2005; Goldman *et al.*, 2007; Gemmill *et al.*, 2008).

Empirical evidence suggests that drug cost sharing in the form of reference pricing and tiered formularies may also reduce drug expenditures either directly by causing pharmaceutical manufacturers to lower drug prices or offer discounts and indirectly via encouraging patients to shift to lower priced drug substitutes (Gibson *et al.*, 2005; Gemmill *et al.*, 2008). For instance, studies from Canada, New Zealand, the Netherlands, and Germany suggest that reference pricing was associated with manufacturers lowering prices of drugs (typically to the reference price) in several therapeutic categories (Gemmill *et al.*, 2008). There is also consistent evidence that patients typically switch from drugs priced above the reference price to drugs priced at the reference price (Goldman *et al.*, 2007; Gemmill *et al.*, 2008). Similarly, adding a third tier for nonpreferred brand drugs has been typically associated with reductions in the use of these medications and an increase in the use of preferred brand-name drugs; however, the extent of substitution varies by drug class (Gibson *et al.*, 2005). Perhaps surprisingly, there is little evidence of generic substitution in the face of differential copayments for generics and brand-name drugs (Gibson *et al.*, 2005; Gemmill *et al.*, 2008). These results may be due to the fact that the generic brand copayment differentials in most studies have been quite small and a majority of the evaluations were conducted during a time frame when fewer generic options were available for brand-name drugs compared to what exists today given patent expirations for numerous block-buster drugs. For the US, this may also reflect the fact that in the widespread presence of state generic substitution laws (wherein a pharmacist can substitute a generic even if the script is written for a brand, unless the physician requires the brand), differential copayments for generics and brand-name drugs may yield minimal additional impact

Health care outcomes, use, and expenditures

In this section, the empirical evidence on the complementary and substitution effects of prescription cost sharing is reviewed. If prescription cost sharing decreases prescription drug use, then to the extent that physician visits serve as complements to the use of prescription drugs (given that they are required for having a prescription written) their use may also decrease. However, reductions in medication use, particularly for drugs considered 'essential' for stabilizing and improving health may have consequences in terms of worsened disease symptoms and clinical outcomes and consequent substitution with other more resource-intensive health care services such as emergency room visits, outpatient visits, hospitalizations, and nursing home admissions.

Although there is a large literature on the effects of cost sharing on prescription use and spending, far fewer studies have examined its effects on health outcomes and nondrug health services utilization and expenditures. The lack of studies on health outcomes is largely due to the unavailability of clinical data (e.g., laboratory test values), vital status, and/or patient self-reported information (e.g., worsening of symptoms) to link with the administrative data on prescription and medical service use. The most compelling results on clinical outcomes come from a US study examining elderly patients in a Medicare managed care plan with a cap of $1000 on annual drug costs compared to those in an uncapped plan (Hsu *et al.*, 2006). Not only were relative rates of mortality higher among those in the capped plan, but physiologic outcomes such as blood pressure, cholesterol, and hemoglobin A1c levels were relatively worse among patients being treated for hypertension, hyperlipidemia, and diabetes, respectively. Evidence on associations between mortality and cost sharing also comes from studies in Canada (Quebec) and Italy (Gemmill *et al.*, 2008).

Most of the evidence on nonmedical service use comes from studies conducted in the US and Canada. Furthermore, the findings are mixed and depend largely on the population being studied and the type of cost sharing changes being evaluated. Evidence from a few studies in the US and Germany suggest that physician visits serve as complements to the use of prescription drugs and their use is lower with increases in drug cost sharing (Gemmill *et al.*, 2008). Contrary evidence on physician visits serving as substitutes comes primarily from studies in Canada (British Columbia) wherein there was no cost sharing for physician visits and hence, perhaps some patients substituted free physician care for prescription drugs in the face of increases in drug cost sharing (Gemmill *et al.*, 2008).

Evidence of substitution effects with other medical services comes primarily from US based studies focusing specifically on patients with chronic diseases such as congestive heart failure, hyperlipidemia, hypertension, and schizophrenia; such studies have linked higher drug cost sharing with greater likelihood of outpatient, inpatient, and/or emergency care (Goldman *et al.*, 2007; Eaddy *et al.*, 2012; Gemmill *et al.*, 2008). Also, and not surprisingly, the evidence of such adverse effects is much stronger and clear-cut for more extreme forms of cost sharing that involve benefit caps in the form of annual benefit caps and monthly prescription limits especially which have been applied in some settings for the elderly and/or poor patients in the US (Hsu *et al.*, 2006; Soumerai *et al.*, 1993). Increase in serious adverse events (acute care hospitalizations, long-term care admissions, mortality) and emergency room visits have also been reported among the poor and the elderly in Canada (Quebec) after cost sharing requirements changed from minimal or no copayments to a 25% coinsurance with income-based annual out-of-pocket maximums (Tamblyn *et al.*, 2001).

The studies that have not found substitution or complementary effects between drug cost sharing and nonmedical

service use are generally those that evaluated cost sharing changes designed to encourage patients to switch to lower cost drug substitutes (i.e., tiered formularies and reference pricing) rather than deter any drug use (Gemmill *et al.*, 2008); those that examine a broader population (not limited to specific chronic diseases) (Goldman *et al.*, 2007); and/or those in which the cost sharing did not have an impact on medication adherence either due to the nature or magnitude of cost sharing changes or the price inelasticity given the severity of illness (e.g., post heart attack) in the population being studied (Eaddy *et al.*, 2012; Gibson *et al.*, 2005).

It is unclear from this sparse literature with mixed findings on whether the net effect of an increase in drug cost sharing results in cost savings or whether it results in increased long-term or short-term total spending due to substitution with other resource-intensive medical services. Most studies examining nonmedical service use have failed to extend their evaluation to examining cost offsets. As expected, formal or informal cost offset calculations from studies of benefit caps in the form of annual caps on drug spending and monthly prescription limits indicate that the drug cost savings are offset by the increases in nonmedical service use such as hospitalizations, emergency room visits, or nursing home admissions in elderly and poor patients (Soumerai *et al.*, 1993; Hsu *et al.*, 2006). A more recent study of drug cost sharing in privately insured adults with employer sponsored coverage suggests that 35% of the cost savings due to reductions in drug spending were offset by increases in other medical spending; however, increases were observed only in outpatient spending (no effects on inpatient spending) (Gaynor *et al.*, 2007).

Effects of Cost Sharing for Specialty Drugs

Specialty drugs represent a relatively new innovation in the pharmaceutical market and hence few studies to date have been conducted that examine the effects of higher cost sharing on the use of such medications and related outcomes and spending. Furthermore, almost all the evidence on this topic comes from data on privately insured patients in the US from a time period when few patients were subject to aggressive cost sharing strategies for specialty drugs that are increasingly becoming more commonplace (e.g., in the US Medicare Part D program).

Specialty drug use and expenditures

The earliest study addressing this topic examined specialty drug use and spending among privately insured patients with one of four conditions (cancer, kidney disease, multiple sclerosis, and rheumatoid arthritis) which are treated with specialty drugs. The authors estimated a fairly inelastic price elasticity of total drug spending, ranging from -0.01 for cancer drugs to -0.21 for rheumatoid arthritis drugs (Goldman *et al.*, 2006).

A recent study estimated the elasticity of demand associated with five specific specialty drugs used to treat cancer in privately insured patients. The authors found that demand elasticity for initiating the five specialty cancer drugs ranged from -0.19 to -0.26 and that for continuing to fill prescriptions among those who initiate was even lower ranging from -0.04 and -0.11 (Goldman *et al.*, 2009). Evidence from a study focusing specifically on use of specialty biologics in privately insured patients with rheumatoid arthritis also suggests that the demand for such RA drugs is relatively inelastic with elasticity estimates of -0.93 and -0.038 for biologic initiation and continuation, respectively. In other words, the authors found a 9.3% reduction in the probability of initiating therapy and a 3.8% reduction in the probability of continuation among those who initiate if average out-of-pocket costs for these drugs were to double (Karaca-Mandic *et al.*, 2010). Another study examining the impact of patient out-of- expense on prescription abandonment (defined as the patient never actually taking possession of the medication despite evidence of a written prescription generated by a prescriber) suggested somewhat more price sensitivity for multiple sclerosis drugs (Gleason *et al.*, 2009). A majority (83%) of the patients with multiple sclerosis had an out-of-pocket expense of $100 or less and these patients had an abandonment rate of 5.7%. In the remaining patient groups whose out-of-pocket expense was greater than $200, the abandonment rate was significantly higher, with more than 1 in 4 patients abandoning their specialty drug prescriptions (Gleason *et al.*, 2009).

Finally, a recent study has reported that long-term users of antiinflammatory, immunosuppressant, cancer, and multiple sclerosis medications whose specialty medication copayments had been increased only experienced a minor decline in adherence, suggesting that responses to cost sharing changes for specialty biologics are not as large as those for traditional small-molecule products (Kim *et al.*, 2011).

Health care outcomes, use, and expenditures

No study has examined the impact of higher cost sharing for specialty drugs on health care outcomes and nondrug medical services use and expenditures. Further research on this topic is needed.

Value-Based Insurance Design

As highlighted in the previous sections of this article, several studies have documented that increased prescription cost sharing not only reduces use of low-value medications but also use of and adherence to highly effective medications needed to appropriately manage chronic conditions. This may be because patients underestimate the marginal benefits of the drugs. This issue has raised the concept of 'value-based' cost sharing, now commonly referred to as value based insurance design (VBID) in the US (Chernew *et al.*, 2007; Pauly and Blavin, 2008).

The premise of VBID is that patient copayment or coinsurance levels are set relative to the value offered by the medication (benefit and costs), and not its cost alone (Chernew *et al.*, 2007). This implies lower cost sharing when clinical benefits of the drug exceed the costs (i.e., medication offers high value) and high cost sharing when benefits do not justify the cost (i.e., medication offers low value), regardless of the actual cost of the drug. However, not all classes of drugs are amenable to value-based cost sharing and due to practical hurdles applications of VBID in the US have been limited

to lowering cost sharing for broad classes of drugs such as antihypertensives, cholesterol-lowering agents, anti diabetic agents, and/or asthma medications (Chernew *et al.*, 2007; Choudhry *et al.*, 2010). Although such VBID approaches are being increasingly adopted by US employers and insurers, only a small number of studies, mostly observational and many without control groups, have evaluated the direct impact of reducing copayments on prescription and medical service use, spending, and outcomes (Fairman and Curtiss, 2011; Choudhry *et al.*, 2010).

One of the first quasi-experimental studies in this area evaluated a VBID program implemented by a large US employer as part of a disease management (DM) program for diabetes Chernew *et al.* (2008). A control employer that used the same DM program but did not change cost sharing levels was utilized to conduct a pre-post analysis to understand the effect of the VBID program. For five classes of medications, copayment levels were reduced from $5 to $0 for generics, from $25 to $12.50 for preferred-brand drugs, and from $45 to $22.50 for nonpreferred-brand drugs. Among patients using angiotensin converting enzyme (ACE) inhibitors or angiotensin II receptor blockers (ARBs), beta-blockers, diabetes drugs, or statins, there was a statistically significant increase in adherence of 2.6–4.0 percentage points. These improvements in adherence translated to price elasticities of -0.11 to -0.20. Among patients taking inhaled corticosteroids, adherence increased by 1.9%, but the effect was not significant (Chernew *et al.*, 2008).

The Post-Myocardial Infarction Free Rx Event and Economic Evaluation (MI FREEE) trial was the first randomized controlled study to examine the impact of VBID; furthermore it not only examined medication adherence to medications prescribed to patients following a myocardial infarction but also clinical outcomes and total health care costs (Choudhry *et al.*, 2011). Patients who were discharged from a hospital after suffering a myocardical infarction were randomized at the employer level to either no cost sharing (i.e., VBID group) or usual cost sharing (i.e., control group) for statins, beta-blockers, ACE inhibitors, and ARBs. Adherence to medication was significantly higher by 4–6 percentage points in the no cost sharing group relative to the control group. However, there were no significant differences between the two groups in the primary end point of the rate of first major vascular event or revascularization. Nevertheless, the secondary outcome of total major vascular events was significantly lower among the no cost sharing group compared to the control group (21.5 vs. 23.3 per 100 person-years). Furthermore, total health care spending was similar between the two groups. The MI FREEE trial concluded that the elimination of cost sharing improved adherence to medication, decreased rates of total major vascular events, and decreased patient spending without increasing total health care costs.

It should be noted that the MI FREEE trial was conducted in patients who had suffered a heart attack in whom improved medication adherence due to reductions in cost sharing is more likely to be cost neutral due to reductions in future cardiovascular events. However, few studies have examined the impact of VBID on medical and total spending when used in the general population of patients with chronic conditions such as hypertension, hyperlipidemia, diabetes, and asthma. The limited number of studies suggest that VBID is either cost-neutral or at times cost saving; however, the reliability of the evidence is highly questionable given that these studies either fail to report results from a payer's perspective, are based on economic modeling using weak assumptions, or do not permit isolation of the impact of the VBID program from concurrent disease management programs (Fairman and Curtiss, 2011). Despite the lack of strong evidence of effectiveness or cost-effectiveness of copayment reductions for medications, employers and payers are increasingly adopting VBID approaches. Hence, there is a clear need for further rigorous evaluations of the clinical and economic outcomes of the impact of lowering medication copayments.

Conclusion

Substantial evidence suggests that patient cost sharing for prescription drugs can reduce third-party payer drug expenditures. These reductions in drug spending have been shown to occur via several mechanisms including a direct shift in costs to patients as well as reductions in the quantity and price of drugs used. However, the mechanisms and magnitude of effects vary considerably by type of change in cost sharing, type of therapeutic drug class, and the type of study population subject to cost sharing. Reductions in medication use have been reported for drugs essential for maintaining or improving health as well as other drugs. Evidence suggests that these reductions in use occur via both decreases in the probability of drug initiation and increases in nonadherence to or discontinuation of ongoing medications for chronic conditions. Although limited data exist on the effects of prescription cost sharing on health outcomes and spending, evidence in certain conditions suggests that higher cost sharing is associated with increased used of nondrug medical services such as hospitalizations and emergency care visits.

Specialty biologics represent a marked shift in the pharmaceutical landscape, with more complex manufacturing methods and significantly higher prices as compared to traditional drugs. The limited evidence on the effects of higher cost sharing for these medications suggest relatively inelastic demand for these products. However, this evidence base is exclusively limited to the experience of privately insured US patients from a time period when very few patients were subject to aggressive cost sharing strategies for specialty drugs such as those seen in the US Medicare Part D program.

In conclusion, as private and public payers continue to experiment with prescription benefit designs in the coming years, research examining the effects of various drug cost sharing policies on prescription and medical use, spending, and outcomes will be essential and of high value.

Price Elasticity of Demand for Medical Care: The Evidence since the RAND Health Insurance Experiment

AD Sinaiko, Harvard School of Public Health, Boston, MA, USA

Glossary

Cross-price elasticity The effect of a change in the price of one good or service on the consumption or utilization of another.

Marginal cost The additional cost incurred if the output rate is increased by a small amount.

Marginal value The maximum amount someone is willing to pay for a small increase in consumption or utilization.

Moral hazard Moral hazard can occur when the insurer has imperfect information on the likely behavior of insured individuals. There are two main types. Ex ante moral hazard refers to the effect that being insured has on safety behaviour, generally increasing the probability of the event insured against occurring. Ex post moral refers to the possibility that insured individuals will behave in such a way after an insured event has occurred that will increase the claim cost to insurers, partly because the user-price of care is lower through insurance and demand may therefore rise. It is also often related to insurance fraud.

Price elasticity of demand It is a measure of the change in quantity demanded of a good with a change in its price. It may also be called own-price elasticity of demand.

Introduction

In health insurance, cost-sharing refers to payments that a patient makes directly (i.e., out of pocket) for medical services. Cost-sharing includes a deductible, which is the amount of money a patient pays for services before their health insurance coverage begins, copayments, which are flat payments made for particular products or services (e.g., $15 for a doctor visit or $10 for a prescription), and coinsurance, which is when patients are required to pay a fixed percentage of the cost of their care (e.g., 20% of the cost of a hospital stay).

The extent that cost-sharing affects patient demand for care has long been an important topic in health economics, and research aims to answer questions about how to trade-off moral hazard and risk protection and determine optimal levels of cost-sharing. Risk protection describes protection from financial loss in the case of serious illness, and is often the reason people purchase health insurance. With more complete insurance (i.e., lower cost-sharing) consumers have better protection against losses in wealth from medical care utilization. In contrast, moral hazard in health insurance occurs when patients choose to consume care that they value less than its marginal cost because they pay little or no cost-sharing for the care. Thus, in contrast to risk protection, more complete insurance induces greater use of economically inefficient care.

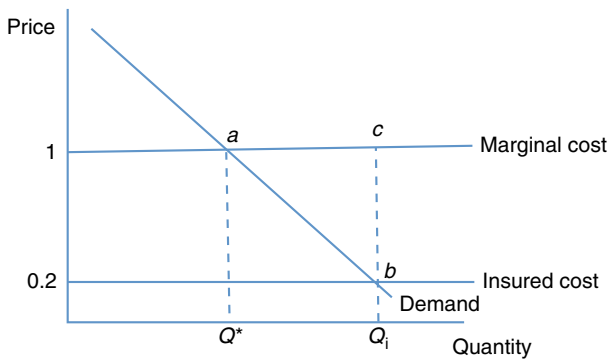

Figure 1 Moral hazard.

The framework that economists have traditionally used to analyze cost-sharing and to depict the inefficient use of resources due to moral hazard is illustrated in Figure 1. A demand curve (D) shows the valuation placed by the consumer on units of medical care, and the marginal cost curve represents opportunity cost, i.e., the valuation placed by consumers on those resources if used to produce other goods or services. In a competitive economy, price equals marginal cost. Each additional unit of medical care that is consumed beyond where the marginal valuation equals marginal cost (point a in Figure 1) carries with it inefficiency, because the medical care is valued less than the cost of the resources used to produce it. This deadweight loss is equal to the vertical distance between the demand curve and the marginal cost curve. It can be seen from this framework that the subsidy provided by health insurance, which reduces the consumer's cost for medical care from marginal cost to the insured cost (here assuming a 20% coinsurance rate), induces additional resources into the production of medical care services beyond the efficient level (the insured consumer demands the amount Q_i, which is greater than Q^*). In Figure 1, the deadweight loss from this moral hazard is depicted by the triangle abc. Deadweight loss from moral hazard varies with price elasticity of demand: Insurance providing coverage for services that are more price elastic will induce more inefficiency than insurance coverage for services that are less price elastic.

The argument made in this welfare economics framework requires several strong assumptions, many of which likely do not hold in healthcare settings. One that is certainly violated

 doi:10.1016/B978-0-12-375678-7.00801-4

is that patients have well-defined preferences for medical care and that when they visit a doctor those preferences are honored in the manner they wish. Instead, the asymmetrical information between a patient and his physician makes the agency relationship central to delivery of healthcare (e.g., patients visit their physician precisely to obtain a diagnosis and be advised on treatment) and there is considerable evidence that the way that providers are paid affects how patients are treated. Under these circumstances, an observed demand curve does not accurately reflect patient's preferences. There is also growing evidence that in complex, high-stakes settings (an apt description of many healthcare settings) consumers do not make rationally consistent choices, which violates a tenant of utility maximization that is required for this framework to hold. Hurley (2000) offers a thorough discussion and critique of the traditional framework, and reviews an alternative framework, which taking a distributional approach at the societal level, suggests the focus be on utilization with an aim toward allocating resources so as to achieve equality of health across individuals. The behavioral response to cost-sharing and estimates of elasticity of demand are important to achieving optimal outcomes under this framework as well.

A Brief Review of the RAND Health Insurance Experiment

The gold standard for evidence on the price elasticity of demand for medical care is from the RAND Health Insurance Experiment (HIE), a large-scale project that implemented a randomized study design to assess the impact of cost-sharing on demand for healthcare in the 1970s and early 1980s. The HIE randomly assigned nonelderly families to commercial insurance plans with varied coinsurance rates and deductible levels, and followed them from 3 to 5 years to study their medical care use and health. Briefly, researchers found that consumers facing higher cost-sharing consumed less care, and they estimate an elasticity of demand for medical care of 0.2 for almost all services studied, except for mental health services and dental services for which demand is estimated to be more responsive. For an average person the difference in medical care utilization did not have an adverse impact on health; individuals who were sick and had low income did experience some adverse health effects as a result of consuming less care in the higher cost-sharing plans. Aron-Dine *et al.* (2013) have recently reexamined this experiment and note that nonlinearities in health insurance contracts can have important effects on how consumers make decisions about their spending at different levels of budgets.

Need for More Recent Evidence

A few factors have led to continued interest in research on the price elasticity of demand for medical care following the HIE. The HIE studied the cost-sharing provisions included in insurance policies of the 1970s. At that time it was rare for a health plan to have a network of physicians or to provide coverage for prescription drugs. At present, insurers create networks of physicians and drug formularies in order to increase their negotiating power to receive more favorable prices. Physicians, physician groups, or pharmaceutical companies have an incentive to grant a lower price or a discount to be in the network or on the formulary in order to obtain a greater volume of business due to the lower patient payment for the drug or visit. For patients, physician networks and formularies has meant that cost-sharing is differential by provider or by drug, so that patients pay lower cost-sharing to see a physician who is in their plan's network or to buy a prescription drug that is a generic or a preferred brand (i.e., on the 'formulary'). Differential cost-sharing raises the empirical question of estimation of cross-price elasticities, which is the impact of a change in the price of one medical service on use of another medical service. If changing the price of one medical service increases (decreases) the use of another medical service, this would either add (or subtract) from the moral hazard that occurs as a result of demand for the service whose price changed.

The way health plans pay providers has also changed since the 1970s, with implications for estimates of elasticity of demand. Capitation, where plans pay providers a fixed, per-member-per-month payment, has been employed by Health Maintenance Organizations (HMOs) and Preferred Provider Organizations (PPOs) over the past 20 years and is an important component of the new Accountable Care Organizations. Under this payment mechanism providers are incented to deliver less care, despite any demand by patients, because they keep the balance of their capitated payments. These incentives did not exist in the health plans that were studied under the HIE, where providers were reimbursed their full charges on a fee-for-service basis.

For the most part, the HIE also did not study use of differential cost-sharing by type of service, though one plan in the HIE varied the cost-sharing a patient would pay for inpatient versus outpatient services (i.e., cost-sharing was applied to outpatient services and inpatient services were free to the patient). The price of outpatient care was not found to affect the demand for inpatient care. However, consumers today face numerous differential prices for medical services, including across types of visits (office visits vs. emergency room visits), types of drugs (generic vs. brand), and even for some, according to the efficiency and quality of their provider through tiered provider networks. In the current environment, optimal cost-sharing depends on cross-price elasticities along with own-price elasticities.

Finally, the HIE focused on a generally healthy, commercially insured population and did not study whether demand response varied differentially for subgroups of consumers (e.g., low income/uninsured, the elderly, and racial minorities).

Thus, due in part to the evolution in benefit design and in part to the desire to test the generalizability of the HIE estimates, several studies of demand response to aspects of medical care have been conducted since the HIE. All are observational studies, the best generally consisting of natural experiments such as the introduction of new insurance policies when patients are subject to plausibly exogenous changes in cost-sharing for medical services.

Estimates of Own-Price Elasticity of Demand since the HIE

Prescription Drugs

Much recent work has studied demand response for drugs in formularies, where the typical structure is either two-tiered, where the lowest cost-sharing tier contains generic drugs and the higher tier branded drugs, or more commonly, three-tiered, where the lowest cost-sharing tier contains generic drugs, the middle tier 'preferred' branded drugs, and the highest cost-sharing tier 'nonpreferred' branded drugs. Several papers review this literature and find that overall, increasing pharmaceutical cost-sharing results in lower utilization of prescribed drugs, i.e., own-price elasticities are negative, and in steering patients away from nonpreferred branded drugs. Gibson *et al.* (2005) review 30 studies from 1974 to early 2005 and report price elasticity of demand ranging from -0.1 to -0.4. In their review of 20 years of this literature (1985–2006), Goldman *et al.* (2007) report that for each increase in cost-sharing of 10%, prescription drug spending decreased by 2–6% (i.e., price elasticity of demand range from -0.2 to -0.6). Huskamp *et al.* (2003) and Goldman *et al.* (2007) show that these findings are consistent across classes of drugs, including medications known to be efficacious for certain chronic diseases, such as statins, angiotensin-converting-enzyme (ACE) inhibitors, antihypertensives, and antidiabetics.

Research on pharmaceutical cost-sharing among non-commercially insured populations is still emerging. The most recent work on the effect of cost-sharing for pharmaceuticals has studied demand response among the elderly following the introduction of Medicare Part D, the Medicare prescription drug benefit. A large literature has found evidence that the introduction of Part D plans has led to lower out-of-pocket spending and higher utilization of prescription drugs, suggesting negative elasticity of demand for pharmaceuticals among the elderly. Joyce *et al.* (2009) found this effect on demand particularly among lower-income beneficiaries. Duggan and Scott Morton (2010) estimate the effect of Part D on changes in utilization and report that their estimates suggest an own-price elasticity of -0.38 for a Medicare recipient with average prescription drug spending.

Future work should continue to study the extent to which demand response varies for population subgroups, especially vulnerable groups such as low-income populations and racial/ethnic minorities. Some recent work by Chernew *et al.* (2008) compares the experience of patients living in low-income areas (based on median household income in patient's zip code of residence) with that of patients in high-income areas, and finds that elasticity of demand for pharmaceuticals is higher for patients in low-income areas. For the most part data limitations (specifically the lack of an indicator for race or socioeconomic status in administrative claims data) have made this research difficult.

Effect of New Health Plan Designs

The rise of managed care since the mid-1990s has meant provider payment in the form of capitation that has increased pressure on providers to curb patient utilization of care, as discussed above. Natural experiments involving the expansion of managed care provide an opportunity to study the elasticity of demand for medical care in the presence of these supply-side incentives. Chandra *et al.* (2010) study changes in copayments for physician office visits and prescription drugs that accompanied the transition of the elderly (retirees) to PPO and HMO plans in the early 2000s by California Public Employees' Retirement System, and estimate that arc elasticities of demand in a managed care environment are less than 0.1, which is about half of that observed in fee-for-service plans studied in the HIE. Goldman *et al.* (2006) find that in the context of implementation of parity for mental health services, supply-side management techniques kept utilization levels largely unaffected by increases in the generosity of mental health coverage, a particularly interesting finding because elasticity of demand for mental healthcare was found to be twice that for other medical care in the fee-for-service environment of the HIE.

Another form of insurance design that has experienced increasing popularity since the early 2000s is high-deductible health plans, where consumers face a large deductible (e.g., $1000 for individuals and $2000 for families) before their health plan begins to cover their costs of care. Preventive services are often exempt from the deductible, and these plans may be paired with a Health Savings Account (HSA). In a large study of the HSA plans from over 700 employers (but from 1 health insurer), LoSasso *et al.* (2010) found that the deductible reduced medical spending by approximately 5%, and the services that were affected tended to be smaller patient-driven services.

Cross-Price Elasticities

Several studies have investigated the impact of differential cost-sharing across medical services, which is now prevalent in health insurance, on demand. In general, this literature reports trends in spending and utilization suggesting that services are substitutes (which implies that cross-price elasticity is positive) or complements (i.e., negative cross-price elasticity), but does not calculate and estimate elasticity of demand.

Pharmaceuticals and Other Medical Services

The vast majority of the studies on this topic consider the cross-price elasticity between pharmaceuticals and other medical services. Evidence is suggestive that pharmaceuticals and other medical services are substitutes. In their review, Goldman *et al.* (2007) summarize the evidence that increased cost-sharing is associated with adverse medical events and outcomes for patients with chronic diseases including congestive heart failure, lipid disorders, diabetes, and schizophrenia. For example, Soumerai *et al.* (1991, 1994) showed that limiting the number of prescriptions in a month in a Medicaid program to three saved money on drugs but led to offsetting increases elsewhere; in the case of schizophrenic patients, the increase in other spending was 17 times the savings on drugs.

Evidence suggesting similar positive cross-price elasticities has also been observed in the Medicare population following

the introduction of Medicare Part D. McWilliams *et al.* (2011) studied spending on nonpharmaceutical medical services in a nationally representative sample of Medicare beneficiaries, and found that the introduction of Medicare Part D resulted in a significantly differential reduction in spending for beneficiaries with limited prior drug coverage (i.e., beneficiaries who had more significant decreases in out-of-pocket spending on pharmaceuticals and presumably increased their utilization and adherence) than beneficiaries with generous prior drug coverage (i.e., those who experienced less change in out-of-pocket spending). They observe the reduced spending predominantly from lower use of inpatient services and skilled nursing facility services. Likewise, in their study of California retirees, Chandra *et al.* (2010) find that increased cost-sharing for pharmaceuticals led to increased utilization of inpatient hospital services. Applying this finding in the opposite direction, Rosen *et al.* (2005) have simulated that it would save money and improve outcomes if ACE inhibitors were made available for free for elderly diabetics in Medicare. When compared with the default cost-sharing in the Medicare drug benefit, the induced increase in the use and cost of ACE inhibitors if they were free would be more than offset by other averted medical costs.

Provider Network

Early efforts (in the 1980s and mid-1990s) by health plans to organize physicians into networks were heavily driven by the provider price or the amount of the discount a provider granted the plan from their price, and simply allowed for physicians to be 'in-network' or 'out-of-network.' These network designs required patients to pay significantly more of the cost of their care if they chose to see an out-of-network physician, and to my knowledge, there is no literature estimating cross-price elasticities for in-network versus out-of-network physicians.

More recently, insurers have begun to offer 'tiered provider networks,' where health insurers sort providers into tiers based on cost and quality performance, and patients pay lower cost-sharing to see a provider in a higher-performing tier. In a tiered network, although the cost-sharing differential across hospitals can be significant (i.e., differential deductible or coinsurance) the cost-sharing difference across providers is usually more modest (differential office visit copay amounts on the order of $10 or $20).

Few studies have assessed consumer response to differences in cost-sharing across tiered providers (the cross-price elasticity of demand) despite the fact that health plans have been experimenting with tiered networks since the early 2000s. Two recent studies analyzed patient-level claims data and find some evidence that consumers switch to preferred providers when the price differential between preferred and nonpreferred tiers is large (i.e., on the order of hundreds of dollars). Scanlon *et al.* (2008) found that some workers were more likely to select a preferred hospital (preferred status based on whether the hospital met set patient safety standards) for medical visits, workers in a second union and all patients admitted for a surgical diagnosis were no more likely to choose the preferred hospitals. Rosenthal *et al.* (2009) analyzed patient loyalty following the narrowing of a PPO physician network that excluded 3% (48 out of 1800) of physicians from the network. The authors find that 81% of patients of affected physicians did not continue to see those physicians following their exclusion from the network, and an additional 7% of patients saw their excluded physician only one more time.

Implications for Insurance Design

An important finding from this literature is that the simple rule that insurers should offer less generous coverage for medical services with higher demand elasticity, is not necessarily ideal. First, the large body of evidence suggesting strong cross-price elasticities across medical services (i.e., that drug consumption lowers the use of other medical services) would call for more generous coverage for prescription drugs, despite the fact that their demand response is relatively elastic. In other words, some patients, especially those with certain chronic diseases, can be induced by less cost-sharing to take actions today that will reduce their future use of medical services and/or improve their future health. It thus follows that optimal cost-sharing could vary across persons and across specific medical goods and services. This logic underlies value-based insurance design (VBID), a mechanism proposed by Chernew *et al.* (2007) where copayments for high-benefit services, such as medications for treatment of chronic disease, would be kept low or set to zero. Although early experience with VBID has shown promise, Baicker and Goldman (2011) offer a thoughtful discussion of the challenges of how to design the benefit design beyond pharmaceutical coverage for individuals with chronic illness, and how to address the potential for risk segmentation of patients into plans with this design.

Final Comments

The empirical research conducted since the 1970s reports estimates of own-price elasticities that are largely in line with those from the RAND HIE. Demand response for pharmaceuticals is also found to be slightly more responsive than that for other services. There is some preliminary evidence suggesting that the most vulnerable populations are more responsive to out-of-pocket medical spending; however, this question should be tested further.

In the context of managed care, cost-sharing is not the only tool to curb inefficient use of medical services. Along with capitation, insurers can apply tools such as gatekeeping and utilization review to affect consumption of medical services. Supply-side mechanisms may affect the estimates of demand response and limit the generalizability of these findings because the effect of the supply-side policies may not be known. However, that physicians have been found to treat their patients in a consistent pattern, such that patterns of care induced by managed care supply-side incentives spillover to a physician's entire patient panel, might limit concerns about generalizability.

There is currently still much more to learn. Efforts to estimate elasticity of demand for medical services for uninsured

populations is now possible due to currently ongoing natural randomized experiment among a Medicaid eligible population in Oregon (Finkelstein *et al.*, 2012); this evidence, not yet available, will greatly enrich the literature. Several opportunities for future research in this area remain. One potential vein is to study how to incorporate findings from behavioral economics, which indicate that consumer decision-making is subject to heuristics and biases, to improve the effect of lowered cost-sharing on consumer demand and the implementation of VBID. Improving our understanding of how cost-sharing can lead to overall cost savings or encourage demand for high quality, effective medical care is an exciting future research agenda.

Pricing and Reimbursement of Biopharmaceuticals and Medical Devices in the USA

PM Danzon, University of Pennsylvania, Philadelphia, PA, USA

Introduction

The US is the largest market for pharmaceuticals in the world. It is also one of the few countries in the industrialized world that does not regulate pharmaceutical prices. This largely reflects the predominance in the US of competing private health insurance plans. Although the public insurance programs, mainly Medicare and Medicaid, now account for more than 40% of total health expenditures in the US, their design has historically been influenced by the design of the private insurance sector. In particular, Medicare Part D, which covers outpatient drugs for seniors, was designed to be run by competing private sector prescription drug plans (PDPs) and the enabling legislation explicitly bars the government from negotiating drug prices.

In the US, as in every other country, insurance that provides financial protection to consumers thereby also tends to make consumers insensitive to prices. For patented biopharmaceuticals, this enables producers to charge higher prices than they would in the absence of insurance. In countries with either national health insurance or regulated social insurance, government payers respond to this effect of insurance by constraining prices either directly, through price controls, or indirectly by making reimbursement contingent on cost-effectiveness. In the US no single private payer has sufficient market power to control pharmaceutical prices. Rather, the negotiation of prices with producers and the design of cost-sharing and other access controls are dimensions of competition between health plans. Fundamentally, health plans that are more restrictive on price to suppliers can offer consumers lower cost plans but with restricted access to services.

In practice, most private health plans and Medicare use similar approaches to negotiating prices and/or setting reimbursement rules for pharmaceuticals. This article describes the predominant reimbursement rules used by these US payers and the effects of these rules on manufacturer pricing, highlighting the important differences based on where a drug is dispensed and between onpatent brands and generics.

Overview of the Drug Distribution System and Price Levels

In the US pharmaceutical market there are multiple prices, corresponding broadly to different levels of the distribution chain and whether the price is a list price or a transactions price (that reflects discounts or rebates off the list price). The main price levels and types are outlined here in summary, and the following sections describe the system and its effects in more detail.

Pharmaceutical manufacturers typically sell drugs to wholesalers at a list price, the wholesale acquisition cost (WAC), sometimes with modest discounts (1–2%) for prompt payment. Wholesalers distribute drugs to retail pharmacies (including mail-order pharmacies) and hospital pharmacies, adding a competitively determined mark-up to cover their distribution costs. Traditionally, an estimate of the average price at which wholesalers sold to pharmacies was published by pricing agencies as a list price called average wholesale price (AWP). This list price was widely used by payers as a basis for their reimbursement to pharmacies. However, AWP became an increasingly unreliable (usually inflated) measure of the actual average transaction price at which wholesalers sell to pharmacies. Although AWP and other list prices have remained the basis for payer reimbursement to pharmacies, there is usually a significant discount. For example, a payer may set pharmacy reimbursement at AWP-18%, where the discount off AWP is negotiated between the payer and the pharmacy chain. This reimbursement price is intended to allow the pharmacy to cover the cost of drug acquisition plus a competitive dispensing fee. The payer reimburses the pharmacy at this price, net of any patient cost-sharing that the pharmacy must collect from the patient, depending on the payer's plan design.

Private payers also negotiate discounts from manufacturers of patented drugs directly. These negotiated discounts are usually paid by electronic transfer from the manufacturer to the payer, thus bypassing the wholesaler/retailer system. This preserves confidentiality of the payer-specific discount amounts and prevents price arbitrage, that is, the manufacturer transfers the discount directly to the payer for whom it is intended. The ability of payers to extract these discounts from manufacturers depends on the payer's ability to influence drug use through its formulary design. The average price received by manufacturers, taking into account these discounts given to private payers, is called the average manufacturer price (AMP). Medicaid and some other public payers by statute get mandatory rebates off AMP.

This system of a manufacturer list price, combined with negotiated discounts to private payers and mandatory rebates to government payers, is similar for generics, except that the negotiated discounts given by generic manufacturers are targeted at dispensing pharmacies, rather than at health plans/payers, because the pharmacies are the ultimate decision-makers for multisource drugs (off-patent products with originator and generic suppliers). This is described below.

Discussion of pharmaceutical pricing in the US tends to focus on prices charged by manufacturers, including both the list prices and the discounts/rebates, because these exmanufacturer prices form the basis for prices paid by final payers, with the addition of wholesaler and pharmacy margins that are competitively determined. The wholesale segment in the US is highly concentrated with three firms accounting for more than 80% of the national market, reflecting large economies of scale. It is nevertheless highly competitive, partly due

to increasing concentration and strong competition at the retail pharmacy (including mail order) level, where the top six chains now account for more than 60% of dispensing sales. Pharmacy regulation in the US requires that retail pharmacies employ a licensed pharmacist, but there are no requirements that pharmacies be owned by pharmacists and no restrictions on chain pharmacies, in contrast to restrictive pharmacy ownership regulations in many other industrialized countries. Over the last two decades, the large chain pharmacies, such as Walgreens, RiteAid, and CVS, have grown by increasing their number of outlets and the range of products and services they offer, besides drugs. Conversely, some large supermarkets and department stores like Walmart operate pharmacies within their stores. These large, chain retailers take advantage of economies of scale and scope, and play a major role in driving competition in the wholesale and the generics sector, as described below. Within each geographic market multiple chains compete and competitive pressure on pharmacy margins is enhanced by the bargaining power of large health plans and pharmacy benefit managers (PBMs) such as Express Scripts and Caremark, including competition from their mail order pharmacies that compete with bricks and mortar pharmacies. Similarly, for inpatient drugs, hospitals purchase through large group purchasing organizations that negotiate with wholesalers and put competitive pressure on distribution margins.

Thus in the US, the exmanufacturer list price and discounts, the wholesale mark-ups, retail mark-ups, and final prices to payers/consumers are freely determined, constrained by market competition, in contrast to most other countries where prices and mark-ups at each of these levels are set by regulation. In this article 'price' refers to the exmanufacturer price, before discounts, unless otherwise noted. The term 'cost-sharing' is used to refer to the component of the final price paid by the consumer.

Why Biopharmaceuticals Markets are Different

Although US biopharmaceutical markets are structurally competitive, as described above, several important factors differentiate biopharmaceutical markets and pricing from those for most goods. For most goods that are sold in reasonably competitive markets to reasonably informed consumers, standard economic theory implies that competition will align prices with value to consumers and marginal cost to producers, yielding outcomes that are broadly consistent with economic efficiency. Achieving efficient pricing for pharmaceuticals is complicated by several factors. First, R&D is roughly 17% of sales for the US-based originator pharmaceutical industry, compared to 4% for other US industries. Marginal cost-pricing, which is the expected outcome in competitive markets, would achieve first best static efficiency but would fail to cover total costs and would violate the requirement for dynamic efficiency that producers capture the full social surplus produced by innovation. To address the need for R&D incentives, patents (and other exclusivities) bar generic competitors for a limited term. Patents intentionally enable originator firms to price onpatent products above marginal cost and thus potentially recoup R&D expenses. Although patent-induced pricing above marginal cost may lead to only 'second best efficient' utilization of patented products, patents are the generally accepted way to pay for R&D, as reflected in the World Trade Organization's Trade-Related Intellectual Property (TRIPS) provisions. Thus, patents and the resulting temporary market power are not intrinsically a cause for concern over pharmaceutical prices.

Second and more problematic is the effect of comprehensive insurance coverage on pricing. Insurance protects consumers from financial risk and, through cross-subsidies, makes health services more affordable to low-income consumers. However, because such insurance makes patient demand highly price-inelastic, insurance creates the potential and incentives for manufacturers to charge prices that exceed the level that would result from patents alone. Public and private insurers may use various strategies to constrain this 'producer moral hazard.' In most industrialized countries payers either control prices directly, through price or reimbursement regulation, or require evidence that the drug is cost-effective, which indirectly limits the manufacturer's price based on the drug's incremental effectiveness. Third, patients, payers, and even physicians often lack good information about effectiveness of medical goods and services, which may undermine price-sensitivity. For biopharmaceuticals and devices, this uncertainty is mitigated by regulation of safety, efficacy, manufacturing quality, and promotion. Thus the effect of insurance is the main cause for concern over pharmaceutical prices.

Private and public payers in the US use neither direct price regulation nor indirect price control through incremental cost-effectiveness thresholds as a requirement for reimbursement. Rather, US payers influence the prices charged by manufacturers primarily through use of tiered formularies that offer preferred formulary position and therefore larger market share to drugs that are favorably priced (or give larger discounts), relative to therapeutically similar drugs. Medicaid and other smaller public programs receive mandatory rebates off the manufacturer's price. These approaches leave list prices unconstrained but do achieve significant discounts on onpatent drugs in crowded drug classes with several close therapeutic substitutes. However, these approaches provide little constraint on prices of drugs that are more unique, including most specialty drugs and biologics. By contrast, reimbursement and substitution rules for generics result in highly price competitive generic markets and very low generic prices in the US. The following sections describe in detail these reimbursement rules and their effects on pricing in the US.

Reimbursement Rules for Onpatent Brands

In the US, payer rules and approaches to pharmaceutical reimbursement differ, depending on where the drug is dispensed – retail pharmacy, physician office, or hospital inpatient (Table 1). Reimbursement differences largely reflect the historical evolution of insurance coverage. Retail pharmacy (54% of prescription sales) and mail order pharmacy (17% of sales) dispense self-administered drugs and are reimbursed on a fee-for-service basis by a private insurer's pharmacy benefit or by Medicare's Part D benefit for seniors. Drugs dispensed as part of an inpatient hospital admission (approximately 10% of sales) are covered by the patient's inpatient benefit

Table 1 US: Reimbursement rules depend on product type and distribution channel

Channel	*Retail pharmacy*	*Physician office*	*Hospital inpatient*
Medicine type	Orals, creams, and self-injectibles	Biologics, infusions, and vaccines	All types
Benefit	Pharmacy/Medicare D	Medical/Medicare B	Hospital/Medicare A
Reimbursement	Tiered formularies with access controls	Buy-and-bill with ASP + 6%	Hospital is paid DRG per admission

(Medicare Part A for seniors). Inpatient drugs are reimbursed, along with all other inpatient costs, in a single bundled payment for the hospital admission. Drugs that are dispensed in physicians' clinics (approximately 12% of sales), including infusions and vaccines, are covered by the patient's medical benefit (Medicare Part B) which pays for physicians' services. Because many new, expensive biologics are physician-dispensed, including many oncologics, the reimbursement rules for this category are critical to pricing of biologics in the US.

Pharmacy-Dispensed Drugs

Primary care drugs

Private health plans use PBMs to manage drugs that are dispensed through retail pharmacies. PBMs developed in the 1990s as stand-alone, independent contractors that managed drug benefits on behalf of self-insured employers and other health insurers. Since then, some large insurers have developed their own in-house PBMs that compete with the stand-alone PBMs. When Medicare Part D was created in 2003 to provide outpatient drug coverage for seniors, administration of the Part D benefit was assigned to competing, private entities called prescription drug plans (PDPs), which are similar to PBMs, with important differences noted below. Many private health insurers and PBMs also serve as PDPs.

Private PBMs and Medicare PDPs use similar strategies to manage drug costs. Specifically, a pharmacy and therapeutics (P&T) committee, which includes physicians and pharmacists, evaluates alternative drugs and designs the formulary, that is, the list of drugs that are covered, with associated patient cost-sharing levels and any other controls. Most plans use a formulary with three or more tiers with corresponding copayments. The first tier is for generics and has a US$0–10 copayment per prescription (or a month's supply of a chronic medication); the second tier includes preferred onpatent brands with a modest (US$25–45) copayment; and the third or nonpreferred brand tier has significantly higher copayment, currently approximately US$45–90 per month. In addition, a fourth tier is increasingly used for expensive specialty drugs and usually has a 25–30% coinsurance of the drug's price. Additional tiers with high coinsurance rates may also apply to 'lifestyle' drugs. These tiers and associated differential copayments are designed to incentivize patients and their physicians to accept generics, if available, or choose 'preferred' brands among onpatent brands.

In addition to these differential copayments, plans increasingly also use direct controls to achieve appropriate utilization. Most common are a step edit (a computerized block that automatically rejects reimbursement of a drug unless the patient meets certain conditions, such as prior failure on a generic alternative) and prior authorization (which requires the physician to obtain prior approval from the health plan before a drug is reimbursed).

Formulary design with tiered cost-sharing, step edits, and prior authorizations enables PBMs/PDPs to shift drug utilization toward preferred drugs. This ability to 'shift share' within a therapeutic class gives plans leverage to negotiate price discounts from manufacturers in return for preferred formulary positioning. For example, a plan that is willing to severely limit the number of preferred brands and impose a large copay differential for nonpreferred brands creates leverage in price negotiations, because a drug manufacturer may be willing to give a large discount to be the only brand on the preferred tier, whereas they may give little or no discount if they share the preferred tier with all competitor products in the class.

Thus, this tiered formulary approach enables PBMs to gain significant leverage over manufacturer prices provided that there are several clinically similar drugs in a class and the PBM is able/willing to limit patient choice of drugs. More restrictive PBM plans that limit patient choice and impose high cost-sharing on nonpreferred drugs can get lower prices and offer lower premiums. Essentially, this process structures patient cost-sharing and utilization controls to increase the cross-price demand elasticity facing manufacturers. It gives payers and patients a trade-off between drug choice and cost of coverage. It has worked reasonably well for large, primary care therapeutic classes, such as statins or antiulcerants, where the availability of several, therapeutically similar drugs has enabled PBMs to drive deep discounts, particularly once generics become available in a crowded class. Because these discounts are confidential, comprehensive data are not available and conclusions here are based on anecdotal and the limited, publicly available data.

Discounting has been challenged by retail pharmacists in antitrust litigation alleging collusive pricing and price discrimination by drug manufacturers (Scherer, 1997). Dispensing pharmacies do not receive the discounts on onpatent drugs comparable to those given to PBMs because pharmacies cannot - and arguably should not – independently influence a physician's/patient's choice between therapeutic substitutes. This litigation conspicuously excluded off-patent drugs and generics, because for these drugs the discounts go to the pharmacies as decisionmakers in choosing between generically equivalent versions of a prescribed compound (see below). Under the settlement of this litigation, manufacturer discounts were to be made available on the same terms to all purchasers; however, because PBMs/PDPs and payers design the formularies that drive therapeutic substitution, they remain the main recipients of discounts on onpatent drugs, whereas pharmacies (including mail-order pharmacies) are the main recipients of discounts on generics.

Consistent with this theory, that the largest discounts go to payers that have greatest control over market share, the

conventional wisdom is that Kaiser gets among the deepest discounts, because Kaiser, as a staff-model health maintenance organization whose physicians work only for Kaiser, can enforce formulary adherence and steer utilization toward preferred drugs. By contrast, most private payers have limited ability to enforce their formularies and influence the prescribing practices of independent physicians because each payer's patients account for a small fraction of each physician's practice.

Specialty drugs

The tiered formulary approach works reasonably well for large classes with several drugs that are close clinical substitutes. However, it works less well for specialty drugs and other classes with few close substitutes. 'Specialty drugs' refer to relatively high-priced drugs used to treat complex diseases for which most prescribing is done by specialist physicians, such as cancer, rheumatoid arthritis, multiple sclerosis, and all rare diseases. Even specialty drugs for the same indication often differ in efficacy and tolerability for individual patients, such that doctors and patients are unwilling to accept payer control over clinical choices. Over the past decade, biopharmaceutical innovation has increasingly shifted toward such specialty drugs, including many biologics that each has distinct risks and benefits. For such specialty drugs, PBMs' only tools to control spending are high patient cost-sharing and/or prior authorizations and step edits, to assure that the patient tries any cheaper alternatives first. These mechanisms at most control utilization, but have little direct effect on price. The limited control of payers over the price of specialty drugs is one factor making these drugs a more attractive target for pharmaceutical R&D compared to primary care therapeutic classes with close substitutes and potential genericization.

Medicare PDPs have taken the lead in placing pharmacy-dispensed specialty drugs (which Medicare defines as drugs that cost US$600 or more a month) on a fourth 'specialty' tier with a 25–33% coinsurance, and PBMs are increasingly following this approach. These high coinsurance percentages applied to very expensive drugs potentially imply patient cost-sharing of hundreds of dollars per month. Simple insurance theory suggests that such high patient cost-sharing may imply inappropriately high financial risk for patients and make patients highly price sensitive (and noncompliant), which might constrain manufacturer prices. However, in practice, the majority of patients are protected from such high cost-sharing by other features of their coverage or by manufacturer assistance programs. Specifically, low income seniors are protected from most cost-sharing by Medicare Part D's low income subsidy, and all seniors are protected by the catastrophic stop-loss on Part D cost-sharing, which in 2013 is US$4750 per year, after which the patient pays at most 5% of the drug price (0 for Medicaid-eligibles). Moreover, manufacturers are required to give Medicare patients a 50% discount while they are in the coverage gap ('doughnut hole') where they must pay the full drug cost. These discounts are ignored in calculating beneficiary's out-of-pocket expenses, so effectively they reach the stop-loss after lower cost-sharing. Some private patients may also face high cost-sharing and some currently have no catastrophic stop-loss. For such patients, manufacturers increasingly provide patient assistance programs (PAPs) for low income patients and cost-sharing coupons for other patients (such coupons are illegal for Medicare patients).

Thus although patients nominally face high cost-sharing for specialty drugs, in practice actual marginal cost-sharing is often minimal due to the combination of supplementary insurance through Medicaid and other private coverage, stop-loss limits, copay coupons, and patient assistance programs. In that case, cost-sharing is ineffective at constraining manufacturer prices for specialty drugs. There is little robust evidence on effects of this recent high cost-sharing for costly, specialty drugs, and obtaining reliable estimates is difficult if those who truly do face the 25–30% coinsurance simply forego the treatment. However, it seems likely that for an increasing fraction of new drugs, patient costsharing, which is the main approach to constraining prices in the US, cannot simultaneously constrain manufacturer pricing and enable appropriate patient use.

The fact that Medicare PDPs typically have significantly higher copayments for nonpreferred brand drugs than private PBMs, and more PDPs use specialty tiers with a 25–30% coinsurance for specialty drugs, suggests that PDPs' increasing use of these cost-sharing strategies may partly reflect the greater financial and adverse selection risk born by PDPs, due to three factors. First, to incentivize PDPs to control costs, by law the PDP is at risk for 15% of a patient's cost beyond the Medicare catastrophic threshold (US$6955 in 2013). By contrast, PBMs are not directly at risk for the drug spending of their enrollees, rather, they are reimbursed a fee per script and retain a fraction of the discounts they negotiate. Second, PDPs face greater adverse selection risk because most Medicare beneficiaries can choose between several stand-alone PDPs. If one PDP in an area were to offer more generous coverage of specialty drugs, it might attract a disproportionate share of the patients who need these and other drugs. By contrast, each private employer offers their employees only one PBM, hence that PBM does not face adverse selection within the employee pool. Third, by law Medicare PDPs are exempt from tier exemption requests for drugs on a specialty tier, hence use of a specialty tier may reduce the administrative cost burden of exemption requests for PDPs, which would likely be significant if the PDP were to place some specialty drugs on a preferred tier while putting others on a nonpreferred tier with very high cost-sharing.

Medicaid

Unlike the Medicare Part D drug benefit, which is operated by private sector entities that use similar tiered formularies and negotiated discount strategies to private PBMs, the federal-state Medicaid program uses mandatory rebates. Because Medicaid beneficiaries are low income families with children, seniors and the disabled, even modest patient cost-sharing may lead to noncompliance. Rather than use tiered cost-sharing, since 1990 Medicaid has required manufacturers to give a mandatory rebate equal to the greater of 15.1% off the AMP (which is the manufacturer's average price charged to the private sector, including discounts) or the 'best price' (largest rebate) given to any private payer. For generics, the mandatory Medicaid rebate was a flat 11%, unrelated to discounts to other payers. When Medicare Part D was established in 2003, drug coverage for 'dual eligible' seniors (who are eligible for both

Medicaid and Medicare) was exempted from these Medicaid rebates, and rebates to Medicare PDPs were exempted from the definition of 'best price.' Under the Affordable Care Act of 2010 (ACA), the minimum Medicaid rebate on brand drugs was increased to 23.1% (13% for generics) and Medicaid Managed Care Organizations are required to pay this rebate on Medicaid-eligible enrollees.

By requiring that manufacturers of brand drugs give to Medicaid the largest discount they give to any private purchaser, Medicaid's 'best price' rule effectively raised the cost of giving discounts that exceed the mandatory minimum Medicaid rebate (15.1% before 2010, now 23.1%) to private payers. Manufacturers rationally give discounts to customers who use formularies to create elastic demand. But paying the government a rebate for Medicaid usage has no effect on drug utilization by Medicaid patients, as the rebate is unrelated to preferred formulary status or incentives of patients or prescribers. Therefore, from the perspective of manufacturers, tying a mandatory rebate to Medicaid to a discount given to private payers reduces the overall elasticity of response to private rebates beyond the mandatory minimum, which is now the weighted average of the (presumably elastic) response of the private enrollees and the totally inelastic response of Medicaid enrollees. Thus, the Medicaid best price requirement reduced manufacturer willingness to give discounts to private payers in excess of the mandatory minimum Medicaid rebate, particularly for drugs with relatively high usage by Medicaid patients.

Empirical studies have confirmed that private sector rebates declined in response to this Medicaid best price. When Congress established Medicare Part D, discounts given to Medicare PDPs were explicitly excluded from the Medicaid best price calculations, in order to encourage manufacturers to give deep discounts to PDPs. The 2010 increase in the mandatory minimum Medicaid rebate to 23.1% means that the 'best price tax' now only applies to private sector discounts larger than 23.1%, hence increased discounting up to this 23.1% threshold is expected, ceteris paribus.

Mandatory Medicaid rebates may also create an incentive for manufacturers to raise the price from which the rebate is calculated. Anticipating this effect, Medicaid requires an additional rebate equal to the cumulative excess increase in a drug's price over the consumer price index (CPI), since the drug's launch. This 'excess-CPI rebate' has not been sufficient to eliminate increases in manufacturer prices for onpatent drugs faster than the CPI in recent years. Thus, the Medicaid mandatory rebate provisions have probably contributed to both higher list prices and smaller discounts for private sector payers. Consistent with this, Duggan and Scott Morton (2006) found that drugs with a higher Medicaid share experienced larger increases in prices (including discounts) to private payers.

Physician-Dispensed Drugs

Drugs that require infusion or injection, including many cancer drugs and other biologics, are dispensed in physician clinics. For Medicare patients, physician-dispensed drugs are covered under Medicare Part B (which covers physician services) rather than Medicare Part D (which covers pharmacy-dispensed outpatient drugs). Before 2005, Medicare reimbursed dispensing physicians at 95% of AWP, an unregulated list price, and most private payers followed suite. This reimbursement rule created incentives for manufacturers to compete for market share by offering discounts off AWP to physician practices, in order to increase the margin between their acquisition cost and the reimbursement. Evidence has confirmed that financial incentives influenced physician prescribing choices (Epstein and Johnon, 2012). Lawsuits have also alleged that some manufacturers raised AWP in order to increase the physicians' margin. The margin accrued to dispensing physicians because Medicare and other payers did not attempt to reduce their reimbursement price to capture the discounts. This contrasts to payer response to a similar incentive system for generics in the US (see below) or in Japan. In Japan, manufacturers similarly offer discounts below the reimbursement price to physicians who dispense drugs, as an inducement to use their drugs. However, the Japanese payers (partially) capture these competitive discounts by reducing their reimbursement price paid to dispensing physicians, based on a biennial audit of actual acquisition prices.

Following substantial litigation over the alleged manipulation of AWP and large margins given to dispensing physicians, in 2005 Medicare changed its Part B reimbursement, intending to align reimbursement more closely to actual acquisition prices. Under the new rules, Medicare Part B reimburses dispensing physicians at the manufacturer's Average Selling Price (ASP) plus a six percent margin. Manufacturers are required to report each drug's ASP quarterly, which is defined as the volume-weighted average manufacturer selling price, including all discounts, lagged two quarters. In the short run, this shift to ASP + 6% reimbursement reduced the prices that Medicare Part B pays for drugs. But in the longer run, the ASP + 6% formula eliminates incentives for manufacturers to compete on price, because any discounts offered to physicians in quarter T reduce the ASP and hence reduce the reimbursement price and the 6% margin for all physicians in period T + 2. Moreover, the ASP + 6% reimbursement rule creates perverse incentives for manufacturers to compete by charging high rather than low prices, because a higher price offers a larger margin to the dispensing physician. The main impact of the perverse ASP + 6% incentives is for higher launch prices. Raising prices postlaunch by more than one or 2% a quarter risks squeezing physicians' margins because their reimbursement only rises after a two quarter lag. Because many private payers follow Medicare reimbursement, this Part B reimbursement rule and its perverse incentives have probably contributed to higher prices for oncologics and other biologics in the US.

Despite the perverse price-increasing incentives created by Medicare's ASP + 6% reimbursement rule, two factors may provide some constraint. First, as prices for these drugs rise and increasingly exceed $40 000 or even $100 000 per treatment course, physicians that 'buy-and-bill' face significant cash flow cost and even risk, if reimbursement is uncertain. Thus, uptake of some very costly drugs has initially been slower than expected, at least until payer reimbursement is assured. Second, the 20% Medicare Part B patient cost-sharing should in theory act as some constraint on manufacturer

prices. However, in practice most seniors are protected from this cost-sharing by supplementary insurance through either Medicaid (for low income seniors) or Medigap (employer-sponsored or privately purchased). Similarly, although private insurance plans usually have cost-sharing, most private patients have a stop-loss limit on annual out-of-pocket costs and such limits become mandatory under the PPACA. Further, for uninsured or privately-insured patients who face significant out-of-pocket costs, most manufacturers offer copay coupons or patient assistance programs (copay coupons are illegal for Medicare patients). As a last resort, although physicians cannot waive copayments without risk of violating antikickback statutes, they can refer patients to a hospital outpatient department, which may waive copayments. Thus similar to the situation for pharmacy-dispensed specialty drugs, most patients are protected from the nominally high cost-sharing on physician-dispensed drugs. If so, manufacturers face highly inelastic demand and little if any constraint on pricing.

Hospital Inpatient Drugs

Drugs that are dispensed as part of an inpatient episode are generally not reimbursed separately but are included in the bundled diagnosis-related group (DRG) payment for the hospital admission. Medicare updates its DRG payment rates over time, based on national average costs, by DRG, as reported in hospital cost reports. Private payers negotiate various forms of bundled payment for inpatient hospital care, with private rates generally above Medicare rates but also no separate reimbursement for inpatient drugs. Thus in the short run the cost of new inpatient drugs (or price increases for existing drugs) are borne by hospitals, with pass-through to payers with a lag, if/when the drug becomes standard of care and reflected in average cost for the DRG. In exceptional circumstances, a very high-priced new drug may be reimbursed separately from the DRG temporarily, until its cost is included in an increased DRG payment.

This system of bundled payment for inpatient admissions puts hospitals at risk for inpatient drug costs in the short run. Hospitals therefore have incentives to be price sensitive in designing their formularies and negotiate price discounts with manufacturers in return for preferred formulary placement. Larger hospital systems that negotiate on their own behalf and can enforce formularies have greater bargaining power and get larger discounts than smaller hospitals and those that bargain indirectly through group purchasing organizations (GPOs). However, as with PBMs/PDPs, hospitals have little or no leverage to negotiate discounts for drugs that have few or no close substitutes, which includes many specialty drugs.

Generics

In 2011, 80% of all prescriptions were dispensed as generics in the US, and for compounds with a generic available the generic share of scripts was 94%. By contrast, generics account for only 27% of dollar value of sales (IMS, Health Informatics Institute, April 2012). This high generic share by volume reflects both the large percentage of drugs for which patents have expired (or been successfully challenged) and the rapid conversion to generics once they become available. The much lower generic share of sales by value reflects the low generic prices, relative to originator prices. Compared to most other high income and some middle income countries, generic penetration is more rapid and generic prices are lower absolutely in the US (Danzon and Furukawa, 2006).

The high-generic volume share and low generic prices in the US relative to most other industrialized countries reflects several institutional features that interact to produce a highly price-competitive generic market in the US. First, the statutory rules governing generic entry are designed to reduce costs of entry and encourage patent challenges. Under the 1984 Hatch Waxman Act, generic versions of chemical drugs can file an Abbreviated New Drug Application (ANDA) with the Food and Drug Administration (FDA). By demonstrating bioequivalence to the originator drug, generics can be approved as substitutable for the originator, while simply referencing the originator's clinical trials to establish safety and efficacy, rather than doing new clinical trials. This dramatically reduced the cost and time required for generic approval. The Hatch-Waxman Act also incentivized generics to challenge patents, by offering a 180-day market exclusivity to the first completed ANDA that successfully challenges the originator's patents (a Paragraph IV filing). This FDA requirement, that generics demonstrate bioequivalence to the originator, is the basis for confidence on the part of physicians, consumers, and payers that generic substitution by pharmacists is safe. Although bioequivalence and substitutability apply to the great majority of small molecule drugs, certain compounds are considered too high risk or too difficult to characterize to permit safe substitutability.

Second, payers incentivize patients to accept generics by structuring formularies with low copayments (US$0–10) for generics, whereas the patient may have to pay the full price or a nonpreferred tier copayment for the originator. Third, the rapid uptake of generics reflects the rules and financial incentives for pharmacy substitution. The great majority of states have adopted the default rule that pharmacists may substitute any FDA-substitutable generic, even if the physician writes the script for the originator brand, unless the physician explicitly requires that the brand be dispensed. Thus the pharmacy decides which version of the compound to dispense, if substitutable generics are available and the physician does not require the brand. Payers incentivize pharmacies to prefer low-priced generics by reimbursing the same 'maximum allowable cost' (MAC) regardless of whether they dispense a generic or the brand. The MAC is similar to a reference price used in many other countries. Payers generally set the MAC at a relatively low generic price, though methodologies for setting and updating MACs vary. Because the pharmacy captures the margin between the MAC reimbursement and the acquisition cost of the drug, generic manufacturers compete by offering discounts on the acquisition cost to increase this margin. Over time, the payers revise the MACs downward to capture some of this discounting on generic prices, which leads to further price cutting by generics. Thus once multiple generics enter for a given drug, aggressive price competition and rapid generic erosion of brand sales occur, because pharmacy substitution is incentivized by MAC reimbursement and patient acceptance of generics is incentivized by low cost-sharing.

In a pharmacy-driven generics market such as the US, where generics are required by regulation to be bioequivalent and pharmacies are authorized and incentivized to substitute, generics have little incentive or possibility to use branding to create a perceived quality differential. Generics are therefore unbranded and compete on price and service to their highly-price conscious pharmacy customers. By contrast, in countries where generics are not required by regulation to be bioequivalent, which includes most middle and lower income countries, actual and perceived quality differences can play a big role in choice between supposedly similar products. In such regulatory regimes, there are often multiple 'similar' or 'copy' products that claim to have the same active ingredient as the originator brand, but there is no assurance that they in fact have exactly the same active ingredient and an equivalent therapeutic effect, quite aside from issues of substandard or counterfeit products. Given such intrinsic quality uncertainty, generic producers have strong incentives to sell branded generics, where brand becomes a proxy for quality. With quality uncertainty, physicians prescribe by brand – either the originator brand or a specific branded generic – and pharmacy substitution is not legally authorized, although it may not happen in practice. Branded generics are promoted and detailed to physicians, just like originator brands, which adds significant marketing costs. Generics also promote their brand to pharmacies in countries where pharmacies dispense without a prescription. In such branded generic markets, competition between generics focuses on brand as a proxy for quality, not price. On the contrary, branded generic prices are relatively high, compared to the originator price in that country and compared to US generic prices, in part because a low price might be interpreted as a proxy for low quality. In physician-driven, branded generic markets, originator brands usually retain a significant market share even after patent expiry, in contrast to the virtually complete originator brand erosion in the US.

Generic prices have traditionally been lower in the US than in major European markets, including Germany, France, and Italy, in contrast to onpatent brand prices which are higher in the US. But since the late 1990s most western European countries have changed their regulatory and reimbursement rules to permit and incentivize pharmacy substitution and generic price competition, which has increased savings to payers from generics. In Germany, since 2007 payers are authorized to contract directly with generic companies, using competitive tenders to drive and capture savings from price competition. So far, branded generics markets remain the norm in Latin America, Africa, and most Asian countries, including China. In such countries, generic quality is uncertain and some branded generic prices are relatively high. Some multinational originator companies are entering these relatively high-margin, branded generic markets through licensing arrangements with branded generic producers. This strategy draws on their brand selling expertise and brand image. However, because this physician-driven branded generic model delivers only modest savings to consumers and payers, compared to the pharmacy-driven unbranded, price-competitive generics model of the US, it seems likely that the US unbranded, price-competitive generic model will eventually become the norm in most countries.

The relatively high concentration on the purchaser side of the US generic market probably contributes to low generics prices. As discussed earlier, the US retail pharmacy market has become concentrated into large chains and large national wholesalers purchase on behalf of independent pharmacies. These concentrated buyers purchase a sufficient absolute volume and market share to have significant leverage in price negotiations with generic suppliers. Because these large purchasers are the decisionmakers for (intramolecule) generic substitution, generic suppliers target their discounts to them in the first instance, whereas originator companies target discounts on onpatent drugs to payers or PBMs who are the decisionmakers with respect to formulary design and (intermolecule) therapeutic substitution. The system relies on competition at the retail pharmacy and PBM levels to pass on these discounts on generics and onpatent brands to ultimate payers and consumers.

Competitive pressure on generic prices also depends on number of generic competitors. Price competition is weaker when there are few generic competitors, which occurs in at least two instances. First, the Hatch-Waxman Act intentionally grants a 180-day exclusivity to the first ANDA generic to successfully challenge all relevant patents. During those 180 days, the originator typically maintains or raises its price, but may also launch an authorized (licensed) generic to capture some of the more price sensitive market. During this period of at most two generics, their pricing is typically approximately 60–80% of the originator price. By contrast, once the exclusivity period expires, if multiple competing generics enter, generic prices fall rapidly to 10–20% of the preexpiry originator prices. Thus, the much higher price and margin during the exclusivity period creates an incentive for generic firms to incur the significant litigation costs and risks in challenging patents. Second, more complex formulations and specialty drugs with small markets typically attract fewer generic competitors than oral formulations with large markets. With fewer competitors, generic prices and margins can remain relatively high.

Brand Pricing after Patent Expiry

The evidence indicates that originator firms typically raise prices before and after patent expiry, rather than reduce price to compete with generics. One theory that accounts for such pricing is that the originator pursues a segmentation strategy (Frank and Salkever, 1992). In this model, before patent expiry, the originator selects the profit-maximizing price based on the weighted average of price elasticities of all customers in the market. After patent expiry, the more price elastic customers switch to generics, and the originator targets only the most brand-loyal, price-inelastic customers, which results in a higher, profit-maximizing price. This model was appropriate in the early 1990s, when many consumers in the US paid out-of-pocket for drugs and pharmacy substitution was less the norm. It is also useful in understanding price competition in self-pay, branded generic markets in emerging markets. However, in the current US context where most consumers have tiered insurance coverage and most states have pharmacy substitution, the price-inelastic market segment is very small. Moreover, during the 180-day exclusivity period, some originator firms have given

some payers sufficiently high discounts to get the originator drug placed on the generics tier, such that consumers have no reason to prefer generics. This strategy rarely continues beyond the 180-day exclusivity period, presumably because the discount required to compete on price with generics becomes too large.

A second rationale for originators to raise price before and after patent expiry is to encourage patients and payers to switch to a new formulation or a follow-on version of the drug that still enjoys patent protection or data exclusivity and therefore is not subject to generic competition. For example, before the patent-expiry on the standard twice-a-day tablet formulation, the firm may launch a once-a-day, timed release version of the drug that receives some market exclusivity for doing new clinical trials. By raising the per-day price of the old tablet such that it exceeds the price of the new delayed release formulation, the firm encourages payers and patients to prefer the new formulation. If the script is written for the exclusivity-protected formulation, pharmacies cannot substitute a generic because substitution is permitted only within the identical formulation. Such launch of a new formulation or product, together with price increase on the older formulation, is the most effective defense against generic erosion on a patent-expired drug in the US.

Biosimilars

In contrast to the price-competitiveness of generics for small molecule (chemical) drugs, biosimilar versions of biologics are unlikely to compete aggressively on price in the US, for several reasons. First, the higher clinical trial and manufacturing costs of biosimilars are expected to result in fewer competitors. Second, the greater complexity of biologics molecules means that the FDA is unlikely to declare them to be substitutable with the originator or with each other, except possibly for the simplest biologics. If pharmacies cannot substitute, physician-prescribers will be the decisionmakers. Thus biosimilars in the US will likely be branded products, detailed to physicians and marketed on brand rather than price, more like branded originator drugs than unbranded, price-competitive chemical generics. It is possible that payers may use tiered formularies, tiered cost-sharing, step edits, and prior authorizations to attempt to drive utilization toward preferred biosimilars, in which case they may extract significant discounts. However, this would be a departure from their current passive role with regard to use of biologics and other specialty drugs.

For biosimilars that require infusion in a physician office, the nonsubstitutable biosimilar would receive a different reimbursement code from the originator and have a separate ASP. Under current Part B reimbursement, this could discourage price competition by biosimilars, because reducing the price would reduce the physician's margin. The PPACA therefore provides that the 6% margin would be calculated on the originator's ASP, regardless of whether the originator or the biosimilar is dispensed. This eliminates any financial incentive for physicians to prefer the originator versus the biosimilar, but still provides at best weak incentives for biosimilars to compete on price.

As availability of clinically similar biologics increases, including both biosimilars and 'bio-betters,' payers may attempt to change reimbursement rules for specialty drugs in order to stimulate some price competition and value-based purchasing. Some US payers are requesting comparative effectiveness data and evidence of outcomes as a condition of favorable formulary placement. Some payers are also starting to adopt bundled payments for episodes of care that includes drugs. If providers are at risk for the cost of drugs as part of a care episode, they have strong incentives for cost-conscious choices with respect to volume and type of drugs. In addition to DRGs for inpatient care, Medicare has adopted bundled payment for dialysis, and at least one private payer uses bundled payment for certain episodes of cancer care. Therapeutic reference pricing, as used in Germany for certain classes of drugs, has also been mentioned in the US, but so far seems unlikely.

Discussion and Conclusions

The US reimbursement system for pharmaceuticals, which permits manufacturers to set prices freely and relies on patient cost-sharing and health plan bargaining to drive discounts off these prices, has been reasonably effective at constraining prices for drugs in crowded classes with clinically close substitutes. Once generic entry occurs, pharmacy substitution and reimbursement incentives assure low generic prices and rapid generic erosion. However, for specialty drugs – which typically have few close therapeutic substitutes and include many biologics – current insurance reimbursement and cost-sharing arrangements create incentives for manufacturers to set high prices with few constraints, especially for physician-dispensed drugs. Although patients nominally face very significant cost-sharing, such cost-sharing is ineffective at constraining manufacturer prices due to supplementary insurance, stop-loss limits, manufacturer coupons, and patient assistance programs. The ACA stop-loss limits will further reduce the elasticity of demand facing manufacturers for high-priced drugs. Stop-loss limits provide appropriate financial protection for patients but imply that other payer constraints on prices may be appropriate.

After double-digit growth rates in the late 1990s, the rate of growth of drug expenditures has moderated since the early 2000s in the US. This is due largely to savings from patent expirations and consequent generic erosion on many high-volume drugs, combined with a modest flow of new drugs that have generated insufficient new sales to replace sales lost to patent expiries. The resulting savings to payers and consumers have created budget headroom for higher prices on newly-launched drugs and substantial postlaunch price increases. However, this will change as the wave of patent expiries tapers off around 2015 and if the recent uptick in number of new drug approvals continues.

Thus, the combination of an increasing share of new drugs (biologics, orphan drugs, and other specialty drugs) for which traditional PBM/PDP-tiered formulary mechanisms work poorly, with more (and appropriate) stop-loss limits on patient cost-sharing under the ACA, make some change in reimbursement mechanisms increasingly likely. Although none of the ACA provisions relate directly to pharmaceutical

reimbursement, the inducements for bundled payments and outcomes-based reimbursement for hospital and physician providers may eventually spill over to pharmaceuticals. If payers require evidence of comparative and cost-effectiveness, as an input for making coverage and reimbursement decisions, this would incentivize manufacturers to set prices commensurate with incremental health benefit delivered. This form of flexible and indirect price constraint, that aligns prices with incremental health benefit, provides more appropriate incentives for R&D and for efficient use of drugs than either the status quo or alternative price control mechanisms that have been proposed.

Pricing and User Fees

P Dupas, Stanford University, Stanford, CA, USA

Glossary

Allocative efficiency This exists when a product or service is allocated in such a way as to maximize the health benefit of the population.

Placebo–price effect When a higher price for a product or service affects beliefs about its quality and this belief translates into higher actual experience of the product's efficacy.

Price-elasticity The responsiveness (elasticity), of the quantity demanded of a good or service to a change in its price.

Sunk cost When costs previously incurred cannot be retrieved or saved by ceasing production, they are said to be 'sunk'. They should be irrelevant to a rational calculating decision maker.

Introduction

Governments throughout the world intervene in the health sector. One motivation is that under Article 25 of the Universal Declaration of Human Rights access to adequate healthcare is a fundamental human right. A second motivation is that the health sector is subject to many market failures, due to, for example, consumption externalities, imperfect information, and imperfect credit. Consumption externalities exist when private consumption of health services yields positive or negative social returns. Immunization is a prime example: when individuals get immunized, the disease transmission rate falls, yielding increased protection for the whole population. In the case of imperfect information, people do not have all the information they need to make healthcare decisions. There may, for example, be information asymmetries: the patient typically has less information about her private returns to consuming a given health procedure or drug than the physician trying to sell that service or drug. In the case of imperfect credit, people might not be able to finance lumpy health investments that yield positive returns, such as preventive care. In the presence of these market failures, private consumption of health products and services is socially suboptimal. Thus, in the presence of positive externalities, immunization rates are too low; in the presence of information asymmetries that favor the provider who has incentives to oversell, the utilization rate for services or drugs is too high; and with imperfect credit investments in preventive products is too low. Governments intervene in the health sector to remedy these market failures and achieve the social optimum. They do so in four main ways: public provision of health services, subsidies for private provision, regulation of private provision, and public provision of information. In the first three cases, an important dimension of a government's intervention concerns the pricing of health products and services.

This article is concerned with the question of how to decide what price should be set or charged for what health service or product. How much should patients pay for health services at government clinics? How large should the subsidy be for preventive health products that exhibit positive externalities? What should be the maximum price that private medical practitioners are allowed to charge for primary care services? Although many of the points discussed here are directly relevant to the issue of optimal price controls, price regulation, which is covered in the previous article, will not be discussed. Instead, focus is on the issue of user fees (or user charges) for public health services. Public health services account for more than two-thirds of medical services provided in sub-Saharan Africa and between one-third and two-thirds in Southeast Asia. For our purposes, public health services will be broadly defined. They will include the delivery of subsidized health products, even if receipt of these products does not require a health professional. In other words, as defined here, public health services encompass both inpatient and outpatient medical care and the implementation of subsidies for vaccines, bed nets, antimalarial pills, and other privately produced health products.

User fees have implications for cost-effectiveness, allocative efficiency, equity, progressivity of public healthcare spending, and quality of service. Each of these is a desirable policy end in itself, and so each is an important factor in the optimal pricing decision. However, they are not always compatible with each other. Furthermore, they all have to be financed from a single, and typically constrained, budget. Thus governments have to tradeoff over them. Although the relative importance accorded to each factor will depend on the government's objectives, most are likely to place nonzero weights on most factors. In addition, these five factors have to be considered both for the product or service in question and for other products and services funded from the same budget. Each factor, then, has to be carefully analyzed when setting a pricing (user fee) system for public health services. This article reviews the theory and empirical evidence on the effects of user fees on each factor.

Cost-Effectiveness

A first reason to charge a user fee for a given health service or product may be to reduce the public cost per unit provided. This per-unit cost reduction would make it possible to increase the quantity provided within a given budget – that is, to

 doi:10.1016/B978-0-12-375678-7.00123-1

become more cost-effective. Two conditions are necessary for a user fee to reduce the unit cost.

User Fees and Administrative Costs

User fees can only improve cost-effectiveness if the administrative costs of collecting and managing the fee revenue are lower than the fee itself. This is an obvious enough condition, but one that is not always easy to satisfy. Record keeping at the point of service in many developing countries is done manually. This makes the aggregation of data needed for effective management time-consuming and difficult. In particular, ensuring that fees are properly collected and remitted in full can require either costly monitoring, or costly incentives for health workers, or both.

User Fees and Fixed Costs

When fixed costs are important, the impact of user fees on cost-effectiveness will depend on the price-elasticity of demand. Fixed costs for healthcare are often large: both the facility costs and staff costs must be paid whether patients use the facility or not. This means that a change in demand can have a substantial impact on the average cost. Imagine, for example, that 15 patients use a prenatal clinic daily when the price is zero, but only 9 when a user fee is charged. The fixed costs, for example, the salary of the prenatal nurse, would be the same for 9 patients as for 15. As such, the per patient cost of delivering prenatal care could actually be higher when fees are introduced and utilization rates decrease. A recent example of the effects of utilization rates on cost-effectives in the presence of important fixed effects comes from a randomized trial in Udaipur, India. When parents were offered in-kind incentives to use free immunization services, demand increased so much that costs per child immunized were halved compared with when they received free service alone. In other words, with higher demand fixed costs were spread over many more beneficiaries, so that the negative price was more cost-effective than a zero price.

The question of the price-elasticity of demand for health services gained prominence in the mid-1980s. After the Alma-Ata 'Health for All' Declaration was signed in 1978, which made access to basic healthcare a fundamental right, many countries in Africa implemented free primary healthcare. In the mid-1980s, however, it became apparent that free delivery was not financially sustainable, and in 1987 the World Health Organization, United Nations Children's Fund and a group of African health ministers launched the Bamako Initiative calling for self-financing mechanisms at the local level, including user fees, particularly, for drugs. The evidence available at the time was mixed and therefore controversial. Earlier studies, using cross-section variation in prices, had estimated that demand for healthcare was relatively price-inelastic. The price range over which the elasticity could be estimated was relatively narrow, making it difficult to gauge how truly price-sensitive people were. Later studies, using the introduction (or suspension) of user fees, found large drops (increases) in utilization in response to the policy change. For example, the suspension of user fees in Madagascar following a political crisis has been credited for a very large uptick in utilization rates. All in all, the empirical evidence so far suggests that policymakers should give close attention to potential reductions in utilization rates when considering user fees as an instrument for reducing the unit costs of public health goods.

Allocative Efficiency

Perhaps a second reason to charge user fees is to improve allocative efficiency – that is, ensure that the product or service is provided to those that actually need it the most. In particular, user fees may help prevent overutilization, that is, utilization by those for whom the conferred benefits, both private and social, are lower than costs of providing them the good. If user fees do prevent such waste, then the resulting reduction in demand would be desirable even when universal access to services is one of the objectives. There are three mechanisms through which user fees can act on allocative efficiency: screening effects, psychological effects, and moral hazard deterrence effects.

User Fees Can Improve Allocative Efficiency

First, by screening out those who do not value the product or service enough to pay for it. This allocative role of market prices is a standard tenet of price theory. Households, just like governments, are budget-constrained. They, too, are unlikely to invest in a health good – be it prenatal care or a water purification product – if the expected benefits are lower than the costs, both the monetary costs and the time costs. Persons with a simple cold, for example, is less likely to be interested seeking care if it will cost money or it will take 2 h of their day. Instead if they have severe malaria, they will probably want to make the investment in medical care, even at a high cost. In the end, whether or not they seek care and what kind of care they seek will depend on the prices they face. In other words, the prices determine the allocation of public health goods. As it is theoretically based on the user's valuation of the good, this priced-determined allocation is efficient.

The allocative efficiency of prices breaks down under three market imperfections – externalities, imperfect credit, and imperfect information. First, when there are positive externalities to private consumption, private consumption should be subsidized up to the social value to ensure that those for whom the private value is lower than the market price (but the sum of the social and private value is higher than the price) still invest in the good.

Second, when credit markets are not perfect, people cannot borrow to invest in goods that yield positive returns. Limited access to credit means that people may not have the ability to pay for their full valuation of the good; ability to pay and willingness to pay can then become disjoint. User fees could in such cases bar access to some people for whom the health returns to the health good would be high, but who are too poor to pay for it.

Third, when information is imperfect people may not know exactly the private value of the good. For example, they may not have the information or the ability to process

available information; they would then not be able to assess how much they would benefit from, and so should want to pay for, a given medical procedure or product. For some goods, they may only be able to acquire the information by first trying the good. In these cases of imperfect information, user fees could screen out those that do not know they need the product, preventing them from ever learning that the good could benefit them. However, in the presence of imperfect information, how much a service or product is sold for may be interpreted as a signal of its quality. If so, setting user fees too low could discourage usage by setting too low expectations about the quality being provided. In a randomized study in urban Zambia, researchers find that offering a new, unknown water purification product at too low a price dampened demand for the product compared with a higher-priced, well-known product. This signaling effect of prices can be mitigated by information provision; however, in the Zambia study, accompanying the subsidy with a marketing message that informed customers that the new product was as effective as the well-known product led to higher demand at subsidized prices. Likewise, information that the user cost is subsidized might be sufficient to ensure that low prices are not taken as a signal of low quality (i.e., if people infer something about the value of a service from the extent to which it is subsidized).

Evidence from recent randomized experiments suggests that the extent to which user fees can improve allocative efficiency depends on the context as well as the good. In another randomized study in urban Zambia, researchers randomized the fee charged for a chlorine-based water purification product. They found that higher fees screen out households that would not benefit health wise, because, for instance, they would use the product for house cleaning rather that water purification. In rural Kenya, researchers randomized the fees charged for artemisinin-combination therapy (ACT), the latest class of antimalarial drugs, and found that higher fees increase the likelihood that the ACTs are bought by those with a verified case of malaria. However, when they randomized the fee charged for antimalarial bed nets, also in rural Kenya, they found the opposite result: higher fees significantly reduced demand by screening out those who value the product and would use it efficiently if they got it for free but cannot afford to pay for it. A third study in rural Kenya found that the reduction in demand associated with high fees can prevent households from learning the true private value of antimalarial bed nets, which dampens future willingness to pay.

Given these dynamic learning effects, and the pervasiveness of credit constraints, a potential alternative to setting user fees is to use nonmonetary costs as an allocative mechanism. Studying the adoption of a water chlorination product similar to those in the Zambia studies discussed earlier, a study in Kenya shows that compared with simply handing out the product for free at clinics, distributing free vouchers redeemable at a local store can improve allocative efficiency. This is because the transaction cost of going to the store to redeem the coupon, though small, seems to be enough of a deterrent to dissuade people from picking up a chlorination product they will not use, while not discouraging those who will actually use the product.

User Fees Could Improve Allocative Efficiency

Second, by way of the psychological effects of prices, including the sunk cost fallacy and placebo–price effects. The effectiveness of some health goods will depend on the behavior – compliance – of the user. For example, the effects of an iron supplementation regimen on anemia depend on the behavior of the recipients. If they do not comply with the regimen, say taking a pill once a week instead of once a day, the treatment will not work as well. The same goes for a bed net; if it is not hung up or used, it will not protect anyone from malaria. Some services also have the same property. If a pregnant woman does not listen to the nurse during her prenatal care visit, she might not learn enough to benefit from the visit. For such goods, user fees might help induce the complementary behavior required for full effectiveness. They could do so through two psychological channels – the sunk cost fallacy and placebo–price effects

First, the sunk costs fallacy. When this fallacy is operative, the higher the price paid for a good, the higher the likelihood that it is used to its full potential. This is because the buyers want to avoid feeling that they wasted money. People, it seems, do not recognize when they should consider costs incurred in the past as sunk costs. Studies in the US have found evidence of sunk cost fallacy effects for entertainment products. It is possible that such effects could apply for health products, with, for example, people who pay more likely to comply with an expensive course of treatment or more likely to use a bed net. Two of the randomized pricing studies discussed in Section User Fees Can Improve Allocative Efficiency were specifically designed to test for sunk costs fallacy effects for health products, one in urban Zambia and one in rural Kenya. However, neither found evidence for such effects.

Second, placebo–price effects. In this case, paying a higher price increases the psychological investment of the user, boosting effectiveness. Thus, it was found that people who are charged full price for a drink supposed to boost mental acuity perform better on mental tasks than those who are told they had received a price discount. Whether such placebo–price effects are at play for public health goods remain to be directly tested. The evidence from Zambia and Kenya mentioned in Section User Fees Can Improve Allocative Efficiency indirectly suggests that such placebo–price effects are not large enough to boost usage of water chlorination products or bed nets, but they could increase the effectiveness of medication for mental health, for example. There is no evidence to date on this issue.

User Fees Can Improve Allocative Efficiency

Third, by deterring *ex ante* moral hazard. If health goods are costly, people are more motivated to stay healthy. Thus, when treatment for injury is expensive and out of pocket, people would be more motivated to avoid injuries than when treatment is free. More to the point, people would have a higher incentive to invest in preventive goods if curative care is costly. Note, however, that this argument can be used to motivate larger fees for curative services, but not for preventive care. For preventive care, the argument is exactly the opposite; user fees would reduce preventive investments, leading to higher demand for curative care in the future, potentially increasing

total healthcare costs. Evidence on the importance of *ex ante* moral hazard in the context of a developing country is rare, probably because it is considered unlikely or minimal. Looking at the impact of introducing health insurance for informal workers in Nicaragua, a study found no evidence of moral hazard behavior.

Equity

Improving equity in access to healthcare (if not equity in health) is one of the objectives of most governments. The impact of user fees on equity in access depends on the price-elasticity of the demand for health services and products, and how it varies by socioeconomic status.

As discussed in Sections User Fees and Fixed Costs and User Fees Can Improve Allocative Efficiency, there is a large literature on the price-elasticity of demand for health goods. The price-elasticity of the demand for preventive care has recently received a lot of attention, and the evidence from randomized field experiments suggests quite a large price sensitivity in a number of settings. The evidence on the price-elasticity of the demand for curative care is somewhat mixed and for the most part imperfectly estimated, but overall it suggests that user fees tend to compromise access, especially among the poor, who tend to be more price-sensitive than others.

An obvious way to amend a user fee system to foster equity is to price discriminate, that is, charge the poor less than the rich for a given health service or product, for example, through the distribution of vouchers. This is not always easy to do in practice. Most of the poor in developing countries are subsistence farmers or employed (often self-employed) in an informal business. This means that they are not part of the tax base; there is thus no record of their earnings, which makes it difficult to identify who should be eligible for the lower fee/voucher.

Progressivity of Public Health Spending – the Redistributive Implications of User Fees

A related issue is that of redistribution. Redistribution is often a health policy objective. In that case, public health services are an integral part of poverty alleviation efforts. An important consideration when setting user fees is their impact on who benefits from public health spending, or benefit incidence.

Higher user fees for health goods can make public spending regressive as they disproportionately affect the poor. If user fees are set below the average cost but remain substantial enough that they reduce the demand for public health services proportionately more for the poor than for the rich, then they would make public health spending regressive: benefits would accrue disproportionately to the rich. Even if user fees do not reduce health service utilization among the poor, they could have negative redistributive implications through negative cross-price-elasticities. The more the poor have to pay for their healthcare, the less money they have left to invest in, say, education. If user fees for health reduce enrollment in public schools among the poor, that might undermine the goal of primary education for all, another objective common to most governments of developing countries.

Although, to the best of our knowledge, there is no evidence on cross-price elasticities for publicly provided services, there is, as discussed in Section User Fees Can Improve Allocative Efficiency, a large literature on the price-elasticity of demand for health goods, and this literature suggests that the poor are much more price-sensitive than others, which would imply that user fees are likely regressive. A study looking at public spending on curative healthcare in seven sub-Saharan countries found that public health spending is disproportionately benefiting the less poor, consistent with the price-elasticity literature. The richest 20% receive much more than 20% of public health subsidies, whereas the poorest 20% receive less than 20%. This is because a large fraction of public health subsidies go to services that the poor do not use, such as hospital care, which the poor do not access because they typically live far from any hospital. A recent review of the evidence compiled in the 2004 World Development Report shows that this phenomenon is not limited to Africa.

A potential solution to ensure that public health spending is targeted at the poor is, here again, to use the strategy of price discrimination. Although price discrimination for a given product can be difficult when identifying the poor is itself difficult, an alternative is to charge high fees for products and services that only the rich demand/use, and low or no fees for the products and services used primarily by the poor. That would mean, for example, charging high fees for hospital care and low fees for care at primary facilities; or if there is geographic segregation, charging higher fees in richer areas and lower fees in poorer areas.

Quality of Service

The last factor to consider in the pricing decision is that of the quality of the healthcare received by the population. This means considering both the quality of those health services subsidized or provided by the government as well as the quality of the alternatives that people would have to resort to if user fees deter them from accessing public services.

User Fees and the Quality of the Services for Which a Fee Is Charged

User fees can have a direct positive impact on the quality of the services for which they are charged if the revenue they generate is retained by the local facility charging them, and used locally. This can come about through two main mechanisms. First, the user fees can finance quality improvements such as maintenance or renewal of the equipment or the facility or in-service training for health workers. Second, the revenue from the user fees can be used to incentivize health workers: if health workers can pocket the user fees, they have a higher incentive to be present and serve than if their payoff function is flat. However, pay-for-service can lead to overprovision of services, that is, moral hazard on the part of the provider. There is, to the best of our knowledge, no rigorous evidence to date on these issues in the context of a developing country. It is therefore not known how potential quality improvements attained through user fees would compare with

direct investments in quality by the government, such as incentive pay systems paid out of general revenue. There is, however, some evidence from the private sector suggesting that the margins that can be made by providers on health products are so low that the incentives effect is almost nonexistent. In a randomized trial in Zambia, it was found that nonfinancial rewards (e.g., social recognition) for agents selling condoms are more effective than allowing the agents to keep a margin on their sales. Please also see the article by Miller and Babiaraz in this section of the Encyclopedia for a more detailed discussion of pay for performance considerations in developing countries.

Even if the revenue from user fees is not used to directly finance quality improvements, user fees could impact quality indirectly. One can think of two such potential indirect effects. First, the total revenue raised in user fees by a given health facility could be interpreted by the central authority as a signal of the quality of the services this facility provides. Indeed, it has been shown that demand is responsive to quality levels. The government could then allocate quality-enhancing projects based on this measure of quality, or use it as a way to monitor the local providers. Second, user fees might provide incentives for users to monitor their local providers and to demand better care: if they have to pay for the service, they have an incentive to demand high quality to ensure they get their money's worth. This argument was put forth quite forcefully by the 2004 World Bank Development Report titled 'Making Services Work for Poor People.' It is not clear, however, that users can easily judge the quality of the services they receive. One study shows that, despite extremely low quality of the healthcare they are getting, and their poor resulting health status, people in Udaipur (India) are quite satisfied with their own health and the services they receive. As such, community monitoring of local health providers might require information provision, such as through report cards, even in the presence of user fees. Such report cards were found very effective in Uganda.

User Fees and Health Outcomes

Even if user fees can enhance the quality of the services for which fees are charged, the quality change might not translate into better health outcomes for the population if user fees reduce utilization of those services and divert people to private alternatives of low quality, such as private practitioners with dubious qualifications, or self-treatment. It is therefore critical to know the price and quality of the alternatives available to people, as well as the likely impacts of a change in public sector fees, in order to fully assess the ultimate impact of user fees on the quality of healthcare that is received.

The effects of users on quality may be dynamic. An example is that of pricing for antimalarial drugs. Artemisinin-based therapies now constitute the only treatment effective against *Plasmodium falciparum* in Africa, where parasite resistance to earlier generations of antimalarials is widespread. Monotherapies are cheaper to produce than combination therapies (which combine an artemisinin derivative with a partner drug), and therefore favored by consumers. However, the use of monotherapies is suboptimal from a social standpoint as it contributes to faster resistance development to artemisinin. This means that high fees for combination therapies today may lead to a lower drug quality in the future, if they deter demand and instead lead patients to purchase monotherapies from the private sector. Here again, considering cross-price elasticities is thus critical when determining optimal pricing strategies.

Conclusion

Governments intervene in the healthcare sector primarily to improve health outcomes. However, their ability to intervene is limited by a budget constraint. This means that optimal pricing for public health services has to strike a delicate balance: it has to minimize the likelihood that needy persons do not access the health products or services that could benefit them, while also minimizing the likelihood that these products and services are used by those for whom the returns are low. The critical parameters to take into consideration when setting a price or user fee are thus price-elasticities: the price-elasticity of the demand for the health product or service under consideration, and how it varies with income and health status; and also the cross-price elasticities of other human capital investments that the government might care about.

Overall, the empirical evidence suggests that the price-elasticity of the demand for health products and services is relatively important in developing countries, but often not because of frivolous demand at low prices – rather, because of underutilization at high prices. This suggests that in many cases the introduction of user fees might need to be paired with exemptions for the poor in order to achieve the objectives of improving aggregate health outcomes and equity of access. The question then becomes one of cost-effectiveness: if running a scheme of user fees with exemptions is costly to administer, it might be much simpler and no more costly to have a blanket no-fee policy.

Identifying what price is optimal for a given service, drug or product, given the local context and given the objective function, is not necessarily simple, as the discussion above highlighted. Even once it has been identified, implementing the chosen price schedule is not necessarily that simple either. Providers at public health facilities might demand under-the-counter payments from clients for drugs, services, and other products on top of the set user fee. The importance of this type of petty corruption – which could undermine even the most carefully designed and progressive user fee system – are a part of a separate but related and extremely important theme on which research has been and is currently being performed.

Primary Care, Gatekeeping, and Incentives

I Jelovac, University of Lyon, Lyon, France, and CNRS, Ecully, France

Glossary

Capitation Payment arrangement for health care service providers that pays a physician or group of physicians a set amount for each enrolled person assigned to them, per period of time, whether or not that person seeks care.

Fundholding (in the National Health Service in Britain) System enabling general practitioners to receive a fixed budget from which to pay for primary care, drugs, and non-urgent hospital treatment for patients.

Gatekeeping Feature of many health care systems according to which a patient can access specialized care only after a PCP has issued a referral.

Managed-care Program intended to reduce unnecessary health care costs through a variety of mechanisms.

Patient (self-) selection Selection of a health care organization by patients. A consequence of patient (self-) selection is that, when both gatekeeping and free access systems coexist, gatekeeping is expected to attract individuals who are healthier on average than the free access does.

Primary Care Provider (self-) selection Selection of a remuneration system by PCPs. A consequence of PCP (self-) selection is that, when several remuneration methods coexist, each one is expected to attract PCPs according to their personal characteristics.

Referral Transfer of care for a patient from one clinician to another.

Third-party payer Organization other than the patient or the health care provider involved in the financing of personal health services.

Introduction

In its World Health Report 2008, the World Health Organization (WHO) advocates in favor of a central role for primary care in health care systems. The WHO defines the specific features that should characterize primary care to ensure improved health and social outcomes: person-centeredness, continuity, comprehensiveness, and integration. Person-centeredness is about adapting medical advice to individual life circumstances. Continuity would allow the best use and sharing of information between individuals and primary care providers (PCPs). The concepts of comprehensiveness and integration stress the multiple roles of a PCP: health promotion and prevention, diagnosis and treatment or referral, and chronic or long-term care. As for the organization of health systems, the WHO promotes to switch the entry point to the health system from hospitals and specialists to PCPs.

Evidence has been reported about favorable medical outcomes in systems with an emphasis on primary health care. For instance, continuity of care contributes to lower all-cause mortality. Person-centeredness is responsible for an improved quality of life and increased treatment compliance. Comprehensiveness contributes to better health outcomes and to fewer patients admitted for preventable complications of chronic conditions. The effect of the supply of primary care is not so clear-cut. A superficial observation negatively relates the number of PCPs per capita to the mortality rates. However, more PCPs are expected to work in areas with a worse case-mix of patients. Accounting for this simultaneity effect, the negative relationship between the number of PCPs and the mortality rates disappears.

On top of the evaluation of the benefits of primary care, the contribution of health economics to the trend toward strengthening primary care has been taking the following forms: to analyze possible organizations to bring primary care upfront; and to think of ways to make individuals and health care providers adhere to the aim of strengthening primary care. A lot of attention has been devoted to the gatekeeping role of PCPs and to the incentives of PCPs and patients to adequately use primary care as an entry point to the health care system. The selection of patients and PCPs into different primary care organizations is also an interesting issue even though it has been less debated so far. The notions of primary care, gatekeeping, incentives, and selection are therefore the core of this article. The aim is to understand each of these aspects independently from each other as well as their interactions with each other.

The remaining of the article is structured as follows. The following section discusses gatekeeping versus direct access to specialists. The next section reports on patients' incentives to use primary care as an entry point to the health system. It also analyzes the PCPs' incentives to fulfill their roles. The next section tackles the issue of selection that appears when several organizations for providing primary care or accessing specialized care coexist. The penultimate section extends the discussion to the supply of specialized care. The final section concludes the article.

Gatekeeping

The most obvious way to bring primary care upfront is to forbid patients' direct access to specialists. The PCP is thereby empowered with a gatekeeping role. Patients can access specialized care only after the PCP has issued a referral. The WHO has stressed the importance of the gatekeeping system as an organizational model to structure health care. Gatekeeping is typical of the health care systems in Denmark, Finland,

 doi:10.1016/B978-0-12-375678-7.01311-0

Ireland, Italy, the Netherlands, Norway, Portugal, Spain, and the UK; whereas Austria, Belgium, France, Germany, Greece, Iceland, Luxembourg, Sweden, and Switzerland allow free access to most medical specialists.

Empirical comparisons between gatekeeping systems and systems with free access to specialists repeatedly report the following three effects. Gatekeeping decreases patients' satisfaction, even though it earns a better acceptance in countries where specialists are in short supply as in the UK. Also, gatekeeping is significantly associated with a lower utilization of health services and lower expenditures.

To appreciate the influence of gatekeeping on the utilization of medical services and on the resulting expenditure, it is important to understand the possible relationships between gatekeeping, medical utilization, and medical expenses. Gatekeeping is primarily meant to limit the use of expensive specialist services to the necessary cases only and to avoid them for patients needing primary care only. Therefore, a decrease in utilization and expenses can reflect an efficient use of medical services only if it decreases unnecessary visits to specialists. Empirical evidence on unnecessary care under free access to specialists is therefore needed to support this relationship; otherwise it is admitted to think that gatekeeping can cause a decrease in necessary specialized care too.

Another aspect of the relationship between gatekeeping versus free access, utilization, and expenses is selection. Gatekeeping in the public system coexists with free access in the private sector in countries such as Spain and the UK whereas they coexist in the private sector in Switzerland and in the USA. When both gatekeeping and free access systems coexist, the authors expect gatekeeping to attract members who are healthier on average than the free access system does. This selection process would automatically result in lower medical utilization and expenses for the gatekeeping system, independently of a possible gain in efficiency. Limited evidence is available about the existing efficiency effect, once the selection bias is accounted for.

The effects of gatekeeping versus free access are also dependent on the financial incentives they are associated with. For example, gatekeeping is often associated with PCPs' financial incentives to limit referrals to specialists, whereas system with free access provides generally little incentives of this kind. Therefore, the lower medical utilization and costs observed in gatekeeping systems might be due to the financial incentives rather than to the gatekeeping barrier itself. The empirical literature on gatekeeping versus direct access to specialized care so far has not disentangled the effect of both patients' and PCPs' financial incentives from the effects of constrained access to specialists.

Some theoretical arguments help comparing gatekeeping with direct access considering the optimal provision of incentives to PCPs. The next section discusses how to provide adequate incentives to PCPs. At this stage and for the sake of comparison between gatekeeping and free access, it can be mentioned that incentives to PCPs are meant to minimize two types of possible errors: the use of specialized services when unnecessary (type-I error) and the lack of specialized treatment when necessary (type-II error). Without adequate incentives to PCPs, gatekeeping is expected to generate more type-II errors than type-I errors. Conversely, free access may result in more type-I than type-II errors. With adequate (though costly) incentives to PCPs, one can minimize both types of errors in a gatekeeping system because decisions are in the hands of the PCP. However, type-I errors would remain in a free access system because those are independent of the PCPs' decisions. Therefore, when optimal incentives are provided, gatekeeping performs better, in theory. Conversely, free access might perform better when the patients' pressure to refer anyway is high or when the quality of the patients' self-health information is either highly accurate (in which case the patients' self-referral is very efficient) or weakly accurate (in which case the PCPs' financial incentives are very costly).

Incentives

Incentive mechanisms are increasingly popular in the health care sector to deal with the inefficiencies caused by asymmetric information between physicians, patients, and third-party payers. Incentive mechanisms exist for both patients and physicians to encourage the adequate utilization of health care services. The incentives for the efficient utilization of primary care versus specialists is discussed here, starting with the incentives directed to patients and following on with those directed to PCPs.

In a free access system, patients can be motivated to access PCPs first by making them bear an additional out-of-pocket payment when they choose to directly visit a specialist. This system is in use in France since 2005 as well as in some health maintenance organizations in the USA. It is a soft version of the gatekeeping system. However, financial incentives directed to patients bring the issue of equity in the access to health services, which was absent from the pure gatekeeping system. The financial incentives directed to patients may also limit the scope for quality (non-price) competition between specialists. Indeed, if the patients' co-payment is proportional to a specialist's fee, the best reply of the specialist to an increase in patients' co-payment is to decrease his fee to sustain demand. The specialist earns thereby less revenue per patient, which results in lower incentives to invest in costly quality. However, for these financial incentives to prove efficient in terms of utilization of primary versus specialized care, empirical evidence is needed about the actual behavior of patients with and without out-of-pocket payments. The French experience with out-of-pocket payments has proven disappointing because direct access to a specialist was very limited even when no such payments were due.

As for the PCPs, incentives are generally provided through their remuneration scheme and they are expected to influence their referring behavior. The aim is to limit the discretionary and unnecessary referrals to specialists. Many authors have written about the incentive properties of the most traditional payment schemes. If one ignores the issue of referrals, the classical analysis of traditional payment systems yields the following conclusions. Fee-for-service (FFS) payments may encourage physicians to provide too many medical services to maximize their revenue. Capitation may lead physicians to limit either the amount or the quantity of the medical services they provide. FFS can thus be responsible for excessive health care costs and utilization, whereas capitation can be responsible for

low quality/amount of care. Salaried doctors have an incentive to minimize their effort during the consultation because they receive the same income irrespective of this effort.

However, some of the aforementioned incentives can be reversed in the case of PCPs who can refer patients to specialized care. PCPs paid by capitation can save on personal costs by simply referring their patients to expensive specialized care. PCPs' altruism reinforces this effect because referrals allow for own cost minimization without prejudice to the patient.

Salary may bring the same incentives as capitation regarding referrals. To minimize their effort during consultation, salaried doctors have an incentive to refer more often than needed. This is even more so if one considers that PCPs derive utility from the well-being of their patients, because referrals do not harm the patients.

PCPs paid on an FFS basis earn more revenue when treating the patients on their own rather than referring them to a specialist. In that case, FFS would lead to lower total costs and quality compared to capitation, if it is supposed that the costs and the quality of specialized care are higher than those of PCPs' care and it can be abstracted from professional duty considerations.

In theory, fundholding shares the same incentives as FFS regarding referrals. Fundholding enables PCPs to receive a fixed budget from which to pay for primary care, drugs, and non-urgent hospital treatment for patients. It has been used in the UK between 1991 and 1999 and reintroduced in 2005. Again, if non-urgent hospital treatment is more expensive than primary care, PCPs have an incentive to limit referrals.

Empirical studies clearly confirm the positive theoretical relationship between capitation and the number of (unnecessary) referrals. Empirical support also exists for associating fundholding with a lower rate of referrals.

As many professionals, physicians might actually be heterogeneous in the way they respond to financial incentives because they are actually heterogeneous in both the ability and sense of professional duty. Under FFS or fundholding, it can be expected that very altruistic yet not very able PCPs refer all patients to specialists. PCPs who are relatively altruistic and very able might decide to either treat or refer according to their diagnostic. The very selfish yet able PCPs might treat all their patients to either maximize their earnings under FFS or minimize their expected expenditure under fundholding. Empirical evidence is needed to eventually confirm these theoretical predictions.

Selection

Incentives need not be uniform for a given population within a health care system. For instance, physicians in the US can work either in a traditional FFS setting or in a managed-care organization with a capitation arrangement. Primary care practices in the UK in the beginning of the 1990s had the choice to adopt the fundholding scheme or not. PCPs in France can voluntarily participate in the Contract for Improving Individual Practice (CAPI) scheme, which pays PCPs a performance payment for satisfying guidelines on prescription and prevention behavior. On the demand side, patients in the US can enroll into either gatekeeping health plans or plans allowing direct access to specialists.

In theory, the ability of selecting one or another type of organization may result in a pooling of individuals with the same profile in each organization type, which potentially results in increased inequalities. It can also increase efficiency, thanks to a better match between individuals and organizations.

Allowing PCPs to select between FFS or capitation can be optimal if savings on specialists' costs are not the main concern of a regulator. Otherwise, all PCPs should be paid on an FFS basis to avoid the incentive that associates capitation to excessive expensive referrals. Limited empirical evidence exists about either the existence or the lack of PCP selection into one or another plan. The French experience with the CAPI system shows no PCP selection according to their profile. Conversely, there is some evidence of British selection concerning groups of PCPs enrolling in the fundholding system in 1991. Evidence about the effects of selection is not available so far.

On the patients' side, patients enrolling into gatekeeping health plans are expected to be less likely to see a specialist than are others in plans with unrestricted access to specialists. There is significant evidence of selection into plans with gatekeeper and/or network selection in the US. Self-selection occurs because individuals, possessing knowledge of their own health attributes and economic constraints, select plans accordingly. These attributes that partly determine the individual's choice of health plans also affect their expected utilization of services. Individuals in plans that require sign-ups with a PCP have more visits to nonphysician providers of care, more surgeries, and hospital stays but substantially fewer emergency room visits.

To sum up, there are three channels through which the choice of remuneration scheme may affect PCPs' output or productivity: First, certain kinds of behavior may be encouraged by the scheme itself (the incentive effect); second, certain kinds of physicians may be attracted to certain types of physician practices, which, in turn, are influenced by the remuneration scheme (the physician selection effect); third, certain kinds of patients may be attracted to certain types of physician practices, which, in turn, are influenced by the remuneration scheme (the patient selection effect).

The Supply of Specialized Care

Gatekeeping systems have developed in countries with a limited supply of specialists, as in the UK. There is also empirical evidence that the supply of specialists is an important system determinant of referrals. Therefore, controlling the market for specialists might help improving the organization of primary care. For instance, in health systems with lots of PCPs and few specialists per medical discipline, specialists enjoy in theory a high level of monopoly power eventually leading to high fees. Therefore, increasing PCPs' qualification may decrease the monopoly power of specialists.

Increasing the number of PCPs makes the primary-care market more competitive too. Together with a capitation payment for a patient-list system, more PCPs may experience a patient shortage from the more intense competition. There exist empirical evidence that this may lead to more referrals.

Intuitively, against more competition, PCPs refer patients more often, responding positively to patient requests. Therefore, the cost-saving effect of the substitution of specialists by PCPs may be weakened by the PCPs' reactions.

Efficiency gains that are usually attributed to gatekeeping cannot be taken for granted. In the short run, better matches between patients and specialists may lead to efficiency gains. However, in the long run, specialists have an incentive to adjust their specialization so that differentiation between specialists increases. This would increase the monopoly power of specialists, which might counteract the positive short run effect.

Conclusion

This article has discussed issues related to the organization of the primary-care sector. The following important relationships have been reported. Gatekeeping arrangements result in lower expenditures and utilization of health care services although no significant effect has been proven on health care outcomes. Concerning PCPs' incentives, capitation is associated with an increase in referrals to specialists, whereas the fundholding scheme seems to limit these expensive referrals. Concerning the choice of a health plan, patients opting for a gatekeeping plan are less likely to see a specialist than are others in plans that allow direct access to specialists. However, when regulating the primary care sector, it is important to anticipate its consequences on the behavior of specialists.

France is now witnessing a movement from solo PCP practice to group practice. This change may result in new incentives and behaviors. An opportunity for relevant research appears there, to follow on the recent interest of economists for group practice and norms.

Primer on the Use of Bayesian Methods in Health Economics

JL Tobias, Purdue University, West Lafayette, IN, USA

Introduction

Bayesian econometrics has become an increasingly popular paradigm for the fitting of economic models, since the early 1990s. Although Bayesian efforts in economics existed well before this time – perhaps originating in our specific discipline with the pioneering work of Zellner in the early 1970s – Bayesian applied work before 1990 was relatively scarce and often resorted to approximate or asymptotic posterior analysis in order to make the approach operational.

The rather dramatic upswing in popularity that occurred in the 1990s seemingly, and perhaps surprisingly to many previously embroiled in the Bayes/frequentist debate, had little to do with ideology or a conversion of the masses to the tenets of Bayesian theory but instead was derived from a simulation-based 'revolution' that greatly facilitated Bayesian computation. Although, in principle, posterior distributions could always be obtained on the combination of prior and likelihood, numerical characterization of the posterior and its specific properties offered a daunting – and often insurmountable – computational challenge.

The purpose of this article is to review, in very general terms, two popular simulation-based algorithms that have greatly simplified the practice of Bayesian econometrics: the Gibbs sampling and the Metropolis–Hastings (M–H) algorithms, and to illustrate how these can be used to fit various microeconometric models commonly employed in health economics. The article reviews the basic procedures for implementing these algorithms, discusses strategies for diagnosing their convergence (or nonconvergence) and, finally, illustrates their application in various examples involving wages and their relationship to the Body Mass Index (BMI).

The outline of the article is as follows. The following section reviews the general approach to Bayesian estimation and inference and then provides details of both the Gibbs sampling and M–H algorithms in a representative setting. The authors then apply the Gibbs sampling algorithm in a linear regression model and review issues of convergence diagnostics and posterior prediction within that context. The Section Bayesian Inference in Latent Variable Models extends these ideas to nonlinear settings, thereby providing a generic representation that encompasses a variety of discrete choice models widely used in health applications. This article concludes with a brief summary.

How It Works

To begin, by consider a model $\mathcal{M}$ that yields a parametric likelihood function $L(\theta; y)$. The reader with no previous exposure to Bayes will likely find this portion of the empirical exercise familiar: Distributional assumptions on unobserved components of the model induce a sampling distribution for the data y, denoted as $p(y|\theta)$. Common examples include the assumption of normally distributed errors in linear regression, yielding the classical normal linear regression model (LRM), or extreme value-distributed errors in the context of a binary choice problem, leading to the logit. Regarded as a function of θ given the observed data y, this defines the likelihood function.

A non-Bayesian or frequentist econometrician who is willing to go so far as to impose enough model structure to define a likelihood stops at this point, often proceeding with well-established tools for point estimation and known asymptotic approximations for inference. The Bayesian, however, continues beyond the specification of a likelihood and adds to it a prior, denoted as $p(\theta)$, describing their beliefs regarding values of the parameters before having witnessed the data. In some cases, the adopted prior may be 'informative,' constructed from results obtained from past studies or information offered to the researcher by an expert. What is commonly done in practice, however, is to employ a prior that is proper (i.e., it integrates to unity) yet suitably 'diffuse' or 'noninformative' in the sense that the data information will typically overwhelm whatever information is insinuated through the prior.

It is at this stage of adopting a prior that the frequentist often becomes uncomfortable, fearing that the analysis is no longer objective and that the Bayesian practitioner could and may have derived the results they want simply by choosing the prior accordingly. Although commenting on issues of prior sensitivity falls a little outside the very general goals of this article, such questions will inevitably be posed to any Bayesian practitioner. In light of this, it seems useful to at least make a few brief points on this front, both as a means to motivate the Bayesian approach and also to offer the novice Bayesian a few possible responses to these kinds of queries.

First, it is useful to point out that in smooth, finite-dimensional models – such as all those considered here – the priors employed typically have little effect on posterior results with even moderate data. Although prior sensitivity is certainly a concern, the issue is often overblown and raised by those with an inherent distrust of Bayesian methods and, often, little knowledge of their operation. The influence of the prior is, however, of first-order importance in Bayesian model selection and comparison – an issue which is not addressed in detail here but is discussed in the references provided at the conclusion of this article.

Second, to say that frequentist econometrics is prior free and clearly differentiated from the Bayesian approach by its lack of subjectivity is simply incorrect. The very process of model/variable selection is inevitably personal and subjective: Imagine, for example, two different researchers locked in separate rooms, each in possession of a data set such as the National Longitudinal Survey of Youth or National Health and Nutrition Examination Survey and seeking to use it to answer the same economic question. It does not seem controversial to conclude that these two researchers will almost surely arrive

 doi:10.1016/B978-0-12-375678-7.00708-2

at different final models with resulting summary point estimates. The fact that ordinary least squares (OLS) or some other 'objective' estimator was used in the estimation of parameters in the final models simply masked the appearance of prior information that was used at earlier parts of the modeling process. One researcher will have deemed one subset of covariates as relevant and worthy of potential inclusion and further consideration, whereas the other, via his or her own beliefs and decision making, will likely focus on a different set of explanatory variables. These types of judgments are simply prior beliefs at work, and these types of priors that sculpt the classes of models to be entertained are, in fact, more restrictive than priors over parameters that the Bayesian employs, because the data can at least revise the latter type of belief, whereas no amount of data can revise the former.

Finally, there are a variety of numerical strategies for assessing the sensitivity of posterior estimation results with respect to the prior, and care regarding the prior and its influence should be a component of any serious Bayesian endeavor. Given the goals of this article, these methods cannot be discussed in detail, but the reader is advised to refer again to the references at the conclusion of this article.

Bayesian Computation

Now turn to the practical issue of Bayesian computation. Given the likelihood $L(\theta; y)$ and prior $p(\theta)$, the joint posterior distribution, denoted as $p(\theta|y)$, is obtained via Bayes' Theorem as:

$$p(\theta|y) = \frac{L(\theta;y)p(\theta)}{\int_{\Theta} L(\theta;y)p(\theta)d\theta} \quad [1]$$

The posterior distribution in eqn [1] summarizes beliefs regarding θ after having combined the prior and likelihood and represents the output of any Bayesian analysis. When θ is univariate or bivariate, this output can be summarized by simply plotting the prior times likelihood in the numerator of eqn [1] over different values of θ, thus providing the analyst with a sense of the overall shape of the joint posterior. In most cases, however, $p(\theta|y)$ is high dimensional, rendering this type of visual analysis practically infeasible.

In models of even moderate complexity, moments or specific features of eqn [1] cannot be directly calculated, as the denominator – the normalizing constant of the posterior – cannot be determined analytically. Moreover, even if this normalizing constant were known, calculation of a posterior moment or posterior quantile of interest from eqn [1] will define an additional integration problem that would likely lack a closed-form solution.

Fortunately, recent simulation-based methods like the Gibbs sampler and M–H algorithms offer convenient and powerful numerical strategies for the calculation of statistics and features of eqn [1]. These algorithms deliver a series of draws, say, $\theta^{(0)},\theta^{(1)},\theta^{(2)},\ldots$ that are constructed to converge in distribution to the joint posterior described in eqn [1]. The draws are Markovian, with the value of the draw at iteration $t+1$ depending on the current parameter value $\theta^{(t)}$. Once convergence to the target density is 'achieved' these draws can be used in the same way as one would use direct Monte Carlo integration in order to calculate posterior means, posterior standard deviations, and other posterior statistics. For example, in order to estimate a posterior mean of θ, one can simply take a sample average of the simulated θ draws. In practice, care should be taken to diagnose that the parameter chain has converged to the target density, to discard an initial set of the preconvergence draws (often called a burn-in period), and then to use the postconvergence sample to calculate the desired quantities.

The postconvergence draws that is obtained using these iterative methods will prove to be correlated, as the distribution of, say, $\theta^{(t)}$ depends on the last parameter sampled in the chain, $\theta^{(t-1)}$.

If the correlation among the draws is severe, it may prove to be difficult to traverse the entire parameter space, and the numerical standard errors associated with the point estimates can be quite large.

With this general preview of the methods in place, and broad concerns regarding their performance in mind, the details of two commonly used simulation-based methods for Bayesian estimation and inference will now be discussed.

The Gibbs sampler

Let θ be a $K \times 1$ parameter vector with associated posterior distribution $p(\theta|y)$ and write $\theta = [\theta_1\ \theta_2 \ldots \theta_K]$. The Gibbs sampling algorithm proceeds as follows:

(i) Select an initial parameter vector $\theta^{(0)} = [\theta_1^{(0)}\ \theta_2^{(0)} \ldots \theta_K^{(0)}]$. This initial value could be arbitrarily chosen, sampled from the prior, or perhaps could be obtained from a crude estimation method such as least squares.

(1) Sample $\theta_1^{(1)}$ from the complete posterior conditional density:

$$p(\theta_1|\theta_2 = \theta_2^{(0)}, \theta_3 = \theta_3^{(0)}, \cdots \theta_K = \theta_K^{(0)}, y)$$

(2) Sample $\theta_2^{(1)}$ from $p(\theta_2|\theta_1 = \theta_1^{(1)}, \theta_3 = \theta_3^{(0)}, \cdots, \theta_K = \theta_K^{(0)}, y)$.

$\vdots$

(K) Sample $\theta_K^{(1)}$ from $p(\theta_K|\theta_1 = \theta_1^{(1)}, \theta_2 = \theta_2^{(1)}, \cdots, \theta_{K-1} = \theta_{K-1}^{(1)}, y)$

(ii) Repeatedly cycle through (1)→(K) to obtain $\theta^{(2)} = [\theta_1^{(2)}\ \theta_2^{(2)}\ \theta_K^{(2)}]$, $\theta^{(3)}$, etc., always conditioning on the most recent values of the parameters drawn (e.g., to obtain $\theta_1^{(2)}$, draw from $p(\theta_1|\theta_2 = \theta_2^{(1)}, \theta_3 = \theta_3^{(1)}, \ldots \theta_K = \theta_K^{(1)}, y)$, etc.). Also note that some groups of parameters can be blocked together (such as a full vector of regression parameters) and the conditionals in (1)–(K) need not be univariate.

To implement the Gibbs sampler, the ability to draw from the posterior conditionals of the model is required. Although the joint posterior density $p(\theta|y)$ may often be intractable, the complete conditionals prove to be of standard forms in many cases, particularly in hierarchical models and latent variable models using data augmentation. For this reason, the Gibbs sampler is now routinely used to fit a variety of popular econometric models. An illustration of the power of the Gibbs algorithm will be provided in the following sections.

The Metropolis–Hastings algorithm

The M–H algorithm is an accept–reject type of algorithm in which a candidate value, say θ_c, is proposed, and then one decides whether to set $\theta^{(t+1)}$ (the next value of the chain) equal to θ_c or to remain at the current value of the chain, $\theta^{(t)}$. Formally, let $P(\theta|\theta^{(t)})$ be an approximating proposal density (where the potential dependence on the current value of the chain is made explicit), and consider generating samples from $P(\theta|\theta^{(t)})$ instead of the target distribution $p(\theta|y)$. Supposing that θ_c is sampled from $P(\cdot|\theta^{(t)})$, set $\theta^{(t+1)}=\theta_c$ with (M–H) probability

$$\min\left\{1, \frac{p(\theta_c|y)}{P(\theta_c|\theta^{(t)})}\frac{P(\theta^{(t)}|\theta_c)}{p(\theta^{(t)}|y)}\right\} \quad [2]$$

and otherwise set $\theta^{(t+1)}=\theta^{(t)}$. In the case of a symmetric proposal density (the original Metropolis algorithm), the above probability of acceptance reduces to $p(\theta_c|y)/p(\theta^{(t)}|y)$, wherefrom candidate draws from regions of higher density are always accepted in the algorithm, and draws from regions of lower density are occasionally accepted.

The Gibbs sampler and the M–H algorithms are often used in combination in a given application. For example, it might be the case that the complete conditionals for $K-1$ of the elements of θ have convenient functional forms, wherefrom the Gibbs sampler can be used to sample from these $K-1$ posterior conditionals. The complete conditional for the remaining parameter, however, may not take a standard form, and for this parameter, one could use the M–H algorithm to generate samples. This type of sampling is often (though mostly inappropriately) referred to as a 'Metropolis-within-Gibbs' step, and in (partially) nonconjugate situations, the use of both algorithms in combination often proves to be computationally attractive.

To illustrate the application of Markov Chain Monte Carlo (MCMC) methods in practice (and the Gibbs sampler in particular), the following section provides a simple example in the context of the LRM.

A Simple Linear Regression Example

To serve as a starting point, consider estimation and posterior prediction in an LRM. The goal in this section is to review a Gibbs sampling algorithm for the basic linear model, to briefly discuss methods for diagnosing convergence of a posterior simulator, and to illustrate how the posterior simulations can be used to calculate a variety of objects of interest. Under the assumption of conditionally normally distributed errors and homoskedasticity, the linear model can be written as:

$$y_i = x_i\beta + u_i, \quad u_i|X \overset{iid}{\sim} \mathcal{N}(0,\sigma^2) \quad [3]$$

where x_i is a $1\times k$ vector of covariate data and $\mathcal{N}(\mu, \sigma^2)$ denotes a normal distribution with mean μ and variance σ^2.

The likelihood function is implied by eqn [3], and a Bayesian analysis is completed by specifying prior distributions for the model parameters which, for this model, are β and σ^2. Here, priors that are conditionally conjugate are specified, meaning that they combine naturally with the likelihood and will yield conditional posterior distributions that are of the same distributional families as the priors. Specifically,

$$\beta \sim \mathcal{N}(\mu_\beta, V_\beta) \quad [4]$$

$$\sigma^2 \sim IG(a,b) \quad [5]$$

are chosen, with $IG(a, b)$ denoting an inverse gamma density with parameters a and b. The hyperparameters μ_β,V_β,a and b are chosen by the researcher to accord with their prior beliefs and, often, are specified so that the prior densities will be quite flat over a large region of the parameter space.

To effect a Gibbs sampling scheme for fitting this model, the conditional posterior distributions $\beta|\sigma^2, y$ and $\sigma^2|\beta, y$ are required. With a bit of algebra, one can show that these conditional distributions are normal and inverse gamma, respectively. The conditional posterior mean of β can be expressed as a matrix-weighted average of the prior mean μ_β and the OLS estimate $\hat{\beta}=(X'X)^{-1}X'y$. As the size of the data set (n) grows, this posterior mean places increasing weight on the OLS estimate and, given a fixed prior, equals the OLS estimator in the limit. Similarly, the conditional posterior mean of σ^2, $E(\sigma^2|\beta, y)$, can be written as a simple weighted average of the prior mean and the maximum likelihood estimate (given β), $\hat{\sigma}^2=(y-X\beta)'(y-X\beta)/n$. For fixed a and b it is again the case that as $n\to\infty$, the conditional posterior mean collapses on $\hat{\sigma}^2$.

A Gibbs algorithm for fitting this model, as previously discussed in the Section How It Works, involves iteratively sampling from the conditional multivariate normal density $\beta|\sigma^2, y$ and the inverse gamma density $\sigma^2|\beta, y$. Although routines for sampling from a multivariate normal are well known, sampling from the inverse gamma is probably less familiar, although equally easy to do, as such a simulation can be obtained by inverting a draw from a gamma distribution.

Obesity Example

To fix ideas, a specific LRM using a sample of female data ($n=1782$) from the study of Kline and Tobias (2008) is considered. These authors used data from the British Cohort study and sought to estimate the impact of BMI on labor market earnings. The regression of interest used in this study, therefore, uses log wages as the dependent variable and also includes an obesity indicator (BMI ≥ 30), tenure on the current job (and its square), family income, a high school completion indicator, an indicator for an A-level degree, an indicator for a college degree, and finally, union and marriage indicators as controls.

To fit this model, the Gibbs sampler is run for 5500 iterations and the first 500 of these are discarded as a burn-in period. Recall from the previous Section The Gibbs sampler that Gibbs is an iterative algorithm – eventually the samples that are produced will represent a correlated set of draws from the posterior, although the initial set of simulations may not have converged to the posterior. To mitigate such effects, the first 500 draws are thrown out and the final 5000 simulations are used to calculate posterior means and standard deviations of parameters of interest. For the priors, fairly noninformative choices are made by setting $\mu_\beta=0$, $V_\beta=100I_k$, $a=3$ and $b=2.5$.

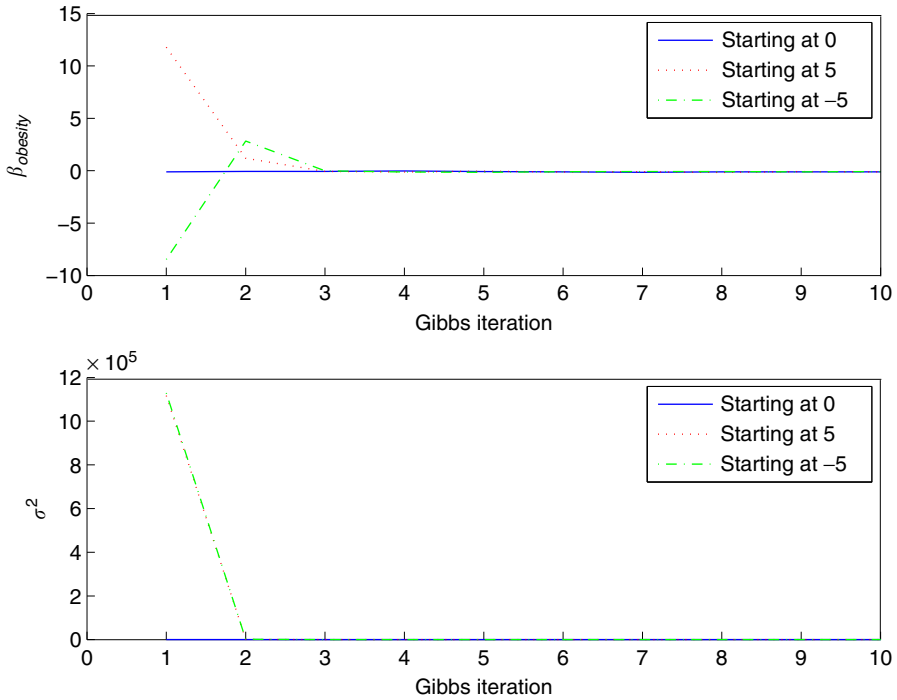

Figure 1 Initial Gibbs simulations from LRM example.

Convergence diagnostics and mixing

Before discussing the estimation results, the issue of convergence of the MCMC sampler used in the study is first considered and it is sought to determine if 500 draws represent an adequate burn-in period for the application. One popular method for assessing convergence is to repeat the Gibbs analysis several times, each time using a different set of starting values, where the starting values are typically chosen to be intentionally 'extreme' so that the progression of the parameter draws can be clearly monitored as they move toward exploring the common posterior surface.

Figure 1 presents graphical results of such an exercise, which is denoted as a trace plot in the literature. Here, three separate Gibbs chains are run: one starting with $\beta=0$ (for all elements of the coefficient vector), a second starting with $\beta=5$, and a third starting with $\beta=-5$. The top portion of the figure plots the path of a representative coefficient – the coefficient on obesity, denoted $\beta_{obesity}$, from all three Gibbs samplers (not plotting the initial condition itself). The lower panel similarly plots the paths of σ^2 for all three chains. If the paths of these parameters from the three separate chains reveal no intersection, this provides evidence that the samplers have not yet converged, that a longer burn-in period is required, and potentially, that the algorithm itself may need to be refined in order to accelerate convergence. However, if it is observed that the simulations quickly move away from their overdispersed (and incorrect) starting values to eventually explore a common region of the parameter space, this provides evidence of convergence within the viewed number of iterations.

As Figure 1 clearly suggests, within just three iterations, the three separate chains appear to settle down and explore the same region of the parameter space. When starting with the unreasonable values of $\beta=5$ or $\beta=-5$, the first few iterations of the sampler produce very large values of the variance parameter σ^2, which is not at all surprising given the extent to which the very early values of β are far from the mass of the posterior density. However, within just three iterations, it appears as if the variance parameter simulations shake off the influence of these starting values and then settle down to explore a common area.

The evidence offered by these graphs is that convergence to the posterior happens very quickly in the example: by discarding the first 500 iterations, one can credibly guard oneself against the problem that the early set of simulations produced by the chosen sampler are not draws from the joint posterior distribution and should not be used in the calculations.

Figure 2 offers a second trace plot, but this time graphs of the first 50 postconvergence simulations obtained from the sampler (i.e., the draws obtained from iterations 501–550 for each of the three chains). The obesity coefficient is provided in the top panel and the variance parameter in the bottom panel. First note the tremendous refinement in scale in Figure 2 relative to Figure 1: The data convey substantial information regarding these parameters, and once convergence has been achieved, the simulations explore the posterior surface and are no longer influenced by initial conditions. Second, the three separate chains appear to have very similar properties, such as means and variances, again providing evidence of convergence. Finally, the graphs also speak of the mixing of the chains. If the draws in a Gibbs algorithm are highly correlated, then the trace plot will reveal very long cycles. The plot in Figure 2, however, does not appear to exhibit any type of strong cyclical behavior and, instead, appears more like that of an electroencephalography, as can be seen under iid sampling from the posterior distribution.

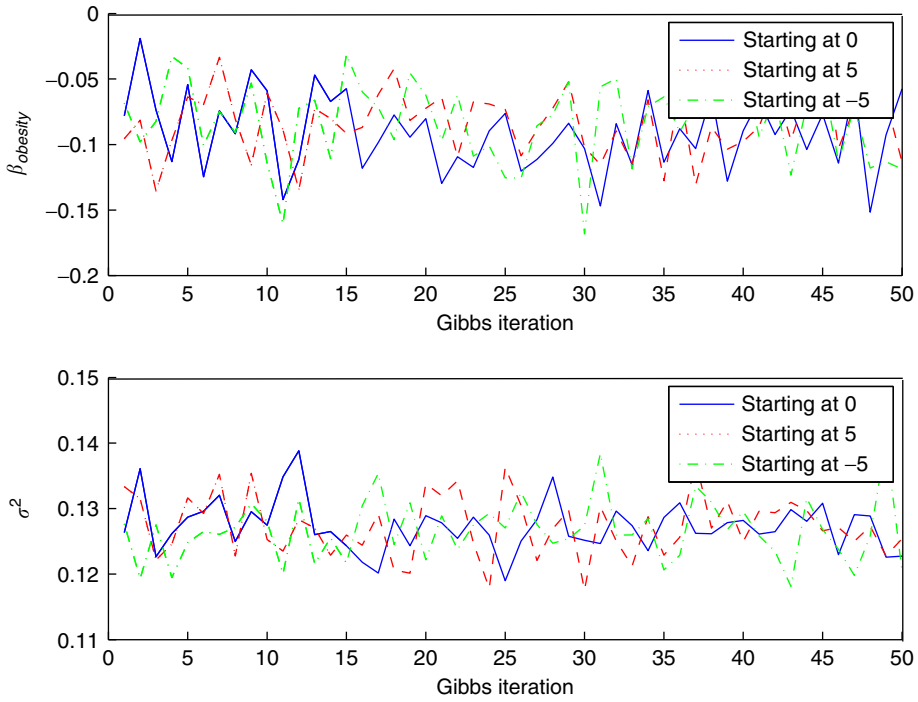

Figure 2 Gibbs iterations 501–550 from LRM example.

A more formal procedure one could use here in order to assess the mixing of the simulations is to report the so-called inefficiency factors for the parameters. These quantify the loss from adopting a Gibbs or M–H sampling approach (whose draws are autocorrelated) relative to an iid sampling scheme. These inefficiency factors can be obtained by calculating:

$$ineff_k = 1 + 2\sum_{j=1}^{J} \rho_k(j) \qquad [6]$$

where $\rho_k(j)$ refers to the lag-j autocorrelation for parameter k. These can be calculated from the simulated output by simply computing the correlation between simulations j iterations apart. The upper limit of the summation, J, is typically chosen in accord with some type of rule of thumb – for example, once the lag-J correlation is smaller than, say, .05, the contribution of lag-t correlations, for all $t > J$.

When $ineff_k$ is near 1, the mixing of the posterior simulations is near the iid ideal. The value of $ineff_k$ is also directly interpretable: If a value equal to $c > 1$ is obtained, this implies that one must run the sampler for $c \times M$ iterations in order to reproduce the numerical efficiency found in M *iid* simulations. For this linear regression example, it is found that the inefficiency factors for all parameters are very close to 1, indicating that the Gibbs algorithm effectively mimics the performance of iid sampling from the joint posterior.

Estimation results

Presented in Table 1 are posterior means, posterior standard deviations, and posterior probabilities of being positive for the parameters of the LRM used in the study. For reference, the first column also reports OLS coefficient estimates, which are seen to be virtually indistinguishable from the reported posterior means, which is to be expected with ($n = 1782$) and fairly noninformative priors. With respect to the key parameter of interest, it is found that obesity clearly has a negative impact on log wages, and this finding can be summarized via the statement: $[\Pr(\beta_{obese} < 0|y) \approx .999]$. In terms of the point estimate, obese females earn approximately 8.2 % less, on average, than women who are not obese. With respect to the quantity $\Pr(\beta_{obese} < 0|y) \approx .999$, note that it offers a very natural interpretation of the evidence at hand: conditioned on the model, the priors, and the observed data, it can be confidently (nearly certain) claimed that obesity has a negative effect on wages.

Table 1 Posterior statistics from LRM

Variable	*OLS*	$E(\cdot\|y)$	$Std(\cdot\|y)$	$\Pr(>0\|y)$
Intercept	1.68	1.68	0.030	1.00
Obese	−0.082	−0.082	0.029	0.001
Tenure	0.025	0.025	0.007	0.999
Tenure^2	−0.001	−0.001	0.0005	0.015
FamInc	0.001	0.001	0.0001	1.00
High school	0.068	0.069	0.0224	0.998
A-level	0.282	0.282	0.0332	1.00
Degree	0.347	0.347	0.0254	1.00
Union	0.251	0.247	0.0195	0.897
Married	−0.019	−0.019	0.0176	0.142

Although the Bayesian posterior probabilities reported in the final column of Table 1 may seem somewhat similar to the frequentist p-value, it is important to recognize that they are vastly different in terms of interpretation. First, such statements are entirely inappropriate in the classical paradigm, as β_{obese} is a fixed parameter and is, therefore, either negative,

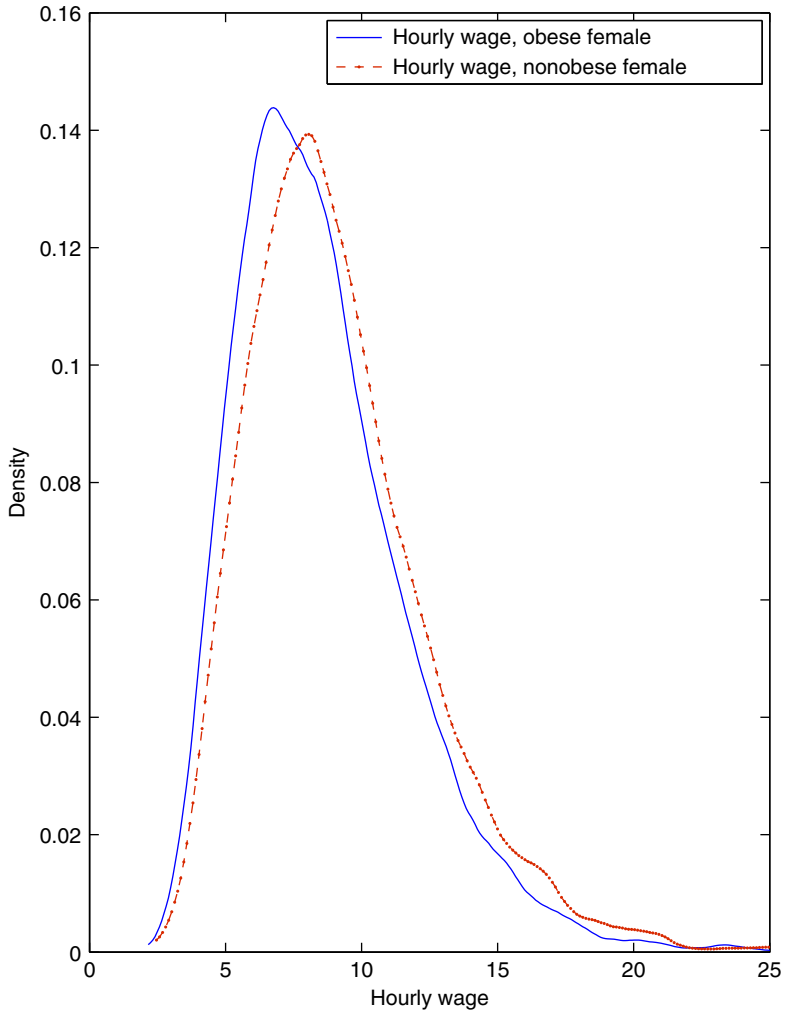

Figure 3 Posterior predictive wage densities for obese and nonobese females.

positive, or zero. The probability statement that the Bayesian is able to provide, however, seems to be exactly what was expected to obtain from the analysis and offers a very useful quantity to offer to medical professionals and/or policy makers. Second, any probabilistic interpretation of effects in the frequentist case is derived from the sampling distribution of the estimator, highlighting the fact that such an approach places primary importance on what estimates one may have obtained had other data sets actually been observed. For the Bayesian, this sense of importance is misplaced, as decisions and recommendations should be based on the data at hand, and averaging over data sets that could have been observed, but were not, is neither advisable nor relevant.

Posterior prediction

The last exercise focuses on posterior prediction. Here, it is sought to move beyond the narrow (and too often terminal) goal of parameter estimation to use the model to make predictions about future outcomes. In the context of the LRM used in this study, let w_f denote the hourly wage (not log wage) of the individual, and let x_f denote a given set of fixed characteristics. Because the predictive outcome $w_f = \exp(y_f)$ is a function of the regression parameters β and σ^2, the posterior predictive distribution of w_f via simulation is numerically approximated. That is, for every $\beta(r)$ and $\sigma^{2,(r)}$ simulation from the posterior, it can be simply calculated as:

$$w_f^{(r)} = \exp[x_f \beta^{(r)} + \sigma^{(r)} \varepsilon^{(r)}] \quad [7]$$

where $\varepsilon^{(r)} \sim^{iid} \mathcal{N}(0,1)$. Proceeding in this way generates a series of draws from the posterior predictive wage distribution – one draw obtained for each (β, σ^2) simulation from the joint posterior.

In Figure 3 this approach is used and posterior predictive wage distributions are reported for obese and nonobese females, keeping the other explanatory variables constant and approximately equal to overall sample mean values. These densities are obtained by kernel-smoothing the simulated draws from the posterior predictive density.

As shown in the figure, the wage density for the nonobese female is right-shifted relative to that of the obese female. To contrast this with a frequentist alternative, note that such an approach would likely proceed by plugging in point estimates of β and σ^2 into an expression for the hourly wage density. Although such an expression can be analytically derived in this

particular example (i.e., the wage density is lognormal), this exercise can often require a messy change of variables. Furthermore, such an approach suppresses parameter uncertainty and instead conditions on values of the parameter point estimates. The Bayesian approach to this exercise is quite appealing by comparison, as simulations can be used in place of analytic derivations, and parameter uncertainty is automatically accounted for, as they are properly integrated out to obtain the posterior predictive distribution $p(w_f|x_f,\gamma)$.

Bayesian Inference in Latent Variable Models

Although useful as a starting point and surely of interest in its own right, the previous treatment of the LRM is far from fully satisfactory, as it does not cover Bayesian model fitting in wide array of alternate models – including nonlinear and limited dependent variable models, for example – that are widely used in health research. In this section, a very general structure that nests many popular nonlinear microeconometric models is, therefore, introduced and posterior simulation for this general case is discussed. To this end, consider the following specification:

$$p(\theta) = p(\beta)p(\Sigma^{-1}) \quad [8]$$

$$z_i|X,\theta \overset{ind}{\sim} \mathcal{N}(X_i\beta,\Sigma), \quad i = 1, 2, \ldots, n \quad [9]$$

$$y_i|z_i = g(z_i), \quad i = 1, 2, \ldots, n \quad [10]$$

Equation [8] introduces a prior for the model parameters, consisting of a set of regression coefficients β and an inverse covariance matrix Σ^{-1}. Equation [9] depicts the generation of a (potentially) multivariate latent variable z_i, whereas eqn [10] links the observed outcomes y_i to the latent data z_i.

The generality of eqns [8]–[10] should not be overlooked. To illustrate, note for a univariate outcome y_i:

- The probit model is a special case of eqns [8]–[10], where z_i is a scalar, Σ^{-1} is absent from the model (i.e., the scalar variance parameter is normalized to unity), and eqn [10] specializes to $y_i = I(z_i > 0)$, where $I(\cdot)$ denotes the standard indicator function.
- The tobit model is produced when z_i is a scalar, $\Sigma = \sigma^2$ is a scalar variance parameter, and eqn [10] specializes to $y_i = max\{0, z_i\}$.
- The ordered probit model is produced when z_i is a scalar, Σ^{-1} is absent from the model, and the observed data is connected to the latent data via a cutpoint vector: α:

$$y_i = j \quad if \quad \alpha_j < z_i \leq \alpha_{j+1}$$

In this final instance, eqn [10] must be generalized to allow the link between latent and observed outcomes to depend on the cutpoint vector α.

The equations outlined in eqns [8]–[10] also cover a wide variety of multivariate models. For example, the seemingly unrelated regressions model, the hurdle and sample selection models, generalized tobit models, multivariate ordinal models, models with continuous and discrete endogenous variables (as discussed in more detail below), and the multivariate probit (MVP) and multinomial probit (MNP) models can be regarded as specific cases of this general structure. As such, knowing how to estimate a system of equations like eqns [8]–[10] enables the applied researcher to estimate a wide variety of popular microeconometric models.

Applying the idea of data augmentation, the latent data z in eqn [9] can be treated like another parameter of the model, giving rise to the augmented joint posterior distribution $p(z,\beta,\Sigma^{-1}|y)$. A Gibbs sampler, then, draws from each of the three constituent posterior conditional distributions.

In some models, the required simulations are almost trivially performed, whereas other specifications will demand refinement of any general scheme. In many cases, β will be sampled from a multivariate normal, Σ^{-1} from a Wishart distribution, and z_i from a truncated normal. Posterior simulation in the probit model, for example, simply involves generation of a multivariate normal random variable for sampling β and a series of (independent) univariate truncated normals for sampling the latent data z. In terms of the latter, the observed binary response y_i serves to truncate the value of the latent variable: $y_i = 1$ indicates that z_i must be positive, whereas $y_i = 0$ restricts z_i to be nonpositive. In the MNP and MVP models, however, additional care must be taken to normalize the associated variance parameter(s) to unity. The general sampling of the latent data will also prove more challenging in some models than in others, and an appropriate method of sampling the latent data must be carefully considered for the model in question.

With these practical implementation details noted, the reader should still recognize the generality and scope of coverage that the simple description of eqns [8]–[10] offers, as well as the fact that in many cases, nonlinear model fitting only requires the ability to sample from standard distributions (such as the normal, truncated normal, and Wishart). Further details and associated references regarding a variety of specific models are provided in the further reading section of this article.

Posterior Simulation with an Endogenous Binary Variable

To provide a specific example of a popular model 'covered' by eqns [8]–[10], the well-studied case of a continuous outcome model with a dummy endogenous variable is considered. In this case, eqn [9] might specialize to:

$$z_{i0} = r_i\gamma + u_{i0} \quad [11]$$

$$y_{i1} = \alpha_0 + \alpha_1 y_{i0} + s_i\alpha_2 + u_{i1} \quad [12]$$

where

$$y_{i0} = I(z_{i0} > 0) \quad [13]$$

Equation [11] is a latent variable equation governing the generation of an endogenous binary outcome y_{i0}. The variable y_1 is a continuous outcome variable, which is completely observed. The variables r and s are assumed to be exogenous, with r containing at least one element that is not in s.

Table 2 Posterior statistics from binary endogenous variable model

Coefficient	*Log wage equation*			*Obesity probit equation*		
	$E(\cdot\|y)$	$Std(\cdot\|y)$	$\Pr(>0\|y)$	$E(\cdot\|y)$	$Std(\cdot\|y)$	$\Pr(>0\|y)$
Constant	1.70	0.033	1.00	−4.91	0.451	0.000
Obese	−0.278	0.086	0.001			
Tenure	0.025	0.007	0.999			
$Tenure^2$	−0.001	0.001	0.015			
FamInc	0.001	0.001	1.00	−0.001	0.001	0.375
HighSchool	0.068	0.023	0.998	−0.001	0.108	0.500
Alevel	0.286	0.034	1.00	0.150	0.162	0.821
Degree	0.334	0.027	1.00	−0.304	0.140	0.015
Union	0.025	0.019	0.912			
Married	−0.014	0.018	0.198	0.065	0.087	0.775
momBMI				0.087	0.011	1.00
dadBMI				0.062	0.014	1.00
ρ_{01}	0.305	0.122	0.986			
σ_1^2	0.131	0.005	1.00			

With a bit of finesse, this bivariate system of equations can also be mapped into the form of the system in eqn [9]. In terms of posterior simulation, the variables can be stacked and the vector of parameters $\beta=[\gamma\ \alpha_0\ \alpha_1\ \alpha_2]$ can be sampled from a multivariate normal. A straightforward reparameterization of the problem enables the simulation of the variance parameter σ_1^2 and the covariance between the errors of eqns [11] and [12], denoted σ_{01}. Finally, the latent data z_{i0} can be sampled from a univariate truncated normal, where the region of truncation is governed by the observed value y_{i0}.

Obesity Example, Revisited

For illustration purposes and to expand the application of Section 3 (where the potential endogeneity of female obesity was ignored), the binary endogenous variable model of Section 1 is fitted and applied to wage/obesity data. The continuous outcome y_{i1} remains the log hourly wage and the binary endogenous variable y_{i0} is the obesity indicator. The covariates in the wage equation remain the same as those employed in Section 2, whereas in eqn [11] maternal and paternal BMI are included as exclusion restrictions (i.e., variables that are assumed to affect the respondent's BMI but have no conditional effect on the respondent's log wage). In addition, this equation also includes a set of education indicators, family income and a marriage indicator. The Gibbs algorithm is run for 10 000 iterations, with the first 1000 discarded as the burn-in. Results of this analysis are provided in Table 2.

Apart from the values of the obesity and union coefficients, the values of the log wage regression coefficients remain very similar to those presented in Table 1. In the obesity equation, consistent with the prior expectations, strong evidence that higher parental BMI leads to a higher likelihood of child obesity and that the college educated have lower rates of obesityis found.

The interesting difference in results relative to those in Table 1 lies in the estimated impact of obesity on log wages and its interpretation. As shown in the second-to-last row of Table 2, ρ_{01} is found to be positive with very high posterior probability. One interpretation of this result, which is also offered by Kline and Tobias, 2008, is that individuals who are very dedicated to their job, perhaps working long hours in order to earn a high conditional wage, may forego investments in health capital in order to earn such a wage. As a result, unobserved factors leading an individual to earn a high conditional wage will also positively correlate with unobservables affecting the production of obesity, consistent with the positive value of ρ_{01} in Table 2. The results in Table 1, then, have presented a conservative estimate of the obesity penalty, as they have combined the actual obesity penalty with an effect arising from unobservable characteristics of productive workers that also contribute to obesity. When separating these effects, as the analysis of Table 2 seeks to do, a much larger estimate of the obesity penalty is seen, as the coefficient has increased (in an absolute sense) more than three-fold, with a posterior mean now equal to −.278.

Although the specific results of this application are of secondary importance, what is most important to appreciate is the relative ease with which these results have been obtained; fitting the model only required the ability to draw from normal, inverse gamma and univariate truncated normal distributions. This simplicity is not specific to the model considered here but applies to many specifications that fall within the class of models described by eqns [8]–[10]. Given the relative ease with which parameter and latent variable simulations can be obtained from the joint posterior, it then becomes easy to move beyond point estimation to calculate marginal effects and to conduct various counterfactual or policy experiments.

Conclusion

This article has reviewed the basics of the Bayesian approach to estimation and inference, focusing in particular on applications of the Gibbs sampler and M–H algorithms. In conjunction with data augmentation, these algorithms greatly ease estimation in a variety of microeconometric models, many of which are commonly employed in health economics applications. Although the material presented here only offers a superficial review of the Bayesian approach, the references

provided contain significantly more information on both the theory and application of these methods.

Glossary

Cost-benefit analysis A form of economic evaluation by comparing the costs and (money-valued) benefits of alternative courses of action.

Cost-consequence analysis A method of assembling the components of the costs and benefits of a project or investment option, usually in noncomparable units, without any attempt to combine them into a single monetary cost figure or combined artificial construct.

Cost-effectiveness analysis A method of comparing the opportunity costs of various alternative health or social care interventions having the same benefit or in terms of a common unit of output, outcome, or other measure of accomplishment.

Equity Equity is not necessarily to be identified with equality or egalitarianism, but relates in general to ethical judgments about the fairness of the distribution of such things as income and wealth, cost and benefit, access to health services, exposure to health-threatening hazards, and so on. Although not the same as 'equality,' for some people, equity frequently involves the equality of something (such as opportunity, health, and access). There are, however, also fair inequalities. For example, an unequal allocation of health care may be necessary in order to achieve more equal health.

Marginal The additional benefit, health, cost, etc. attributable to a small increase in a factor bringing it about (other things equal).

Multi-criteria decision analysis A technique, akin to cost-effectiveness analysis (CEA), for helping decision makers to take decisions. It differs from CEA by explicitly helping decision makers to consider factors beyond standard welfare or health maximization.

Opportunity cost The value of a resource in its most highly valued alternative use. In a world of competitive markets, in which all goods are traded and where there are no market imperfections, opportunity cost is revealed by the prices of resources: the alternative uses forgone cannot be valued higher than these prices or the resources would have gone to such uses.

Programme budgeting marginal analysis (PBMA) PBMA combines program budgeting with marginal analysis to provide a means of both determining which resources have been allocated to which program goals and analyzing the opportunity cost of marginal changes in the sizes of programs and the mix of inputs in comparison with the consequential changes in goal outcomes.

Quality-adjusted life expectancy Life-expectancy using quality-adjusted life-years rather than years of life.

Introduction

There is an established 'healthy public policy' agenda concerned with the social determinants of health, which recognizes that nonhealth sectors of public policy often have greater impacts on population health and health inequalities than health sector policies. This political agenda has been promoted by the World Health Organization (WHO) since the 1980s (see Box 1), and has led to a widening of the definition of public health interventions to include nonhealth sectors.

In line with this agenda, there are increasing calls for economists to help generate evidence that investing in the social determinants of health, for the explicit purpose of improving health and tackling health inequality, can represent good value for money. To date, however, health economic research in this area is relatively limited. This article reviews existing economic principles and methods of priority setting, and discusses how they can most fruitfully be applied to support the 'healthy public policy' agenda. The discussion focuses on supporting this agenda at the local government level (e.g., city or state level), which has important impacts on the social determinants of health, yet has hitherto received particularly limited attention by health economists. However, the economic principles and methods reviewed can of course also be applied to public policy making at national and supranational levels.

The section The Scope of the Challenge: The Social Determinants of Health illustrates the challenges faced inpublic health, where interventions that have major impacts on health originate from multiple policy sectors and are led by decision makers are primarily motivated to deliver specific nonhealth

Box 1 The WHO 'Adelaide Recommendations' on healthy public policy

"Healthy Public policy is characterized by an explicit concern for health and equity in all areas of policy and by an accountability for health impact. The main aim of healthy public policy is to create a supportive environment to enable people to lead healthy lives. Such a policy makes health choices possible or easier for citizens. It makes social and physical environments health-enchancing. In the pursuit of healthy public policy, government sectors concerned with agriculture, trade, education, industry, and communications need to take into account health as an essential factor when formulating policy. These sectors should be accountable for the health consequences of their policy decisions. They should pay as much attention to health as to economic considerations"

Second International Conference on Health Promotion, Adelaide, South Australia, 5–9 Apr 1988

outputs such as new housing. Intersectoral impacts are a common feature of most public policies; health is not a special case in this respect. Therefore, the wider challenge is how to encourage different policy sectors to consider and value all major intersectoral impacts of importance to society as a whole, including health.

The section How to Encourage Intersectoral Alignment: the Role of Economic Evaluation describes how economics is well-placed to encourage intersectoral coordination by developing the economic evidence in order to identify, measure and value the intersectoral spillovers of policies and the overall impact on social welfare. It begins by offering a brief primer on the economic way of thinking about priority setting. It emphasizes that a distinctive advantage of the economic way of thinking is its ability to adopt a broad societal perspective, which considers how best to allocate scarce resources to improve overall social welfare, making appropriate tradeoffs between different and potentially conflicting social objectives. Economics is thus not constrained to a narrow focus on one particular outcome or objective, such as improving health or reducing health inequality, but is capable of combining multiple objectives into the same analysis. Therefore, the scope of 'healthy public policy' fits naturally within an economic approach. The practical challenge is to engage with decision makers both to address sector specific concerns and to identify areas where further coordination can improve social welfare.

The article then considers appropriate approaches to economic evaluation and contends that the best approach is to combine cost consequence (CCA), cost effectiveness (CEA), and cost benefit analysis (CBA). This would account for and report all major intersectoral impacts, including health, and value these impacts in terms of net social welfare. It then reviews standard economic tools for priority setting and discuss their potential role in helping to coordinate different policy sectors, frame the decision process, make explicit stakeholder objectives, and translate economic evidence into policy. Taken together, the sections on economic evaluation and priority setting tools lay out an 'integrated societal framework' to enable all impacts to be accounted for, valued, and taken into consideration by decision makers.

The section Translating Evidence into Policy: The Role of Priority Setting Tools briefs how economic evidence can then be used by decision makers. It reviews standard economic tools for priority setting and discusses their potential role in helping to coordinate different policy sectors, frame the decision process, make explicit stakeholder objectives, and translate economic evidence into policy. Taken together, the sections on economic evaluation and priority setting tools lay out an 'integrated societal framework' to enable all impacts to be accounted for, valued, and taken into consideration by decision makers.

The Scope of the Challenge: The Social Determinants of Health

The Rise of the 'Healthy Public Policy' and 'Social Determinants of Health' Agendas

Alongside the political agenda for 'healthy public policy', there is also an established research agenda regarding the social determinants of health, with contributions from a number of eminent scholars from different disciplines. Much of this research from outside the discipline of economics has been usefully collated in the 2008 report of the WHO Commission on the Social Determinants of Health; though this report does not offer comprehensive coverage of economic contributions to theory and evidence on this topic.

Public health interventions can impact on health directly through the provision of public goods, such as water and sanitation; or through changes in legislation, such as environmental standards or food industry regulations. Other sectors also impact on health indirectly by influencing the willingness and ability of communities and individuals to invest in health, for example, through behaviors like healthy eating. For instance, education in childhood influences aspirations and future adult employment, which may in turn provide the means for individuals to invest in themselves and their children. Further, community interventions such as housing and regeneration may offer an incentive to invest in and protect neighborhoods from crime and antisocial behavior, which may be especially harmful for childhood development. Figure 1 attempts to summarize the wide array of drivers of population health. The diagram is limited in that the interaction between the various drivers is not captured and nor is the lifecourse, where an individual's early years development can influence their future adult outcomes. Nonetheless, it is a commonly used and helpful illustration that health is not simply the product of healthcare.

As a consequence, a 'healthy public policy' agenda has emerged, which may be crudely described as an advocacy movement. The contention is that interventions from nonhealth sectors should be thought of as 'upstream' public health interventions, which can have larger impacts on population health and health inequalities in the long run than health sector interventions.

A particular concern of the 'healthy public policy' agenda is that health impacts are still not being (fully) considered when nonhealth sectors make decisions. Further, in times of fiscal tightening, when public sector budgets are being reined in, policymakers understandably concentrate on short-term priorities such as the provision of amenities that are currently and visibly in high demand from voters and interest groups, which may then be detrimental to long run goals of improving population health and reducing health inequalities.

In recent years, there have been growing calls for economists to engage more fully with this agenda to generate economic evidence on which investments in the social determinants of health represent the best value for money.

Engaging with the 'Healthy Public Policy' Agenda: The Need for Intersectoral Alignment

In considering how best economists can engage with the 'healthy public policy' agenda, there are three important observations. The first is that decision makers are primarily incentivized to deliver sector specific outputs. Health outcomes, if considered at all, are byproducts and not the main priority of nonhealth sectors. Second, intersectoral impacts are a common feature of most policies. Third, health is

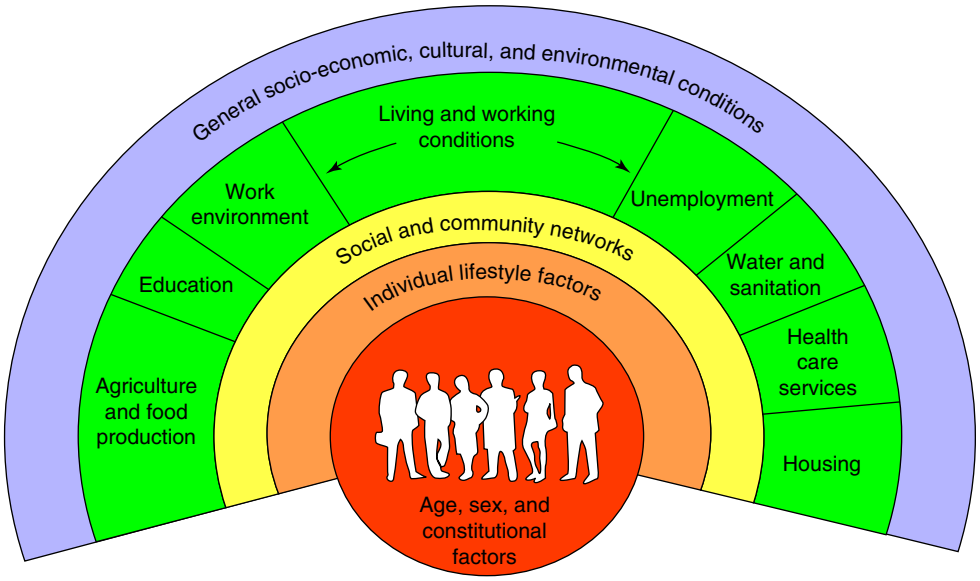

Figure 1 The drivers of population health. Reproduced from Dahlgren, G. and Whitehead, M. (1991). *Policies and strategies to promote social equity in health*. London: Institute of Fiscal Studies. Available at: http://ideas.repec.org/p/hhs/ifswps/2007_014.html (accessed 01.11.12).

nevertheless an outcome of particular importance for social welfare, which people value both as a consumption good and as an investment good that allows them to lead flourishing lives and act as productive members of their family and of the wider economy and society.

Taken together, these observations suggest that simply advocating to nonhealth sectors the importance of considering the health consequences of policies may not be enough to influence decision makers. There is a need to generate a '*quid pro quo*' to incentivize decision makers to consider health impacts. A productive way forward may be for all sectors to be encouraged to move beyond narrow sector perspectives to consider all major intersectoral impacts. Consequently, the challenge is not simply 'how can we persuade nonhealth sectors to produce health outcomes?' but 'how can we help coordinate and align sectors where health is valued as one important input toward achieving the common overall aim of increasing social welfare?'

Opportunity for Intersectoral Alignment: Local Decision-Making

Before considering how economics can help the ability of decision makers to coordinate, it is important to identify whether decision makers have the willingness to do so. This short section discusses where economists may have the most immediate opportunities to improve policy coordination.

It can be helpful to distinguish multiple policy 'levels' that drive health, including: international, national, regional, and local. However, these levels are not necessary strictly demarcated, and there are interactions between them. At the international level, major drivers include global warming and trade legislation. At the national level, the fiscal allocation of resources to spending departments is an important issue, and there is a dialog at the national level, which is synchronized with political cycles where spending departments bid for funds. Government economists are typically closely involved in this process. These national and international issues are important but not the focus of the present discussion. Rather, the focus is on the local level of decision-making (e.g., local authority, state, and city), an area that health economics has paid relatively little attention to, thus far.

Local decision makers increasingly have a culture where different sectors and agencies operate together in partnership working. This provides a real opportunity for 'horizontal' coordination across sectors (and ideally 'vertical' coordination between levels of the system). For instance, the Public Health Agency of Canada has expanded its remit from coordination of interventions to prevent infectious disease outbreaks, to developing a vision that seeks to harness the social determinants of health to protect, maintain, and improve population health, more generally.

Policy coordination needs supporting institutional structures. There are promising examples from across the world that this is happening. For instance, in the UK, the Department for Health in England has devolved responsibility for public health to local levels with budgets being transferred accordingly. Public health can now be considered along with the wide range of other public sector concerns. Existing decision-making forums, such as 'One Place,' can also facilitate the development of common objectives that all sectors work toward. Another example is an innovation in Scotland called the Single Outcome Agreement, which provides joint targets that policies need to demonstrate progress against. A third example is the 2009 Australian National Partnership Agreement on Preventive Health. This illustrates the use of a national-level institutional structure to support local public health policy coordination, encouraging both horizontal coordination between sectors and vertical coordination between local and national levels.

The emerging notion of a 'systems approach' to public health policy-making recognizes the multiple social determinants

of health, and the interaction between policies, and looks for better ways to coordinate. For instance, health inequalities are the result of a system of influences, in which social disadvantages often cluster on the same groups in society, such as poor education, low employment, poor housing, and high rates of crime. It has therefore been argued that policies to reduce health inequalities should be developed (and evaluated) as 'multisectoral packages' rather than 'sector specific interventions.'

How to Encourage Intersectoral Alignment: The Role of Economic Evaluation

The Need to Take a Societal Perspective in Evaluation

From first principles, the fundamental problem economics is concerned with is scarcity: wants are infinite, but means are finite. The overarching purpose of normative economics is to inform the allocation of scarce resources with a view to improving 'social welfare' (variously known in other disciplines and contexts as 'social value', or 'the social good', or 'the public interest').

Prioritization is inevitable and normative economics is concerned with how to do this explicitly and rationally, given the information available. According to one of the founding fathers of health economics, Anthony Culyer, economic analysis ought to:

> "...identify relevant options for consideration; enumerate all costs and benefits to various relevant social groups; quantify as many as can be sensibly quantified; not assume the unquantified is unimportant; use discounting where relevant to derive present values; use sensitivity analysis to test the response of net benefits to changes in assumptions; and look at the distributive impact of the options"

Therefore, the challenge of greater intersectoral alignment, discussed previously, is congruent with the first principles of health economics.

An Integrated Approach to Economic Evaluation: Combining 'Broad' and 'Narrow' Approaches

The approach outlined by Culyer fits most comfortably within the general method of economic evaluation known as 'CBA,' which seeks to quantify all relevant social costs and benefits, and value them in the common currency of money. However, the practical reality is that decision makers in particular policy sectors are not primarily incentivized to make decisions purely on the basis of increasing general social welfare. Therefore, simply reporting net social welfare impacts is not ideally suited for decision makers. Therefore, the challenge is to take an approach to economic evaluation that satisfies the immediate sector specific concerns of decision makers, but also demonstrates the wider impacts of decisions and pinpoints where better coordination can lead to improvements in social welfare.

It is suggested here that an integrated approach to economic evaluation should be taken, where different approaches can be seen as complementary, rather than necessary competing. The starting point could be to undertake a CCA, which is essentially a social accountancy exercise, detailing the major impacts that result from an intervention. Economists can then use the CCA to develop the outcomes that different end-users are interested in **Figure 2**.

First, as the funding sector(s) may be primarily interested in the provision of specific outputs or amenities, the economic evaluation can take a 'narrow' CEA approach and simply report cost per unit of output – for example, cost per unit of social housing of a required standard. This evidence can be used to inform technical efficiency; to identify interventions that provide a certain output, at least cost.

Second, the consequential impacts on health can be evaluated within a CEA that focuses on a generic measure of health. The CCA could include a relevant generic health related quality of life (HRQoL) questionnaire, such as SF-12 or EQ-5D measuring how HRQoL has changed following an intervention(s) on a ratio scale between 0 (for zero health) and 1 (for full health). Responses are then weighted, by population preferences regarding the desirability of different states, to generate a single score of 'preference-weighted' HRQoL. This summary score is sometimes referred to as a 'health utility' and can be used on its own in evaluation, or used to weight length of life to generate quality-adjusted life-years, or disability adjusted life expectancy. The suggested reading list at the end includes an encyclopedia entry which discusses the methods used to generate the weights in deriving the health utility score (e.g., time tradeoff and standard gamble).

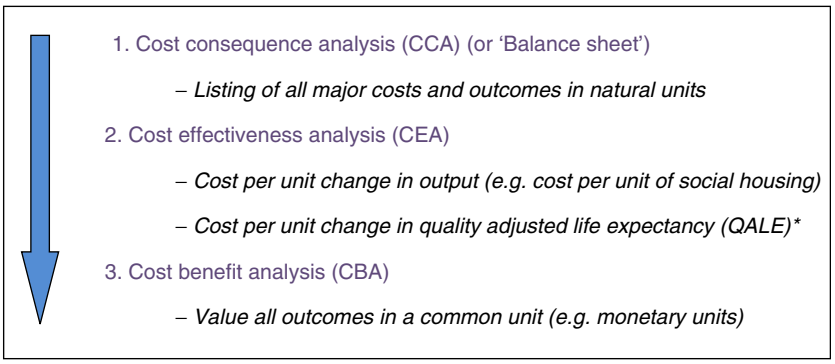

Figure 2 Integrated approach to economic evaluation: combining approaches.

Third, a CBA can then be conducted, which values all major outcomes detected in the CCA to then estimate net social benefit. The most common approach in CBA is to value all outcomes in financial terms. The suggested reading list includes an encyclopedia entry that discusses the methods used to attach financial values to outcomes (such as contingent valuation or discrete choice experiments). This 'broad' approach is then intended to estimate the overall social worth of alternative interventions.

Overall, combining approaches (CCA, CEA, and CBA) would have the strength of explaining how different stakeholder interests are related to one another, and how they are valued as part of overall social welfare. In this respect, the approaches of CCA and CEA can be seen as 'nested' within the overall framework of CBA.

It is important to recognize that producing economic evidence is only the first step in how economists can influence priority setting. The next step is to help decisionmakers to translate evidence into policy.

Translating Evidence into Policy: The Role of Priority Setting Tools

This penultimate section first explains why economic evaluation, while necessary, is rarely sufficient for decisionmakers when setting priorities: economic evidence is only one consideration. It then discusses how economists can help frame the priority setting process, helping to bring stakeholders together to articulate objectives, intervention options and value judgements. Crucially, this process should articulate decision-making criteria, so that economic evidence can then be used systematically alongside other relevant considerations.

The Two Key Principles in Priority Setting

There are two key economic principles that underlie priority setting from an economics perspective. The first is 'opportunity cost': when investing resources in one area, the most relevant cost for the decisionmaker to consider is the opportunity for benefit that is forgone because those resources are not invested elsewhere. The second is that of the 'margin': when changing the resource mix, the most relevant costs and benefits for the decisionmaker to consider are the marginal costs and benefits resulting from the proposed change in the resource mix, rather than the average or total costs and benefits of all the historical resources used. The concept of the margin is important regardless of whether budgets are changed or remain the same. If additional resources are made available, the key is to use the evidence to invest in the options offering best value. If the budget is decreasing, then the challenge is disinvestment, and budget should then be taken from interventions that provide the least value. Even with static budgets, there may be scope for reallocation to produce outcomes more efficiently. Economic evaluation is intended to provide this information to make explicit the costs and benefits of alternative courses of action, and the impacts of shifting resources at the margin. However, rarely will economic evidence be immediately translated into decisions. It is important to discuss why this is the case.

Economic Evidence Is Necessary but Not Sufficient for Priority Setting

For economic evidence to be sufficient for policymakers to use as the sole basis for making policy decisions, five conditions would need to be satisfied. First, the decisionmakers involved would need to clearly articulate and agree on the policy objective(s). This then would allow economists to develop an appropriate generic outcome measure, which all alternative courses of action can be measured against. Second, the valuation of outcome measure(s) would need to incorporate all relevant ethical considerations for decision-making, including considerations of fairness or equity as well as considerations of efficiency in maximizing the sum total of social benefits net of social opportunity costs. Third, the methods used by economic evaluation would need to be fully trusted by decisionmakers. Fourth, there would need to be no additional political constraints on decisionmakers beyond considerations of efficiency and equity. Fifth, economic evidence would need to be available to use. If these conditions were satisfied, then the role of policymakers would be largely passive. That is, once the initial objectives were articulated, economic evaluation could then produce a final all-thing-considered policy recommendation, which could determine the policy decision.

These conditions are unlikely to hold in practice. First, given that the scope of public health is multisectoral, there are likely to be competing objectives and value judgements. Different stakeholders are incentivized to produce different outputs. Second, equity has not been properly addressed in economic evaluation so far. Rather, units of benefit are typically valued equally regardless of which groups in society are affected. This is clearly a problem for public health, where many interventions are in fact delivered primarily in an attempt to reduce inequality (e.g., social housing for deprived communities). This suggests that a unit of benefit for a deprived individual can in some contexts be valued higher than the same unit of benefit for a less deprived individual. The issue of equity is becoming a key research focus for health economics, and the reading list refers to relevant articles in the encyclopedia. Third, decisionmakers typically lack the specialist expertize to fully understand economic evaluation methods and findings, and as a result may view economic evidence with suspicion. This is an area of contention, however. Distilling the impacts of an intervention into a single index is important to enable direct comparison of the impacts of different interventions, but perhaps economists need to improve the communication with decisionmakers to foster greater trust and reliance on the academic peer review process to ensure that methods are appropriate and fit-for-purpose. Fourth, decisionmakers often have to balance economic concerns with institutional and political concerns. Political concerns may result in certain decisions being taken largely in the absence of evidence, driven by opinions, values, and political constraints. Institutional concerns relate to both 'inhouse politics' and 'lags' in policy-making, where resources can rarely be instantly transferred between uses. For instance, services often involve a precommitment to funding over certain time periods and involve contracted and skilled staff who may not be easily transferred to alternative uses. This slows the process of improving allocative efficiency. Fifth, there is a general lack

of economic evidence regarding investments in the social determinants of health. To date, health economics has overwhelmingly concentrated on interventions within the health sector.

Furthermore, there are real difficulties in developing robust economic evidence. Many public health interventions are complicated in the sense that they are often multicomponent, making it difficult to identify active ingredients and to distinguish between a good intervention and poor implementation. Interventions are also complex in the sense that they can interact with local context (e.g., past and present interventions). In effect, context is an effect-modifier. Also, interventions may have the greatest impact over the long-term and even intergenerationally (e.g., urban regeneration). These common features can cause difficulties in establishing both causality (e.g., the opportunity for randomized trials is limited) and the generalizability of evidence, given that context can vary substantially between settings. The interaction of economic evidence with context provides an opportunity for interdisciplinary research in the future in order to improve both the generation and generalizability of evidence. Further, economics has a distinctive role to play in addressing the importance of context by analyzing how individual and organizational choices and behavior are likely to respond to changes in context-specific incentives and constraints.

Priority Setting as a Management Process

Priority setting is essentially a management process. This process needs to balance a wide range of concerns given that stakeholders often have competing objectives and diverse political and institutional constraints, and given the difficulties of generating robust evidence regarding likely policy outcomes. Owing to lack of evidence, the prioritization process is often fundamentally driven by value judgements. The priority setting process grows even more challenging when we consider the challenge of coordination between multiple policy sectors.

Priority Setting Tools: Framing the Decision Process

The priority setting process can often lack transparency and accountability. Policymakers themselves have expressed frustration regarding a lack of priority setting frameworks that they can use to guide decisions and enhance the credibility of resource allocation decisions. There is an opportunity for economists to help apply (and further develop) frameworks to steer decisionmakers through the process of priority setting, in addition to the generation of economic evidence.

There are a variety of priority setting tools that have been developed over the past 40 years, often as part of an interdisciplinary process. So despite the frustrations of policymakers, the issue may be more of awareness and application of existing tools – from both policymakers and perhaps economists too. Two of the most common tools are program budgeting marginal analysis (PBMA) and multicriteria decision-making. The rationale for using such tools is similar: to make explicit and improve the transparency and accountability of the priority setting process. For illustration, PBMA can be discussed briefly.

Table 1 Program budgeting marginal analysis (PBMA)

The five key steps in PBMA
1. What resources are available in total?
2. In what ways are these resources currently spent?
3. What are the main candidates for more resources and what would be their effectiveness and cost?
4. Are there any areas which could be provided to the same level of effectiveness but with the less resources, so releasing those resources to fund candidates from (3)?
5. Are there areas which, despite being effective, should have less resources because a proposal from (3) is more effective (for s spent)?

Source: Adapted from Mitton, C. and Donaldson, C. (2004). Health care priority setting: Principles, practice and challenges. *Cost Effectiveness and Resource Allocation* **2**(1), 3.

PBMA has been used in mainly in the UK, Canada, Australia, and New Zealand. Further, it has mainly been applied within the health sector. However, PBMA could in principle be used in any priority setting process and to coordinate multiple sectors.

An advisory panel is normally established with key stakeholders to identify the aims and scope of the priority setting exercise. Thereafter, five simple steps are in the process that is aimed at ultimately identifying areas for investment and disinvestment. The first step is to articulate the resources available for consideration in a reallocation exercise. The second step is to map out how existing resources are currently spent. The third step is to then identify the main candidates for more resources that offer the greatest value for money. The fourth step is to look at ways by which existing resources can be spent more efficiently to free up resources for Step 3 (Table 1).

The fifth step is to then make comparisons across spending areas and transfer resources if the interventions identified in Step 3 offer greater value.

Ideally, economic evidence would exist and be comprehensive enough to inform steps 3–5. However, often this is not the case or there are additional political or institutional concerns. Therefore, a key issue is for stakeholders to develop explicit decision-making criteria. This may include things such as health gain, access, innovation, sustainability, staff retention/recruitment, and system integration. This is where multi-criteria decision analysis (MCDA) can be nested within a PBMA approach to help decisionmakers choose between options. MCDA essentially involves four main steps: identifying interventions; identifying evaluation criteria; measuring interventions against the criteria; and combining criteria scores using a weighting to produce an overall assessment of each intervention.

Applying Priority Setting Tools

In effect, there are three potential applications of priority setting tools. The first is to determine the initial funding to individual sectors. If health improvement and tackling health inequality are priorities, then funding nonhealth sector interventions may be a more productive approach than health

sector interventions. Second, there is scope to use tools for the reallocation of funding within sectors to improve the efficiency of delivering outputs. This is particularly important when budgets may be under pressure due to a tighter fiscal environment. Third, these tools can in principle be used to coordinate sectors. This is where it becomes important for economic evidence to take an 'integrated approach' (combining different approaches to economic evaluation) and demonstrate to policymakers in different sectors the impacts of their decisions on one another, and the implications for health and overall social welfare. Through an explicit priority setting process, sectors can either compensate each other for the impacts of policies on one another, or ideally coordinate policies to create synergies and promote overall social value.

Conditions for Successful Priority Setting

For priority setting exercises to be successful certain conditions are required. Key amongst these is leadership. There needs to be willingness and commitment by leaders within organizations to the process and to ensure that resource reallocation can and does actually take place. Without leadership, the process can lack credibility. Priority setting exercises can also be time-consuming and involve senior staff in organizations. The opportunity to undergo these exercises may be limited to the start to the next budget cycle. Further, there needs to be a willingness to repeat the exercise, as experience has shown that organizations need a learning-by-doing period for the priority process to improve and develop credibility.

Overall, priority setting is inherently a messy process, involving economic, political, and institutional concerns. Priority setting tools can help willing participants to make explicit the decision process, articulate all issues and improve the rationality and accountability of resource allocation decisions. Tools such as PBMA can shape the decision process to accord with economic principles, to use the available economic evidence and make gains in technical and allocative efficiency.

Conclusions

This article has considered how economists can best engage with the 'healthy public policy' agenda, which is concerned with the social determinants of health where nonhealth sectors are considered to have significant impacts on population health and health inequalities. The practical challenge is how to generate and then translate economic evidence into decision-making in nonhealth policy sectors where, at present, health impacts are often considered as 'byproducts'. Given intersectoral impacts are a common feature of most policies, the wider challenge is to facilitate the process of intersectoral coordination and alignment toward improvements in overall social welfare, where health is just one important element.

By taking an integrated societal approach, economists can produce a consistent body of evidence that is commensurate both with the most pressing objectives of funding sectors and with the first principles of economics. The aim is to help policymakers move beyond narrow sector-specific perspectives and take decisions to improve overall social welfare. An integrated approach can begin with a CCA and then convert outcomes into relevant cost effectiveness measures (both cost per unit of output and cost per generic unit of health gain), and then value all outcomes consistently within a CBA. In this sense, the seemingly different approaches of economic evaluation can be viewed as complimentary, where CCA and CEA are 'nested' within an overall CBA.

Priority setting tools can then be used to facilitate the translation of evidence into decision-making. Tools such as PBMA are consistent with a societal approach and can help frame the scope of the priority setting exercise, facilitate stakeholders coming together, and make explicit the decision-making criteria so that evidence can be used systematically.

Overall, economics has much to offer public health to help facilitate intersectoral alignment so that decisionmakers take account of wider social determinants of health. Equally, public health has much to offer health economics; providing an opportunity to rediscover the societal approach where the ultimate aim of economics is to allocate scarce resources for the improvement of overall social welfare, wherein health is just one important element.

Private Insurance System Concerns

K Simon, Indiana University, Bloomington, IN, USA, and National Bureau of Economic Research, Cambridge, MA, USA

Introduction

As compared to public insurance systems, private systems face a unique set of market problems that have occupied a central position in health economics research. These ethical and efficiency problems that arise in market transactions plague national insurance systems to a much lesser degree and involve different solutions. This article first considers the reasons why private insurance systems exist in their current forms; next, it examines the ways in which private and public systems attempt to solve market failures; finally, it ends with a discussion of regulations related to perceived problems in the private market.

Healthcare appears in some ways a very well-suited market for private insurance transactions, as it involves high and unpredictable costs for a large segment of the population. However, numerous problems can potentially lead to classic market failures or otherwise societally unacceptable outcomes in a private health insurance system. The efficiency related problems of such a system include adverse selection due to a lack of perfect information and moral hazard due to price responsiveness in the demand for medical care. There are also several ethical questions that surround the affordability of insurance for the poor and high premiums for the sick, which lead to private-system regulations that borrow features of a public system. As expected, private systems maintain a delicate balance between ethical and efficiency concerns: various practices adopted by private insurance markets in response to adverse selection and moral hazard problems have heightened ethical concerns, while government policies adopted within private systems designed to alleviate ethical concerns have sometimes had market failure consequences.

Purely public systems, described in other articles in this Encyclopedia in terms of the history of health insurance in developed countries (John Murray) and a comparison between such insurance systems (Victor Rodwin), are distinct from the largely private system that exists in the US (see the article by Tim Jost on the history of health insurance in the US). Yet, as a thought exercise, one could imagine a private market, that under certain conditions recreates the essential elements of social insurance for healthcare, providing cradle-to-grave mandatory insurance that is financed by progressive taxation.

A Private-System Equivalent of Standard Public Insurance

Even with private insurers selling health insurance, it is theoretically possible that all policies offered are based on lifetime contracts, purchased at birth and priced uniformly. What leads such a scenario to be infeasible? For one, there is no mechanism in the private market to retain the feature of equity present in a public system through progressive taxation based financing. Even if lifetime policies were available, parents would have to purchase them for their children based on private funds. As long as there was an unequal distribution of incomes, there would be some level of uninsurance.

Even among families whose lifetime expected incomes could pay for lifetime insurance policies for their children, liquidity constraints and borrowing market imperfections would preclude them from paying for a policy that covers a long timeframe and thus would prevent the system from being considered universal and mandatory. One could design a lifetime policy with periodic payments, as is done for long-term care (see the article by Tamara Konetzka) and life insurance. A version of this long-term policy proposal was first considered by Cochrane. For several reasons including lack of contract enforceability, long-term insurance contracts are not available. Requiring periodic payments incentivizes the customers to not delay purchase until their health deteriorates and creates incentives on the part of insurers to reinterpret or rescind sales to those whose health has deteriorated since the initial contract was established. This leads to selection issues, which are one main form of difficulty experienced by a private system.

Government regulations are another reason that long-term policies do not exist in health insurance. Some regulations in current-day private systems attempt to create an equitable financing system by providing subsidies and supplemental public systems that pay for those with lower incomes. In other ways, community rating and guaranteed-issue-type regulations redistribute wealth from the healthy to the sick and could actually have regressive elements, as age and health status are correlated negatively, whereas age and income are correlated positively. Because of the risk of insurance companies refusing to cover those who experience a negative health shock after years of being continuously covered (revision of risk), regulations such as guaranteed renewability, protection of preexisting conditions coverage, and portability laws have arisen to protect consumers. These regulations address equity problems but could themselves lead to efficiency concerns. For example, guaranteed issue and community rating without a strong mandate for purchasing coverage could lead to worsened adverse selection and instability in insurance markets, as has occurred in the individual health insurance market in New York in the past two decades. The availability of publicly financed health insurance for low-income families could lead to reductions in the private provision of health insurance, as has been pointed out in the case of Medicaid expansions in the US.

Some solutions to problems affiliated with a private health insurance system come from the private market itself rather than from regulation. The fact that employer groups are the main organizing form of health insurance provision in the US helps mitigate problems with adverse selection, especially among large employers who provide stable pools for insurers. Private insurance plans also impose a guarantee issue period in a plan year; enrollees must select coverage within a certain window of time within the US or else forgo coverage for that

entire plan year. If employees were able to select coverage at any point in the year, the system would suffer from greater adverse selection.

A Model of a Pure Private Health Insurance System Absent Market Problems

In addition to considering the reasons why a private system replica of the standard public insurance model does not exist, it is important to consider why problems arise in a private system for health insurance. In theory, private markets could solve the risk inherent in medical care demand provided the correct conditions exist. John Nyman's article in this Encyclopedia on theory of demand provides further details on the welfare implications of health insurance. Suppose that health insurance is available each year to risk-averse individuals who face identical risks and are inelastic in their demand for medical care. In such a setting, optimal risk protection would be full insurance, and the price of insurance would be above or at an actuarially fair price, depending on the degree of customer risk aversion, loading costs, and degree of competition among sellers of insurance.

Problems of Imperfect Information

The world described above does not match reality in many ways. For one, individuals are not identical in their risk profiles, and insurance sellers cannot easily discern this information. At any price, insurers would find that those whose probability of needing coverage is higher than the population average would be more likely to buy insurance, causing insurers to experience 'adverse selection death spirals.' Seminal work addressed the problems of asymmetric information in insurance markets. Other economists developed insurance models to consider the equilibria that could exist in health insurance markets where hidden information is held by two groups of insurance customers; they concluded that the information imperfection could lead to loss of welfare. If insurers are allowed to offer different insurance contracts, a separating equilibrium could occur in which the group with the lower but unverifiable risk gets partial insurance and the high-risk group gets full insurance. The high-risk group thus imposes an externality on the low-risk group. If insurers are only able to offer one insurance contract, the market could fail to exist altogether because of the unsustainability of a pooling equilibrium.

The importance of the insights from seminal authors writing on information problems in economics in general was recognized when in 2001 Joseph Stiglitz and two other economists jointly received the Nobel Prize in Economics. However, this early work left the reader with a rather pessimistic view of possible solutions to the information problem in the health insurance market. A large literature since then has discussed the conditions under which equilibria may exist, including cases in which consumers differed in risk aversion as well as in risk probabilities. Most recently, researchers have introduced the possibility that there could be advantageous selection in insurance markets whereby those who are lower risk or more risk averse purchase more insurance than those who are higher risk. This literature has shown that advantageous selection exists in the case of Medicare supplemental plans in the US. However, other empirical investigations have also found evidence in favor of adverse selection.

Private market solutions to adverse selection problems

As Arrow noted several decades ago, private markets may be able to solve information failures by finding ways to convey information to sellers. In the US, health insurance is provided by employers as the predominant form of insurance to nonelderly individuals. This results in more stable insurance markets than those available for individuals, because insurers understand that health is not the primary reason for the formation of employer groups. Thereby, both the fact that employment is a signal of one's health and the fact that the heterogeneity of the production function is a signal that a firm was not just formed for the purpose of purchasing health insurance enable insurers to be less on guard regarding adverse selection.

Health insurance tied to the workplace: How does this affect job mobility?

An issue related to the labor market that public systems need not consider is the relationship between the labor market and health insurance. In the US, it is plausible that because of the important role played by employers, those who value health insurance may not leave their job for one that pays higher wages but does not pay for health insurance. One way in which private markets lessen this problem is by 'portability' laws that make it easier for someone to change jobs and obtain insurance without serving new waiting periods.

Insurer practices to guard against adverse selection

Insurers are aware of their information disadvantage and attempt to gather as much information as possible on their customers' health profiles. Insurers aim to base their prices on the information gathered, and they sometimes refuse outright to sell a policy to someone with past health problems in a practice known as 'red lining.' Another insurer practice used to guard against adverse selection is the refusal to cover preexisting conditions, defined as conditions that were diagnosed or treated in the past so many years or months, for the first so many years or months of a policy.

Although in one way these practices can be seen as necessary for the functioning of insurance markets, these practices are often also seen as unfair because they cause those who are unhealthy to pay more for health insurance. As a result, the US private insurance system has undergone several changes to address the concern that insurer practices guarding against adverse selection lead to inequities that society does not find fully acceptable. The latest set of such changes is being made through the Affordable Care Act, but there is long history in the US of regulating terms of sale.

The ability of insurers to place preexisting condition exclusions and other antiadverse selection restrictions on policies sold in the American individual and small group insurance markets has been regulated heavily by states since the early 1990s. The most progressive state in this topic, New York, has since 1992 prohibited insurers from charging different premiums, differentiating plan characteristics, or denying the sale of insurance based on any health or demographic factors,

except to allow slightly different prices according to whether one lives in the northern or southern part of the state. This approach is known as pure community rating, and it is supplemented by guaranteed issue, guaranteed renewability, and limitations on preexisting conditions exclusions. Most other states have taken what is known as a modified community rating approach to the pricing restrictions, in which they allow some adjustments for age or gender. Although these practices are most prevalent in the individual and small-group markets, laws of this nature have been strengthened and applied to all health insurance markets by the federal US government through the Health Insurance Portability and Accountability Act of 1996 and further through the Affordable Care Act of 2010.

Long-Term Contracts for Insurance

As described when delineating the private market replica of the public system, even if insurance markets do not suffer from information problems, they may still have efficiency problems in the real world because of the relatively short term of insurance contracts. If all insurance was to be sold on a long-term basis (e.g., if it was purchased by parents on behalf of children at the point of conception or birth), adverse selection problems would be mitigated because there would be relatively little known information about the health of the customer at this point in their life. Time consistent health insurance asks why insurance contracts offered in the current market are 1 year in length at most, which causes difficulties in purchasing insurance the year after an illness manifests itself. The lack of long-term insurance contracts is suboptimal because it makes it impossible for people to insure against reclassification risk. That is, risk-averse individuals may want to protect themselves not just against the unpredictable costs of insurance in the next year, but also against the unpredictability in risk-rated premiums in the future that could result from unpredictability in health. Early research in the field acknowledged that the current lack of long-term contracts is rooted in several logistical issues, including the lack of court enforcement, the likelihood of contracts being reinterpreted after illness occurs, and regulation. The literature concluded that regulation is the main impediment to the existence of such markets.

Reclassification Risk

Even though long-term health insurance contracts do not exist, many policies are written with a clause called guaranteed renewability, which means that the policy will be available the next year, too. Of course, the risk protection offered depends on the extent to which insurers can change an individual's premiums if their health status changes. Recent work has addressed the value of guaranteed renewability clauses in allowing individuals who purchase insurance to be protected against the risk that they might become worse health risks over time.

Portability and Preexisting Condition Exclusions

Even if insurance policies are written to have a within-policy guarantee of issue through a guaranteed renewability clause, this may not be enough protection against reclassification risk in employment-based insurance systems such as the one in the US. That is, once an individual who has been insured through the policy of one employer decides to switch jobs, the insurer of the next employer may treat him or her as a new entrant. Any reclassification risk the customer had enjoyed may disappear. This is especially the case if the new form of employment is self-employment, in which case the new insurer may be the individual market. A closely related practice is preexisting condition exclusion. Those who are switching between insurers lose their risk protection because of clauses that reassess their premiums based on current health status and because policies can exclude coverage for preexisting conditions.

Moral Hazard

In another departure from the quintessential perfectly competitive insurance market, real-world healthcare demand is not insensitive to price. This behavior, known as moral hazard, simply means that we consume more when we are faced with lower prices; we react to economic incentives. Although full insurance would be the optimal insurance contract if demand for care were completely price inelastic, insurers use cost sharing to reduce the inefficient overuse (use beyond the point at which marginal benefit equals marginal cost to society) of medical care by those who are insured. The most compelling data on the price responsiveness of medical care consumption come from the RAND Health Insurance Experiment, which placed individuals randomly into plans with different cost-sharing structures and discovered that individuals adjusted their healthcare use accordingly.

In the standard economic model, moral hazard is a source of inefficiency, as it creates dead weight loss. In the optimal design of an insurance contract, one must weigh the benefits of risk protection against the costs of inducing moral hazard and dead weight loss. As RAND researchers have pointed out, the optimal contract will depend on risk aversion parameters as well as the elasticity of demand for different forms of medical care. Other work pointed out that there is an interesting parallel between optimal cost sharing to avoid moral hazard and the optimal taxation rules set out by Ramsey. In optimal taxation, we attempt to avoid the dead weight loss of induced behavioral changes by taxing inelastic behaviors more. By analogy, cost sharing could be lower in inelastically demanded care, implying that insurance would lower their prices to a greater extent without inducing moral hazard. This works especially well if services that are inelastically demanded are also the ones in which we most value risk protection.

An alternative view of moral hazard holds that in the face of income constraints it is not all welfare reducing. Writers have raised the concern that moral hazard may act to transfer income from those who are healthy to those who are sick in ways that we could consider efficient. This would happen to the extent that income constraints cause insured individuals to respond by using coverage and to the extent that society as a whole would want an individual to purchase care even when the out-of-pocket cost of doing so is lower than the price paid by society.

Public System Solutions to Moral Hazard Problems

Although in theory adverse selection concerns are mitigated in public systems that offer a single mandatory and free insurance option through taxpayer-based financing, the risk of moral hazard after becoming insured is possibly as high in such systems as it is in private systems. A pure public system might not have as much ability as a private system to pursue solutions that rest on cost sharing. Private systems rely on many forms of cost sharing in the form of fixed or variable copays and (increasingly) high deductibles. Insurance plan formularies for medication place higher-cost drugs with more competitors into high cost-sharing tiers. Although the tiering of inpatient-service cost sharing is not prevalent, private systems are not prevented from such tiering and may decide to develop such systems in the future to mitigate cost growth.

In contrast, it is generally believed that public systems use nonprice methods to ration care (in the economic sense of the word). For example, one may have to be on a waiting list for services that are considered non essential. Researchers have compared waiting times for elective surgery in 12 Organization for Economics Cooperation and Development nations and found that mean wait times more than 3 months are quite common. These delays typically result from the fact that hospitals are paid according to a global budget and use wait times to adjust supply to demand in the absence of a pricing system. The use of a global budget with either a cap or a target is a tool by which public systems institute a nonmarket reimbursement scheme that would control costs. In a target setting, there is a fixed quota of services with fixed fees but there are some additional (lower) fees provided for producing above the quota. The cap system establishes a total budget for a set period and reimbursements rates are calculated *ex post* depending on the quantity of services that were provided. Fan *et al*. provide a theoretical explanation for why a cap is more effective than a target at controlling the quality of services provided. Regardless of the specific type, global budgets are similar in spirit to the provision of capitated reimbursements to providers under managed care within a private insurance system, also global budgets apply at the population level, whereas capitation in managed care usually applies at the individual patient level.

An additional way by which public systems counteract moral hazard on the supply side is by using cost effectiveness in decisions to cover one type of medical technology over the other, when close substitutes are available. Public systems use a ratio of expected benefits to expected costs to prioritize decisions such as whether to place a certain drug on the national formulary, whereas within a private system a formulary usually uses differences in out of pocket costs to steer consumers toward certain medications. Within private systems, managed-care organizations also tend to use this type of information to some degree, but its use is much more widespread in public systems.

Moral hazard is also tempered within public systems by the fact that often only basic care is covered by the public system whereas more expensive treatments, and perhaps treatments with more price-elastic demand, are covered by private and voluntary supplemental systems. Often the supplemental system will also cover cost sharing imposed by the public system. The literature noted that in France, private payments account for a quarter of national spending. They show that within a mixed system, supplemental coverage may increase spending for the public system as well. Even if a supplemental plan were to only cover services not provided by the public system, that coverage could stimulate the additional use of public covered services, too, through complementarities. Robust evidence of spillover effects from supplemental private coverage to the public system has been shown to exist in the case of Medicare and Medigap plans in the US as well.

Moral hazard also affects the supply side in both private and public insurance systems. Some of this can be interpreted as supplier-induced demand, where information asymmetry allows providers to misrepresent the benefits of healthcare (Arrow) even more if that care is paid for by insurance companies rather than the patient; other forms of moral hazard can be seen in rises in technology adoption due to the reduced cost sharing introduced by insurance. The advent of Medicare in the US introduced a vast array of medical technology; this may be viewed as a dynamic response to moral hazard incentives.

As mentioned earlier, both private and public systems have used managed care type arrangements (capitation or global budgets) to counteract moral hazard. Another way that public and private systems can reduce moral hazard on the part of suppliers is by extending the Ramsey rule related insight on optimal patient cost sharing to optimal provider reimbursement setting. Researchers have presented a theory of optimal pricing for regulators, who can consider using principles of Ramsey pricing to reduce oversupply in settings where physicians can extend demand. This suggests that regulators should consider setting lower reimbursements for procedures with more demand inducement possibilities.

The above discussion has focused on *ex post* moral hazard, the behavior of consumers and providers after they are covered by insurance. *Ex ante* moral hazard refers to a dynamic form of response that occurs at the individual level when one knows that consequences of risky health behaviors may be mitigated by insurance coverage. In fact, public systems face greater risk of *ex ante* moral hazard because of their inability to price according to health status, regardless of whether those health conditions result from health behavior choices that provided instantaneous gratification at the expense of worse health later in life. Once again, the waiting times for elective procedures may be seen as partially counteracting this form of moral hazard, as does the banning of direct to consumer ads to consumers. Seeing attractive images associated with lifestyle drugs may increase awareness and demand among consumers to these drugs. Aside from the US, only one country (New Zealand) allows the advertising of medications to consumers.

Coverage for those who are unable to pay for private insurance

The largest social issue faced by private systems is probably the question of payment. For many reasons, a private market may not reach universal coverage. This is not an outcome predicted by insurance theory, where there should be an insurance policy by which everyone is fully insured. Assuming no moral hazard and no asymmetric information, the market should provide an opportunity for risk-averse insurance buyers and

risk-neutral sellers to find mutually beneficial policies that reflect at least the actuarial price of coverage.

This textbook model assumes that the risks faced do not exceed available resources; relaxing just this one assumption leads to a world in which individuals will go uninsured and presumably less than fully insure, incurring debt or receiving inadequate care when they fall ill. Additional reasons for lack of insurance also include myopia and other threats to rationality. Insurance involves payment now for problems that could occur in the future, and theories of limited rationality suggest there will be under investment in such expenses leading to *ex post* regret when someone is injured while uninsured. The literature on health insurance affordability considers approximately one-fourth to three-fourth of uninsured adults to be able to afford insurance, using various measures of affordability.

Other reasons for uninsurance have to do with whether free care is provided as the 'outside good.' The US provision that hospitals shall provide stabilizing care regardless of pay, the availability of charity care, and other public provisions could influence an individual's decision to remain uninsured, avoiding the payment of insurance premiums. It could also be that due to regulations or market institutional reasons, an individual may not find the policy described by the textbook model where price is relevant to that individual's risk profile and coverage provided is relevant to the risk events they face. For example, young adults may not find prices that reflect their low statistical probability of illness because policies are based on community rates and do not vary by age, or because insurance laws mandate that the policy include coverage for types of care that young customers are unlikely to use.

When the available policy is too expensive for an individual because of their level of income, because of imperfect rationality, because of the availability of charity care, or because of the lack of a full spectrum of insurance policy options, uninsurance results and becomes a societal problem leading to concerns of equity and to financial and psychological stress rooted in inadequate access to healthcare. A private insurance system must then decide whether certain populations will be placed into a public system as well as the means by which such care will be paid. In reality, such a public system may include substantial out of pocket costs, as in the case of the US Medicare.

Summary

Public and private systems that aim to insure individuals against the uncertain need for medical care face different issues. Specifically, private systems are much more likely than public systems to suffer from adverse selection and equity concerns. Both sectors risk moral hazards but take different approaches to solving them. This article starts with the question of why a private system does not mimic a standard public insurance system and achieve universal coverage through equitable methods of financing. Issues such as affordability, selection, moral hazard, and legal contract enforceability lead to private systems providing coverage on terms that are often viewed as socially unacceptable. Both regulations and private market solutions exist to counteract these problems. However, regulations could themselves exacerbate efficiency problems in the private market, leading to a delicate balance between intended and unintended consequences, and between risk pooling and moral hazard.

Problem Structuring for Health Economic Model Development

P Tappenden, University of Sheffield, Sheffield, UK

Glossary

Conceptual model The abstraction and representation of complex phenomena of interest in some readily expressible form, such that individual stakeholders' understanding of the parts of the actual system, and the mathematical representation of that system, may be shared, questioned, tested, and ultimately agreed.

Design-oriented conceptual model Conceptual models which are focused on the consideration of alternative potentially acceptable and feasible quantitative model designs, to specify the model's evidence requirements and to provide a basis for comparison and justification against the final implemented model.

Disease logic model A problem-oriented conceptual model which sets out the disease-specific events and processes within the system in which the decision problem exists.

Problem-oriented conceptual model A form of conceptual model which is developed to understand the decision problem and the system in which that problem exists.

Problem structuring methods A set of formal methods developed within the field of Operational Research intended to develop consensus, structure, and make sense of complex or messy problems.

Service pathways model A problem-oriented conceptual model which sets out the elements of the service which are relevant to the system in which the decision problem exists.

Introduction

The economic evaluation of health care is a general framework for informing decisions about whether particular health-care technologies represent a cost-effective use of health-care resources. Commonly, the evidence required to inform a decision about the cost-effectiveness of a given set of competing health technologies is not available from a single source. The use of mathematical modeling can be used to support this decision-analytic framework thereby allowing the full range of relevant evidence to be synthesized and brought to bear on the decision problem (Briggs *et al.*, 2006). The process of developing a decision-analytic model is generally seen as being iterative, and requires the model developer to make a substantial number of choices about what should be included in a model and how these included phenomena should be related to one another. These choices take place at every stage of the model development process, and include choices about the comparators to be assessed, choices about which health states and sequences of events will comprise the model's structure, choices about which evidence sources should be used to inform the model parameters, and choices about statistical methods for deriving the model's parameters, to name but a few. Importantly the absence of perfect information through which to comprehensively validate a model means that there is rarely a definitive means through which to prospectively determine whether these choices are right or wrong. Instead, model development choices are made on the basis of subjective judgments, with the ultimate goal of developing a model which will be useful in informing the decision at hand.

Therefore, model development is perhaps best characterized as a complex process in which the modeler, in conjunction with other stakeholders, determines what is relevant to the decision problem (and at the same time, what can reasonably be considered irrelevant to the decision problem). This notion of relevance has a direct bearing on the credibility of a model and on the interpretation of results generated using that model. Failure to account for the complexities of the decision problem may result in the development of models which are "mathematically sophisticated but contextually naïve" (Ackoff, 1979). The development of useful mathematical models therefore requires more than mathematical ability alone: first, it requires the model developer to understand the complexity of the real system that the model will attempt to represent, and the choices available for translating this understanding of complexity into a credible conceptual and mathematical structure. It is perhaps surprising that while much has been written about the technical aspects of model development, for example, the statistical extrapolation of censored data and methods for synthesizing evidence from multiple sources, there is a comparative dearth of practical guidance surrounding formal processes through which an appropriate model structure should be determined. It is this complex and messy subject matter that forms the focus of this article.

The purpose of this article is not to rigidly prescribe how model development decisions should be made, nor is it intended to represent a comprehensive guide of 'how to model.' The former would undoubtedly fail to reflect the unique characteristics of each individual decision problem and could discourage the development of new and innovative modeling methods. Conversely, the latter would inevitably fail to reflect the sheer breadth of decisions required during model development. Rather, the purposes of this article are threefold:

1. To highlight that structural model development choices invariably exist;
2. To suggest a generalizeable and practical hierarchical approach through which these alternative choices can be prospectively exposed, considered and assessed; and

 doi:10.1016/B978-0-12-375678-7.01410-3

3. To highlight key issues and caveats associated with the use of certain types of evidence in informing the conceptual basis of the model.

The article is set out as follows. The article begins by introducing concepts surrounding the role and interpretation of mathematical models in general, and attempts to highlight the importance of conceptual modeling within the broader model development process. Following on from this, existing literature surrounding model structuring and conceptual modeling is briefly discussed. The article then moves on to suggest a practicable framework for understanding the nature of the decision problem to be addressed in order to move toward a credible and acceptable final mathematical model structure. A series of potentially useful considerations is presented to inform this process.

The Interpretation of Mathematical Models

A mathematical model is a "representation of the real world… characterized by the use of mathematics to represent the parts of the real world that are of interest and the relationships between those parts" (Eddy, 1985). The roles of mathematical modeling are numerous, including extending results from a single trial, combining multiple sources of evidence, translating from surrogate/intermediate endpoints to final outcomes, generalizing results from one context to another, informing research planning and design, and characterizing and representing decision uncertainty given existing information (Brennan and Akehurst, 2000). At a broad level, mathematical or simulation models in Health Technology Assessment (HTA) are generally used to simulate the natural history of a disease and the impact of particular health technologies on that natural history in order to estimate incremental costs, health outcomes, and cost-effectiveness.

All mathematical models require evidence to inform their parameters. Such evidence may include information concerning disease natural history or baseline risk of certain clinical events, epidemiology, resource use and service utilization, compliance/participation patterns, costs, health-related quality of life (HRQoL), survival and other time-to-event outcomes, relative treatment effects, and relationships between intermediate and final endpoints. However, the role of evidence is not restricted to informing model parameters. Rather, it is closely intertwined with questions about which model parameters should be considered relevant in the first place and how these parameters should be characterized. The consideration of how best to identify and use evidence to inform a particular model parameter thus first requires an explicit decision that the parameter in question is 'relevant,' the specification or definition of that parameter, and some judgment concerning its relationship to other 'relevant' parameters included in the model. This often complex and iterative activity is central to the process of model development and can be characterized as a series of decisions concerning (1) what should be included in the model, (2) what should be excluded, and (3) how those phenomena that are included should be conceptually and mathematically represented.

The need for these types of decisions during model development is unavoidable, rather it is a fundamental characteristic of the process itself. Although this activity already takes place in health economic model development, it is often unclear how this process has been undertaken and how this may have influenced the final implemented model. In practice, the reporting of model structures tends to be very limited (Cooper *et al.*, 2005) and, if present, usually focuses only on the final model that has been implemented. In such instances, the reader may be left with little idea about whether or why the selected model structure should be considered credible, which evidence has been used to inform its structure, why certain abstractions, simplifications, and omissions have been made, why certain parameters were selected for inclusion (and why others have been excluded), and why the included parameters have been defined in a particular way. This lack of systematicity and transparency ultimately means that judgments concerning the credibility of the model in question may be difficult to make. To produce practically useful guidance concerning the use of evidence in models, it is first important to be clear about the interpretation of abstraction, bias, and credibility in the model development process.

Credibility of Models

A model cannot include every possible relevant phenomenon; if it could it would no longer be a model but would instead be the real world. The value of simplification and abstraction within models is the ability to examine phenomena which are complex, unmanageable, or otherwise unobservable in the real world. As a direct consequence of this need for simplification, all models will be, to some degree, wrong. The key question is not whether the model is 'correct' but rather whether it can be considered to be useful for informing the decision problem at hand. This usefulness is directly dependent on the credibility of the model's results, which is, in turn, hinged on the credibility of the model from which those results are drawn. Owing to the inevitability of simplification and abstraction within models, there is no single 'perfect' or 'optimal' model. There may, however, exist one or more 'acceptable' models; even what is perceived to be the 'best' model could always be subjected to some degree of incremental improvement (and indeed the nature of what constitutes an improvement requires some subjective judgment). The credibility of potentially acceptable models can be assessed and differing levels of confidence can be attributed to their results on the basis of such judgments. The level of confidence given to the credibility of a particular model may be determined retrospectively – through considerations of structural and methodological uncertainty *ex post facto*, or prospectively – through the *a priori* consideration of the process through which decisions are made concerning the conceptualization, structuring, and implementation of the model.

Defining Relevance in Models

The purpose of models is to represent reality, not to reproduce it. The process of model development involves efforts to reflect those parts of reality that are considered relevant to the decision problem. Judgments concerning relevance may differ

between different modelers attempting to represent the same part of reality. The question of 'what is relevant?' to a particular decision problem should not be judged solely by the individual developing the model; rather making such decisions should be considered as a joint task between modelers, decision-makers, health professionals, and other stakeholders who impact on or are impacted on by the decision problem under consideration. Failure to reflect conflicting views between alternative stakeholders may lead to the development of models which represent a contextually naïve and uninformed basis for decision-making.

The Role of Clinical/Expert Input

Clinical opinion is essential in understanding the relevant facets of the system in which the decision problem exists. This clinical opinion is not only relevant, but essential, because it is sourced from individuals who interact with this system in a way that a modeler cannot. This information forms the cornerstone of a model's contextual relevance. However, it is important to recognize that health professionals cannot fully detach themselves from the system in which they practice; their views of a particular decision problem may be to some degree influenced by evidence they have consulted, their geographical location, local enthusiasms, their experience, and expertise, together with a wealth of other factors. Understanding why the views of stakeholders differ from one another is important, especially with respect to highlighting geographical variations. As such, the use of clinical input in informing models and model structures brings with it the potential for bias. Bias may also be sourced from the modeler themselves as a result of their expertise, their previous knowledge of the system in which the current decision problem, and the time and resource available for model development. Whenever possible, potential biases should be brought to light to inform judgments about a model's credibility.

Problem Structuring in Health Economics and Other Fields

It is important at this stage to note that although related to one another, there is a distinction between problem structuring methods (PSMs) and methods for structuring models. The former are concerned with understanding the nature and scope of the problem to be addressed, eliciting different stakeholders' potentially conflicting views of the problem and developing consensus, exploring what potential options for improvement might be available, and even considering whether a problem exists at all. There exist a number of methods to support this activity which have emerged from the field of 'soft' Operational Research; these include Strategic Options Design and Analysis (SODA) and cognitive mapping, Soft Systems Methodology (SSM), Strategic Choice Approach, and Drama Theory to name but a few. All stakeholders are seen as active 'problem owners' and each of their views are considered important. The emphasis of PSMs is not to identify the 'rationally optimal' solution, but rather to lay out the differing perceptions of the problem owners to foster discussion concerning potential options for improvement to the system. The value or adequacy of the PSMs is gauged according to whether they usefully prompt debate, with the intended endpoint being some agreement about the structure of the problem to be addressed and the identification and agreement of potential improvements to that problem situation. They do not necessarily assume that a mathematical model is appropriate or required. These methods are not discussed further here, but the interested reader is directed to the excellent introductory text by Rosenhead and Mingers, 2004.

Conversely, formal methods for model structuring, which relates principally to developing a conceptual basis for the quantitative model, remain comparatively underdeveloped, both in the context of health economic evaluation as well as in other fields. A recent review of existing conceptual modeling literature (Robinson, 2008) concluded that although conceptual modeling is 'probably the most important element of a simulation study,' there remains for the most part, a vacuum of research in terms of what conceptual modeling is, why it should be done, and how it may be most effectively implemented. Where formal conceptual modeling viewpoints have emerged, there is little consensus or consistency concerning how this activity should be approached.

This problem is particularly applicable in the field of health economics. Recently, a qualitative research study was undertaken to examine techniques and procedures for the avoidance and identification of errors in HTA models (Chilcott *et al.*, 2010). Interviewees included modelers working within Assessment Groups involved in supporting NICE's Technology Appraisal Program as well as those working for outcomes research groups involved in preparing submissions to NICE on behalf of pharmaceutical companies. A central aspect of these interviews involved the elicitation of a personal interpretation of how each interviewee develops models. These descriptions were synthesized to produce a stylized model development process comprising five broad bundles of activities (**Box 1** and **Figure 1**).

One particular area of variability between interviewees concerned their approaches to conceptual model development. During the interviews, respondents discussed the use of several approaches to conceptual modeling including

Box 1 Main stages in the model development process

1. Understanding the decision problem: Activities including immersion in research evidence, defining the research question, engaging with clinicians, decision-makers, and methodologists, and understanding what is feasible.
2. Conceptual modeling: Activity related to translating the understanding of the decision problem toward a mathematical model-based solution (Robinson, 2008).
3. Model implementation: Implementation of the model within a software platform.
4. Model checking: Activity to avoid and identify model errors. This includes engaging with experts, checking face validity, testing values, structure and logic, checking data sources, etc.
5. Engaging with decision: Model reporting and use by the decision-maker(s).

documenting proposed model structures, developing mock-up models in Microsoft Excel, developing sketches of potential structures, and producing written interpretations of evidence. For several respondents, the model development process did not involve any explicit conceptual modeling activity; in these instances, the conceptual model and implementation model were developed in parallel with no discernable separation between the two activities. This is an important distinction to make with respect to model credibility and validation (as discussed in Section Definition and Purpose of Conceptual Modeling) and the processes through which evidence is identified and used to inform the final implemented model.

Definition and Purpose of Conceptual Modeling

Although others have recognized the importance of conceptual modeling as a central element of the model development process, it has been noted that this aspect of model development is probably the most difficult to undertake and least well understood (Chilcott *et al.*, 2010; Law, 1991). Part of the problem stems from inconsistencies in the definition and the role(s) of conceptual modeling, and more general disagreements concerning how such activity should be used to support and inform implementation modeling. The definition and characteristics of conceptual modeling are dependent on the perceived purposes of the activity. For the purpose of this document, conceptual modeling is taken as: "the abstraction and representation of complex phenomena of interest in some readily expressible form, such that individual stakeholders' understanding of the parts of the actual system, and the mathematical representation of that system, may be shared, questioned, tested, and ultimately agreed."

Although there is inevitable overlap associated with processes for understanding the decision problem to be addressed, conceptual modeling is distinguishable from these activities in that it is targeted at producing tangible outputs in the form of one or more conceptual models. In the context of health economic evaluation, conceptual model development may be used to achieve a number of ends, as highlighted in Box 2. Broadly speaking, these roles fall into two groups: (1) those associated with developing, sharing, and testing one's understanding of the decision problem and the system in which this exists and (2) those associated with designing, specifying, and justifying the model and its structure. Therefore it seems sensible to distinguish between problem-oriented conceptual models and design-oriented conceptual models; this distinction has been made elsewhere outside of the field of health economics (Lacy *et al.*, 2001). The characteristics of these alternative types of conceptual model are briefly detailed below. Both of these types of model may be useful approaches for informing the relevant characteristics of a health economic model.

Problem-oriented conceptual models: This form of conceptual model is developed to understand the decision problem and the system in which that problem exists. The focus of this model form concerns fostering communication and understanding between those parties involved in informing, developing, and using the model. In health economic evaluation, this type of conceptual model is primarily concerned with developing and agreeing a description of the disease and treatment systems: (1) to describe the current clinical

Box 2 The roles of conceptual modeling in health economic model development

Problem-oriented conceptual models

- To ensure that health professionals understand how the model will capture the impact of the interventions under consideration on costs and health outcomes.
- To ensure that the proposed model will be clinically relevant – that all relevant events, resources, costs, and health outcomes have been included and that these reflect current knowledge of disease and treatment systems.
- To ensure that the proposed model will meet the needs of the decision-maker.
- To provide a reference point during model implementation.
- To highlight uncertainty and variation between health-care practitioners.

Design-oriented conceptual models

- To provide a common understanding amongst those involved in model development regarding model evidence requirements before model implementation.
- To provide an explicit platform for considering and debating alternative model structures and other model development decisions before implementation (including the *a priori* consideration of structural uncertainties).
- To provide a reference point during model implementation.
- To provide the conceptual basis for reporting the methods and assumptions employed within the final implemented model.
- To provide a basis for comparison and justification of simplifications and abstractions during model development.

understanding of the relevant characteristics of the disease process(es) under consideration and important events therein; and (2) to describe the clinical pathways through which patients with the disease(s) are detected, diagnosed, treated, and followed-up. This type of conceptual model is therefore solely concerned with unearthing the complexity of the decision problem and the system in which it exists; its role is not to make assertions about how those relevant aspects of the system should be mathematically represented. The definition of 'what is relevant?' for this type of conceptual model is thus primarily dependent on expert input rather than the availability of empirical research evidence. In this sense, this type of conceptual model is a problem-led method of inquiry.

Design-oriented conceptual models: This form of conceptual model is focused on the consideration of alternative potentially acceptable and feasible quantitative model designs, to specify the model's anticipated evidence requirements, and to provide a basis for comparison and justification against the final implemented model. To achieve these ends, it draws together the problem-oriented conceptual views of relevant disease and treatment processes and interactions between the two. The design-oriented conceptual model sets out a clear boundary around the model system, defines its breadth (how far down the model will simulate certain pathways for particular patients and subgroups) and sets out the level of depth or detail within each part of the model. It therefore represents a platform for identifying and thinking through potentially feasible and credible model development choices before actual implementation. Within this context, the definition of 'what is relevant?' is guided by the problem-oriented models and therefore remains problem-led, but is mediated by the question of 'what is feasible?' given the availability of existing evidence and model development resources (available time, money, expertise, etc.).

Conceptual modeling activity, however defined, is directly related to model credibility and validation (Sargent, 2004). The absence of an explicit conceptual model means that a specific point of model validation is lost. As a model cannot include everything, an implemented model is inevitably a subset of the system described by the conceptual model. This hierarchical separation allows simplifications and abstractions represented in the implemented model to be compared against its conceptual counterpart, thereby allowing for debate and justification (Robinson, 2008). However, in order to make such comparisons, conceptual model development must be overt: the absence or incomplete specification of a conceptual model leads to the breakdown of concepts of model validation and verification. Without first identifying and considering the alternative choices available, it is impossible to justify the appropriateness of any particular model. Furthermore, without first setting out what is known about the relevant disease and treatment processes, the extent or impact of particular assumptions and simplifications cannot be drawn out explicitly. Therefore, the benefit of separating out conceptual modeling activity into distinct problem-oriented and design-oriented components is that this allows the modeler (and other stakeholders) to first understand the complexities of the system the model intends to represent, and then to examine the extent to which the simplifications and abstractions resulting from alternative 'hard' model structures will deviate from this initial view of the system. Figure 2 shows the hierarchical relationship between the real world, the problem- and design-oriented conceptual models, and the final implemented model.

Practical Approaches to Conceptual Modeling in HTA

This section suggests how conceptual modeling could be undertaken and which elements of model development activity should be reported. Practical considerations surrounding conceptual model development are detailed below with reference to a purposefully simple model to assess the cost-effectiveness of adjuvant treatments for a hypothetical cancer area. These considerations are intended to be broadly generalizeable to economic analysis within other diseases and conditions. It should be noted that the illustrative model is only intended to suggest how the alternative conceptual models forms may be presented and used. The problem-oriented model is divided into two separate conceptual model views: a disease logic model and a service pathways model.

Problem-Oriented Conceptual Modeling – Disease Logic Models

Figure 3 presents a simple example of a conceptual disease logic model for the hypothetical decision problem. The focus of this type of model is principally on relevant disease events and processes rather than on the treatments received. At each

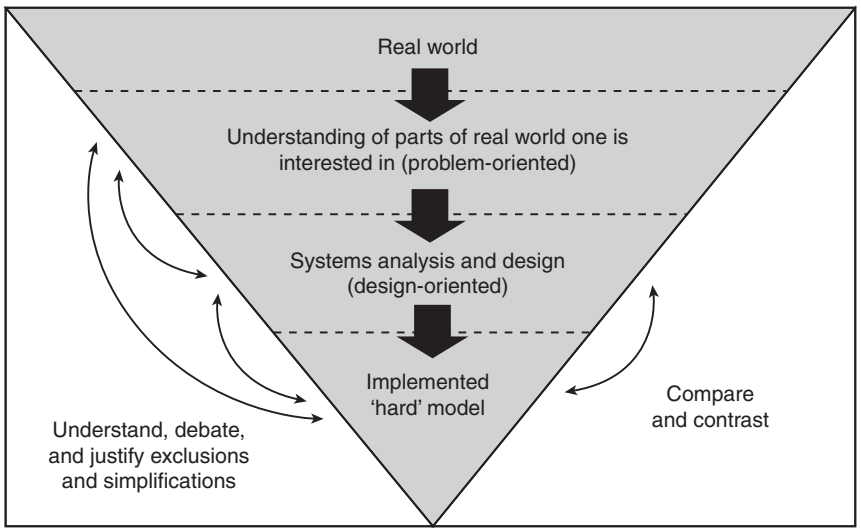

Figure 2 A hierarchy of models.

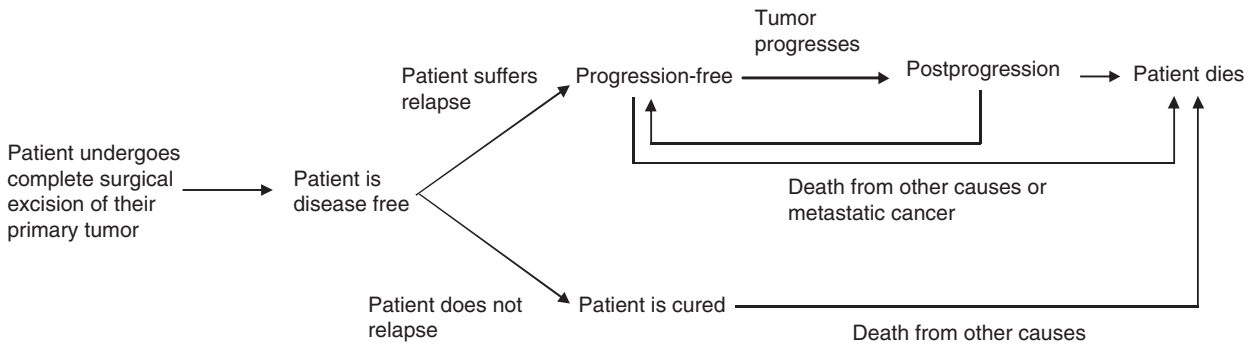

Figure 3 Illustrative disease logic model.

point in the pathway, the focus should therefore relate to an individual patient's true underlying state rather than what is known by health-care professionals at a particular point in time. It should be reiterated that this type of conceptual model does not impose or imply any particular decision concerning modeling methodology or appropriate outcome measures; it is solely a means of describing the relevant clinical events and processes within the system of interest. It should also be noted that such conceptual models should be accompanied by textual descriptions to support their interpretation and to capture and factors or complexities which are not represented diagrammatically.

The following nonexhaustive set of issues and considerations may be useful when developing and reporting this type of problem-oriented conceptual model:

Inclusion/Exclusion of Disease-Related Events

- What are the main relevant events from a clinical/patient perspective? Does the conceptual model include explicit reference to all clinically meaningful events? For example, could a patient experience local relapse? Or could the intervention affect other diseases (e.g., late secondary malignancy resulting from radiation therapy used to treat the primary tumor)?
- Can these relevant events be discretized into a series of mutually exclusive biologically plausible health states? Does this make the process easier to explain?
  - If so, which metric would be clinically meaningful or most clinically appropriate? Which discrete states would be clinically meaningful? How do clinicians think about the disease process? How do patients progress between these states or sequences of events?
  - If not, how could the patient's preclinical trajectory be defined?
- Do alternative staging classifications exist, and if so can/should they be presented simultaneously?
- Are all relevant competing risks (e.g., relapse or death) considered?
- For models of screening or diagnostic interventions, should the same metric used to describe preclinical and post-diagnostic disease states?
- Is the breadth of the conceptual model complete? Does the model represent all relevant states or possible sequences of events over the relevant patient subgroup's lifetime?

- What are the causes of death? When can a patient die from these particular causes? Can patients be cured? If so, when might this happen and for which states does this apply? What is the prognosis for individuals who are cured?

Impact of the Disease on HRQoL and Other Outcomes

- Is there a relationship between states, events, and HRQoL? Which events are expected to impact on a patient's HRQoL?
- Does the description of the disease process capture separate states in which a patient's HRQoL is likely to be different?
- Does the description of the disease process capture different states for prognosis?

Representation of Different-Risk Subgroups

- Is it clear which competing events are relevant for particular subgroups?
- Does the description of the disease process represent a single patient group or should it discriminate between different subgroups of patients?
- Are these states/events likely to differ by patient subgroup?

Impact of the Technology on the Conceptualized Disease Process

- Have all competing technologies relevant to the decision problem been identified?
- Can the conceptual model be used to explain the impact(s) of the technology or technologies under assessment? Do all technologies under consideration impact on the same set of outcomes in the same way?
- Are there competing theories concerning the impact(s) of the technology on the disease process? Can these be explained using the conceptual model?
- Does the use of the health technology result in any other impacts on health outcomes that cannot be explained using the conceptual disease logic model?

Problem-Oriented Conceptual Modeling – Service Pathways Models

Figure 4 presents an illustrative service pathways model for the hypothetical decision problem. In contrast to the disease logic model, the focus of the service pathways model is principally concerned with the health-care interventions received based on what is known or believed by health-care practitioners at any given point in time. Again, such conceptual models should be accompanied by textual descriptions to ensure clarity in their interpretation and to retain any complexity which is not or cannot be captured diagrammatically.

The following issues and considerations may be useful when developing and reporting this type of conceptual model:

Relationship between Risk Factors, Prognosis, and Service Pathways

- Is it clear where and how patients enter the service? Is it clear where patients leave the service (either through discharge or death)?
- Does the model make clear which patients follow particular routes through the service?
- Are there any service changes occurring upstream in the disease service which may influence the case-mix of patients at the point of model entry? For example, if surgical techniques were subject to quality improvement might this change patient prognosis further downstream in the pathway?
- Does the model highlight the potential adverse events resulting from the use of particular interventions throughout the pathway? What are these? Do they apply to all competing technologies under consideration?
- Are there any potential feedback loops within the system (e.g., resection → follow-up → relapse → re-resection → follow-up)?
- Which patients receive active treatment and which receive supportive care alone? What information is used to determine this clinical decision (e.g., fitness, patient choice)?

Distinction between What Is True and What Is Known

- How does the pathway change on detection of the relevant clinical events, as defined in the conceptual disease logic model? For example, at what point may relapse be detected?
- Is the occurrence of certain events likely to be subject to interval censoring?

Geographical Variations

- How do the service pathways represented in the model vary by geographical location or local enthusiasms? What are these differences and which parts of the pathway are likely to be affected most?

Nature of Resource Use

- What are the relevant resource components across the pathway and what is the nature of resource use at each point of intervention? For example, routine follow-up dependent on relapse status, once-only surgery (except for certain relapsing patients), cycle-based chemotherapy, doses dependent on certain characteristics, dose-limited radiation treatment, etc.
- Does the conceptual service pathways model include all relevant resource components?
- Which resources are expected to be the key drivers of costs?

Impact of the Technology on the Service Pathway

- Which elements of the conceptual model will the intervention under assessment impact on? For example, different costs of adjuvant treatment, different mean time in follow-up, different numbers of patients experiencing

Box 3 Recommendations for practice – problem-oriented models

1. Develop the structure of the problem-oriented conceptual model using clinical guidelines and health professionals.
2. Use other health professionals not involved in model development to provide peer review and to check understanding of the conceptual models.
3. The precise graphical approach for presenting the conceptual models is important only in that they should be easily understood by health professionals and other decision stakeholders.
4. For the sake of clarity, it may be beneficial to present the model in both diagrammatic and textual forms using nontechnical, nonmathematical language.
5. Develop the problem-oriented models before developing the design-oriented model. The feasibility and acceptability of the design-oriented conceptual model should have no bearing on the adequacy of the problem-oriented conceptual models.

metastatic relapse? What are expected to be the key drivers of costs?

Box 3 presents recommendations for developing and reporting problem-oriented conceptual models.

Practical Considerations – Design-Oriented Conceptual Models

Figure 5 presents an example of a design-oriented conceptual model for the hypothetical decision problem (again, note that this is not intended to represent the 'ideal' model but merely illustrates the general approach). This type of model draws together the problem-oriented model views with the intention of providing a platform for considering and agreeing structural model development decisions. By following this general conceptual approach it should be possible to identify the anticipated evidence requirements for the model at an early stage in model development.

Anticipated evidence requirements to populate the proposed illustrative model are likely to include the following types of information:

- Time-to-event data to describe sojourn time/event rates and competing risks in States 1–4 for the current standard treatment.
- Relative effect estimates for the intervention(s) versus comparator (e.g., hazard ratios or independent hazards time-to-event data).
- Information relating to survival following cure.
- HRQoL utilities for cancer and cured states.
- Estimates of QALY losses or utility decrements and duration data for adverse events.
- Information concerning the probability that a relapsed patient undergoes active/palliative treatment.
- Survival and other time-to-event outcomes for relapsed patients.
- Resource use and costs associated with:
  - Chemotherapy (drug acquisition, administration, pharmacy/dispensing, drugs to manage adverse events, line insertion);
  - Resource use and unit costs for follow-up;
  - Supportive care following relapse; and
  - Active treatments following relapse.

It may be helpful to consider the following issues when developing design-oriented conceptual models.

Anticipated Evidence Requirements

- What clinical evidence is likely to be available through which to simulate the impact of the new intervention(s)? How should these parameters be defined and what alternatives are available? Should independent or proportional hazards be assumed?
- Are all relevant interventions and comparators compared within the same trial? If not, is it possible for outcomes from multiple trials to be synthesized? How will this be done?
- What evidence is required to characterize adverse events within the model? What choices are available?
- Beyond the baseline and comparative effectiveness data relating to the technology itself, what other outcomes data will be required to populate the downstream portions of the model (e.g., progression-free survival and overall survival by treatment type for relapsed patients, survival duration in cured patients)?
- Will any intermediate–final relationships be modeled? What external evidence is there to support such relationships? What are the uncertainties associated with this approach and how might these be reflected in the model?
- Which descriptions of HRQoL states are possible and how will these parameters be incorporated into the final model?
- Will all model parameters be directly informed by evidence or will calibration methods (e.g., Markov Chain Monte Carlo) be required? Which calibration methods will be used and why should these be considered optimal or appropriate?
- What premodel analysis will be required to populate the model? Which parameters are likely to require this?

Modeling Clinical Outcomes

- Which outcomes are needed by the decision-maker and how will they be estimated by the model?
- How/should trial evidence be extrapolated over time?
- If final outcomes are not reported within the trials, what evidence is available concerning the relationship between intermediate and final outcomes? How might this information be used to inform the analysis of available evidence?
- How will the impact(s) of treatment be simulated? How will this directly/indirectly influence costs and health outcomes? What alternative choices are available?

Modeling Approach

- Which methodological approach (e.g., state transition, patient-level simulation) is likely to be most appropriate? Why?
- Is the proposed modeling approach feasible given available resources for model development?

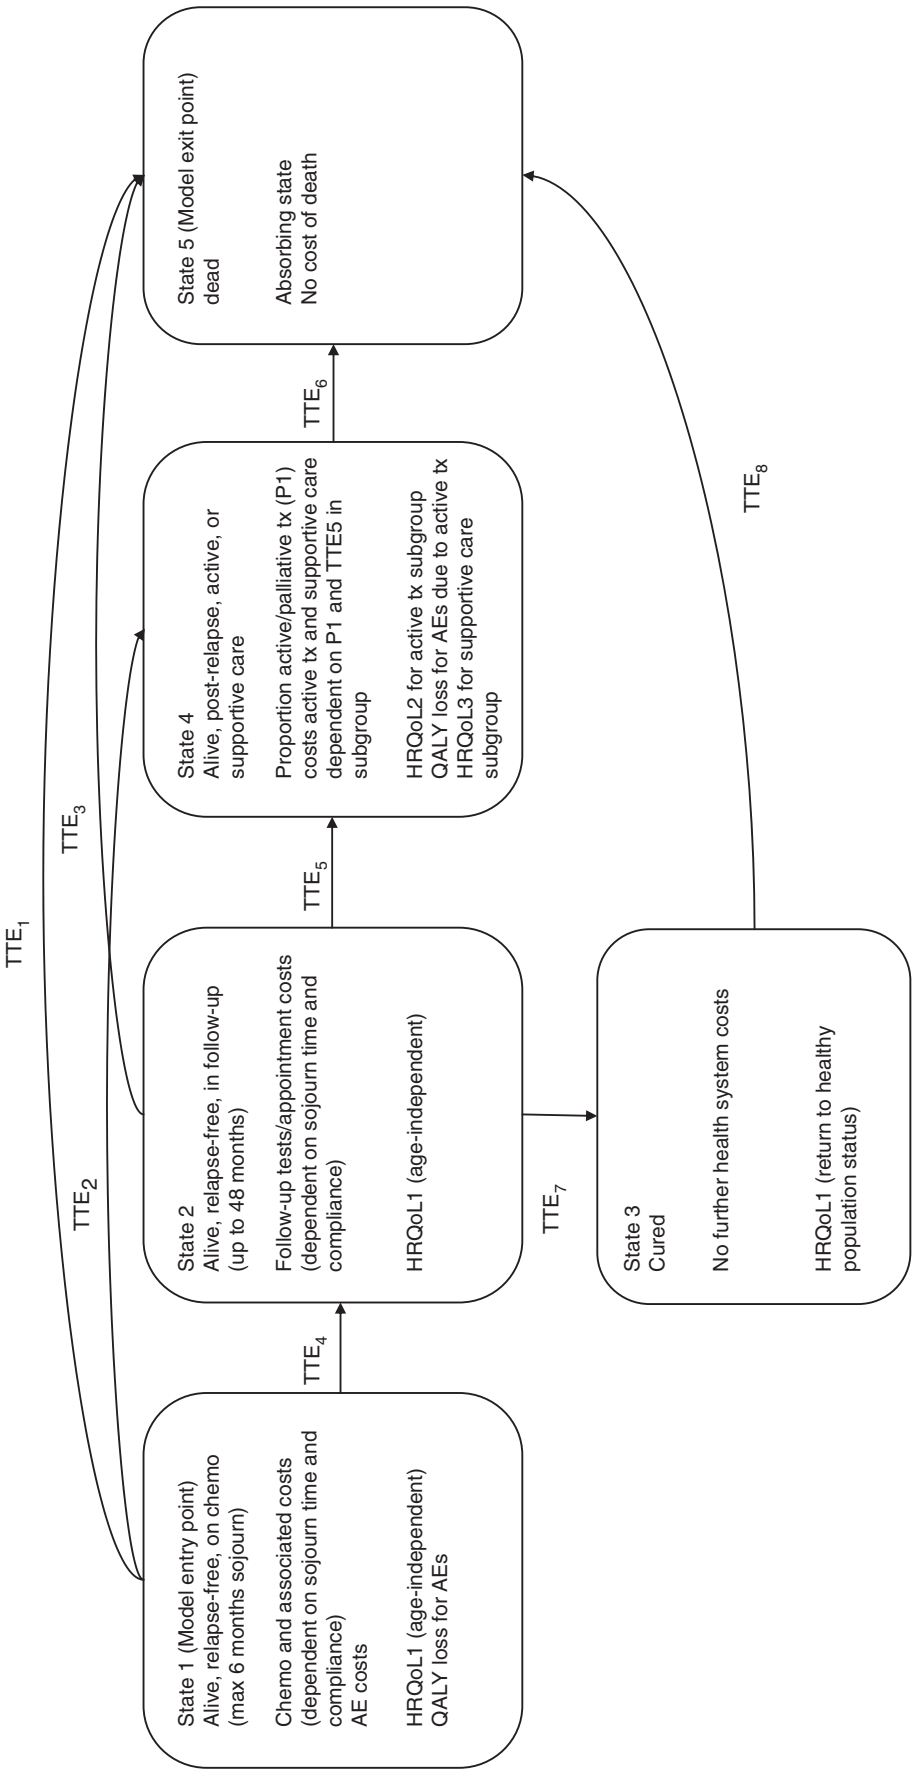

Figure 5 Illustrative design-oriented conceptual model. AE, adverse event; TTE, time to event.

Box 4 Recommendations for practice – design-oriented conceptual models

- The design-oriented conceptual model should be developed initially before the development of the final implementation model. It may, however, be revisited and modified within an iterative process during the development of the quantitative model.
- Model development involves making a large number of decisions and judgments. Not every decision or judgment made during model development will be important. The key decisions are likely to be those whereby the implemented model clearly deviates from the problem-oriented models (e.g., a part of the system is excluded) or whereby several alternative choices exist but none of which are clearly superior (i.e., structural uncertainties). These decisions should be clearly documented and reported.
- The sources of evidence used to inform model structure and the methods through which this information is elicited should be clearly reported.
- Where possible, alternative model development choices drawn out at this stage should be later tested using the quantitative model to assess their impact on the model results. This will not, however, always be possible or feasible.

- How does the approach influence the way in which certain parameters are defined? What alternatives are available (e.g., time-to-event rates or probabilities)?
- Does the proposed modeling approach influence the level of depth possible within certain parts of the model?

Adherence to a Health Economic Reference Case

- Will the proposed model meet the criteria of the reference case specific to the decision-making jurisdiction in which the model will be used? If not, why should the anticipated deviations be considered appropriate?

Simplifications and abstractions

- Have any relevant events, costs or outcomes been purposefully omitted from the proposed model structure? Why? For what reason(s) may these omissions be considered appropriate?

Table 1 Roles and concerns regarding the use of evidence to inform alternative model structures

Existing economic evaluations/ models	*Expert input (including clinicians and potentially patients/service users)*	*Clinical guidelines/ previous TA guidance/ local treatment protocols*	*Empirical clinical studies and reviews (e.g., RCTs, cohort studies)*
Principal role(s) in conceptual model development			
• To apply previously developed model structure to the current decision problem under consideration • To use existing economic analyses to highlight key evidence limitations • To identify possible options for model development decisions • To identify relevant treatment pathways	• To inform problem-oriented conceptual model development • To scrutinize the credibility of alternative model structures • To elucidate uncertainty regarding geographical variation	• To identify existing treatment/management pathways • To highlight gaps in the existing evidence base	• To identify available evidence to inform relationships between intermediate and final endpoints • To investigate what evidence is available
Issues and caveats associated with use			
• Existing models should not be relied on without considerable scrutiny. • Publication or other forms of dissemination of an existing model does not guarantee that the previous model was either appropriate or credible. • Advances in knowledge may render an existing model redundant • There may exist a gap between the decision problem that the model was developed to address and the current decision-problem under consideration	• Seek input from more than one health professional to capture the spectrum of clinical opinion • Use multiple experts located in different geographical locations • There exists a trade-off between seeking support from individuals with considerable expertise and standing (may not have much time but more experience/knowledge) and less experienced clinicians (may have more time to engage but lesser knowledge of evidence base). • Health professionals cannot be completely objectively detached from the system the model intends to represent • May be difficult to distinguish between conflict and geographical variations • Potential conflicts of interest • Potential ethical restrictions	• Current practice may have evolved since publication of guidance • Such evidence sources may not provide sufficient detail to inform the current decision problem • Local protocols may not reflect geographical variations between centers • Local protocols and guidelines may not be evidence-based • There may exist a gap between what should happen and what does happen in clinical practice	• Potential reliance on the availability of evidence rather than the structure of the problem • Differences between studies may suggest competing theories regarding (1) the nature of the disease process and (2) the relevance of particular events. This is not a problem as such but should be drawn out during conceptual model development • Treatments and comparators may reflect historical rather than current or best practice

Abbreviations: RCT, randomized controlled trial; TA, technology appraisal.

- Are there any parts of the disease or treatment pathways that have been excluded altogether? Why?
- What is the expected impact of such exclusion/simplification decisions? Why?
- What are the key structural simplifications? How does the design-oriented model structure differ from the problem-oriented conceptual models? Why should these deviations be considered appropriate or necessary? What is the expected direction and impact of these exclusions on the model results?

Box 4 presents recommendations for developing and reporting design-oriented conceptual models.

Evidence Sources to Inform Conceptual Models

A number of potential evidence sources may be useful for informing these types of conceptual model. Although the evidence requirements for any model will inevitably be broader than that for traditional systematic reviews of clinical effectiveness, the task of obtaining such evidence should remain a systematic, reproducible process of inquiry. Possible sources of evidence to inform conceptual models include: (1) clinical input; (2) existing systematic reviews; (3) clinical guidelines; (4) existing efficacy studies; (5) existing economic evaluations or models; and (6) routine monitoring sources. Table 1 sets out some pragmatic concerns which should be borne in mind when using these evidence sources to inform conceptual model development.

Production Functions for Medical Services

JP Cohen, University of Hartford, West Hartford, CT, USA

Glossary

Average Product Total output rate divided by the amount of a variable input used in its production.

Cobb–Douglas production function The Cobb–Douglas production function has the form $Y = AK^a L^b$, where Y is the output rate A, a and b are positive constants, A is a variable broadly representing 'technology', and K and L are capital and labour services respectively.

Data envelope analysis A linear programming technique that uses empirical evidence of the most efficient producers of outputs to locate an envelope that predicts the maximum outputs achievable with a variety of different inputs.

Leontief production function A Leontief production function has fixed input proportions, implying zero substitutability between the various inputs: There is no increase in one input rate that would compensate for a reduction in the rate of use of another (keeping output constant).

Marginal product The increase in output associated with a small increase in an input.

Production function A technical relationship between inputs and the maximum outputs or outcomes of any procedure or process. Also sometimes referred to as the 'technology matrix'. Thus it may relate to the maximum number of patients that can be treated in a hospital over a period of time to a variety of input flows like doctor- and nurse-hours, and beds.

q-Complementarity Two inputs in a production function are termed q-complements when an increase in the rate of one raises the marginal product of the other.

q-Substitutability Two inputs in a production function are termed q-substitutes when an increase in the rate of one lowers the marginal product of the other.

Stochastic frontier analysis An empirical method of estimating the maximum outputs obtainable from given resources and, hence, the degree to which actual operations fall short of the most efficient way of operating.

Translog production function Translog is an abbreviation of 'transcendental logarithmic', a form of production function having greater generality than the Cobb–Douglas form of the function.

Introduction: Distinction between Production Functions for Medical Care versus Production Functions for Health

Production function studies in health economics have taken three divergent approaches. Some of these studies focus on the production function for general and regress health (such as reduced mortality) against a variety of factors. Another strand examines the technological relationship between medical care and the inputs that are used to produce medical care. A third approach examines medical care production efficiency more specifically through stochastic frontier or data envelopment analysis techniques. This article describes all three approaches with a primary focus on production functions and on efficiency analysis.

The production of health approach involves a more general specification of the production process, including a variety of societal factors as inputs, such as consumption of medical care, technology, demographics, and personal health habits. Findings in this literature include a positive relationship between medical care and health; demographics (such as education and income) and health; and avoiding risky behaviors (such as smoking and other substance abuse) and health. One recent example of this approach is production function estimation for health in the Organization for Economic Co-operation and Development (OECD) countries, which postulates that life expectancy at the age of 65 years depends on health expenditures, medical technology, and lifestyle. Health expenditures significantly affect life expectancy at the age of 65 years in OECD countries.

In contrast, two other major strands of production function estimation have examined the technology and efficiency associated with production of medical care, which is the primary focus of this article. One approach examines the technological relationship between inputs (such as employment of different types of health care workers, physical capital, and possibly other inputs) and output or outputs, which can include client counts (admissions or discharges), relative value units, or others. More recently, interest has focused on the relationship between inputs and the quality of output, but this is an area deserving much greater attention. The outputs have centered around a variety of different health care services, ranging from hospitals, to physicians and specialty care treatment centers.

Hospital Production Functions

The literature on hospital production functions is quite extensive. In the general hospitals literature on production functions, researchers examine individual hospitals (or other medical entities such as practices) which maximize utility rather than minimize costs, where utility may be defined as a function of effort and leisure. Effort is defined as the number of discharges or admissions. The hospitals maximize their utility, given a budget, labor market conditions, and a

 doi:10.1016/B978-0-12-375678-7.01010-5

production function. The production function for each hospital describes the technological relationship between the capital and labor inputs, and the process by which capital and labor are translated into output.

A typical hospital production function can be estimated by least squares regression techniques, after adding an 'error' term.

It is noteworthy that 'output' can be represented by admissions, discharges, and/or relative value units; the stock of physical capital can be measured by beds, and/or value of equipment and structures; the supply of labor can include either full-time equivalents, number of total employment hours, or one of these measures for several separate labor categories such as physicians, nurses, etc. The labor variable may include one type of labor and focus on aggregate hours or full-time equivalents, whereas alternatively separate labor variables can be included for different types of hospital workers (i.e., physicians, nurses, clinicians, clerical workers, etc.). The latter can be advantageous in assessing the substitutability of different types of workers. Often a vector of client mix or client demographic variables that affect the position of the production function is included in the statistical estimation.

The derivative of output with respect to each input is denoted as the marginal product of the input; it describes how output changes when there is a small change in the amount of one input, while holding constant all other factors of production. Specifically, in the hospital context, the marginal product of physicians is the additional patients who can be treated when there is a slight increase in the number of physicians. This marginal product is required to be positive, and the value of output should be zero in the presence of zero inputs (i.e., if there is only one labor input, hospital full-time equivalents, then zero hospital full-time equivalents implies zero patients treated). If there are several labor inputs (i.e., physicians, nurses, clinicians, clerical workers, etc.), it is permissible that some (but not all) of these labor inputs equal zero. Also, the production function should increase at a decreasing rate – in other words, the marginal product decreases as more physicians (or nurses) are added.

Functional Forms

Before estimating the medical care production function with regression analysis, a functional form must be specified. There are several common functional form assumptions that have been used in the literature, including Cobb–Douglas, translog, and generalized Leontief. A Cobb–Douglas production function is perhaps the most straightforward because of its linear structure in logarithms. A convenient feature of the Cobb–Douglas is that the regression parameter estimates are also elasticities. In assessing the marginal product of labor, for instance, this would be the elasticity of output with respect to labor, times the output level divided by the employment level.

Although the Cobb–Douglas has some advantages due to computational simplicity, and it diminishes the potential for multicollinearity because of a lack of interaction terms, a disadvantage is that it does not allow the elasticities of substitution among different types of hospital workers (or among a particular type of hospital employee and number of beds, for instance) to be different from unity. In other words, a hospital production function can generate information on how the facilities are able to substitute capital for labor by examining the elasticity of substitution, but the Cobb–Douglas production function assumes this elasticity is constant and equal to one at all levels of input use. For most hospitals, this assumption is quite restrictive and unrealistic. So, some researchers have considered an alternative that is more flexible, known as the translog. The translog production function is a generalization of the Cobb–Douglas – in other words, it builds on the Cobb–Douglas by adding interaction terms (in logarithms) for all of the possible combinations of inputs.

One advantage of the translog, compared with the Cobb–Douglas production function, is that the translog allows for the possibility of elasticities of substitution between physicians and nurses to be different from unity, and these elasticities can vary across hospitals. This is a desirable feature of the translog because it provides valuable information that can be useful in policy recommendations. But a potential problem with the translog arises when there is a zero in one or more of the inputs for some hospitals. For instance, if the labor inputs in the model include physicians, nurses, clinicians, and clerical workers, and if some hospitals have no clinicians, then this will be problematic because the log of zero is undefined. As an alternative, researchers have considered a generalized Leontief production function. Typically, the generalized Leontief hospital production function models admissions and/or discharges as a function of total labor and capital inputs and other shift variables. Alternatively, several types of labor can be included along with one type of capital and several shift factors. The generalized Leontief allows for interaction of the square roots of each variable (i.e., every type of labor, capital, and other shift variables).

Interpretation of Production Function Estimates

Average and Marginal Products

There are a couple of possible scenarios that may be evident with the production function estimates. First, hiring additional workers may provide resources for clerical workers to perform more administrative tasks while allowing physicians and clinicians to specialize in treating patients, leading to higher average numbers of patients treated per employee. Alternatively, there may be a sufficiently large number of employees at clinics so that having additional workers might lead to office overcrowding, physicians and clerical workers getting in each others' way, and possibly more difficulty in getting reimbursements for treatment because of additional bureaucratic layers within these organizations. If the regression estimates of the production function support this second scenario, having fewer employees at clinics would be expected to result in higher average number of patients treated per employee. The marginal product of labor is the additional clients that can be treated when an additional worker is hired, while the average number of patients treated by workers is the average product of labor. If the marginal product of labor is greater (less) than the average product, then the average product of labor rises (falls) as more workers are hired.

Elasticities of Complementarity and Substitutability

Clinicians or physicians may work better when they have access to additional equipment, such as computers that may help with record keeping and billing. If so, the additional physical capital may allow the physicians to focus on the tasks they are trained to perform (that is, treating patients), while physical capital can be used for other tasks. This scenario is called q-substitutability; else, would physicians be able to treat greater numbers of patients if the hospitals were to hire additional support workers (such as nurses, clerical staff, or other employees)? This scenario is called q-complementarity. In other words, through the production function regressions one can address the question of whether workers and physical capital or two individual types of labor, are q-complements or q-substitutes.

The technological relationships between any two factor inputs can be assessed by examining the production function for q-complementarity. Here, capital and labor will be q-complements (q-substitutes) if an increase in capital increases (decreases) the marginal product of labor. More generally, the Hicks elasticity is defined as the product of output and the change in marginal product of labor resulting from a change in capital, all divided by the product of the marginal product of capital and the marginal product of labor. The Hicks elasticity measures the relative ease by which one factor can be substituted for another, while keeping admissions or discharges constant, so if the Hicks elasticity is positive (negative), this implies capital and labor are q-complements (q-substitutes). Nonphysician labor has been found to significantly impact physician productivity in the context of hospitals and a translog production function. Other translog production function analysis explains the relationships between physicians and other employees in health care settings. A common finding is that physicians and nonphysician employees are q-complements. In the context of hospital efficiency with a generalized Leontief production function, capital and physicians have been found to be q-complements; capital and technicians/aides have been found to be q-complements as well.

Stochastic Frontier Estimation and Data Envelopment Analysis

The third type of health production function studies focus on efficiency analysis. These studies, which also estimate production functions for medical care, are based on stochastic frontier models, and data envelopment analysis.

Stochastic frontier models (sometimes referred to as 'frontier models') are based on the assumption that the regression error term distribution does not follow a normal distribution. Because the production function models described in the section Hospital Production Functions are actually ideal production function models when there is no inefficiency, whenever the error term is nonzero there is inefficiency. In other words, technological inefficiency for any given hospital occurs when the error term is nonzero. Also, frontier models are assumed to have a typical production function functional form (such as Cobb–Douglas, translog, or generalized Leontief), as well as two error terms. One of these error terms is because of 'technical efficiency' and is assumed to be negative (because of the inability of a hospital to reach the frontier), and another error component is because of unobservables and other measurement difficulties. For any individual hospital, the frontier model can be written as a term that includes the production function as well as the inefficiency error term, and a separate error component from unobservables. Each hospital's deviation from the mean efficiency can be calculated, to assess how inefficiently individual hospitals are operating. The model can be estimated by assuming the errors follow half of a standard normal distribution, and then using maximum likelihood estimation techniques.

Multiproduct Adjustments

When there are multiple outputs, such as different services provided in each hospital, a distance function stochastic frontier approach is appropriate. A stochastic frontier distance function to assess efficiency in Australian hospitals with several outputs has found a range of efficiency scores between 0.7 and 0.75, whereas there were a handful of outliers with efficiency scores that were close to 1. A distance function approach is crucial in the context of hospitals because most hospitals produce many different outputs, including inpatient and outpatient services. But a more disaggregated approach to address the efficiency of an array of many different hospital services necessitates a distance function approach. This can be done by specifying a 'netput' (or net input) transformation function, where a function of vectors of inputs and outputs are set equal to zero.

An alternative that can address the multiple outputs issue is a hospital cost function approach. Duality implies that profit maximization, through input choice for the production function, yields the 'same' result as cost minimization, where inputs are chosen to minimize costs. The optimal cost function depends on input prices and outputs, which can include several outputs. In this respect, a cost function approach to efficiency can be estimated using least squares regression techniques, to test for the presence of economies of scale; or, a cost function approach to represent technology can also be implemented as part of a stochastic frontier estimation.

Data envelopment analysis is a nonparametric approach to measure hospital efficiency, after considering several outputs and inputs. It uses the approach of linear programming, to estimate a model. Here, an 'expansion factor' for each hospital must be chosen so that the 'expanded' output of each type at any hospital must be no greater than the weighted average of all other firms' output of that same type. At the same time, this hospital must use each input in such a manner that it is no less than the weighted average of all other firms' input usage of that same input type. In this approach, which essentially estimates a production possibilities frontier, hospitals' inefficiencies lead to deviations from the frontier. Some of the advantages of this approach are that no functional form needs to be imposed, and also it is possible that in some situations firms can produce outside the production possibilities frontier. In other words, if efficiency is defined as the inverse of the optimal value of this linear

programming model, then the hospital is efficient relative to the other hospitals in the sample if the inverse of the optimal value equals 1. If the inverse of the optimal value is less than 1 for a given hospital, then that hospital is inefficient relative to the other hospitals in the sample. This measure of efficiency can be obtained by solving this optimization problem for each hospital in the sample.

Specific Applications: Specialty Care

Although there are few known applications of production function estimation for substance abuse treatment, there are more mental health applications. One application evaluates how changes to mental health workforce levels, composition, and degree of labor substitutability, affect practice output (measured as relative value unit's) at US Department of Veterans Affairs mental health practices. This estimates the q-complementarity/q-substitutability of mental health workers, using a generalized Leontief production function, examining many labor types, including residents, and then estimates the marginal product for each labor type as well as the substitutability and complementarity of physicians and other mental health workers. Among 28 unique labor–capital pairs, 17 are q-complements and 11 are q-substitutes. Complementarity among several labor types provides evidence of a team approach to mental health service provision at these providers.

Another application studies the efficiency of nursing homes in the state of Connecticut, USA, using a data envelopment analysis approach and finds that among the 140 nursing homes in the state, nearly 100 are more efficient than the mean. The mean efficiency score for Connecticut nursing homes is approximately 0.90, whereas similar studies of nursing homes in other locations have found a range of efficiency scores approximately from 0.57 to 0.93.

A general practice dentistry application estimates a translog production function for a sample of approximately 29 000 dentists in the US, and finds that dentists tend to use dental assistance in practices where they are 'profitable' in terms of their marginal products. Also, dentists in the age range of the mid-40s tend to be the most productive among all age ranges in the sample.

Conclusion

Since the 1970s, production functions in efficiency and productivity studies have been pervasive in a wide variety of applications. Future research should focus on how to assess quality of care in addition to quantity. This would be helpful to practitioners who might rely on marginal product estimates in compensation decisions and to governments in pay-for-performance calculations.

Public Choice Analysis of Public Health Priority Setting ☆

K Hauck, Centre for Health Policy, Imperial College Business School, London, UK
PC Smith, Imperial College, London, UK

Glossary

Bureaucrat A bureaucrat is a nonelected government official, usually a member of an administrative policy-making group within an institution of the government. Street-level bureaucracy is the subset of members of a public agency or government institution who carry out and enforce the actions required by laws and public policies. It is accompanied by the idea that these individuals vary the extents to which they enforce the rules and laws assigned to them.

Cost-effectiveness analysis (CEA) An economic evaluation in which the costs and consequences of alternative interventions are expressed as cost per unit of health outcome. CEA is used to determine technical efficiency; i.e., comparison of costs and consequences of competing interventions for a given patient group within a given budget.

Decision-making The process of making a selective intellectual judgment when presented with several complex alternatives consisting of several variables, which defines a course of action or an idea.

Externalities An externality is a cost or benefit that results from an activity or transaction and that affects an otherwise uninvolved individual(s) who did not choose to incur that cost or benefit. For example, if majority of a community is vaccinated against an infectious disease, the resulting herd immunity benefits those who have not been vaccinated.

Interest group A voluntary association that seeks to publicly promote and create advantages for its cause.

Median voter The voter (or pair of voters) in the exact middle of a ranking of voters along some issue dimension, e.g. from the most left-wing to the most right-wing.

Priority setting The planning for equitable allocation, apportionment, or distribution of available health resources.

Public choice It is concerned with the study of political behavior. In political science, it is the subset of positive political theory that models voters, politicians, and bureaucrats as mainly self-interested. In particular, it studies such agents and their interactions in the social system either as such or under alternative constitutional rules.

Public good A good or service is both nonexcludable and nonrivalrous in which individuals cannot be effectively excluded from use and when used by an individual does not reduce the availability to others. Examples of public goods include fresh air, knowledge or national defense.

Public health The activities that society undertakes to assure conditions in which people can be healthy. These include organized community efforts to identify, prevent and counter threats to the health of the public.

Resource allocation The societal or individual decisions about the equitable distribution of available resources.

Many public health interventions are extremely good value for money. Advice from doctors to give up smoking, vaccinations against communicable diseases, or improved access to clean water in low-income countries are often relatively low cost interventions that produce substantial health gains. Where evidence on cost-effectiveness is available, many preventive and public health interventions fare very well when compared with conventional healthcare interventions. So why are not more public funds invested in public health? And why in some situations has it been so difficult to implement common-sense public health interventions such as sewage treatment, vaccinations, or taxes on cigarettes?

The entries 'Economics of public health: overview,' 'Infectious disease externalities,' 'Health behavior externalities' and 'Public health priority setting' discuss the welfare economic theories of public goods and externalities that are relevant to most public health interventions and that support the case on theoretical grounds for their public provision. But these theories also describe the unique characteristics of public health interventions that inevitably put them at a disadvantage when compared with other investments, in particular investments in health care. Although health care is directly consumed by the individual patient and can offer large, immediate, and certain health benefits, public health actions to mitigate externalities typically offer only small, delayed, and uncertain benefits to particular individuals – even though this may add up to large and certain benefits at the population level. In summary, as Glied (2008) put it: "Public health, economic theory says, is most useful and beneficial when nobody can observe cash savings because of the actions of public health; when public health activities don't even try to reduce taxes; when the potential benefits of public health actions are unclear; and when the potential beneficiaries of public health activities aren't even born yet!" These are the sort of reasons why robust evidence of causal effects from controlled trials and natural experiments is often not available, and so it is difficult to demonstrate convincingly the societal value of public health interventions using conventional economic evaluation tools.

The entry 'Economic evaluation of public health interventions: methodological challenges' discusses problems affecting the assessment of the cost-effectiveness analysis (CEA)

☆Some material in this article has been published in Goddard, M., Hauck, K. and Smith, P. (2006). Priority setting in health – A political economy perspective. *Health Economics, Policy and Law* **1**, 79–90.

 doi:10.1016/B978-0-12-375678-7.00411-9

of public health interventions, and how they could be overcome. But can the authors necessarily conclude that it is poor evidence on the value of public health interventions that made policy makers shy away from making these investments? Did the scientific community fail to produce the kind of evidence that would convince policy makers to do the right thing? Or are there more fundamental structural impediments to securing acceptance of the value of such investments?

The authors argue in this article that it is the realities of the political decision-making process that militate against political backing for public health investments, rather than the methodological shortcomings of CEA. Although economic evaluation offers a powerful rational approach to setting priorities, there may be alternative perspectives from which it is rational for decision makers to disregard the recommendations. The authors use three economic models of public choice – the interest group, majority voting, and bureaucratic decision-making models – to explain why it may be rational even for benevolent social welfare maximizing decision makers to diverge from the traditional economic evaluation approach and take into account public choice theory in order to assess the various political constraints on the decision options available to them, and the likely unintended consequences of alternative policies due to the predicted behavioral responses of key stakeholder groups, and possibly even responses of their social decision-making colleagues in other branches of government who unlike themselves may not behave like benevolent social welfare maximizer. The models help us move from the normative approach to priority setting, based on what should be done to maximize some concept of social welfare, into the realm of positive approaches that attempt to understand what happens in practice.

Models of public choice assume that the same behavioral model that can be used to explain decision making in ordinary markets can also be applied to decision making in the public sector. Public policy makers are not necessarily benevolent maximizers of social welfare, but may be motivated by their own self-interest. Firms seek to maximize profits, consumers seek to maximize utility, and policy makers seek to maximize political support or their own personal gain. The models further assume that, although policy errors are certainly possible, it is more informative to assume that the intended effects of a policy can be deduced from the observed effects, especially when such policies persist over time. In doing so, the authors do not of course argue that such behavior is desirable, or that it happens in all circumstances. Of course individuals have various motivations and the authors acknowledge that many decision makers will act with predominantly altruistic and welfare maximizing considerations in mind. The aim is merely to offer a framework for explaining apparently perverse actions on the part of decision makers.

Interest Groups

The interest group model is a powerful way of explaining why policy making diverges from the recommendations of cost-effectiveness analysis. It demonstrates that some groups of the population are more successful in promoting their interests than other groups and seeks to explain the impact this has on priority setting, resource allocation, redistribution of wealth, and even the survival of governments. The 'capture' theory describes interest groups as 'capturing' the regulatory power of the state to achieve a redistribution of wealth between different groups of the population in the form of transfers that may be cash or favors (Stigler, 1971). Generally, small groups with a clearly defined common objective – for example, the pharmaceutical industry – have lower costs in organizing themselves, securing cohesion, and effectively lobbying decision makers to their advantage, at the expense of the larger population whose interests may be more diffuse and experience higher costs of organizing. Some interest groups have privileged access to information that gives them a comparative advantage. The authors shall discuss examples where powerful minority groups with the interest, means, and opportunity to organize themselves have influenced political decisions to their advantage.

In low-income countries (LICs), the interest group model can explain why expenditures have often focused on healthcare services for richer areas or social groups at the expense of preventive and public health services for the poor, even where the latter offers greater cost-effectiveness. Poorer groups and populations based in rural areas may be less informed, less literate, and have an underdeveloped infrastructure for the dissemination of information compared to wealthier groups or those based in the urban areas where access to information resources is less limited. Groups in formal employment and with greater wealth also tend to be concentrated in urban areas, in particular in low-income Asian countries, see **Figure 1**.

Taxpayers represent an important interest group, especially in LICs with high levels of informal employment and a tax base that is highly dependent on a small minority of wealthy citizens. These citizens tend not to suffer to nearly the same extent from the communicable diseases and chronic conditions suffered by poorer citizens. In a democratic system, as the proportion of poor in the overall electorate is relatively large, most tax-financed healthcare expenditure would be devoted to illnesses of the poor in order to secure support of the majority of voters. However, such a policy choice would imply very large financial transfers, through the tax regime, from the rich to the poor. In short, the rich may have to make big tax contributions to public interventions that do not benefit them greatly. This may lead to resistance among the rich, tax evasion, increased collection costs, or even emigration.

An extreme form of tax evasion is illicit export of capital, especially prevalent when systems of governance are weak. It is estimated that the world's poorest countries lose USD$900 bn each year through illicit flows of capital. **Figure 2** shows the top 20 developing country exporters of illicit capital in declining order of average annual outflows, with China being the top exporter by far. Despite these high levels of tax evasion in some developing countries, however, economic theory of tax compliance predicts that global tax evasion should be much greater than it actually is, given the low extent of deterrence in most countries – conceptualized as the product of the probability of being detected and the size of the fine imposed. Empirical studies allude to an effect known as 'fiscal exchange': the more governments provide public services according to the preferences of taxpayers in exchange for a

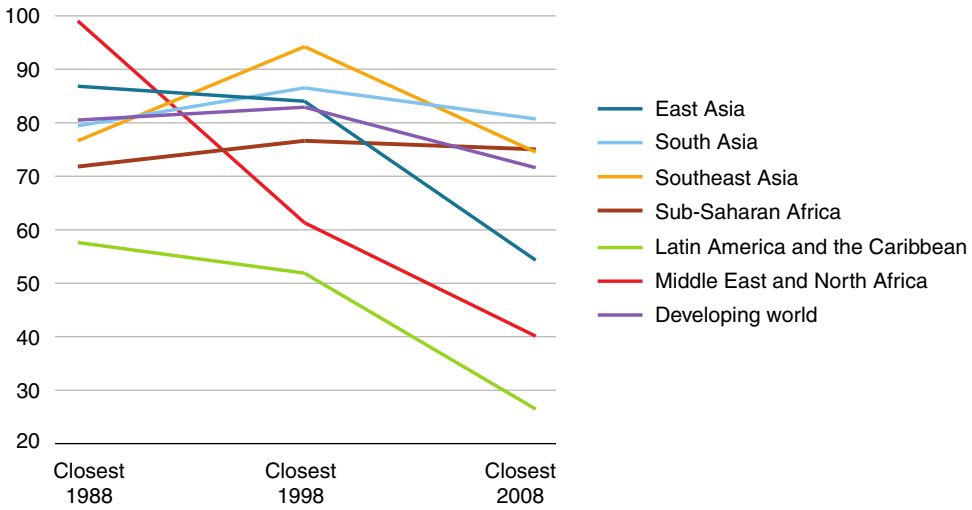

Figure 1 Rural share of total poverty (rural people as a percentage of those living on less than USD$1.25 per day). Reproduced from Figure 2 in International Fund for Agricultural Development (IFAD) (2011) *Rural Poverty Report 2011*, p. 47. Available at: http://www.ifad.org (accessed 11.06.13).

reasonable tax price, the more taxpayers comply with the tax laws. In the mid-nineteenth century Switzerland, a voluntary school tax in the canton of Glarus provided sufficient revenue to finance education services, whereas a voluntary welfare tax to redistribute income in the canton of Appenzell i. Rh. had to be quickly turned into coercive taxation. This concept of 'fiscal exchange' has important implications for healthcare priority setting. To limit tax resistance of this kind among the rich, the government may feel constrained to include some provision for the healthcare needs of the rich in the essential package of care in order to retain the viability of the tax base, even when the associated treatments do not qualify for inclusion on strict cost-effectiveness criteria.

Even in well-functioning democracies, powerful interest groups affect resource allocation decisions. Patient associations have successfully lobbied governments to fund drugs publicly, even if there is doubt about their cost-effectiveness, or even clinical efficacy and safety, for example, the breast cancer drug Herceptin in the English National Health Survey (NHS). Patients with long-term chronic illnesses such as

HIV/AIDS have a clear advantage in organizing themselves over the recipients of public health interventions. As public choice theory predicts, illnesses with comparably low prevalence are at an advantage, at least partly due to the fact that costs of organizing are lower. The preventive nature of many public health interventions implies that there is no clearly defined patient group that is lobbying in their favor, and public health has to rely on individuals or groups with altruistic motivation for support. Further, governments often prioritize sensitive political issues concerning highly visible aspects of healthcare services, at the expense of investments in public health. For example, some countries place a high priority on tackling waiting times for elective surgery, which affect a relatively small group of patients. This preoccupation could be interpreted as a response by politicians to the more media-friendly interests of waiting patients when compared with interventions aimed at the whole population, or large and difficult to delineate subgroups of individuals at risk, such as preventive screening or healthy lifestyle campaigns.

Providers of health services – the healthcare professions – form a crucial interest group in many countries, and governments are often wary of alienating doctors who are in a strong position to mobilize opposition to chosen priorities. For example, in the USA, health professionals and their associations are major lobbyists. In 2012, they have together spent more than USD$40 M to influence directly or indirectly decisions made by Congress and federal agencies, an amount that is nearly 6 times more than the tobacco industry. Although providers would certainly not want to be seen to actively work against the interest of patients, it is unlikely that investments in public health feature prominently among their priorities, especially if such investments are made at the expense of traditional healthcare interventions or even reduce demand for their services.

Doctors may have credible threats that can undermine the implementation of policy shifts, ranging from overt threats such as quitting the workforce to subtle noncooperation and adherence to traditional patterns of care. For example, it has been argued that the retreat from traditional models of managed care in the USA has in large part been due to pressure from physician and consumer groups in a backlash against government and insurers' attempts to cut costs through limiting access and rationing care. In some LICs, doctors may have a preference for high-technology medicine and be alienated by policy changes that seek to develop public health interventions and cost-effective care in community settings. Such alienation may have profoundly important consequences, for example, in the form of shifting employment from the public to the private sector or workforce emigration. Although migration is of course due to a multitude of reasons, it is noteworthy that in some LICs more than 50% of highly trained health workers leave for job opportunities in higher income countries.

The pharmaceutical industry is another powerful interest group that may favor healthcare interventions and drug treatment over public health investments. For example, The Council of the Europe Assembly quite openly voiced the suspicion that the pharmaceutical industry has influenced the World Health Organization's response to the H1N1 flu pandemic. The Council accused WHO of exaggerating the seriousness of the epidemic, which resulted in large amounts of public funds being spent on vaccines and antivirals that were never needed. But the interests of the pharmaceutical industry are not always in conflict with public health or preventive policies. Modern antiretroviral treatment (ART) may prevent secondary HIV infections because HIV patients receiving ART may have a significantly reduced risk of passing on the virus to sexual partner (treatment as prevention), and ART given to healthy persons may reduce their risk of acquiring the virus (preexposure prophylaxis). Using ARTs as prevention would open up a vast new market for pharmaceutical companies, potentially comprising all HIV negative individuals at risk of infections.

Other commercial companies that are driven by economic interests have formed powerful interest groups. **Table 1** summarizes the – strikingly similar – strategies adopted by the tobacco and food-producing industries, and historically water companies, to influence public health decision making to their advantage. Many of the strategies the tobacco industry adopted to frustrate public health actions came to light only when an extensive library of internal tobacco industry documents was released publicly as a result of the 1998 settlement agreement. For decades before, the tobacco industry successfully preempted efforts to limit advertising and sale of cigarettes, by publicly disputing evidence that smoking cigarettes damages health, for example, with the infamous 'A Frank Statement to Cigarette Smokers', half-hearted self-regulation such as the Cigarette Advertiser Code, and public messages and advertising that emphasized individual responsibility to deflect blame from the industry.

Table 1 Popular strategies by interest groups to influence political decisions to their advantage

- Emphasizing consumer's personal responsibility and condemning governmental interventions as autocratic
- Distorting scientific evidence with selective reviews or in the extreme, distribution of false evidence
- Adopting financial tactics including setting up, sponsoring, or otherwise developing associations with foundations or organizations that support the corporations agenda
- Exerting political influence and lobbying to support politicians favorable to the industry
- Adopting legal and regulatory tactics, for example, engaging in half-hearted self-regulation efforts or getting industry lobbyists appointed to governmental regulatory agencies
- Adopting legal and regulatory tactics, for example, engaging in half-hearted self-regulation efforts or getting industry lobbyists appointed to governmental regulatory agencies
- Advertising that connects the image of the corporation with worthwhile or popular causes

"We are proud of the industry's record with respect to cigarette advertising generally and youth in particular. We submit that the record is one of unparalleled restraint and responsibility" – Horace Kornegay, Chairman, the Tobacco Institute. From the US Subcommittee on Health and the Environment's Report to the Committee on Energy and Commerce 'Advertising of tobacco products', House of Representatives, Serial No. 99–167, 18 Jul, 1 Aug 1986.

"Evidence is now available that the 14 to 18 year old group is an increasing segment of the smoking population. RJR must soon establish a successful new brand in this market if our position in the industry is to be maintained over the long term." – RJR's Secret planning assumptions and forecasts for the period 1976–1986 from the RJ Reynolds Tobacco Company Research Department, 18 Mar 1976.

Figure 3 Public statements and internal communications by the tobacco industry. Reproduced from http://legacy.library.ucsf.edu/legal.jsp

Public statements stood in stark contrast to internal communications (**Figure 3**).

Some public health experts now fear that history will repeat itself by comparing the tobacco industries' strategies with current efforts by the food-producing industry to deny the contribution of their products, in particular soft drinks and highly processed snack food, to the obesity epidemic (Brownell and Warner, 2009). They accuse the food industry of following distraction strategies, for example, playing up the importance of physical activity over nutrition, publishing biased reviews of scientific studies, or playing up a relatively harmless health impact (such as tooth decay) to divert attention from the serious one (such as obesity).

The food industry has made highly visible pledges to curtail children's food marketing, sell fewer unhealthy products in schools, and label foods in responsible ways, but has been criticized for their efforts (Sharma et al., 2010). For example, the School Beverage Guidelines developed by various charitable foundations in a partnership with the soft drink industry have been found to be implemented with far less restrictions in high schools, where much of the sugared-beverage intake occurs, than in elementary schools where little intake occurs (for more information visit the Clinton Foundation, http://www.clintonfoundation.org/main/our-work/by-initiative/alliance-for-a-healthier-generation/programs/industry-initiatives/school-beverage-agreement.html).

It is telling that while contributions to federal candidates and political committees from the tobacco industry fell drastically from USD$10.6 M in 1996 when legal battles were at their peak to USD$3.2 M in 2010; over the same period, contributions from the food processing and food retail industry have tripled from USD$10 M to just under USD$30.5 M in 2010. This is possibly attributable to increased congressional action on issues that affect the industry such as food safety, labeling regulations, soft drink taxes, and other anti-obesity initiatives.

There are, of course, differences between food and tobacco as substances. Unlike smoking, eating is necessary to maintain health and life. The associated public health messages are therefore more subtle, seeking to change the types and amounts of food eaten rather than promote abstinence. There is overwhelming evidence that smoking is addictive and damaging to health, whereas research on the addictive properties of food and its impact on human health is only now maturing. Smoking imposes harmful externalities on others through passive smoking, whereas in principle eating an unhealthy diet only harms the eater. The fight against tobacco coalesced around a single product made by a few companies, whereas the food industry is far more complex because it is fragmented, involving an immense array of products made by thousands of companies worldwide.

There are also historic examples of how commercial interests have shaped priority setting in public health. In fact, the public health movement that developed during the industrial revolution in the nineteenth century did so, at least partly, as a reaction to the commercial interests of private water companies. The water companies used their influence to dispute emerging evidence that the poor water quality they provided was responsible for the cholera epidemics and other illnesses that led to the appalling drop in life expectancy in English cities during the industrial revolution, using similar tactics to the tobacco industry 150 years later (Szreter, 2003). The development of germ theory and arrival of microscopic water analysis gave the public health movement the scientific backing to lobby for the construction of publicly funded and maintained sanitary infrastructure (see **Figure 4**).

Employers form an interest group that has traditionally supported public health interventions if they improve and preserve the productivity of their workforce. Historically, investments in public health in low-income countries were driven by the economic interests of colonial countries, and the need to guarantee the health of the workforce seconded to work there. For example, in Britain, in the 1890s, the Colonial Secretary Chamberlain was aware that the poor health of the native workers and the officials sent to serve in the Colonies was a threat to Britain's growing empire. Mortality among officials in some parts of the world, particularly the Gold Coast of West Africa, was soaring and to compensate, salaries were sometimes 100% higher than those of colleagues elsewhere. The economic significance of the control of tropical disease led to establishment of institutions and schools of tropical medicine, such as the London School of Hygiene and Tropical Medicine (UK) and the Pasteur Institute (France). Nowadays, some mining companies are providing free Anti retroviral therapy to their HIV positive employees, for example, Anglo-American. As HIV/AIDS predominantly affects working age adults, companies are possibly motivated by a combination of humanitarian interests and the commercial interest to preserve the human capital established in their workforce.

Even organizations seeking purely 'technocratic' solutions to priority setting by providing scientific evidence on the cost-effectiveness of interventions (e.g., health technology assessment agencies) may be influenced by interest groups in the selection of interventions chosen for assessment. Seeking public involvement in such activities risks capture by interest groups but can be seen as an attempt to increase political

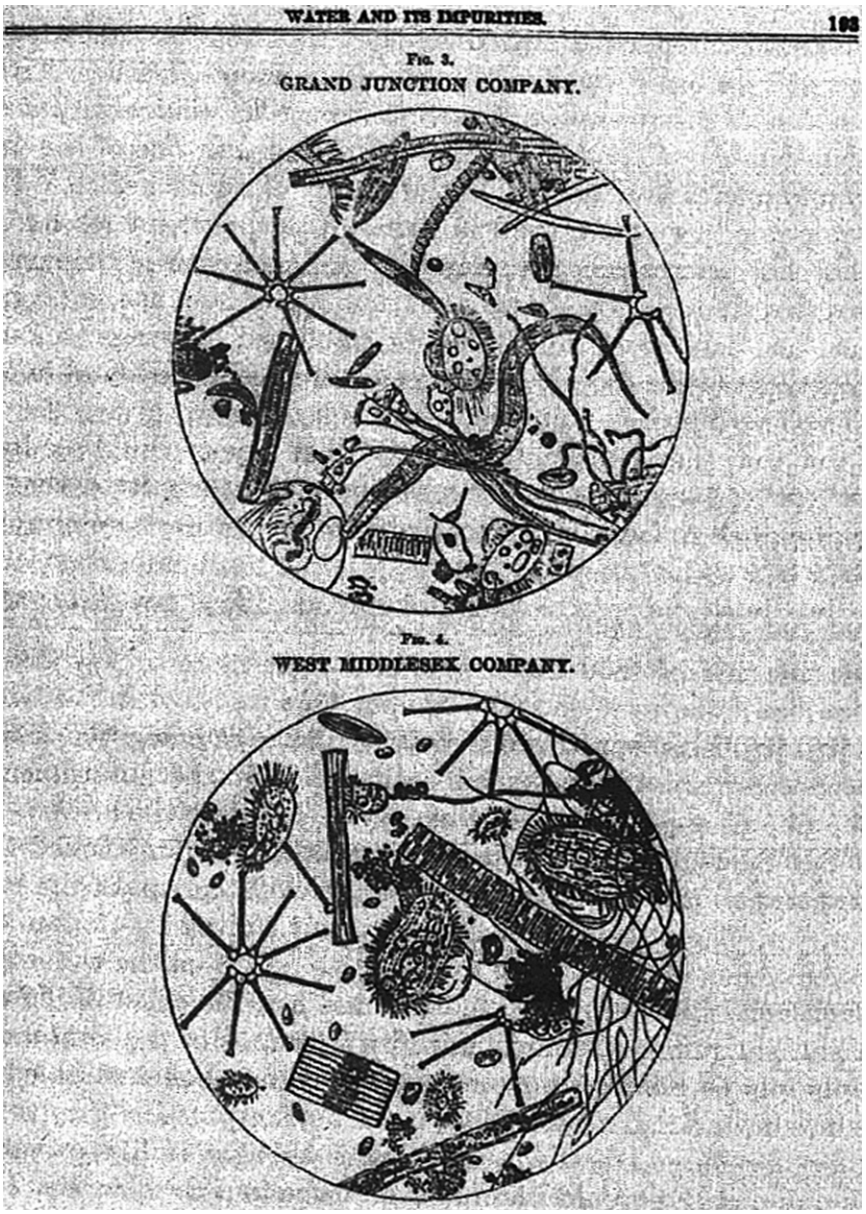

Figure 4 Water impurity in London's commercial supplies, illustrations from *The Lancet*, 1851. Caption below Figure 3: This engraving represents the chief animal and vegetable productions contained the water as supplied by the Grand Junction Company. Caption below Figure 4: The above engraving exhibits the principal animal and vegetable productions contained in the water supplied by the West Middlesex company. Drawn with the camera lucida and magnified 220 diameters. The microscope enabled water analysts to make precise drawings such as these depicting the organic contents of the drinking water supplied by London's increasingly notorious private companies. Some of these companies' defective systems were clearly implicated by pioneering epidemiological research into the major cholera epidemics of the period. Reproduced from Szreter, S. (2003). The population health approach in historical perspective. *American Journal of Public Health* **93**(3), 421–431.

support for decisions. The National Institute for Clinical Excellence in England and Wales has formalized public involvement in technology appraisal and developing interventional procedure guidance, but not without criticism.

Voting Models

Many public health interventions are targeted at conditions that predominately affect disadvantaged groups of the population. Indeed, some even have the primary objective of reducing inequalities in health. This in itself may imply a need to depart from pure cost-effectiveness criteria, which imply an objective of maximizing aggregate health outcomes. The median voter model may explain why such public health interventions often receive less political backing than others that benefit a wider spectrum of the population, or why investments into healthcare are favored over investments in public health. The model focuses on the politician as a maximizer of votes (Hotelling, 1929; Anderson, 1999). The 'median voter' theorem shows

that in a representative democracy, political parties tend to move toward the political position of the median voter in order to secure election.

The median voter model highlights the importance to the government of obtaining the support of crucial electoral constituencies. In public health, this may explain why policy makers seek to direct resources toward key population groups at the expense of others, notwithstanding the apparently reasonable claims of the latter on resources from an efficiency or equity perspective. For example, median voters are likely to perceive that they or their family benefit from screening services for common conditions such as cancers. Therefore, the provision of such services is likely to receive widespread support, even if evidence of cost-effectiveness is weak, or indeed they might do more harm than good, as has been suggested for routine mammography. However, policies directed at poor lifestyle choices (e.g., smoking, alcoholism, and risky sexual behavior) may receive less popular support because the median voter does not perceive any personal or family need for such services. Even if the latter services are very cost effective, politicians seeking reelection may find it difficult to attach high priority to them. Similarly, many common healthcare interventions, such as treatment for acute myocardial infarction, hip and knee replacements, or cataract removals, are likely to be demanded by the median voter at a certain point in life. Following that line of argument, the median voter model cannot explain the success of HIV/AIDS interest groups in lobbying the governments, and it is interesting to note that for HIV/AIDS it stands in disagreement with the interest group model.

More generally, economic models of voting in health services have received little attention in the literature (Tuohy and Glied, 2011). In industrial democracies, an ageing population suggests that older people are becoming an increasingly important electoral force. Although an ageing population is itself partly the result of effective public health interventions, perversely, the preoccupation of older people is likely to be with curative rather than preventative interventions, compared with young people, reinforcing the tendency for politicians to favor health services over public health.

Bureaucratic Decision Making

The behavior of interest groups and voters can be understood only in terms of the institutional context in which they occur (Tuohy and Glied, 2011). Tullock's (1965) and Niskanen's (1971) institutional theories focus on the interests of 'bureaucrats' in maximizing their influence and the effect of their behavior on the level and nature of government output. Here the concept of the bureaucrat is interpreted broadly to embrace all public sector actors with significant influence over the allocation of resources. The essence of this approach is the belief that such bureaucrats receive power and remuneration in proportion to the size of their enterprise, with the implication that bloated, and inefficient public services emerge if there is a lack of effective control on the growth of government. Under the bureaucratic model, government agencies will seek to implement policies that maximize the size of their own enterprises and to undermine activities that are outside their direct control. They are able to do so because they have an informational advantage over their political counterparts. 'Bureaucrats' may therefore influence the pattern of healthcare expenditures in ways that do not accord with efficiency and equity considerations. If this model applies, it would also suggest substantial inertia in spending, making it difficult for politicians to change entrenched patterns of services.

It is difficult to find hard evidence, but the tendency of bureaucrats to maximize their own budgets and sphere of influence at the expense of others can be observed across many government sectors. For example, bureaucrats in health ministries often find it difficult to persuade bureaucrats in other ministries, such as education, to adopt policies designed to improve health, because of the reluctance of each sector to relinquish control. Public health, perhaps more than other government activities, requires collaboration across sectors and cross-departmental actions for which responsibilities cannot be clearly delineated.

Multiple levels of governance add further complexities that affect variations in spending on public health, although the direction and magnitude of effects is likely to depend on specific funding arrangements for such policies (Tuohy and Glied, 2011). A system under which subnational governments make policy decisions, but a significant share of the associated costs is covered by the national government is likely to lead to higher investments in public health than a system under which national governments provide a fixed payment to subnational governments, which then bear the full marginal costs of the interventions. In a decentralized system of governance different levels of government are likely to free ride on interventions with public goods characteristics that are provided by other levels. More than 160 years ago implementation of basic sanitation measures was frustrated by tensions between central government and councilors of Britain's large cities (**Figure 5**).

In the public sector services, it has also been argued that 'street-level bureaucracy' plays a powerful role in the way in which policy is implemented. The considerable degree of discretion accorded to healthcare workers ('street-level bureaucrats') in determining the nature, amount, and quality of services provided by their agencies has a powerful impact on the rationing of resources, and the factors governing their decisions might not be based on cost-effectiveness or similar principles.

Conclusion

The authors have considered three economic perspectives on public choice that help to explain why it has often proven difficult to obtain political backing for apparently commonsense public health interventions. The health and societal implications of many public health interventions can never be assessed in their entirety in advance of implementation. Even if they could, however, public health advocates have often found themselves in conflict with powerful interests groups, and politicians or bureaucrats who pursue their own objectives. This introduces an important and complex set of constraints into the priority-setting process, implying that available funds might be spent in particular areas or on

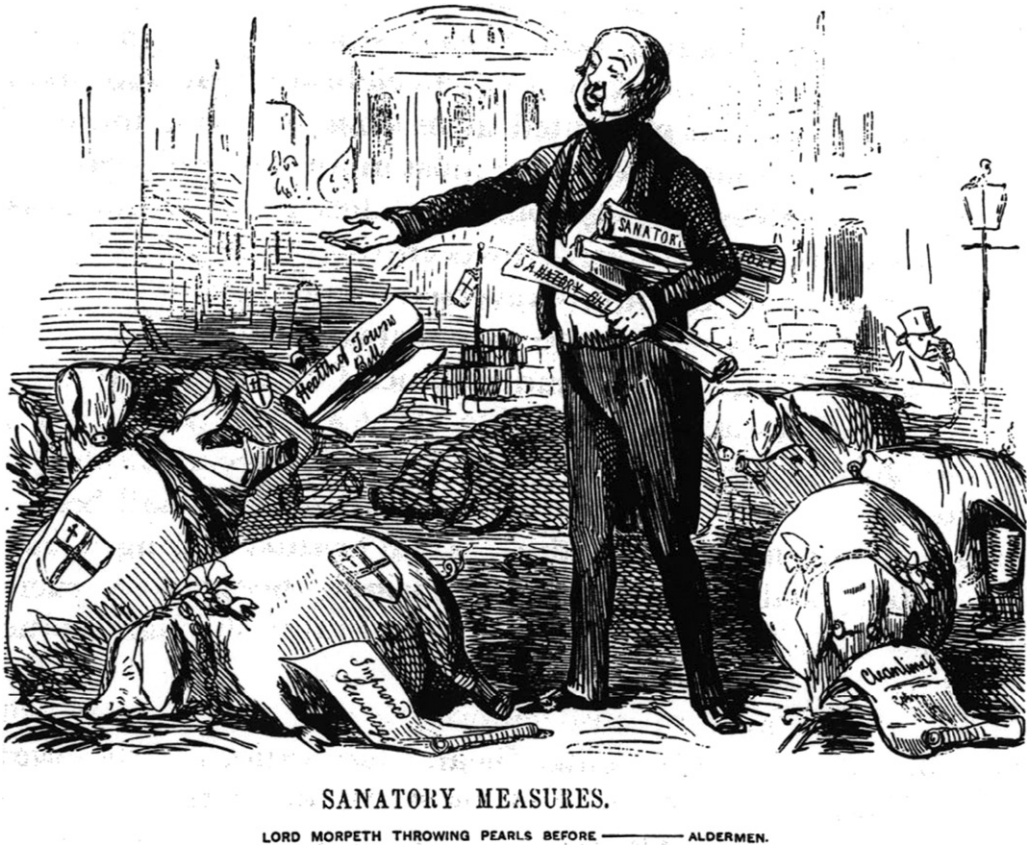

Figure 5 Cartoon about implementation of Chadwick's Public Health Act in British cities, Punch, June 1848. A cartoon of Lord Morpeth, the central government's representative, promoting the bill for Chadwick's Public Health Act. The legislation is depicted as 'sanatory' pearls being thrown in vain by the enlightened national statesman to the unappreciative 'swine,' the councilors of the nation's cities. specific programs determined by informational advantages or power structures within society. In general, such constraints will result in departures from conventional criteria such as cost-effectiveness rules.

Is it possible to counter those powerful influences? History has plenty of success stories. From the second half of the nineteenth century, Britain's major cities embarked on a reform of the municipal social health amenities and social services that resulted in significant improvements in health. Historians believe that a class-bridging coalition between grass root organizations of the growing urban population, a new generation of civic leaders with social conscience that originated from the well-off urban elite, and a strong cadre of public service professionals, notably Medical Officers of Health, secured these reforms. Similar developments happened in other European countries and the USA.

There are modern day examples of spirited initiatives by governments, government departments, or community organizations that instigated radical improvements in public health. For example, the outbreak of the plague in the Indian city of Surat in 1994 led to a decisive reorganization and introduction of stringent performance management of the civic waste department, named 'transformation from AC to DC' – making bureaucrats leave their 'air conditioned' offices to the 'daily chore' of direct supervision of waste management on site. The participatory budgeting model introduced in 1989 in the Brazilian city of Porto Alegre was an innovative reform program that successfully overcame severe inequality in living standards among city residents. Part of the program was introduction of participatory budgeting; community members now decide how to allocate part of the public budget. The recent decisive ruling of the Australian government on plain packaging laws for cigarettes is celebrated as a great success in the fight against cigarette smoking. For decades, the tobacco industry has successfully prevented such laws, to protect the value of their brands' image, which they used more or less openly to link the brand with popular causes or films – such as the placement of Phillip Morris brands in Superman I and II, see Figure 6.

The authors have merely scratched the surface of this underresearched area of study. There is great scope for a much better understanding of decision-making behavior – both in low- and high-income countries – and a range of hypotheses can be tested by examining the priority-setting process itself and the resulting patterns of healthcare and public health expenditure. They would not challenge the desirability of seeking to maximize the health gains of the health system through the use of CEA. However, health economists have not yet taken advantage of the full range of economic approaches at their disposal. Only by securing a better understanding of

Figure 6 Product placement of cigarette brand by Phillip Morris in the youth films Superman I & II. Reproduced from http://www.fitmedia.org/whatsanembeddedad.html

the decision-making process can the impact of CEA be enhanced. They would argue that this can be achieved by augmenting the understanding of the political context of priority setting, using a variety of well-established models of political economy.

Public Health in Resource Poor Settings

A Mills, London School of Hygiene and Tropical Medicine, London, UK

Glossary

Allocative and technical efficiency A resource allocation is efficient if it is not possible to reallocate resources so as to increase one person's utility (or health, or output) without decreasing another person's utility (or health, or output). In health economics the entity maximized is generally assumed to be utility, health, or welfare. Technical efficiency is a part of cost-effectiveness: not using more resources than are necessary to produce a given set of outcomes. There may be many allocations of resources that meet this condition. The least costly of them is the cost-effective allocation.

Cost-effectiveness analysis A method of comparing the opportunity costs of various alternative health or social care interventions having the same benefit or in terms of a common unit of output, outcome, or other measure of accomplishment.

Disability-adjusted life years (DALYs) A measure of the burden of disability-causing disease and injury. Age–specific expected life-years are adjusted for expected loss of healthy life during those years, yielding measures of states of health or, when two streams of DALYs are compared, potential health gain or loss by changing from one health care or social intervention to another.

Global burden of disease The DALYs lost through illness and premature death in all countries of the world.

Gross domestic product or gross national product (GDP or GNP) The total expenditure by residents and foreigners on domestically produced goods and services in a year is GDP. It is the main indicator used to measure the size or output of an economy. GNP is GDP plus income earned abroad by residents less income earned in the economy by foreigners, i.e., GDP plus net property income from abroad.

National health accounts A record of the resource flows in a country's health system by the main elements of health care financing: resource mobilization and allocation, pooling and insurance, purchasing of care, and the distribution of benefits. National health expenditures include in principle expenditures on activities 'whose primary purpose is to restore, improve, and maintain health regardless of the type of the institution or entity providing or paying for the health activity.'

Overseas development assistance The Organisation for Economic Cooperation and Development's term for foreign aid. Also known as overseas development assistance.

Randomized controlled trial A scientific experiment conducted to test the effect of an intervention by randomly assigning participants to a treatment and control group. Differences between the treatment and control group participants are interpreted as the causal effect of the intervention.

Real terms The use of the adjective 'real' in economics is to distinguish monetary changes in value that are merely inflationary from others corresponding to changes in the flow of goods and services. Index numbers are used to deflate nominal values and thereby generate real values.

Introduction

This article addresses the distinctive challenges of planning, financing, implementing, and evaluating public health policies in low- and middle-income countries. By public health is meant the 'science and art of promoting and protecting health and well-being, preventing ill-health and prolonging life through the organized efforts of society' (http://www.fph.org.uk/what_is_public_health).

A key feature of low- and middle-income countries is a health discourse that diverges in some key ways from that in high-income countries. In particular, 'public health' in high-income countries is a recognized and accepted subject area that is generally formally planned and structured, always with agencies with specific public health roles and sometimes even with a government minister for public health. Elsewhere, and especially in low-income countries, it tends to be assessed and planned in ways that are more fragmented, and less coherent, for reasons explored in this article.

What is Distinctive about Low- and Middle-Income Countries?

Burden of Disease

The global burden of disease (GBD) across the world has been studied for some time. In 2012, a comprehensive analysis was published for 2010, including comparison with the original 1990 analysis. It uses the metric of the Disability-Adjusted Life Year (DALY), which combines years of life lost due to premature death with years of healthy life lost due to illness and disability, for specific diseases and conditions. The regional breakdown is done by 21 geographical regions rather than broad country income grouping, although the identification of subregions does largely distinguish lower and higher income groupings within broader regions (e.g., Europe is disaggregated to Western, Central, and Eastern Europe).

Table 1 shows total DALYs and DALYs per thousand population by the 21 regions and the change between 1990

 doi:10.1016/B978-0-12-375678-7.00403-X

Data are DALYs (95% uncertainty intervals) or % change. DALY, disability-adjusted life years; %Δ, percentage change.

Source: Reprinted from Murray, C. J. L., Vos, T., Lozano, R., et al. (2012). Disability-adjusted life years (DALYs) for 291 diseases and injuries in 21 regions, 1990–2010: a systematic analysis for the Global Burden of Disease Study 2010. *The Lancet* **380**, 2197–2223.

and 2010. A full discussion of the data is in the source article. Key points to note are that in 2010 as in 1990, poorer regions have a much greater burden of disease per 1000 population, with the regions with the greatest burden per 1000 being in sub-Saharan Africa. Note, though that these regions have seen some of the sharpest reductions in burden per 1000 (although a marked increase in total burden due largely to population growth).

Figure 1 shows how the total burden of disease is broken down by broad cause in these 21 regions, comparing again 1990 and 2010. In 2010, high-income countries (high-income Asia-Pacific, Western Europe, Australasia, high-income North America, and central Europe) had only 7% of DALYs due to communicable, maternal, neonatal, and nutritional disorders. Cancer and cardiovascular disease accounted for 36% of DALYs. In contrast, in east, west, and central sub-Saharan Africa, the former disease groups accounted for 67–71% of DALYS. Nonetheless, comparing 1990 and 2010, the great reduction in common infectious diseases in poorer regions is evident (the reduction in the light yellow bars), although the rise in HIV is very visible (in dark yellow) in southern and eastern sub-Saharan Africa. Even in the poorer regions there is a significant burden due to noncommunicable diseases and injuries; hence, the common label of the 'double burden' in low- and middle-income countries – the unfinished agenda of communicable diseases and the new burden of noncommunicable diseases and injuries. Analysis by age groups and region can be explored at the GBD website of the Institute for Health Metrics and Evaluation (http://www.healthmetricsandevaluation.org/). For example, the analysis by region of DALYS in children under 5 shows vividly that disease in children is virtually absent in high-income regions and is concentrated in low-income regions (see http://www.healthmetricsandevaluation.org/gbd/visualizations/gbd-2010-patterns-broad-cause-groupunit=pc&sex=B&metric=daly&stackBy=region&year=5).

From a public health point of view, it is important to understand the risk factors that underlie the burden of disease. Figure 2 shows the relative importance for the 21 regions of the risk factors defined in the GBD study. For central, eastern, and western sub-Saharan Africa, for example, the three leading risk factors are underweight, household air pollution from solid fuels, and suboptimal breastfeeding. In South Asia, household air pollution ranks top, although the changing pattern of disease is shown by tobacco smoking and high blood pressure ranking 2 and 3. In high-income regions, top ranking factors are high blood pressure, smoking, alcohol use, and high body mass index. This demonstrates visibly how the pattern of risk factors changes as countries grow richer.

Economic Structure

Economic structures not only help explain the patterns of burden of disease but also have a strong influence on the capacity of countries to respond to public health needs.

Key risk factors have their origins in the economic structure of low-income countries. The overall low level of income, and high proportions of the population living in absolute poverty, help explain under nutrition and the unsafe living environments. 'Structural' factors, such as low levels of education and lack of access to employment and informal employment, also

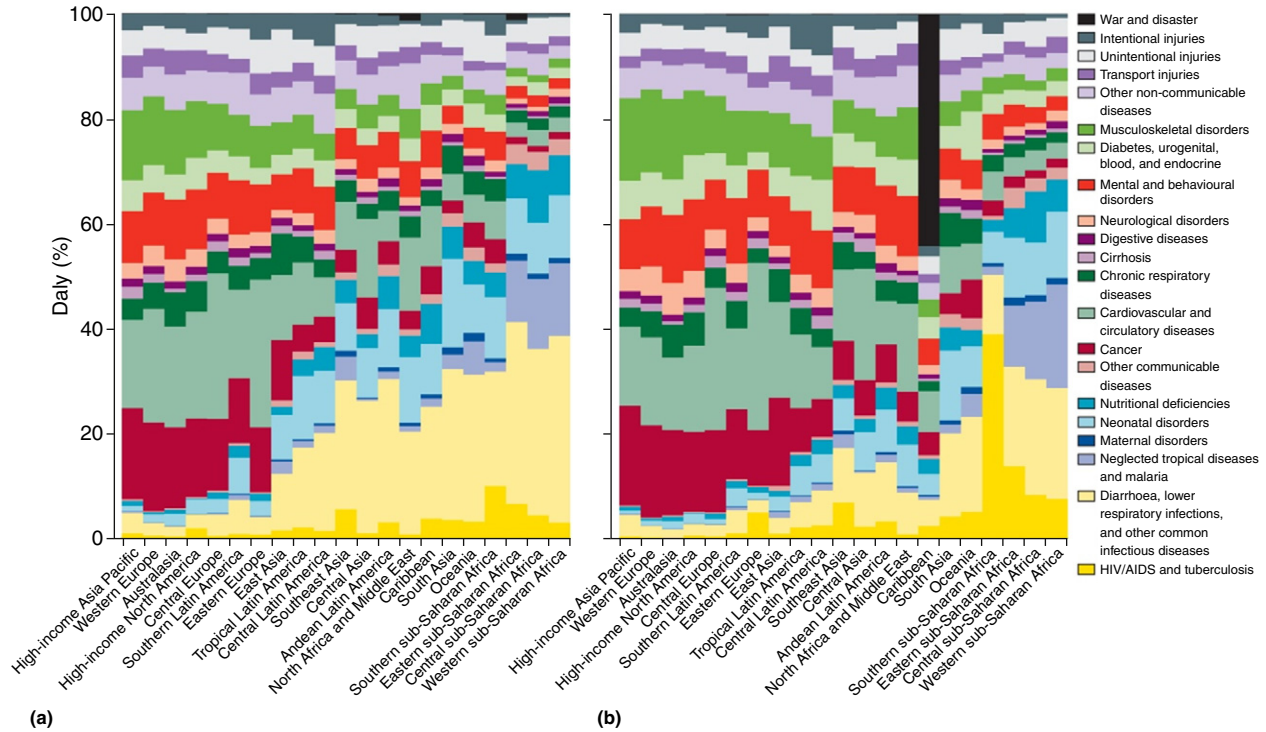

Figure 1 Percentage of disability-adjusted life years by 21 main cause groupings and region, 1990 (a) and 2010 (b). Reprinted from Murray C. J. L., Vos, T., Lozano, R., et al. (2012). Disability-adjusted life years (DALYs) for 291 diseases and injuries in 21 regions, 1990–2010: A systematic analysis for the Global Burden of Disease Study 2010. *The Lancet* **380**, 2197–2223. An interactive version of this figure is available online at: http://healthmetricsandevaluation.org/gbd/visualizations/regional

help explain the prevalence of unsafe sex which encourages the spread of sexually transmitted diseases (note that lack of data led to unsafe sex being omitted from the GBD risk factor list in Figure 2). In middle-income countries, growing affluence and changing behaviors associated with higher incomes, global spread of information and the influence of the multinational industry on diet and smoking help explain the very different pattern of risk factors.

The poverty of a country severely affects its ability to finance an adequate response to public health needs. Figure 3 (taken from the WHO National Health Accounts website) maps levels of per capita government expenditure on health across the world in 2010, and Table 2 shows shares of total, government and private health expenditure by country income group in 2009.

Many low-income governments in Africa and Asia spend less than $34 per capita on all health care. Mean total health expenditure in 2009 in low-income countries was approximately 5% of GDP and less than half of this was channeled through government. In 2001, the WHO Commission on Macroeconomics and Health estimated that a set of 49 priority health interventions, largely for personal preventive and primary care, would cost 6% of the GNP of low-income countries. Hence, current levels of government expenditure are inadequate to fund these priority interventions and in addition are funding many other interventions, which might be seen as lower priority, notably high level hospital care, which is costly but benefits relatively few people. Although private out-of-pocket spending is often at least as high as government spending, the bulk of this is spent on over-the-counter drug purchases rather than the high-priority preventive activities needed to improve the health of the public.

Poverty has another consequence, that of low salaries for heath workers in the public sector. Professionals have always been internationally mobile, and improved communications have made it easier for professionals to move to high-income countries where salaries are higher. Moreover, in a context where government physicians often supplement their low government salaries by private clinical work, public health practice may be less attractive because it offers less scope to increase reputation through clinical practice in the public sector, and postings to the more rural and remote areas limit the opportunity for profitable private practice.

Low levels of government expenditure reflect another consequence of the economic structure, the difficulty of raising adequate taxation to finance public services. Low-income economies have a large share of their populations in the informal sector, making it difficult to levy direct taxes on a significant proportion of the total population.

Political and Social Institutions

A corollary of underdevelopment is that the political and social institutions needed to underpin an effective government tend to be weak. These include the institutions of democracy

and representation, of civil society, and of professional groupings. One consequence for public health is that the ability to regulate health-damaging products may be far more limited than in the rich world. For example, low- and middle-income countries have come under pressure from the global tobacco industry, as well as self-interested governments who benefit indirectly from overseas tobacco sales through domestic tax revenues and employment, not to impose restrictions on the sale of tobacco or on cigarette advertising. In the late 1980s, the US used bilateral trade relations to exert pressure on countries such as Thailand and South Korea to open up their domestic markets to cigarette imports. Regulation of pharmaceuticals is

also often very weak, leading to widespread and uncontrolled usage of antibiotics and antimalarials, for example, which can encourage the development of resistance. Artemisinin, a relatively new antimalarial, is a case in point. WHO has urged countries to adopt regulatory measures to stop the marketing of oral artemisinin-based monotherapies and to promote access to artemisinin-based combination therapies: the effect of the combination is to protect the individual drug elements from the development of parasite resistance. But artemisinin monotherapy remains widely available in many countries due to both inability to enforce regulation and the lack of separation of government and commercial interests.

Management Capacity in the Public Sector

Low- and middle-income countries often struggle to translate policies into action. For example, their plans usually do give priority to diseases and conditions that give rise to the greatest burden of disease, yet in practice coverage rates of interventions such as immunization, vitamin A, and emergency obstetric care, remain well below universal. Although to some extent this reflects a lack of prioritization in resource allocation decisions, it also reflects the limitations of management capacity. This encompasses not only trained managers but also management and information systems more broadly and ability to implement programs effectively across countries with poor communications infrastructure and often remote and hard to reach populations.

Influence of Agencies External to the Country

On average, external financing makes up 27% of the total health expenditure of low-income countries (but far less in middle-income countries). In the last decade or so, official development assistance for health has increased substantially in real terms: it amounted to $7331 m in 2003, and $17 856 m in 2010 (constant 2010 US$). Along with this increase has come a proliferation of agencies at the global level concerned to

address specific health issues. Table 3 lists the key ones, starting with the landmark event of the Alma Ata conference in 1978, which launched the primary care movement. Since then, the tendency has been for more and more of the international initiatives to be focused on specific diseases – known as 'vertical programs' when they are organized and delivered in silos, separate from general health services. Most prominent have been HIV, TB, and malaria, but other diseases also feature, notably vaccine-preventable diseases such as polio and measles and so-called 'neglected' tropical diseases such as filariasis. In partial response to the attention given to these diseases, and to the resources they have attracted, other responses have developed particularly to seek remedy of the relative lack of emphasis on maternal, neonatal, and child health.

These international initiatives have very important consequences for low-income countries. Although they may provide the means to address effectively the needs of certain population groups, such as AIDs patients, they fragment the policy and planning environment at country level. Funds often flow vertically within a particular disease area, from international donors directly down to regional and local levels in a disease-specific chain of command and rarely in response to a systematic and comprehensive cross-disease planning process at country level. Low-income countries are on the receiving end of a multiplicity of funder requirements and procedures, which stretch already limited management capacity. Funders may bypass core government structures, such as central procurement agencies or indeed the Ministry of Health itself, rather than strengthening them.

Despite the growing importance of noncommunicable diseases, there are very few initiatives to address these, the framework convention on tobacco control being the only one in Table 3. An advocacy process, which resulted in a UN high level meeting on noncommunicable diseases in 2011, is generally considered to have produced very little in the way of concrete action.

Addressing Public Health in Low- and Middle-Income Countries

Concerns about the effective functioning of the health systems of low- and middle-income countries have led over many years to processes of what in the 1980s and 1990s were called 'health sector reform' and now are more commonly referred to as health systems 'development' or 'strengthening'. Such efforts can be criticized for focusing primarily on the health care system, rather than on broader public health. For example, from the 1980s onward debates have focused on the choice of policies for health financing. Advocates in international agencies, such as the World Bank, and the UK, French and German bilateral aid agencies, have taken up various positions over time on the appropriate mix of user fees for government health services, community-based health insurance schemes, social health insurance, and increased use of private financing arrangements including private voluntary health insurance. However, notably absent from the policy proposals until very recently have been statements on the critical importance of devoting increased government tax revenue to health. Given that public health above all concerns services that have the characteristics of public goods and externalities, it is apparent that planning for public health will not feature prominently when the main focus of debate is on how to stimulate sources of financing beyond government revenue.

The recent attention given by WHO and other international agencies to the 'social determinants of health' can be seen as an attempt to redress the balance in favor of a comprehensive and multisector approach to health. Social determinants are economic and social conditions, and their distribution among the population, that influence individual and group differences in health status. A WHO-appointed Commission on the Social Determinants of Health, set up in 2005 and reporting in 2008, examined the relationship between a variety of economic, political, legal, social and physical factors, and health. Although the report has been followed by a world conference in Rio and a WHO Executive Board resolution, it is not clear whether any low- or middle-income country has really embedded the thinking of social

Table 4 Key messages of the World Development Report 1993

Foster an environment that enables households to improve health
- Pursue economic growth policies that will benefit the poor (including, where necessary, adjustment policies that preserve cost-effective health expenditures)
- Expand investment in schooling, particularly for girls
- Promote the rights and status of women through political and economic empowerment and legal protection against abuse

Improve government investments in health
- Reduce government expenditures on tertiary facilities, specialist training, and interventions that provide little health gain for the money spent
- Finance and implement a package of public health interventions to deal with the substantial externalities surrounding infectious disease control, prevention of AIDS, environmental pollution, and behaviors (such as drunk driving) that put others at risk
- Finance and ensure delivery of a package of essential clinical services. The comprehensiveness and composition of such a package can only be defined by each country, taking into account epidemiological conditions, local preferences, and income
- Improve management of government health services through such measures as decentralization of administrative and budgetary authority and contracting out of services

Facilitate involvement by the private sector
- Encourage social or private insurance (with regulatory incentives for equitable access and cost containment) for clinical services outside the essential package
- Encourage suppliers (both public and private) to compete both to deliver clinical services and to provide inputs, such as drugs, to publicly and privately financed health services
- Generate and disseminate information on provider performance, essential equipment and drugs, the costs and effectiveness of interventions, and the accreditation status of institutions and providers

determinants into its government-wide public health planning. Indeed, cross-sectoral action is hard to achieve across government departments in rich and poor countries alike.

Thailand offers an innovative approach to financing public health efforts with a focus on health promotion. Borrowing from the model of VicHealth in Australia, which was originally funded by a tobacco levy, The Thai Health Promotion Foundation is funded by a surcharge on tobacco and alcohol excise taxes. It spends approximately USD$100 million a year on health promoting activities and works with a wide range of multisectoral partners. Its status as an independent public agency makes it somewhat less bureaucratic and more flexible than is the case for government departments, and its earmarked tax funding gives it important financial muscle. Although it is difficult to identify its specific impact, Thailand experienced a decline in smoking among more than 15-year olds from 25.47% in 2001 to 20.7% in 2009; a reduction in the proportion of heavy drinkers from 9.1% in 2004 to 7.3% in 2009 (as well as a reduction in household expenditure on alcohol); and a fall in death rates from vehicle accidents from 22.9 per 100 000 in 2003 to 16.82 per 100 000 in 2010.

The Thai experience is very much an exception in its focus on broader public health issues. Most of the discussion on public health in low- and middle-income countries has focused on interventions which address directly the health needs of individuals. It is interesting to track the evolution of this approach. In the early 1990s, there was growing concern about what was seen as the inefficiency of health expenditure patterns in low- and middle-income countries. Although technical inefficiency was a concern, the debate especially focused on allocative inefficiency, with criticism of the high share of government health expenditure going on higher level hospital care when service coverage at the primary care level remained very poor. The landmark World Development Report of 1993 (WDR 93) introduced the DALY metric and analysis of burden of disease in terms of DALYs and also the notion of a 'package' which would respond to the largest elements of the burden. Looking back at the WDR 93, it is notable that not only there was examination of the broader context of disease which led to recommendations on fostering an environment that enables households to improve health (see **Table 4**), but also two packages were recommended, one of public health interventions and the other of essential clinical services. The former included public health action beyond that focused on individuals, including environmental pollution, and addressing drunk driving.

Although the approach of prioritizing a set of interventions has persisted in global health policy, the importance of encompassing both broader public health and clinical interventions seems to have been forgotten. The subsequent two developments of this approach, the WHO Commission on Macroeconomics and Health (2001) and the WHO High Level Taskforce on Innovative International Financing for Health Systems (2009), both defined sets of interventions consisting almost exclusively of those focused on individuals and households (**Tables 5** and **6**). The importance for health of the broader environment appears to have been forgotten. Even water and sanitation did not feature prominently, on the grounds that environmental health interventions of this kind were not considered as cost-effective for health improvement as health interventions targeting individuals.

It is interesting to reflect on the role that evaluation may have played in encouraging this development. The WDR 93 developed its dual package through analyzing both the burden of disease and the cost-effectiveness of interventions. At that time, the evidence base was weak across all areas, so much of the analysis was tentative. Since then, there has been a great increase in the volume of cost-effectiveness analysis but with a focus on specific interventions. Most commonly, the economic evaluation studies have been linked to epidemiological trials of new drugs, diagnostic methods, or more recently health service improvements. Broader public health measures lend themselves less readily to what has been perceived as the gold standard methodology of the randomized control trial.

Table 5 Commission on macroeconomics and health: list of interventions

Disease area	*Nature of intervention*
1. Maternity-related interventions	Antenatal care
	Treatment of complications during pregnancy
	Skilled birth attendance
	Emergency obstetric care
	Postpartum care (including family planning)
2. Childhood disease-related interventions (immunization)	Vaccinations (BCG, OPV, DPT, Measles, Hepatitis B, and HiB)
3. Childhood disease-related interventions (treatment of childhood illnesses)	Treatment of various conditions (acute respiratory infections, diarrhea, causes of fever, malnutrition, and anemia)
4. Malaria prevention	Insecticide-treated nets
	Residual indoor spraying
5. Malaria treatment	Treatment for malaria
6. Tuberculosis treatment	Directly observed short course treatment for smear positive patients
	Directly observed short course treatment for smear negative patients
7. HIV/AIDS Prevention	Youth focused interventions
	Interventions working with sex workers and clients
	Condom social marketing and distribution
	Workplace interventions
	Strengthening of blood transfusion systems
	Voluntary counseling and testing
	Prevention of mother-to-child transmission
	Mass media campaigns
	Treatment for sexually transmitted diseases
8. HIV/AIDS Care	Palliative care
	Clinical management of opportunistic illnesses
	Prevention of opportunistic illnesses
	Home-based care
9. HIV/AIDS HAART	Provision of HAART

HAART: highly active antiretroviral treatment.

Table 6 High-level taskforce on innovative international financing for health systems: list of interventions

Groupings of services	*Include the following interventions*
Maternal and newborn services	Antenatal care (four visits)
	Quality facility births (maternal care during labor, delivery aid immediate postpartum)
	Newborn care (care of the newborn at birth and immediate postnatal care, including exclusive breastfeeding)
	Postnatal care (care provided to the mother up to six weeks after birth and visits at home for the newborn)
	Emergency obstetric and neonatal care (specialized care including treatment of complications during pregnancy, childbirth, and the postnatal period)
	Safe abortion (where legal) and postabortion care
	Family planning
Child services	Oral rehydration therapy
	Case management of pneumonia
	Vitamin A supplementation and vitamin A fortification
	Zinc supplementation, zinc fortification
	Access to processed food, provision of supplementary food and counseling on nutrition
	Full and permanent coverage of immunization programs
	Exclusive breastfeeding for children under six month
HIV	Prevention, treatment, and care programs for HIV
	Prevention of mother-to-child transmission
Malaria	Preventive and curative interventions for malaria
Tuberculosis	Diagnosis and treatment for tuberculosis
Noncommunicable diseases	Heath promotion and early detection of noncommunicable diseases
Presenting conditions	Diagnosis, information, referral, and relief of symptoms for any presenting conditions

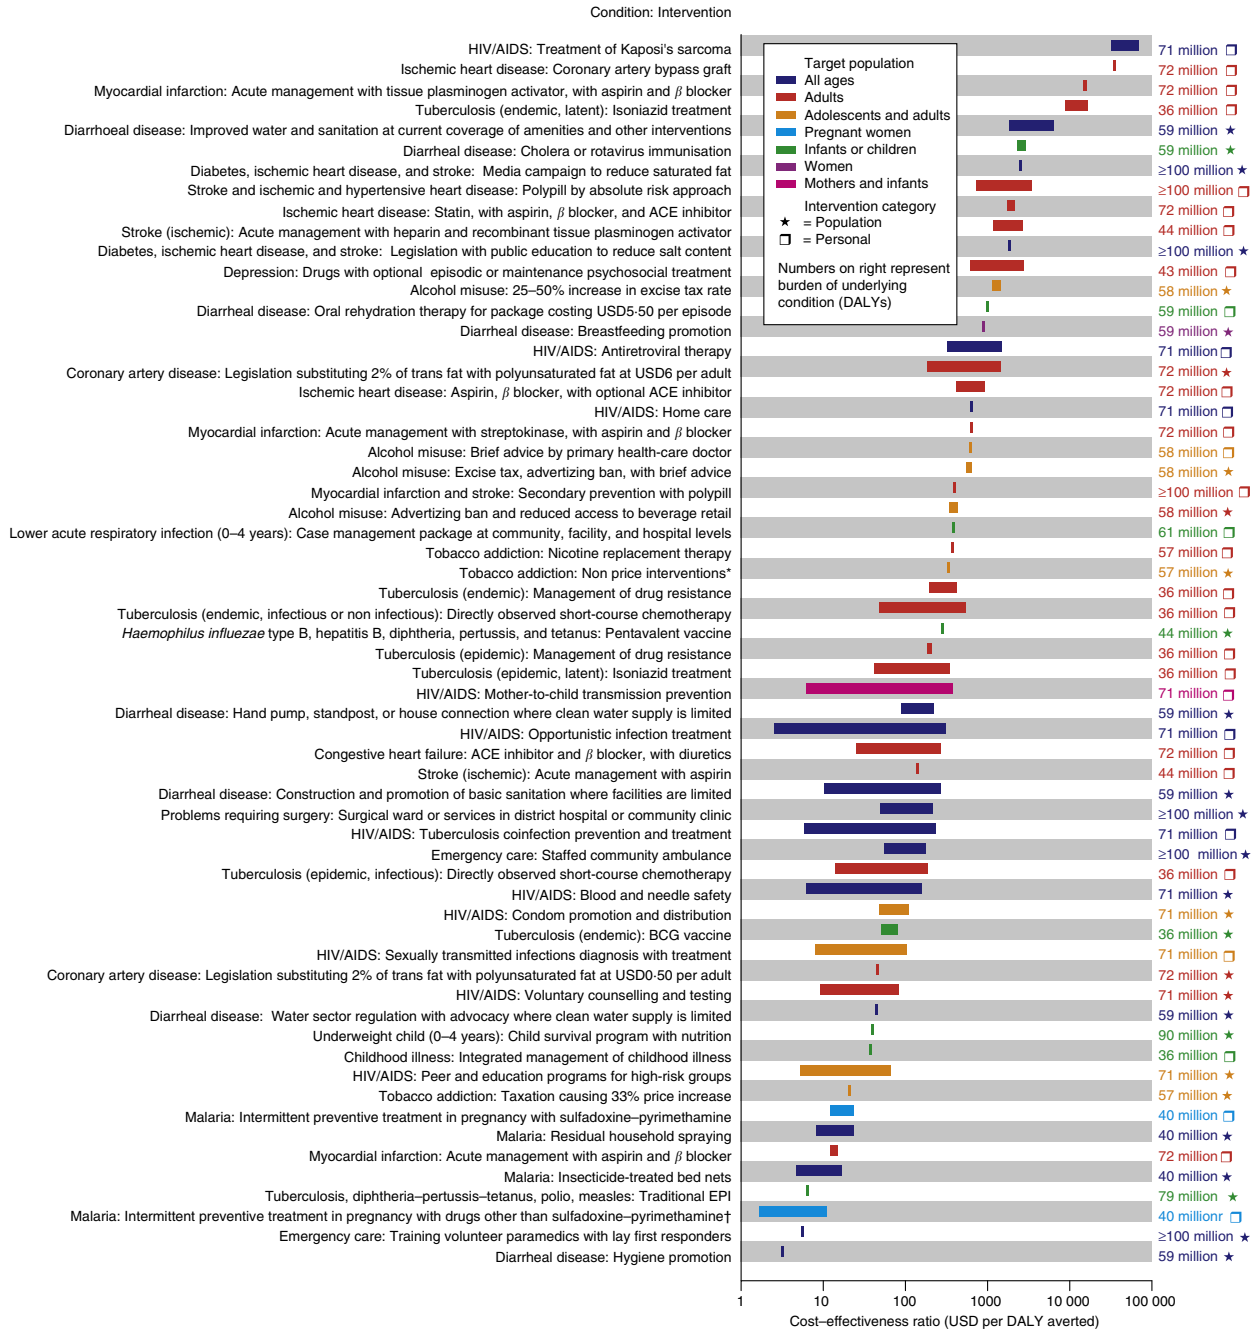

Figure 4 Cost-effectiveness of interventions related to high-burden diseases (>35 million DALYs) in low-income and middle-income countries. Bars = range in point estimates of cost-effectiveness ratios for specific interventions included in each intervention cluster and do not represent variation across regions or statistical confidence intervals. Point estimates obtained from DCP2, calculated as midpoint of range estimates reported, or calculated from a population-weighted average of region-specific estimates reported. Only interventions with cost-effectiveness reported in terms of DALYs are included in figure. *Advertising bans, smoking restrictions, supply reduction, and information dissemination. †Chloroquine = first line drug; artemisinin-based combination therapy = second-line drug; and sulfadoxine-pyrimethamine = first-line or second-line drug. Reprinted from Laxminarayan, R., Mills, A., Measham, A., et al. (2006). Advancement of global health: Key messages from the Disease Control Priorities Project. *The Lancet* **367**, 1193–1208.

Moreover, because such measures tend to have multidimensional outcomes (both different types of health benefit as well as benefits beyond health), but only single health outcomes are usually measured, they appear less cost-effective relative to interventions focusing on specific groups of individuals.

Figure 4 illustrates the problem that broader public health measures can appear less cost-effective relative to specific clinical interventions, using analyses from the Disease Control Priorities Project. This project produced a book, which provided evidence on disease burden and intervention

cost-effectiveness in 73 chapters covering specific diseases and health conditions, risk factors, consequences of disease and injuries, and clusters of services including public health, primary care, hospital care, and surgery. **Figure 4** summarizes the cost-effectiveness of interventions intended to address conditions causing a high disease burden. It is striking how few broader public health measures are included in this list, the only ones being mass media aimed at reducing saturated fat intake, and legislation to influence salt, fat, alcohol, and tobacco consumption.

The analysis on communicable disease control undertaken for the first Copenhagen Consensus (www.copenhagenconsensus.com/Home-1.aspx) also illustrates the difficulties of the evidence base. The Copenhagen Consensus examines the best way to spend aid using the metric of economic evaluation. In terms of benefits relative to costs, and based on the existing evidence, control of HIV/AIDS and control of malaria had far higher benefit cost ratios than the strengthening of basic health services. But it was clear that the nature of the evidence was highly problematic. First, the available evidence for costs and effects of specific disease control measures came mainly from trials, whereas the evidence on strengthening basic health services came from cross-country analyses, which explored the relationship between public expenditure on health care and infant and child mortality rates. One would expect trials to show higher levels of effectiveness that would not be replicated in real life. Moreover, the cross-country studies captured only the health care benefits to children rather than the population as a whole (partly because the benefits of multipurpose health services are not easily captured in a single metric, whereas metrics are readily available to evaluate disease-specific trials). Thus, it is likely that the health benefits of basic health care are underestimated.

Another example of the weaknesses of current evaluation methods, and how they can bias against broader public health action, comes from the HIV literature. Evidence is now strong that HIV incidence is declining in Uganda and Zimbabwe, for example. Yet, given what is known about the effectiveness and coverage of specific interventions, this is hard to explain. It may be that there are synergies among interventions that existing research does not capture; or that there are broader social influences at work (e.g., much greater individual awareness of the risk of HIV as a result of knowing close friends and relatives dying from HIV and behavior change as a result). These again are difficult to capture using traditional evaluation methods.

Awareness is growing of the ways in which evaluation methodologies risk distorting policy choices, especially with the increasing emphasis on requiring policy makers to base their decision making on high-quality evidence. Methods for economic evaluation need to develop beyond their current focus on single intervention approaches and single measures of outcome.

Conclusions

This article has sought to examine some of the specific issues concerned with improving public health in resource poor settings. Its prime conclusion is that a number of influences have led to the broader determinants of health, those that can be addressed by public health action beyond personal health services, being grossly neglected. It is critical that planning and evaluation move beyond their current health care and disease-specific focus, not least given the looming threat of non-communicable disease and the need to address its root causes. This will require innovations in research and evaluation methodology, as well as remedying the current global bias to control of specific diseases rather than broader health improvement.

A further challenge will be the changing global dynamics of relations between richer and poorer countries. Already China and India have graduated from low-income country status. In Africa, economic growth prospects now look brighter, especially given Africa's mineral resources. Traditional financial development assistance is likely in the longer term to decline as a source of influence on health policy. Expertise and knowledge will increasingly be of more use to the developing world than cash. Public health institutions for generating knowledge and acting on it will need to develop and evolve both globally and nationally if past health gains are to be sustained and new health risks tackled.

Public Health Profession

G Scally, University of the West of England, Bristol, UK

Introduction

The origins of public health can be found in ancient Greek and Roman civilizations. Many of the prominent themes in the writings of that era, such as Airs, Waters, and Places from the Hippocratic corpus, have echoes in today's major concerns about how one can have health amid both climate change and an increasing burden of noncommunicable diseases. The Greeks also developed the concept of city physicians. Their role, paid for by the city, was to look after the health of the citizens and to advise on the overall health of the city.

It is a constant difficulty for those working in public health as to how their specialty should be described. Every public health professional will be asked repeatedly during his or her career to explain exactly the meaning of public health. One useful conceptualization describes it as five different, but commonly encountered, images:

1. The system and social enterprise.
2. The profession.
3. The methods (knowledge and techniques).
4. Governmental services (especially medical, and for the poor).
5. The health of the public.

Over the years, many definitions of public health have been used. These often seem to morphose at times of organizational crisis or reorganization. At these times, a definition is needed that fits with the prevailing or future circumstances. But in modern times, whatever definition is used for public health, there remains a publicly accountable system, which is staffed by professionals who identify with the task of improving the health of human populations. The question is, however, sometimes asked as to whether public health is really a system or a profession. In times past, it was sometimes, perhaps accurately, referred to as an 'endeavor.'

The Origins of the Public Health Profession

The history of public health tells us that the major improvements in the health of populations have resulted not through the efforts of medical systems orientated toward the care of individuals with specific diseases but through the improvement of general social conditions such as housing, food supply and quality, water, and sanitation (see Figure 1). Although this is a historical perspective, being mainly associated with the nineteenth century sanitary revolution that started in England in the 1830s and 1840s, the rise in the importance of noncommunicable diseases globally, including obesity, diabetes, and alcohol-/tobacco-related diseases, has underlined the importance of primary prevention. The modern construction, the equivalent of the sanitary movement, is centered around the social determinants of health.

In the UK, the history of professional engagement with public health in a structured way dates back to the mid-nineteenth century when the post of Medical Officer of Health (MOH) was created among the English local authorities. The first MOHs were mostly part-time, who combined the local authority post with clinical practice. The first formal qualification in public health was the Diploma in State Medicine that was instituted in 1871 by Trinity College in Dublin. The breath of public health concern was illustrated by the inclusion in the syllabus of subjects such as statistics, meteorology, and engineering. It was not until the early-twentieth century that the possession of a professional qualification in public health became compulsory in Britain for those holding the MOH post. Other related qualifications, such as those awarded to sanitary inspectors, developed separately but simultaneously with the medical world.

In the USA, the first public health structures came in to being in the second half of the nineteenth century in the port cities on the East coast. By the 1870s and 1880s, most States had established their own public health structures. It was industrialization and rapid population growth that spurred the development of public health in the big cities, just as it had happened in England.

It was the inception of the National Health Service (NHS) across the UK in 1948 that created different strands of medical engagement with population health issues. The main professional public health staffing, and a wide range of public health services, had remained within the remit of local authorities. The new structures of the NHS, however, required population health skills, particularly in healthcare planning, and medical officers were appointed at a senior level within these new organizations. The skill set however was different from that required in the traditional public health role, and the existing professional organizations were not well fitted to service the future requirements of this new mixture of professional roles.

The opportunity to reconstruct the profession engaged in population medicine, in whatever role, came with the 1974 (1973 in Northern Ireland) reorganization of the NHS. It finally brought together the three key components of hospital services, primary healthcare, and public health in the NHS. The transfer of public health from local government into the NHS was not without its problems. Many of the MOHs opposed the transfer and did not appreciate the move of focus away from issues such as infectious disease, housing conditions, educational medicine, and child health. Instead, they found themselves deeply engaged in issues of healthcare management, and were frequently relegated to a purely advisory role with limited command over staff and resources.

This major change in the nature of the profession was the greatest for more than a century, and it was necessary to reconstruct the organs of the profession to match the new challenges. In particular, in order to leave behind the historical baggage of sanitarianism that attached to the title 'public

 doi:10.1016/B978-0-12-375678-7.00402-8

Figure 1 A court for King Cholera.

health,' it was felt that the branch of the medical profession dealing with population health required a new name of 'community medicine' – although this attempted change of name was short-lived as seen below forthwith. The transfer of public health functions from the local authority world into the NHS was not complete however, as environmental health responsibilities still remained with councils.

Academic Public Health

By the first half of the twentieth century, the development of the academic endeavor surrounding public health had moved substantially from its origins in the sanitary revolution. The decline of infectious diseases in Britain had resulted in a change in perspective amongst doctors who were interested in the academic questions surrounding disease prevention and control. From the 1930s onwards, a clinical perspective, which was more closely rooted in the practice of bedside medicine than in sanitarianism, had developed to become the predominant ethos of the academic public health world. The individual being most closely associated with this trend, for leading it in many ways, is John Ryle. Ryle was a political progressive who moved from his post as Professor of Physics in Cambridge University to lead the newly created Institute of Social Medicine at the University of Oxford. He believed that the new paradigm of social medicine, as it thus became, should be based on the study of disease causation in populations of patients. This became the predominant academic approach that was closely associated with the development of epidemiological methods in studying noncommunicable diseases. Although academic departments continue to teach courses leading to the Diploma in Public Health, their research has actually shifted substantially toward a social medicine focus.

The academic bedrock in the USA was established following the publication of the Welch-Rose Report in 1915. Substantial funding from the Rockefeller Foundation in 1916 has enabled the founding of what is now known as the Johns Hopkins Bloomberg School of Public Health. The subsequent development of a network of schools of public health across the USA has set the basis for the system of public health training that continues even today.

The Creation of Community Medicine

The transfer of public health responsibilities and staff to the NHS in 1974 was an opportunity to create a unified group within the medical profession of those whose activities were orientated toward improving the health of the population. Thus three strands were brought together; the former Medical Officers of Health and their staff, the medical administrators in the hospital service, and the social medicine and epidemiology academics. The new title chosen for this unified specialty was 'community medicine.' The creation of such a unified professional grouping had already been recommended by the 1968 report of the Royal Commission on Medical Education, although it took the restructuring of the NHS to give it the momentum for producing the necessary organizational changes.

The Faculty of Community Medicine became the professional organization that was created to be responsible for the training and professional development of the specialty. It was an unusual creation in that it was a faculty of not one but three medical Royal Colleges: the Royal College of Physicians

of London, the Royal College of Physicians of Edinburgh, and the Royal College of Physicians and Surgeons of Glasgow. Membership of the new Faculty was restricted to those who held a medical qualification and, following the period of its formation, to those who passed its two-part examination. It was therefore cast in the traditional mold of a medical college where the training programs followed the well-established pattern for the training of hospital consultants.

Multidisciplinary Public Health

As the great majority of national public health associations across the world have a multidisciplinary membership, the World Federation of Public Health Associations will not admit into membership an association that draws its membership from only one professional background. The American Public Health Association, founded in 1872, has a long tradition of multidisciplinary public health working and, in its case, it has been seen to add to the general strength of the professional group. In the USA, public health training has always been multidisciplinary. By 1938, federally funded training had been provided to more than 4000 people in schools of public health, of whom only approximately 1000 were medically qualified.

In the UK, although the move toward multidisciplinary public health was difficult for many of the more traditionally minded members of the specialty, the way forward was eventually greatly helped by the example of the Royal College of Pathologists that had for some time admitted both medical and nonmedical members. It was the creation of the new specialty grouping of community medicine in the 1970s that created the tensions. The very fact that training for senior positions in the new system was so closely modeled on the medical training scheme, and that the newly formed Faculty of Community Medicine only opened its doors to registered medical practitioners, was regarded as little short of an insult by many of the distinguished academics from disciplines other than medicine, who had been making such a substantial contribution to the various academic departments of social and preventive medicine across the country. The attempt to persuade academic departments to adopt the uniform title of 'Department of Community Medicine' was a failure. Many departments continued to operate with their traditional titles, whereas very few adopted the new title.

As the service component of community medicine found its footing in the new NHS structures during the 1980s, the skill mix began to develop in the building of departments. The multidisciplinary trend was particularly prominent in the growth of health education units as well as their development into the new and more progressive approach of health promotion. Similarly, the requirements in the new organizations for advanced skills in the handling and analysis of large datasets, accompanied by the development of small and usable computers, led to the development of groups of staff with significant epidemiological and statistical skills. The gradual opening up of postgraduate courses in public health to students from disciplines other than medicine meant that there was the beginning of a professional development pathway for nonmedical graduates that would to some extent mirror that of the doctors.

The steady growth of multidisciplinary working in both academic and service settings had gradually increased the demands for a proper career structure for nonmedics working in public health as well as for access to established and recognized training routes. At one point, there was a danger that the specialty would split into two or more professional groupings. However, with a great deal of diplomatic activity, it had eventually become possible to bring together the different factions. In 1997, the Tripartite Group (the Faculty of Public Health Medicine, the Royal Institute of Public Health and Hygiene, and the Multidisciplinary Public Health Forum) signed the Tripartite Agreement taking forward the development of multidisciplinary public health. This formed the basis for admission into the Faculty, on an equal basis, of public health professionals from different professional backgrounds. It also paved the way for equal access to official training posts in the specialty.

Training in Public Health

Across the world there are various routes of entry into specialized public health work. The most common by far is through studying for a Masters level degree in public health at a University or School of Public Health. In many countries, such training may be supplemented by further study to obtain a Doctorate level qualification, which may be obtained through a taught route or by research. This route is usually open to graduates from a wide range of disciplines and to those from vocational backgrounds such as nursing.

The US in particular has a very substantial number of Masters in Public Health (MPH) courses, and approximately 15 000 students study for a MPH every year. The Council on Education for Public Health accredits courses in public health in the USA and has recently started to operate internationally with accreditation taking place in Canada, Mexico, and France. Canada in particular has seen what is described by some as an 'explosion' in MPH courses.

The growth of academic qualification in public health is rightly seen as a bedrock for good public health practice in society. In some countries, however, a longer training period, that usually includes a MPH component, is regarded as the norm for those wanting to become specialists in public health. This is a system that is often based on the British approach to training, which parallels the system for training of doctors in clinical specialties. The approaches adopted in Ireland, Australia, and New Zealand – all involve a significant period of work-based training attachment as well as, in some cases, qualifying examinations.

System Failure

Although community medicine had become embedded within the NHS systems in the UK during the 1970s and 1980s, this had meant a substantial move away from the origins of public health, which were based on the concept of environmental concerns and infectious disease. The connection with NHS

management and the involvement in the functions of NHS administration had meant that public health practitioners had moved ever further away from their origins, and this was not without consequence. There were a series of serious failures of the public health system, resulting in a significant number of deaths. Notably, these included the major salmonella outbreak in 1984 at the Stanley Royd Hospital in Wakefield and the 1985 Legionnaires' disease outbreak at Stafford General Hospital. The then Chief Medical Officer (CMO) of England, Sir Donald Acheson, chaired a review of the public health system and published a report in 1988 entitled 'Public Health in England.' The major thrust of the report was that the specialty had drifted too far from its roots, neglecting some of the major risks to the population's health. Two important outcomes were that the title 'public health' should be restored to the specialty and that the senior post holder at a local level should be designated as Director of Public Health (DPH). He or she was also mandated to produce an annual report on the health of the respective population in much the same way as the predecessor, the MOH, had done.

Doctors specializing in the control of infectious disease became separated from the generalist public health professionals in due course, a move that was reinforced by the incorporation of doctors into a new national body known as the Health Protection Agency, which itself disappeared in 2013. This separation of communicable disease control from general public health is contentious, and is regarded as creating a fault line in the specialty.

The Chief Medical Officer

It is very common for national health systems to have an individual operating at national level with the key responsibility for the population health aspects of the country's health. Inevitably, a range of titles are used to designate such a role, but internationally, the generic title of CMO is often used – in the European Union, for example – even though in some instances, the incumbent may not be medically qualified. A study of all the counties in the European Union has shown that CMOs operate in a wide range of roles. This might be within the central Government Department of health concerns or within a separate agency in charge of undertaking national public health responsibilities. The role of the CMO also ranges from being purely advisory to having substantial executive powers and numerous staff. Very few European countries do not have any identifiable CMO-type posts.

In England, the local post of MOH preceded the post of CMO. The first MOH known to be appointed for a full-time post in the UK was Dr. William Henry Duncan of Liverpool. He was appointed in 1847 as a result of a private Act of Parliament that preceded the 1848 Public Health Acts. He became a well-known figure in the city to the extent of sharing with his contemporary, the famous London physician Dr. John Snow, the accolade of having a public house named in his honor. But although MOHs became prominent local figures, it was indeed the creation of the public health post currently known as CMO at the heart of Government that had become the most enduring one.

The first holder of the post of CMO was Dr. John Simon. He had been an active and outspoken MOH for London, who became the CMO of the General Board of Health in 1855. Never one to shy away from controversy, Simon continued to be a passionate advocate for the health of the population. He demanded that the post of CMO should be of prominence in the structure and functioning of the General Board of Health, and subsequently in the Privy Council. Although he resigned eventually because of the downgrading of the post – particularly on the issue of allowing direct access to ministers, yet Simon had firmly established the principle of a chief public health advisor to the government and the post continues to this day. Although it is nowhere specified that the CMO has to come from a public health background, this has in effect been the position until relatively recently. Only two of the CMOs in England have come from outside the public health system. The requirement to publish an annual report on the health of the population has been a key task of the CMO, which has been seen as analogous to the duty that fell to the MOH, and subsequently, to the DPH, at a local level. The CMO post is, however, under threat in the English system, as the current and 16th incumbent is not only from a nonpublic health background but is also on a short-term contract, and the post itself has been merged with the most senior research and development post in the Department of Health.

The USA has a similarly long-lived tradition of having a doctor close to the center of government. The first Surgeon General of the USA was appointed in 1871 and, unlike the UK position, is a political appointee. The incumbent holds office at the pleasure of the President, and although there is a tradition and public expectation that the Surgeon General will speak out on controversial issues, this at times has led to the President's intervention to dismiss him or her. This has been seen most recently in the dismissal of a Surgeon General by President Clinton because of her statements on sexual health. Former Surgeon Generals have complained publicly regarding political interference in their erstwhile official roles (**Figure 2**). As in the UK, there is a presumption that the post of Surgeon General will be appointed from within the existing public health medical workforce.

A very significant difference between the public health workforce in the USA and the UK is with regard to their official status. In the USA, the Public Health Service Commissioned Corps is one of the uniformed services of government and its uniformed staff is therefore subject to a degree of military style discipline, with the Surgeon General holding the rank of Vice-Admiral in the service.

Future Directions

The development of international cooperation between organizations representing public health professionals appears to be on a steady upward trajectory. The African Federation of Public Health Associations was launched in April 2012, since then representing the latest step in the creation of an effective global, regional, and national network of public health bodies. The basic priority internationally is the development of a global approach to the public health workforce, which would recognize that strengthening the training and the role of

Figure 2 Three former surgeon generals testifying before congress regarding political interference in their role.

public health professionals are key elements for improving global health.

In England, the most recent changes to the NHS have moved public health in a very different direction from the situation in other parts of the UK. The return of a substantial proportion of public health functions to local authorities is a major reversal of the 1974 reorganization. Similarly, the creation of Public Health England, an executive agency of the Department of Health, is remarkably a substantial centralization of power and authority. This centralization is to a greater extent than anything seen hitherto in public health in the UK. Meanwhile, public health in Scotland, Wales, and Northern Ireland continues to be closely associated with the NHS. The effect on professional practice of the changes in England is not yet discernible. The Coalition Government in England has agreed to implement statutory regulation of the specialist cadre of the profession, and this may provide some protection in respect of the *laisser faire* approach that is likely to accompany the local control, which will rest with individual local authorities.

There is a real opportunity arising from the move to local government in England. Many of what are now known as the social determinants of health lie within the remit of local authorities. The ability to influence planning, housing, leisure and recreation, education, economic development, etc. is a prize worth griping. The ability to function effectively within what is a radically different environment is however likely to require a different set of skills from those most recently deployed in the NHS. In particular, the ability to deal efficiently and effectively with, and win the respect of, elected politicians will be at a premium.

The move of a substantial proportion of the public health workforce in England into local authorities will give a new opportunity to rethink approaches to ensuring the quality of public health practice. The current model that is based largely on processes such as audit and revalidation, which are drawn from the clinical world, may well prove to be inadequate in a world where professional hierarchy is dissolved. Instead, new approaches that aim to provide assurance regarding the quality of local public health departments may evolve. This may well be based on recent experience from the USA, where they have been trying to cope with a devolved system that displays significant variation in the quality of public health practice. The development of USA style accreditation systems for local public health departments is one way in which professional standards and development can be assured at a time of increased devolution of authority.

One of the important changes in recent decades has been the way in which doctors in clinical practice have moved away from engagement with preventative medicine and the major public health issues of the day. This is in stark contrast to the successes of the broader medical profession during the later half of the twentieth century in relation to issues such as tobacco, seat belts, crash helmets, and car windscreens. There have however been stark warnings that health services in developed countries will become unaffordable unless there is a wholehearted and wholesale engagement with primary prevention. If this is to materialize, stronger links will need to be forged between clinical medicine in health services and the operation of local authorities and others with control over the determinants of health. This has the potential to usher in a new era of preventative medicine in which the barriers between clinical medicine and public health that have been painstakingly erected over the past hundred years can start to be demolished.

Glossary

Bounded rationality The idea that people may be content with decisions that are merely satisfactory rather than ideal, that they operate by rules of thumb, take short-cuts, etc.
Cost-benefit analysis A form of economic evaluation by comparing the costs and the (money-valued) benefits of alternative courses of action.
Cost-effectiveness A measure of the cost per desired outcome or effect of an intervention or course of action. Whether a given intervention is considered cost-effective typically depends on how it compares to other relevant alternatives with similar outcomes; the intervention with the lowest cost per desired outcome is the most cost-effective intervention.
Epidemiology The study of the relationship between risk factors and disease in human populations, including factors that can change the relationship and the application of such analysis to the design and management of health care systems.
Marginal The additional benefit, health, cost, etc. attributable to a small increase in a factor bringing it about (other things equal).
Observational data Data from studies that observe 'what is' without observer intervention, say, in the form of creating controls or blinding or randomizing.
Public choice theory Public choice study includes collective decision-making and political behavior. Analysts model voters, politicians, and bureaucrats as mainly self-interested. It also includes the study of constitutions and constitutional change.
Quasi experimental or natural experiment Comparative research in which the assignment of subjects to comparator groups is not random or a control group is not used.
Randomised control trial A scientific experiment conducted to test the effect of an intervention by randomly assigning participants to a treatment and control group. Differences between the treatment and control group participants are interpreted as the causal effect of the intervention.
Rent seeking The processes through which individuals and corporations seek to use government to promote their own interests and, in particular, to acquire streams of money (rents). An example is members of a regulated industry manipulating the regulatory agency.

Introduction

The phrase 'public health' can be used to mean (1) population health, or (2) public policy intervention to prevent ill health. This article focuses on public health in the latter sense, as used by the public health profession and the broader public health community. However, the discipline of economics also has much to contribute to understanding public health in the former sense. So by way of background, this introductory section lists a few of the many contributions that economists have made to measuring population health and analyzing its determinants. One can read about these and many other important economic analyses of population health in other entries in the encyclopedia.

Contributions by economists to measuring population health include work by:

- Alan Williams and George Torrance in helping to develop the quality-adjusted life-year measure of overall health.
- Christopher Murray in helping to develop the Disability Adjusted Life Year measure of overall disease burden and the Global Burden of Disease reports, together with epidemiologist Alan Lopez.

What is distinctively 'economic' about these contributions, compared with contributions by clinicians, epidemiologists, psychologists, and others, is the development of overall summary measures of health that allow diverse mortality and morbidity outcomes from diverse health conditions to be compared with one another in terms of a common generic unit of health.

Contributions by economists to analyzing the determinants of population health include work by:

- Samuel Preston on distinguishing the contributions of income growth and new technology to improvements in population health in the twentieth century.
- Victor Fuchs on distinguishing the total contribution of healthcare to population health from the much smaller marginal contribution of additional health care expenditure at the current level of medical technology.
- David Cutler and Mark McClellan on the substantial health benefits of medical innovation in the latter half of the twentieth century, building on work by anesthesiologist John Bunker.
- Angus Deaton on disentangling the relationships between income, health, and wellbeing, including work addressing the hypothesis of social epidemiologist Richard Wilkinson that income inequality is a health hazard.
- David Grossman on the concept of health capital and the contribution of health capital investments over the life-course to the production of health.
- James Heckman, Janet Currie, and Robert Fogel on the contribution of *in utero* and early childhood circumstances to health and human capital formation, building on work by epidemiologist David Barker.

 doi:10.1016/B978-0-12-375678-7.00401-6

- Garry Becker on the theory of rational addiction and subsequent empirical work by Frank Chaloupka and others, confirming some (though not all) of its testable predictions in relation to smoking and other unhealthy addictive behaviors.
- Tomas Philipson on economic epidemiology and the role of prevalence-elastic prevention behavior in determining the prevalence of infectious disease.
- Don Kenkel on the role of antismoking public sentiment as a cause of both antismoking public policy and declining smoking rates, an example of the general issue of 'endogenous policy'.
- Harold Holder on general equilibrium modeling of alcohol consumption ('SimCom'), including feedback loops between alcohol consumption and policy formation.

What is distinctively 'economic' about these contributions includes the focus on marginal analysis (since marginal effects on health are more relevant to decision makers than average or total effects) and the focus on understanding how the health-related behavior of individuals and organizations changes in response to changes in their incentives and constraints.

Other distinctive characteristics of these contributions include the recognition that individuals and governments have important objectives other than health improvement, the explicit modeling of complex causal pathways, and the focus on seeking robust estimates of effect using experimental and quasi-experimental methods. However, it is less clear that these are distinctively 'economic' characteristics as opposed to distinctive characteristics of high quality public health and social science research, more generally.

The Nature and Scope of Public Health Intervention

Public health intervention is an important topic, for two reasons. First, preventing ill health is an important objective. Bad health is not only intrinsically bad but also instrumentally bad, as it makes it harder for people to lead flourishing lives and contribute to society by undertaking productive work, family, and social activities. Second, history suggests that public health intervention can succeed in preventing ill health. Careful analysis of historical mortality and fertility records by historian Simon Szreter and others has shown that the nineteenth century 'sanitary movement' and other historical public health interventions did contribute to the steady improvements life expectancy seen in the past 200 years, despite earlier findings to the contrary by physician Thomas McKeown.

Public health intervention is also a broad topic. In a 1920 article in *Science*, entitled 'the untilled fields of public health', the renowned US bacteriologist and professor of public health at Yale, Charles-Edward Amory Winslow, defined public health as: "the science and art of preventing disease, prolonging life, and promoting physical health and efficiency through organized community efforts for the sanitation of the environment, the control of community infections, the education of the individual in principles of personal hygiene, the organization of medical and nursing service for the early diagnosis and preventive treatment of disease, and the development of the social machinery which will ensure to every individual in the community a standard of living adequate for the maintenance of health." In 1988, the US Institute of Medicine put it more generally, and more succinctly: "Public health is what we, as a society, do collectively to assure the conditions for people to be healthy."

The scope of public health intervention thus potentially encompasses any kind of population level policy instrument (see **Box 1**) implemented by any kind of government or nongovernment organization or group in any sector of social or economic policy (see **Box 2**), which is undertaken with the (not necessarily exclusive) aim of preventing any kind of disease, illness, disability or injury, whether physical or mental, fatal or nonfatal, mild or severe.

Box 1 Public health policy instruments

Eliminate choice through regulation	For example, compulsory isolation of patients with highly infectious disease For example, prohibition of narcotics and prostitution
Restrict choice through regulation	For example, restrict the location and timing of alcohol sales For example, ban smoking in public places
Guide choice through disincentives	For example, cigarette sales taxes, alcohol minimum prices For example, parking and congestion charges
Guide choice through incentives	For example, tax breaks for work-related bicycle purchase For example, payments for stopping smoking in pregnancy
Guide choice through 'nudges'	For example, regulations requiring 'nonneutral' food labeling For example, changing the default option
Enable choice through public funding	For example, public funding of public goods, such as sanitation infrastructure, green spaces, cycle lanes For example, public funding of private goods, such as primary care, sports facilities, free fruit in schools
Provide information through public funding and regulation	For example, publicly funded research on health risks For example, public information campaigns to inform people about health risks and encourage healthy behavior For example, advertising standards, 'neutral' food labeling

Note: The types of policy instrument are listed in ascending order of restriction on individual freedom, based on the Nuffield Council on Bioethics 'interventions ladder.'

Box 2 Public health policy sectors

- Preventive healthcare policy – for example, screening, vaccination, oral health, mental health, child and maternal health; includes secondary prevention such as medication for heart disease as well as primary prevention, such as dietary advice for people at risk of developing heart disease.
- Health education policy – for example, communicating information about disease prevention and healthy lifestyles via clinics, schools, workplaces, and social media.
- Health protection policy – for example, disease surveillance, responses to major incidents, emergency planning, and managing outbreaks of infectious disease; may involve nonhealthcare professionals such as fire services, the police, and army.
- Safety policy – for example, workplace safety, transport safety, and domestic safety.
- Crime policy – for example, policies to prevent homicide and domestic violence.
- Sanitation policy – for example, sewage, waste disposal, and water quality.
- Food policy – for example, food hygiene and safety, nutritional labeling, and food provision.
- Local government policy – for example, policy on housing, green spaces, congestion, air quality, and social services.
- Family policy – for example, preschool education and child welfare services.
- Education policy – for example, general primary and secondary education.
- Employment policy – for example, employment rights, job centers, and regional subsidies.
- Trade policy – for example, international safety standards and intellectual property.
- Social protection policy – for example, unemployment benefits, disability benefits, childcare benefits, and pensions.
- Taxation policy – for example, income taxes, property and inheritance taxes.

Public health differs from healthcare insofar as it involves public policy intervention to reduce the risk of future ill health, rather than to treat current ill health. The risk reductions caused by particular public health interventions are often small and imperceptible at individual level, but can add up to large and tangible benefits at population level. Indeed, public health interventions that deliver small reductions in individual health risk to a large population of relatively healthy people can offer greater total health benefits than healthcare interventions that deliver large individual benefits to a small population of relatively unhealthy people. This is known as the 'prevention paradox', a term coined by the epidemiologist Geoffrey Rose.

Two great pioneers of public health in the nineteenth century were Edwin Chadwick and John Snow. In 1843, Chadwick's Report on the Sanitary Condition of the Labouring Population of Great Britain helped catalyze the sanitary movement that substantially contributed to increases in life expectancy across the globe. Snow is widely considered to be the father of modern epidemiology, following his classic 1855 treatise, On the Mode of Communication of Cholera. Among other things, this treatise reports his famous 1848 study that convincingly traces the cause of an outbreak of cholera in London to the Broad Street water pump by collecting data to test rival hypotheses.

In the nineteenth century, the central task of public health intervention has been to prevent communicable or infectious diseases, to which young children are particularly vulnerable. These 'infectious diseases of childhood' are now reasonably well controlled in most parts of the world, but there is still a substantial burden of disease among young children in much of Africa and Asia from cholera and other diarrheal diseases, lower respiratory diseases, meningitis, tetanus, measles, tuberculosis, malaria, HIV/AIDs, leishmaniasis, hepatitis, leprosy, and other infectious diseases (Figure 1).

Infectious agents such as viruses, bacteria, and parasites or fungi can spread directly from person to person, and people can also shed them into the air or water or onto food or other surfaces where other people may come into contact with them. Infectious diseases therefore generate 'technological externalities': one person can change another person's risk of infection through their actions, without bearing any of the costs or gaining any of the benefits of that change. Externalities provide a standard economic rationale for government intervention to prevent infectious disease, for example though investment in sanitation infrastructure or quarantine regulations. Public infrastructure investments to prevent infectious disease – such as building sewers, or draining malaria-infested swamps – can be seen as 'public goods' in the technical economic sense of being nonexcludable and nonrival: no one can be excluded from use, and one person's use does not reduce the good's availability to others. Governments have a role in providing such public goods, because markets have difficulty providing goods that customers can easily consume within paying anything.

Since the nineteenth century, much of the world has undergone a 'demographic transition' from high to low rates of birth and death. This has important implications for public health in the twenty-first century, which is increasingly focusing on the prevention of noncommunicable chronic diseases and disorders to which older people are particularly vulnerable, such as circulatory diseases, cancers, diabetes, neurological disorders, and musculoskeletal disorders. The nature of this prevention task is different, as one of the main ways of preventing (or, at least, delaying) these 'chronic diseases of old age' is to encourage people to adopt healthier lifestyle behaviors in relation to diet, physical activity, smoking, drinking, substance abuse, and musculoskeletal load. Technological externalities are largely irrelevant to lifestyle behavior, insofar as an unhealthy lifestyle only harms the individual's own health – though of course, there are exceptions such as passive smoking and drink driving. So public health interventions to promote healthy lifestyles are not 'public goods' in the technical economic sense. However, there may be other economic justifications for such interventions, as discussed below.

In most countries, public health interventions in each of the policy sectors listed in Box 2 are planned and implemented by at least one and usually many different organizations. It therefore stretches credulity somewhat to talk about a public health 'system,' as if the organizations in these diverse areas of social and economic policy were all exclusively designed for the purpose of working together to improve population health. Nevertheless, most countries do attempt a degree of coordination between public health interventions in different policy sectors, in at least two ways. First, though an officially recognized 'public health profession,' such as the US

Public Health Service Commissioned Corps and the UK Faculty of Public Health, whose members implement many different public health functions and lead some of the relevant public policymaking agencies. Second, through the appointment of senior policymakers and policymaking agencies with responsibility for cross-government coordination of public health policy, such as the Surgeon General and the Centers for Disease Control and Prevention in the US, and the Chief Medical Officer and Public Health England in the UK.

Economic Arguments for Government Intervention in Public Health

One can distinguish five types of normative economic argument for government intervention in public health:

1. Asymmetric information
2. Technological externality and public goods
3. Pecuniary externality
4. Paternalism and bounded rationality
5. Equity

The first two are classic 'market failure' arguments, which show how fully rational and self-interested market participants can fail to achieve a Pareto efficient outcome due to the presence of a single distortion or imperfection in an otherwise perfect market setting. When markets fail in this sense, it may be possible for government intervention to deliver a Pareto improvement that makes at least one person better off without making anyone else worse off – though this possibility may be constrained by sources of government failure, such as asymmetries of information between government officials and market participants, and self-interested behavior by government officials. The third type of argument relies on the welfare economic 'theory of the 2nd best' in the presence of more than one market distortion. The fourth type of argument relies on

individuals being less than fully rational and self-interested. The final type of argument goes beyond market failure in terms of Pareto inefficiency and analyses distributional concerns for equity or justice.

Asymmetric information refers to a situation in which one party to a market transaction has better information than another party. Healthcare markets are pervaded by asymmetries of information – between doctors and patients, insurers and insurees, buyers and sellers of new medical technology, and so on. These asymmetries may help to justify government intervention in both curative and preventive healthcare. Information asymmetries are also relevant outside the healthcare market. For example, sellers may have better information than buyers about the health risks associated with consuming their goods and services; and employers may have better information than employees about the health risks associated with their working conditions. This asymmetry can provide a market failure argument for ex ante safety regulation (e.g., health and safety requirements enforced by licensing and inspection processes, advertising standards, requirements for provision of safety information) and ex post tort law compensation claims for health damages caused by transactions made on the basis of hidden information. Note, however, that it is the asymmetry of information between market participants about health risk that distorts market behavior and generates market failure, rather than the mere presence of health risk or the mere lack of perfect information about the true nature of health risk. For example, asymmetry of information about the health risks of smoking in the 1950s between tobacco company executives and consumers may have generated market failure. By contrast, continuing uncertainty and imperfect information among all market participants about how far smoking will damage any particular individual's health do not generate 'market failure' in the classic economic sense.

In their renowned 1988 textbook on the theory of environmental policy, William Baumol and Wallace Oates define a technological externality as follows: ''An externality is present whenever some individual's (say A's) utility or production relationships include real (that is, nonmonetary) variables, whose values are chosen by others (persons, corporations and governments) without particular attention to the effects on A's welfare.'' This definition clearly applies to infectious disease externality, because individual A's utility depends on the number and type of infective microorganisms present in their living and working environments, which in turn depends on choices made by other persons, corporations, and governments. It also applies to passive smoking, drunk driving, and other cases, in which individual A's risk factors for noncommunicable disease or injury are directly influenced by other people's choices. It is less clear whether it applies to cases in which individual A's health risk factors are indirectly influenced by other people's choices through their influence on individual A's own choices – for example, choices generating congestion and crime in the local area, which influence individual A's choices about physical activity.

As described earlier, an important class of technological externalities in public health are nonexcludable and nonrival public goods such as investment in sanitation infrastructure to prevent the spread of infectious disease. Public investment in basic universal healthcare and education systems in low and middle income countries also has public good characteristics. Almost everyone is better off living in a high income country with a healthy population and a growing economy (even the super-rich). Yet, the market alone may fail to coordinate this large and sustained infrastructure investment, precisely because almost everyone benefits, whether they pay or not. Another important example of a public good is the creation of new information about health risk through research and development (R&D). R&D is a nonrival and nonexcludable good insofar as the new information it generates can subsequently be acquired by potential beneficiaries at very low cost and is hard to keep secret. These 'information externalities' may help to justify R&D subsidy and government regulation of intellectual property rights, such as patent protection and copyright legislation. It is less clear that information externalities help to justify public health information campaigns, however, because the transmission of existing information (as opposed to the generation of new information) often has the characteristics of a private good – for example, leaflets (as opposed to the information they contain) are excludable goods.

A quite different form of externality arises in the case of external costs imposed upon taxpayers due to public expenditure on health and social care. Here, the externality is monetary or 'pecuniary' in nature, and not a real variable entering into utility or production relationships. According to the welfare economic 'theory of the 2nd best', pecuniary externalities can nevertheless cause market failure to achieve a constrained Pareto efficient outcome in economies with multiple market imperfections (such as information asymmetries, taxes, and so on). However, this argument needs to be used with caution, as policy prescriptions from '2nd best' welfare economic analyses are context-dependent and sometimes counter-intuitive, and it is hard to construct realistic models of actual economies with multiple imperfections.

Another note of caution is that pecuniary externalities are ubiquitous, and can be used as a spurious justification by all sorts of interest groups seeking special favors. For example, there is a pecuniary externality argument for subsidizing private schools, on the grounds that sending a child to private school may reduce the cost of operating public schools. A further note of caution is that pecuniary externality arguments for public health intervention can be a double edged sword. For example, preventing smoking may reduce taxpayer expenditure on healthcare for lung cancer but may increase taxpayer expenditure on pensions and long-term care for those who survive longer. Hence, whether the pecuniary externality associated with a particular form of unhealthy behavior is positive or negative is an open empirical question, and will depend on the context. A final note of caution is that the root cause of pecuniary externalities on taxpayers is government intervention – in this case, public programs offering free health and social care. Some economists argue that limiting entitlements to free health and social care may be a more attractive way of reducing pecuniary externalities than introducing new taxes on unhealthy behavior. Whatever the pros and cons of the latter argument, policymakers do need to bear in mind that taxes can have high administrative costs and unintended behavioral effects. For example, the Danish

government introduced a tax on saturated fats in 2011 but rescinded it a year later. According to a newspaper report in The Economist in November 2012, "in practice, the world's first fat tax proved to be a cumbersome chore with undesirable side effects. The tax's advocates wanted to hit things like potato crisps and hot dogs, but it was applied also to high-end fare like speciality cheeses... Besides the bother and cost of installing new systems to calculate the extra tax, retailers were also hit by a surge in cross-border shopping."

The fourth argument – paternalism and bounded rationality – rests on the view that individuals sometimes fail to act in their own best interests, for example, due to weakness of will or limited information-processing ability. There is by now plenty of evidence from behavioral economics and psychology that individual rationality is imperfect in various ways. For example, people's choices are often strongly influenced by nonrational 'cues' in their decision-making environment. In their book, 'Nudge,' Cass Sunstein and Richard Thaler use this kind of evidence as an argument for 'soft' paternalism, which involves altering the nonrational cues in order to gently 'nudge' people toward choices in line with their own best interests as perceived by the paternalistic decisionmaker. However, one can also use evidence of bounded rationality to make a case for 'hard' paternalism involving traditional public health instruments, such as taxes, subsidies, and regulations, which alter the incentives and constraints that people face. In the phrase of Adam Oliver from the London School of Economics, there may be a role for interventions that firmly 'budge' people toward rational ill health prevention behaviors as well as interventions that gently 'nudge' them.

Finally, the fifth argument – equity – relates to concerns about distributional fairness rather than Pareto efficiency. Some economists take the view that distributional concerns are not a proper subject for economic analysis (e.g., the great early twentieth-century economist, Lionel Robbins). However, other economists (e.g., Tony Atkinson and Amartya Sen) adopt a more inclusive 'social choice' approach to normative economics based on explicit analysis of social objectives, which may or may not include Pareto efficiency. Markets may give rise to substantial social inequalities in health and in ill health prevention activities, and social decision-makers may regard the reduction of such inequalities as a policy objective. This is a 'specific egalitarian' objective, rather than the 'general egalitarian' objective of redistributing income. According to classical '1st best' welfare economic theory, redistribution of income is the most efficient way to reduce inequality in the distribution of welfare between individuals, rather than government intervention in specific markets such as the market for ill health prevention services. However, this theoretical result does not carry over into '2nd best' economies with multiple imperfections, and so there is no general economic case against 'specific egalitarian' policy objectives. Nevertheless, there are dangers with making egalitarian objectives overly specific. For example, one would not want to focus exclusively on reducing social inequality in the uptake of bowel cancer screening services without setting this in the context of more important and more general objectives such as reducing social inequality in bowel cancer mortality and life expectancy.

Economic Evaluation in Public Health

The previous section reviewed potential normative economic justifications for government to 'do something' in public health, rather than leave things to the market. However, these theoretical arguments only go part of the way toward justifying particular public health interventions. Government intervention in public health often imposes costs on public budgets, taxpayers and/or businesses, thus requiring an investment of scarce resources, which could be used for other potentially beneficial purposes. To justify this investment, evidence and analysis are needed to show that the particular government intervention under consideration represents good 'value for money' compared with alternative uses of scarce resources. This is what the economic evaluation of public health interventions seeks to establish. Undertaking such economic evaluations – while being time- and resource-intensive activities in themselves – is useful for at least three reasons:

- Improving public policy outcomes: Economic evaluation can help improve outcomes by helping policymakers identify potentially worthwhile and potentially wasteful public health interventions based on the best available international research evidence.
- Improving clarity of thought: Economic evaluation can help public policymakers think through systematically the pros and cons of alternative ways of designing and implementing public health interventions in their own decision-making context.
- Improving public accountability: Economic evaluation can help hold public policymakers to account by identifying and publishing the factual assumptions and social value judgments underpinning their decisions.

The economic way of thinking about the costs and benefits of public health interventions can be contrasted with two commonly held but misguided alternative ways of thinking. In his classic health economic monograph, 'Who Shall Live?,' Victor Fuchs memorably dubbed these the 'romantic' and 'monotechnic' points of view, respectively. The 'romantic' point of view denies that resources are scarce and that resource allocation decisions have opportunity costs in terms of alternative beneficial uses of scarce resources. The 'romantic' believes that resources can be found for their own favoured cause without impinging on other people's favored causes – for example, by making 'efficiency savings,' by diverting resources from disfavored causes (such as defense spending) or by clamping down on the high pay and tax avoidance behavior of the super rich. Fuchs criticizes this viewpoint, writing that: "Because some of the barriers to greater output and want satisfaction are clearly man-made, the romantic is misled into confusing the real world with the Garden of Eden." He goes on: "Confronted with an obvious imbalance between people's desires and the available resources, the romantic-authoritarian response may be to categorize some desires as 'unnecessary' or 'inappropriate', thus protecting the illusion that no scarcity exists." By contrast, the 'monotechnic' point of view fails to recognize the legitimate plurality of individual and social objectives. The 'monotechnic' fixates on a single objective and is unconcerned if allocating additional resources to this objective imposes opportunity costs in terms of other objectives.

According to Fuchs, the 'monotechnic' view is "frequently found among physicians, engineers, and others trained in the application of a particular technology." He goes on to write: "The desire of the engineer to build the best bridge or the physician to practice in the best-equipped hospital is understandable. But to extent that the monotechnic person fails to recognize the claims of competing wants or the divergence of his priorities from those of other people, his advice is likely to be a poor guide to social policy."

Various organizations have adopted a systematic cost-effectiveness approach to evaluating public health interventions, in line with standard health technology assessment methods being used to evaluate clinical healthcare sector interventions. Publicly accessible repositories of this kind of evidence, each of which assesses the cost-effectiveness of a fairly wide range of public health interventions using a common set of methods, include the WHO-CHOICE database, the US Preventive Services Task Force, the UK National Institute for Health and Clinical Excellence public health guidance, and the ACE-Prevention project in Australia.

However, standard cost-effectiveness analyses of this kind are somewhat less useful in public health than in the healthcare sector, for at least four reasons. First, randomized control trial (RCT) data are scarce, so it is hard to attribute effects to interventions, and the exploitation of 'natural experiments' using large observational datasets is still in its infancy in public health. This means that existing repositories of cost-effectiveness evidence in public health are forced to chart a difficult course between the Scylla of 'RCT fetishism' (i.e., focusing unduly on clinically-oriented types of intervention for which RCT data exist) and the Charybdis of 'practitioner bias' (i.e., using overly favorable effect size estimates based on the opinions of a small coterie of policy enthusiasts rather than robust evidence). Second, important costs and benefits often fall outside the healthcare sector – including costs on taxpayers, business and government agencies, and including a variety of nonhealth benefits such as improvements in education, employment, and crime outcomes. This means that cost-effectiveness analyses focusing on health benefits and healthcare sector costs only may not be relevant to the most important decision makers and stakeholders. Third, public health interventions often have explicit policy objectives relating to inequality reduction. Standard cost-effectiveness analysis does not examine the distribution of costs and benefits, and hence cannot offer policymakers any guidance on the existence and nature of potential trade-offs between concerns for efficiency and equality. Finally, some public health interventions have long-term benefits that arise decades in the future – including benefits to future generations. Standard cost-effectiveness analysis does not explicitly distinguish effects on current and future generations, and the standard approach to discounting implies a hefty penalty to health benefits arising many decades in the future – for example, a 5% discount rate implies that a life-year gained in 50 years time is valued at only 7.7% of a life-year gained this year; or 0.6 of 1% in 100 years time.

There are public repositories of cost–benefit analysis evidence of social policies, which take a broader approach and address some (but not all) of these issues – for example, the Washington State Institute of Public Policy. To date, however, cost-benefit analyses of social policies tend to focus on nonhealth benefits; and if health effects are incorporated at all, they tend to be based on mortality and the saving of 'statistical lives' rather than more comprehensive analysis of effects on length of life and health-related quality of life.

As Helen Weatherly and colleagues from the University of York have argued therefore, more research is needed to produce more useful economic evaluations of intersectoral public health policies, including not only the application of existing cost–consequence analysis and cost–benefit analysis approaches, but also methodological research to develop new approaches.

Conclusion

In line with most of the existing economic literature on public health, this article has adopted a standard 'social choice' approach to normative economics, which focuses on providing analysis and evidence that will be useful to a perfectly benevolent social decision-making institution seeking to achieve a set of socially desirable objectives in the face of market failure. However, it is also possible to adopt a 'public choice' approach that treats government institutions as economic agents with nonbenevolent or at least imperfectly benevolent objectives. Economic models of interest group lobbying, rent seeking, and bureaucratic incentives, can all help to understand government behavior in relation to public health, why some public health interventions are more likely to be adopted than others, and why actual decision-making in public health so often departs from policy prescriptions based on standard 'social choice' analyses of the kind described in this overview. For an excellent overview of government failure in public health, and the potential for future research in this hitherto neglected area, see the article in this encyclopedia by Hauck and Smith on 'public choice analysis of public health priority setting'.

Another important frontier in public health research is the role of behavioral economic evidence and insights in helping to design more effective public health interventions. As described earlier, global economic growth means that the task of public health is increasingly shifting away from preventing the 'infectious diseases of childhood' toward preventing the 'chronic diseases of adulthood.' This implies a shift in the nature of the economic problem away from market failures due to infectious disease externality, toward market failures due to bounded rationality that generates unhealthy lifestyle behavior. There is thus an important new role for behavioral economic research into the nature of bounded rationality and the potential role of interventions to improve lifestyle behavior through appropriate 'nudges' and 'budges'.

Finally, a third important frontier for economic research is the economic evaluation of cross-sectoral public health interventions. Compared to the cost-effectiveness analysis of healthcare technologies, the evaluation of public health interventions poses additional – or, rather, more severe – challenges that require the development of new methods. These methodological challenges include (1) estimating health effects when RCT evidence is scarce, (2) measuring and valuing nonhealth benefits alongside health benefits, (3) analyzing costs falling outside the government healthcare budget, (4) analyzing

distributional concerns when reducing inequality is an explicit policy objective, and (5) valuing long-term health and non-health benefits including benefits to future generations.

Quality Assessment in Modeling in Decision Analytic Models for Economic Evaluation

I Shemilt, Campbell and Cochrane Economic Methods Group, and University of Cambridge, Cambridge, UK
E Wilson, Campbell and Cochrane Economic Methods Group, and University of East Anglia Norwich Research Park, Norwich, Norfolk, UK
L Vale, Campbell and Cochrane Economic Methods Group, and Newcastle University, Newcastle upon Tyne, Tyne and Wear, UK

Glossary

Checklists A means of assessing the quality of a study, which incorporates the extent to which existing guidelines are followed, whereby a set of criteria used to assess the quality of a study are listed and possibly prioritized.

Cohort models Are used to estimate expected costs and benefits based on the average experience of a cohort of identical patients.

Decision trees Represent a systematic approach to describe a problem faced by decision making under conditions of uncertainty. They can be used to determine the costs and outcomes for a hypothetical patient cohort with the disease of interest when they are treated with different clinical strategies.

External consistency Requires that the design and structure of the model makes sense to experts in the field and that the results make intuitive sense as well. A further aspect is consistency of the results compared with other 'independent' data.

Grading of recommendations assessment, development, and evaluation An informal collaboration of people with an interest in addressing the shortcomings of quality assessment tools of research in health care. It has developed a tool used to grade both the quality of evidence and the strength of recommendations (see www.gradeworkinggroup.org/).

Individual sampling models Allow the behavior of individuals within a cohort to be tracked separately. Such models are computationally more demanding than cohort models but allow greater variability in cost and effects as an individual's journey through the events in a model is described rather than an average journey. Such models facilitate the modeling of situations where an individual's future costs and effects depend on that individual's history.

Internal consistency Requires that the mathematical logic of the model is consistent with the model specification and that data have been incorporated correctly, i.e., there are no errors in programming.

Markov chains Are used within Markov models to describe how the health states of individuals change over time. Within this article the terms have been used synonymously with the term Markov model.

Markov models Patients with a specific clinical problem can exist in a finite set of health states (that is: alive in perfect health, alive with a deficit in HRQOL, or dead) between which they can move over time. Movement between these health states occurs during a discrete time interval, usually yearly (known as a Markov cycle) based on preset transition probabilities. By attaching resource costs and health outcome consequences to each Markov state (which may vary based on use of an intervention), it is possible to test how such an intervention might influence clinical outcomes and resource use (on average) for a group of patients with a clinical problem.

Model structure Describes the underlying disease process and service pathways under consideration (see also structural uncertainty).

Parameter uncertainty Relates to uncertainty surrounding the value that a probability, a cost or a utility may take. It might be caused by the statistical imprecision (stochastic uncertainty) or from the existence of multiple conflicting sources of data, the internal or external validity of the data. It can be handled within a model by manually varying the parameter of interest in a deterministic analysis or by sampling from an *a priori* defined distribution in probabilistic sensitivity analysis.

Patient-level simulations See individual sampling models.

Structural uncertainty (also called model uncertainty) Includes uncertainty regarding what comparators should be included in the model; whose costs and benefits are important and how uncertainty around both the disease mechanism and pathways of care might impinge on the design of the model. It also covers uncertainty over how long a treatment effect might persist and how it might best be statistically modeled.

Transmission dynamic models Are a class of more sophisticated individual sampling models that do not assume independence between the individuals modeled. Such models can be useful to model infectious disease where the higher risk of infection is a function of prevalence of disease in the population surrounding the individual which may vary over time and, for example, where an increase in infection rate leads to an increase in risks of further infection and reduce the number of people susceptible.

Introduction

Economic modeling techniques are widely used to provide a quantitative framework for economic evaluations that aim to inform policy decisions. Central to the validity of judgments that are based on the results of economic models is an assessment of the quality of the models themselves. Decision makers should have confidence that the quality of the models they are using is sufficiently robust to justify their decisions, and researchers developing models should demonstrate that their work meets acceptable quality standards.

Although assessment of the quality of models can be argued to be important from several different perspectives (in this article the main arguments are summarized), it is also necessary to consider what factors determine the quality of models and how quality might be assessed. To address these issues several approaches are considered. The article considers structure, data, and consistency as suggested by Philips *et al.* (2004).

In general, the quality of models depends on:

- Its fitness for purpose: relevance to the underlying research question;
- The methods by which data inputs to the model are combined (both of which relate to the quality of the model structure);
- The quality of the source studies from which data are taken; and
- The model's internal and external consistency.

The quality of reporting of methods and results of models are also considered. Finally, key implications for both current practice and further research are highlighted.

Factors Determining Model Quality

Fitness for Purpose

Although there is no 'right' answer and analysts have to exercise judgment, it is important that the choices made by the analyst be explained. This includes the choice of the overall modeling approach. Models developed for economic evaluations can be broadly grouped into cohort models (e.g., decision trees and Markov chains) and individual sampling models (also known variously as patient-level simulations) (Briggs *et al.*, 2006).

The choice of appropriate modeling approach depends on the research question posed. For example, with a treatment for an acute condition where the question is whether the intervention is 'effective' or 'not effective' a decision tree model may be sufficient, whereas chronic diseases, especially those characterized by periods of relapse and remission, can be modeled with Markov chains. When individual risks are contingent on previous events or pathways, individual sampling models may be more appropriate. Similarly, the evaluation of vaccination and screening programs for infectious diseases may be most appropriately modeled with more sophisticated individual sampling models ('transmission dynamic models') that take account of the changing risk of infection as the prevalence of disease changes following the introduction of an intervention as the population begins to gain the advantages of herd immunity. The modeling approach and structure must, therefore, reflect the research question, the properties of the evaluated technologies, the characteristics of the disease, and the treatment/intervention setting (Institute for Quality and Efficiency in Health care (IQWiG), 2009).

Structure

What is a 'good' structure? One answer is plausibility: Whether or not the patient pathways and assumptions represented by a model's structure are plausible. All models by definition simplify reality. The task of the analyst is to design one that is sufficiently complex to reflect the nature and subtleties of the pathway being modeled yet simple enough to be (1) efficiently computed; (2) understood by the intended audience; and (3) capable of generating the necessary information for credible and authoritative guidance.

The degree of simplification and compromise is a matter of judgment, and hence there is no unique model structure that could be considered objectively 'correct.' This introduces a type of uncertainty within decision modeling termed structural uncertainty (also called model uncertainty) (Briggs *et al.*, 2012). This is to be distinguished from parameter uncertainty. Aspects of structural uncertainty include the overall modeling approach; choice of comparator(s); scope; duration of treatment effect; the events handled by the model; and any statistical model used to estimate parameters, clinical uncertainty about the mechanism or pathway of care, and the absence of clinical (and other) evidence (Bojke *et al.*, 2006).

The most common approach to handling structural uncertainties like the duration of treatment effect and the scope of the analysis is through the use of scenarios (Bojke *et al.*, 2006). A 'base case' is commonly recommended, with alternative possible scenarios presented for the decision maker to judge the fit with their setting. Investigating the impact of more fundamental structural choices, such as alternative overall designs of the model or selection of different events such as wider or narrower scopes of costs and benefits may sometimes be possible: Alternative models could be constructed and tested to see if they yielded, or were likely to yield, different results. They could also be formally combined using a variant of Bayesian model averaging (Bojke *et al.*, 2006). As there is a very large number of plausible potential model variants, such attempts will always have to be restricted to a reasonable subset of possible models.

Data Inputs to a Model

The quality of data used in model development can impact directly on the reliability of results. One way in which this can occur is through the impact of data quality on a model's parameters. Each probability, cost, and outcome in an economic model is expressed in terms of a set of measurable, quantifiable characteristics, or parameters. In economic models, common types of parameters are probabilities, costs, relative treatment effects, and utilities (Briggs *et al.*, 2006).

Components of data needed to assign values to these parameters are summarized in Box 1 below.

These data are collected or derived from sources that may include empirical research studies, routine administrative databases, reference sources, and expert opinion. In principle, and often in practice, there is more than one potential source for each data component. For this reason, and because the results of economic models may depend in large part on choices between available sources of data, the processes of data identification, appraisal, selection, and use need to be explained and justified.

However, the use of data in model development is not restricted to the assigning of values to parameters. Data are also used to support every stage of model development, from establishing a conceptual understanding of the decision problem as noted above, through to the choice of sensitivity and uncertainty analysis (Briggs *et al.*, 2006; Paisley, 2010). Thus, economic models have multiple information needs, requiring different types of data, drawn from various sources, and the factors that determine data quality encompass all of these uses, types, and sources.

Philips *et al.* (2004) identify four dimensions of quality regarding data: identification, modeling, incorporation, and assessment of uncertainty. Each dimension has a corresponding set of attributes of good practice, or factors that determine quality, and each attribute refers to the quality of processes used in the identification, appraisal, selection, or use of data at the different stages of the model development process.

Data quality is only one of two criteria to be used in identifying and selecting data in economic models. Before quality assessment, the available data also need to be assessed in terms of applicability or relevance. The initial assessment of applicability may result in a large proportion of potential data sources being rejected (Kaltenthaler *et al.*, 2011).

Consistency

Assessing the consistency, or as some agencies have termed it validity (Canadian Agency for Drugs and Technologies in Health, 2006; Institute for Quality and Efficiency in Health care [IQWiG], 2009), of a model is a subject of debate and there is no unanimous agreement among experts (Philips *et al.*, 2004; Institute for Quality and Efficiency in Health care [IQWiG], 2009 and Canadian Agency for Drugs and Technologies in Health, 2006 all offer different views). Regardless of how it is assessed it is useful to briefly consider what is meant by consistency. Philips *et al.* (2004) identified four aspects: internal consistency; external consistency; between model consistency; and predictive validity. Each of these has been briefly summarized.

Internal consistency

Internal consistency requires that the mathematical logic of the model is consistent with the model specification and that data have been incorporated correctly, for example, that there are no errors in programming. One source of inconsistency in model specification relates to the conditioning of an action on an unobservable event. For example, in a model of cancer surveillance, decisions to change treatment may be made as soon as progression or recurrence of the cancer occurs despite the fact that in reality recurrence or progression would not be observed until some monitoring test has been performed.

Internal consistency may also be affected by asymmetries within the model. Such asymmetries may or may not represent errors but probably serve to highlight areas for further investigation. An example is when the physiological response of a patient to a particular event that occurs at several different points within a treatment pathway is modeled differently in corresponding areas of the model. It goes without saying that internal consistency will also be affected by the accuracy of the model programming and data entry. Errors in the model syntax or administrative errors (e.g., in labeling of data) are, at least initially, inevitable in the design and execution of any model. Proof reading and testing element by element are, therefore, a critical part of the design process. Ideally, these tasks would be completed by a researcher who is familiar with the decision question but who was not involved in the design and execution of the model and hence is less subject to bias and to uncritical acceptance of the often implicit assumptions that the original analysts may have made.

Other checks for internal consistency are to test formulae and equations separately before they are entered into the model to ensure that they are correctly expressed and can give the anticipated results. Sensitivity analyses using extreme or zero values can be used to identify apparently counterintuitive results. Likewise, examining the results of known scenarios, even ones that are unlikely or cannot occur in practice, can also be useful to identify counterintuitive results. The presence or absence of counterintuitive results does not necessarily indicate a problem (or lack of one) with internal consistency. However, when counterintuitive results are identified they should be explained, which will involve unpicking and examining the mechanisms that have led to them. A more elaborate test of internal consistency is to attempt to replicate the model in another software package and then comparing the results of both.

Box 1 Components of parameter data (Kaltenthaler *et al.*, 2011; Coyle *et al.*, 2010)

- clinical effect sizes (i.e., relative treatment effects for beneficial and adverse effects)
- disease natural history or epidemiology
- resource use or service utilization
- unit costs
- health state utilities
- survival
- other time to event data
- compliance or participation patterns
- relationships between intermediate and final endpoints

External consistency

External consistency requires that the design and structure of the model makes sense to other experts in the field (a process that can be aided by presenting the model in pictorial form (Canadian Agency for Drugs and Technologies in Health, 2006)) and also that the results make intuitive sense. This is particularly the case where the results of the model run counter to expectations, and there may be temptation to disbelieve them. Given that the model is internally valid, it should then be structured such that a plausible narrative can be extracted explaining the logic of the results and why, if it departs from prior expectations, it does so.

Such face validity is only one aspect of external consistency. A further aspect is consistency of the results compared with other 'independent' data. However, if such independent data exist it would be more appropriate for them to be included in the model in the first place. This issue is not addressed in methods guides produced by some national HTA bodies (e.g., Institute for Quality and Efficiency in Health Care (IQWiG), 2009 and Canadian Agency for Drugs and Technologies in Health, 2006).

Between model consistency

This type of consistency is sometimes also included as an aspect of external consistency. It relates to a comparison of a model's results with those of other models. The models to be compared should be developed independently but, because models might be developed at different times and in subtly different contexts, interpretation should proceed with caution as results may legitimately differ so that similarity of result does not necessarily confer confidence in the robustness or validity of either, nor does dissimilarity necessarily undermine confidence. Furthermore, even where two models are developed for the same purpose and at the same time, convergence of results might not occur because each model is the product of myriad judgments and assumptions, which might differ between research teams. This occurs in the multiple technology appraisals process conducted for National Institute for Health and Clinical Excellence (NICE) in England. Different stakeholders (usually manufacturers) can submit their own models as evidence to NICE. These models may also be used to inform the development of a further model by an independent academic group. The stakeholders will each have access to different data (as commercially sensitive data will not be shared with other manufacturers) with only the independent academic model having access to all data. Taken as a body these models can all be thought of as providing mutual sensitivity analyses enabling one to identify critical assumptions, important parameters, and the sensitive ranges for those parameters.

Predictive validity

A final form of consistency identified by Philips *et al.* (2004) is predictive validity. They noted that some commentators argue that the predictions of a model should be compared with the results of a predictive study. On the contrary, they argue that it is inappropriate to expect a model to predict the future with such accuracy because it can only use the data and understanding that was available at the time it was constructed.

The reason for constructing a model in the first place is the lack of appropriate data from a single source with which to make a decision, so it inevitably represents a synthesis of current knowledge. Once such an appropriate prospective study has been undertaken, it should surely replace the model. However, such a comprehensive single study is most unlikely to exist in practice. Furthermore, the interventions under evaluation may be implemented under different conditions to those assumed in the model because of factors such as technological change. It is notable that consideration of such an element of consistency is not included in some of the more recent methods guides from Health Technology Assessment Agencies (National Institute for Health and Clinical Excellence, 2008; Institute for Quality and Efficiency in Health care (IQWiG), 2009 and Canadian Agency for Drugs and Technologies in Health, 2006).

Assessing the Quality of Models

Structure

Several tools and checklists have been employed to assess the quality of economic evaluations in general, and of decision models in particular. The majority cover different aspects of the structure, data, and consistency of the model. Philips *et al.* (2004) proposed a framework by which models could be assessed. In common with other quality assessment tools, this framework comprises a series of criteria that capture methodological dimensions which analysts could be expected to have addressed in the conduct and reporting of their evaluations. These can be assessed with specific yes/no responses accompanied by supporting commentary. The nine structural dimensions identified by the Philips checklist are summarized in **Box 2**.

A clear statement of the decision problem is essential to define the entire evaluation: A vague question can either lead to a vague answer or one that fails to address precisely the decision problem at hand. Therefore, the objective of the analysis should be stated, along with a statement of who the primary decision maker is.

Philips *et al.* (2004) suggested that the scope (analytic perspective) of a decision model, which crucially affects which costs and outcomes are included in the analysis, should be stated and justified. Many decision-making organizations have adopted specific perspectives for their reference cases.

Box 2 Structural dimensions in the Philips *et al.* Checklist

Statement of the decision problem/objective
Statement of scope/perspective
Rationale for structure
Structural assumptions
Strategies/comparators
Model type
Time horizon
Disease states and pathways
Cycle length

The structure of the model should reflect both the underlying disease process and service pathways under consideration. As noted above, the model type should be 'appropriate' to the decision question. Similarly, the time horizon of a model should be 'appropriate,' i.e., sufficient to capture all important differences in costs and outcomes between the options.

As again noted above, the model should have a degree of face validity in that its structure should make intuitive sense.

In principle, every 'feasible and practical' alternative treatment strategy should be considered rather than only a subset of comparators. This is because cost-effectiveness is always a relative concept (i.e., a treatment is considered cost-effective relative to another treatment). Therefore, exclusion of relevant comparators may lead to erroneous conclusions being drawn about which intervention(s) to invest in or disinvest from. Current practice should be included among comparators.

Finally, as with the choice of model structure, the disease states/pathways included and cycle length in a decision model with discrete time intervals should ideally reflect the underlying biology of a disease as well as the impacts of interventions.

Data

Most published guidelines on assessment of quality of data in economic models focus on the transparency of reporting of methods and results and on the quality of methods to identify data to populate model parameters. They do not assess methodological quality *per se*, nor do they consider the wider uses of data in the model development process (Kaltenthaler *et al.*, 2011). A key reason for the general lack of consensus on standards for quality assessment with respect to data is that the scope of data relevant to an economic model is not entirely predefined, but emerges in the course of the iterative model development process. As such there is no objectively 'right' or 'wrong' set of data for use to inform the model development process, but rather an interpretation of what data is relevant to the decision problem at hand (Kaltenthaler *et al.*, 2011).

The process of identifying data to inform model development is necessarily an iterative, emergent, and nonlinear process rather than a series of discrete information retrieval activities, such that the searches conducted and the sequence in which they are conducted will legitimately differ between models (Kaltenthaler *et al.*, 2011). Although this process can still be systematic and explicit, it is also highly specific to each individual model. Given these issues, recently published guidelines (Kaltenthaler *et al.*, 2011) have recommended approaches to data identification that focus on:

- Maximizing the rate of return of potentially relevant data;
- Judging when to stop searching because 'sufficient' data have been identified, such that further efforts to identify additional relevant data would be unlikely to improve the analysis; and
- Prioritizing key information needs and paying particular attention to identifying data for those parameters to which the results of a model are particularly sensitive. (There is a potential Catch 22 here in that it is unclear *a priori* which data points the model will be sensitive too. In practice, the analyst relies on experience from other similar models, although a modeling solution is possible in that running a model with dummy data can inform this as well.)

Coyle *et al.* (2010) proposed a hierarchy to rank the quality of sources of the different components of data used to populate model parameters. This hierarchy highlights variation between different components of data in which sources may be regarded as 'high quality,' emphasizing sources that in principle generate causal inferences with high internal validity for clinical effect-sizes, and sources that are in principle highly applicable to the specific decision problem at hand for all other components.

Although such hierarchies can, with refinement, offer a useful tool for the quality assessment of data sources, they do not incorporate assessment of specific dimensions of quality, or risk of bias, within each source (Kaltenthaler *et al.*, 2011). Various instruments and checklists have been developed for assessing risk of bias in both randomized controlled trials and nonrandomized studies of effects that may be used to populate parameters in economic models. Perhaps, the most prominent is the Cochrane Risk-of-Bias tool (Higgins *et al.*, 2011). However, these instruments are not equally applicable to all the diverse potential sources of data for model development. The grading of recommendations assessment, development and evaluation (GRADE) system offers more promise in this respect. It provides a consistent framework and a set of criteria for rating the quality of evidence collected (or derived) from all potential sources for all data for populating model parameters. Sources include both research- and nonresearch-based sources (e.g., national disease registers, claims, prescriptions or hospital activity databases, or standard reference sources such as drug formularies or collected volumes of unit costs) (Brunetti *et al.*, 2013). Consistent with the hierarchy proposed by Coyle *et al.* (2010), the GRADE system allows flexibility in the quality assessment process to include additional considerations alongside internal validity. These include, as part of the 'indirectness' criterion in GRADE, the applicability of data components to the specific decision problem at hand.

Reporting Methods and Results

Lack of transparency in the reporting of methods and results of economic evaluations undermines their credibility and, in turn, threatens the appropriate use of evidence for cost-effectiveness in decision-making. The development and use of increasingly sophisticated economic modeling techniques may increase the complexity of economic models at the expense of transparency. It is, therefore, important for analysts to strike an appropriate balance between scientific rigor, complexity, and transparency, to reduce the 'black box' perception of economic models and provide decision-makers with an ability to understand intuitively 'what goes in' and 'what comes out.' This requires analysts to use and record formal, replicable approaches at each stage of the model development process and report these approaches in a transparent and reproducible way (Cooper *et al.*, 2007).

In the quality assessment checklist based on their 2004 review of published good practice guidelines in economic modeling, Phillips *et al.* found that 19 of 42 identified

attributes of good practice and 33 of 57 questions for critical appraisal related to the transparency of reporting and the explicitness of the justification of methods. These attributes and questions are concerned with transparency and justification of choices made at every stage of the model development process. The key principle underlying checklists for economic models is that decision-makers should be able to reach a judgment easily, based on information in the published report alone, on each of the following:

- Whether analysts have invested sufficient effort to identify an acceptable set of data to inform each stage of the model development process;
- That sources of data have not been identified serendipitously, opportunistically, or preferentially; and
- Whether any choices between alternative sources of data, assumptions (in the absence of data), or adaptations or extrapolations of existing data, are explained and justified with respect to the specific decision problem at hand (Kaltenthaler *et al.*, 2011).

Implications for Practice and Research

As economic models are increasingly used to inform policy and practice, concerns about whether or not their quality is 'good enough' for this purpose come to the fore. Assessing quality is important for the credibility of the whole process but it can be time consuming. Sufficient time must be planned for this work to be undertaken. Given the sometimes pressing time restrictions that modelers face, policy makers need to be aware that a full assessment of all aspects of quality may not be possible. Analysts in such circumstances have to be clear about what they have and have not done. They can help ensure that quality has been maximized within the constraints of the research process by referring to existing checklists described above for assessing the quality of models in general or of those designed for specific circumstances and stakeholders. Because no model can be perfect, any limitations should be explored and if they cannot be rectified or improved then the limitation should be highlighted in the study report along with an analysis of its consequences, the direction, and possible size of any bias and some cautions about external validity.

Quality Reporting and Demand

JT Kolstad, University of Pennsylvania, Philadelphia, PA, USA, and National Bureau of Economic Research, Cambridge, MA, USA

Introduction

The defining feature of health care markets and the economics of the health care sector is information structure. Kenneth Arrow, in his seminal paper, demonstrates the role that 'missing markets' for information play in explaining the existence of the features of health care that distinguish it from other industries and markets (Arrow, 1963). Information structure can explain not-for-profit firms, widespread insurance coverage, and the role of physician agents who both proffer advice on treatments and sell those same services, amongst other unique features. The importance of these missing markets become clear if one considers a 'simple' market for health care services. At almost every turn a consumer faces a substantial if not (at least privately) insurmountable level of uncertainty in decision making.

Picking between health insurance plans, in principal, requires a clear sense of the value of a particular plan in the event that a person becomes ill with a specific disease. What hospitals and doctors would be available? At what cost? Even with all of this information in hand the choice of plan requires that each eventuality, and the associated care available, be weighed taking into account the probability that a particular disease occurs. Once equipped with coverage, the individual must then choose a primary care physician. The hope is that this physician will provide preventive care to manage the totality of the patients health, skillfully diagnose the universe of possible ailments and, should the patient require more specialized care, recommend and support the choice of a specialist and the assessment of their treatment plan. A specific physician may differ in skill across each of these margins. As with insurance, the choice is made without knowing precisely which health issues even might occur and, therefore, which skills are most valuable. If the consumer then requires more intensive treatment, they must choose a specialist. To accomplish this they must, under the duress of illness, try to assess the quality of a particular specialist as well the efficacy of a given treatment approach.

This stylized depiction makes clear how health care decisions made by the consumer are potentially rife with information problems. In light of these informational challenges, in health care how do we think about the basic building block of economics: the demand curve? Perhaps more importantly, from an economists perspective, how do we think about welfare and market function in a market where demand is determined in this manner? (Congdon *et al.* (2011) discuss issues of decision making in an environment with informational constraints and decision makers with nonstandard preferences. They demonstrate the importance of these issues with respect to the theory of welfare and social choice as well as their potential role in public policy.)

Moving from theory to practice, information plays a key role in public policy. Many of the policy approaches to address the perceived quality and cost issues in the health care market rely on, either explicitly or implicitly, attempting to address the information asymmetries in the market. The best known and most studied of these efforts are the provision of information directly to consumers. This article focuses on the experience of using direct information provision to overcome market failures in the market for health care services. Specifically, the focus will be on the provision of quality information and its impact on demand.

The author begins by developing a simple, stylized model of supply and demand to demonstrate the role of information in market function in health care. Then some extensions are introduced to allow for insurance and uncertainty. With the simple economics of quality reporting and demand as a framework, the role of quality information and quality reporting in provider choice is then discussed. The choice of primary care physician is distinguished from specialists and hospital choice as they are distinct choice environments, each yielding unique market failures and potential for market based or policy solutions. Rather than review the complete literature on quality reporting and demand for specialists, thefocus is on the experience in the market for coronary artery bypass graft (CABG) surgery. This market is the oldest and most studied of the applications of quality reporting. The main issues and empirical conclusions can be drawn from the experience in this market. Then the experience of quality reporting in the CABG market is compared to similar efforts in education. This comparison demonstrates the similarities between the fields in the information structure, and its associated market failures, as well as the impact of quality reporting.

Quality Information and Quality of Care

Baseline Model

To frame the discussion of quality information and demand, the author begins by developing a stylized model of the market for healthcare services. Demand is determined by a set of consumers who choose healthcare providers based on their utility from a specific provider relative to another as well as the gain from getting care at all relative to foregoing care. These consumers care about the price they pay for care and the quality of care provided. Quality in this context can be multidimensional. Patients care about the clinical quality of care they receive (e.g., lower chance of getting an infection from hospital care or lower probability of mortality from bypass surgery) and how satisfied they are with their experience and nonhealth amenities (e.g., the comfort of their bed, the quality of food, or the cleanliness of the waiting room).

The supply of healthcare services consists of healthcare providers who determine the quality of care provided by making costly investments to enhance care delivery. For simplicity, assume these investments are a continuous, convex cost function, though the basic intuition holds in different contexts. In the standard model healthcare providers care only

 doi:10.1016/B978-0-12-375678-7.00809-9

about the profit they gain – the price per patient times the number of patients less the cost of supplying healthcare at a given quality level.

This stylized model of the doctor, patient relationship is the workhorse of health economics and adheres closely to the conventional market model that economists rely on in most markets. In this setup the quality and price of healthcare are determined where the supply of care equals demand for care. Importantly, for the present purpose, this model also provides insight into the level of quality selected by the doctor. How this level is determined has both normative and positive implications for the function of healthcare markets and the role of quality reporting in demand.

To see this, consider a provider choosing a level of quality. **Figure 1** presents this simple example graphically. In the standard model, the profit maximizing provider chooses his optimal quality based on the marginal cost of increasing quality of the good (i.e., time spent with the patient assessing their ailment or additional surgical nurses to support him during surgery) and marginal revenue from the improved quality. This point is q^* where the baseline marginal revenue curve ($P^*(q)$) equals marginal cost. As long as consumers can ascertain each provider's quality, they choose the provider that provides them the greatest gain in utility – quality less the price of care. The doctors, who observe their own and their competitor's quality as well as the response of the market to quality, then face a simple optimization; the doctors choose a level of quality investment such that the marginal cost of quality improvement is just equal to the marginal revenue associated with that quality improvement – the additional patients scaled by the profitability of those patients.

This baseline model provides clear positive and normative predictions for the quality and cost of healthcare. Because the competitive supply and demand conditions are met both the first and second welfare theorems hold and the quality and cost of care cannot be improved on without making some individuals worse off (Arrow, 1963). That is, the effort to maximize profit would yield productive and allocative efficiency in the market for healthcare services. Doctors would deploy resources to minimize the cost of supplying quality given the input prices to produce quality (e.g., the wages of additional surgical nurses). Furthermore, the level of healthcare quality supplied would reflect societies underlying preferences for healthcare quality, relative to other forms of consumption. (A number of papers have estimated these preferences and suggest a relatively high willingness to pay for health improvements (e.g., Cutler, 2003; Murphy and Topel, 2006). With diminishing marginal returns to consumption, this willingness to pay is also increasing in income (Hall and Jones, 2005). These estimates can explain much of the high spending in many developed countries as well the focus on quality of care and technological improvement. The author returns to this issue in considering whether demand with limited information is lower than what the true demand would be expected to be.) That is, the well documented quality issues in healthcare as well as the high cost and reliance on technologically intensive provision of healthcare, particularly in the USA, would not pose a public policy concern.

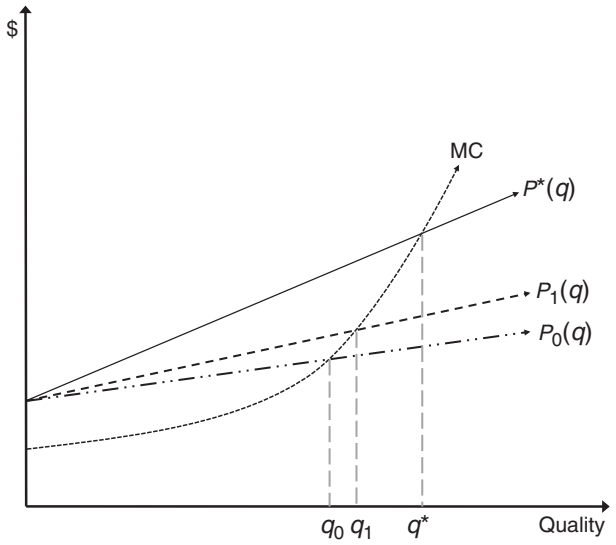

Figure 1 Equilibrium quality with and without quality information.

There are many reasons to doubt the market for healthcare services meets these stringent criteria for market function. One important and pervasive deviation is the presence of adverse selection – another market failure due to information asymmetries. Because consumers differ in profitability (difficulty to treat relative to a fixed payment), even if the respond to quality information providers have an incentive to distort their quality investments to attract relatively more profitable patients. Thus, even with full quality information the equilibrium may not be a first best (Rothschild and Stiglitz, 1976; Glazer and McGuire, 2005). (In practice, enhancing consumer choices can exacerbate adverse selection problems further. Handel (in press) documents this effect empirically in the market for health insurance. Alternatively, appropriately structured information provision can induce first best effort even in the presence of adverse selection (Glazer and McGuire, 2005; Glazer *et al.*, 2008).) Nevertheless, the author starts with this stylized benchmark model because it provides a clear insight into how and why economists and policy makers might expect quality reporting and associated changes in demand to correct market failures in healthcare.

Arguably the single largest violation of the necessary conditions in the benchmark model is the information asymmetry between consumers of healthcare services and producers. In very few cases does an unaided consumer have a good sense of the quality of his or her doctor relative to alternate physicians that might be available or even relative to outside options of a different treatment regime or no treatment at all. Where this is true, a provider who invests in improving the quality of care provided will see few additional patients and, therefore, little additional profit. This is represented by the inverse demand curve ($P_0(q)$) in **Figure 1** that maps quality into a price consumers are willing to pay. $P_0(q)$ is below the full information benchmark curve, $P^*(q)$. Because the provider chooses quality based on trading off the cost of quality improvement compared to the marginal revenue from quality improvement, the equilibrium quality level will be lower than it would otherwise be, q_0 in **Figure 1**. This is not only a positive observation that quality is lower but it also means that the level of quality is suboptimal in a normative

sense. The information problems mean that demand does not reflect the true willingness to pay for quality and therefore the market does not supply the socially optimal level of quality. This can be seen by simply comparing the equilibrium quality under $P^*(q)$ (q^*) to the lower level under $P_0(q)$ (q_0). This basic concern is, either explicitly or more often implicitly, underlying concerns about quality of care provided in most healthcare markets (IOM, 1999).

Quality Reporting to Address the Missing Market for Information

Because asymmetric information is at the heart of the market failure, a natural approach to improving healthcare quality is to try to supply more information to the market actors who are at a relative disadvantage, in this case consumers. Information provision can occur through market-based intermediaries (e.g., consumer reports for consumer products, Yelp for restaurants, or Angies List for skilled professionals including doctors) or as information-based public policy in which government agencies or public–private partnerships gather and disseminate quality information. In both cases, the hope is that consumers will be able to obtain the necessary information to determine the quality of each available healthcare provider and then determine which doctor to choose, given both the cost and the quality of care they will receive. The effect of an intervention of this type can be seen in Figure 1 if the change in marginal revenue from quality after reporting is taken into consideration, represented by $P_1(q)$. Because the information asymmetry has been reduced, it is more profitable to improve quality and the demand curve has rotated upward. As this tracks along the marginal cost of quality improvement a new equilibrium quality level that is higher is reached, q_1. Whether the information is sufficient to overcome the universe of information problems depends on the degree to which $P_1(q)$ moves toward the social optimum, $P^*(q)$. In the example depicted, there remains a large gap both in the incentives ($P_1(q)$ versus $P^*(q)$) and, subsequently, the equilibrium quality, (q_1 vs. q^*).

One appeal of this approach is that changes in quality of care are mediated solely through market incentives, rather than a regulator or payer determining how best to provide high quality healthcare and requiring that physicians practice in a particular manner. Instead, the newly informed consumers will reward the physicians who are best able to provide the quality of care they demand at the minimum cost. (Because demand was relatively unresponsive to quality in the absence of information, such an information intervention is expected to increase the quality of healthcare provided. To the extent that consumers face the true price of care, the improved quality will be unambiguously welfare enhancing.)

Prices and Insurance in Demand

An omnipresent concern in healthcare markets is not merely the information asymmetries in consumer choices but the fact that most consumers seeking care will have access to insurance and, therefore, are unlikely to face the full cost of their care at the margin (Pauly, 1968; Zeckhauser, 1970). The role of moral hazard in demand has important implications for quality reporting for two reasons. First, providing quality information to insured consumers need not enhance welfare even if quality was too low before the information intervention. Because consumers do not face the full cost of their care, they may demand too much quality and this could be exacerbated by the release of quality information. Before quality release the insured consumer was relatively unresponsive to price but could not distinguish high from low quality doctors. Therefore, profit maximizing providers set high prices relative to the cost of their quality, leading to not only inefficiently low quality but excess expenditures given the quality. Once reporting is introduced, the rewards for enhanced quality are greater because higher quality doctors gain more patients. However, because consumers do not face the full price of seeking higher quality care their demand for quality is even greater (they get all of the upside of quality but only pay a fraction of the additional cost). In this case, the introduction of quality information may excessively reward quality improvement relative to the social optimum leading to excessively high investment in quality improvement and, ultimately, quality (Gaynor, 2006; Dranove and Satterthwaite, 2000).

A related issue is the fact that many healthcare providers do not set prices in a standard marketplace. Rather they agree to provide services at an administered set of prices. This is certainly true for doctors and hospitals providing care to patients covered by public programs such as Medicare. Medicare sets prices for hospital services (diagnosis related groups) and physician services (resource based relative value units) based on an estimate for the cost of supplying that particular service. As in any administered price setting, providing appropriate incentives is a challenge (Newhouse, 2002). Because most private payers also base their negotiated price on the Medicare rates these choices not only affect the equilibrium quantity and quality for government paid patients but for the entire market. When prices are more than the marginal cost, the reward for gaining additional patients are large. This leads to the same phenomenon as with moral hazard among consumers. There is a greater reward for additional patients and, therefore, quality improvement. Conversely, when prices are set lower than marginal revenue, administered pricing can lead to inefficiently low quality and reduce incentives for quality improvement associated with shifts in demand. Thus, the introduction of quality reporting in a market with administered prices above cost will yield improve quality of care but may also encourage excess investments beyond the social optimum and vice versa. Clearly there is a relationship here between two policy tools: information provision and the payment rate. If the payer is able to set the appropriate payment such that reimbursement for the marginal patient is just equal to the marginal valuation for quality or care and the marginal cost of quality, the combination of public reporting and payments can provide the first best quality level. (Determining the appropriate marginal patient also poses a challenge. The social planner cares about the average marginal patient but the optimizing provider cares about the marginal patient (Spence, 1980). In this case there can be a further wedge driven between social optimum and competitive equilibrium quality.)

Uncertainty

As with much of healthcare (not to mention other markets), this is easier assumed than done. Distortions to this choice process arise because consumers are typically insured, face uncertain tradeoffs between treatment options and, perhaps most importantly, generally cannot verify the quality of care they received or the quality of different provider options available. Although all of these features contribute to market outcomes in markets for healthcare providers, this article concentrates on the latter: the role of asymmetric quality information and the policy options to address this in determining healthcare quality.

Suppose that consumers (patients) choosing a physician care about three different attributes: price, clinical quality, and amenities. This simplifies the discussion but captures the most salient features of the policy debate regarding cost and quality of healthcare. Dranove and Satterwaite (1992) and Dranove and Satterthwaite (2000) demonstrate the key role that uncertainty plays in determining the level of each attribute and the interaction of consumer preferences and knowledge about each. Although both papers develop technical detail necessary to solve the problem, some simple predictions emerge that motivate this discussion of quality information. If patients are uncertain about two attributes, they will tend to overweigh the observation that is more certain and underweigh the less certain attribute. Translating this into the incentives facing suppliers of care, the relatively observed measure is expected to have excessive investments in improvement and the converse for the relatively harder to observe provider attribute.

This finding is of particular concern in healthcare markets where clinical measure of performance are generally characterized by uncertainty but service amenities are far easier to observe. This is true in the absence of report cards; physicians and hospitals will invest in amenities excessively relatively to efforts to improve clinical quality. For example, hospitals have, for a long time, provided well-appointed entryways and valet parking but their attention to regular hand washing and infection control is a far more recent effort (arguably brought about by Medicare payments not demand changes) (Goldman *et al.*, 2010). It is also relevant in the response to report cards. If quality reporting includes satisfaction or service metrics as well as harder to interpret clinical measures, quality reporting might exacerbate the relative focus on service as opposed to clinical quality.

Evidence on Quality Reporting and Demand

Quality and Demand for Primary Care Physicians

For most patients, their first point of contact with the healthcare system is through their primary care physician. The choice of and role for the primary care doctor distinguishes this choice when quality reporting and demand is considered. Specifically, defining high quality primary care is a challenge and determining what information patients might use to choose a primary care doctor also poses an issue.

Choice of a primary care doctor exhibits the universe of choice problems that characterize demand in healthcare. Quality is highly uncertain and depends on the health of the patient. Jointness in production is also key. A primary care doctor is there to treat conditions but, particularly for patients with chronic conditions, the doctor is likely to suggest complementary behaviors by the patient that are as (if not more) important for improving health. A high quality doctor treating a diabetic patient could screen for the level of sugar in the blood (the HBalC test) but this is not, in and of itself, a treatment for any of the ailments of diabetes. Instead, this measure will allow the physician to adjust medications to manage the disease but also to help council the patients on how they should change their eating habits.

Even when there is a reasonable measure of disease, as in the case of a diabetic patient, defining end points the characterize a high quality primary care doctor is a challenge. Ideally, most patients are healthy and remain so. Attributing the fact that a patient becomes ill to low quality primary care though would not produce the right incentives. Everyone will become ill at one point; death along with taxes are certain in this life. Furthermore, a patient who is identified as becoming ill may have received better care from their primary care doctor because the disease was found.

All of these factors make the introduction of quality report cards for primary care doctors a particular challenge. Instead, most quality reporting efforts in the primary care arena have been focused either on identifying high quality production and documenting such process measures or paying for those measures directly (e.g., pay-for-performance). Some forms of quality information on primary care physicians is becoming widely available through market-based information such as Angie's List. These tools aggregate assessments of physicians quality from customer responses. This form of quality reporting is less studied but presents an important challenge to providing the appropriate social incentives for quality improvement (e.g., whether and how to weigh satisfaction relative to clinical quality depends critically on the form of the production function, consumer tastes and own, and cross quality elasticities with respect to these measures). Recall the results from Dranove and Satterthwaite (2000) discussed above. If people can observe patient satisfaction with relative ease but have a much harder time determining clinical quality or diagnostic ability, these tools may lead to an excess investment in patient satisfaction and an underinvestment in clinical quality. Of course, patients may truly value satisfaction in which case the emphasis on clinical quality could be unfounded. There is, however, ample reason to believe that information problems as well as myriad choice errors documented in behavioral economics are likely to lead to suboptimal choices with respect to clinical quality (Frank, 2004).

Quality Reporting and Specialist Choice

The role of quality information and quality reporting in choice of specialists is the most studied of any of the ways information might impact demand. Specialist choice is also the area in which information-based policy could have the biggest impact on welfare. Specialists perform specific and often measurable tasks. They also encounter patients when

they are sick and receiving the most intensive care; precisely where one might expect quality improvement to enhance outcomes. There is a voluminous empirical literature focused on the response to quality information on specialists. Rather than surveying the literature, a task that has been done in a number of other settings (see, e.g., Kolstad and Chernew, 2008 and Dranove and Jin, 2010 for recent reviews), the focus here is on a specific setting: the introduction of quality report cards in the market for CABG surgery. Though quite specific, the CABG case is the most studied quality reporting initiative. Furthermore, the results, methodologies, and issues are, generally, indicative of the broader findings on the role of quality reporting and demand.

Beginning in 1988, New York State gathered and reported hospital-level risk adjusted mortality rates (RAMR) for CABG surgery. Shortly thereafter, following freedom of information request, surgeon-specific RAMR was reported beginning in 1991. Pennsylvania followed suit shortly thereafter, initially introducing quality report cards in 1993, though report cards were not widely available until 1998 when reports based on 1994–95 data were disseminated. Subsequently, many more states and countries have begun to provide CABG quality report cards. As of 2006, 47 states and the UK all offered CABG report cards (Steinbrook, 2006).

There are two broad veins of literature that provide insight in the CABG surgery experience with quality reporting: survey based and actual choice based. Mukamel and Mushlin (1998) find that both hospitals and doctors with better RAMR saw an increase in market share following the release of quality reporting. Culter *et al.* (2004) also study the New York experience. Their paper extends the basic test for an effect of market share in two important directions. They allow for heterogeneous response to RAMR depending on whether a hospital is above or below expected. They also compare the response of patients who are more likely to be able to switch surgeons, those that are less severe. Their results suggest a significant response to hospitals that are flagged as high mortality (lower quality) than expected. They find a high mortality designation is associated with an average decline of 5 CABG surgeries per month, or approximately 10% of a hospital's volume. Interestingly, they do not find a commensurate increase in demand for hospitals identified as a lower than expect mortality (high quality). The response to quality information is almost entirely driven by changes among patients who are relatively healthy; presumably the patients who have the time and opportunity to choose between hospitals. Dranove and Sfekas (2008) also study the response to the release of quality report cards. Their model makes an important contribution by accounting for prior beliefs of consumers. That is, if consumers or referring physicians already know a hospital is of high quality, one would not expect much effect of releasing information on market share. As in Culter *et al.* (2004), they find that demand responds more strongly to quality information after accounting for prior market-based learning. They also find that there is an asymmetric response with patients more responsive to learning a hospital is of lower than expected quality than to learning a hospital is better than expected. Kolstad (2012) also studies the demand response to quality reporting for CABG surgery, in Pennsylvania in this case. The distinction of this model, with respect to understanding demand, is that it allows for taste heterogeneity among consumers. As with the earlier literature, he finds a significant response to quality after the release of quality report cards. This effect varies significantly in the population with a small share of the population responding very strongly to quality after report cards.

Survey-based evidence also suggests an effect of report cards on demand, though these studies generally find little impact on actual patients with more impact on referring cardiologists. Schneider and Epstein (1996) address this question directly by surveying cardiologists in Pennsylvania. They find that roughly 10% of cardiologists found quality information very important. In New York State, Hannan *et al.* (1996) conducted a similar survey of cardiologists finding a larger response; 38% of cardiologists report that the report card's their referral pattern. A relatively strong responsive of a minority of referring physicians is consistent with the higher-level empirical results that find a similar observed response.

Taken together, these results are indicative of many of the findings in the literature on quality reporting and demand for specialists. First, quality reporting has a small but significant effect on demand. Second, this effect is convex in quality – consumers seem more willing to pay (travel) to avoid low quality specialists than they are to access high quality specialists, even though the change in quality is the same in both cases. Third, there is substantial heterogeneity in the population in whether and how patients respond to the information. A small minority of patients respond strongly by switching hospitals and surgeons but there is relatively little movement by the bulk of the patient population. Fourth, physician agents and/or existing market-based learning means that higher quality providers tend to have greater demand even before the release of report cards. This has the effect both of muting the estimated response to quality information release and suggesting that the institutions of the healthcare market are able to inform consumers somewhat without intervention.

Quality Information and Supply

The focus of this article is on the role of quality information in demand. However, the process of gathering, analyzing, and synthesizing quality information also has the potential to inform suppliers, in this case physicians and hospitals. If these efforts both provide new information and inform suppliers who care about quality beyond the pecuniary rewards, then quality reporting can impact outcomes without shifting demand. How and why this process occurs is a new and relatively unexplored area of research on quality reporting and outcomes. However, Kolstad (2012) demonstrates that, in the market for CABG surgery in Pennsylvania, the impact of information provided to suppliers had an effect on quality improvement that was four times larger than the impact mediated through changes in demand, the type of impact focused on primarily in this discussion. In this model, new information impacts physicians because they care intrinsically about supplying high quality care and quality reporting allows them to better observe their performance relative to their peers. A detailed case study of the impact of New York State's

CABG reporting program also provides anecdotal evidence for a very similar impact. Dziuban *et al.* (2008) document the important role that the release of quality report cards had in motivating efforts to improve the process of care to lower mortality at a large community hospital. Interestingly, they find that the new information led to large changes despite the fact that the hospital had a detailed data capture and outcome review process in place beforehand. This underscores potentially important features that usually characterizes quality reporting: volume and scope of observations and risk adjustment. If quality reporting efforts gather data from across settings (e.g., hospitals or health systems) and develop state-of-the-art risk adjustment models they are likely to provide new information to providers, even if those providers have local monitoring tools in place (e.g., electronic health records or 'morbidity and mortality' conferences to discuss quality and errors). These issues are key to understanding the aggregate role that quality reporting and quality information might play in market outcomes and quality of care. The precise model of beliefs and preferences, however, that leads quality information to affect supplier behavior remains an outstanding question.

Another important supply side response to quality reporting that has been much discussed is the potential for providers to try to select healthier patients to improve their scores. The inclusion of risk-adjustment is intended to address this issue. With sufficiently good risk-adjustment the incentives for selection are eliminated. In practice, however, this is extremely difficult if not impossible. In the absence of perfect risk-adjustment, one must consider the trade-off between selection incentives and the gains in welfare associated with quality improvements due to information. This underscores the fact that the existence of selection against sicker patients does not, in and of itself, eliminate the value of quality reporting efforts. It does, however, raise important welfare trade-offs and require some consideration of the distributional impacts of quality reporting across the spectrum of patients. Despite a great deal of hypothesizing about selection efforts, there are relatively few empirical studies that document selection in response to report cards. The most prominent is work by Dranove *et al.* (2003). They study the impact of New York's and Pennsylvania's introduction of CABG quality reporting in the Medicare population. They find evidence that quality reporting enhanced patient matching to surgeons and hospitals and that there was selection against sicker patients. The aggregate impact of quality reporting was to reduce welfare – the losses from selection outweighed the gains from reduced information asymmetries. This article raises important issues and also presents a useful methodology for evaluating quality reporting efforts.

Quality Reporting and Demand in Other Markets: Comparing Healthcare to Education

Healthcare is one of a number of important fields in which information-based public policy plays a role. It is informative to compare the experience in other markets as a benchmark for understanding the impact of quality reporting on demand. Education provides a useful comparison. There are a number of similarities between choices of healthcare providers and choices of schools that both rationalize the reliance on information-based public policy and make a comparison between the two fruitful. In both cases, information asymmetries are a defining feature of demand. In both cases, consumers are being asked to choose between different suppliers with difficult to verify differences in skills and quality. Outcomes are also characterized by joint production. How much students learn is affected both by teacher effort and student effort. Similarly, the efficacy of many treatments – particularly those for chronic conditions – rely on physician effort as well as patient's willingness to follow advice and change behavior. In both cases, there is also an important component of random noise in outcomes and incentives to teach to the test or select healthy patients. Finally, in both markets the externalities associated with providing the good mean that public provision is preferred and, therefore, most consumers face little, if any, price variation.

So how does the experience with quality reporting in education compare to the CABG market? The main findings appear to be similar, though it is noted this is far from a complete review of the education literature (that would require its own online encyclopedia, let alone section of an article). Hastings and Weinstein (2006) study the response of parents and students to the public provision of information on school quality. They find a significant response to the information on school quality, measured by test scores. After information is released parents are more likely to choose a higher quality school by 5.7 percentage points. They also find that attending a higher quality school improves student test scores. Glazerman (1998) studies school choice and finds that consumers are highly responsive to distance. The effect of quality on choice is diminished substantially as higher quality schools are further away. Hanuscheka *et al.* (2007) study the release of quality information for Texas charter schools. They find that the release of quality information increases the likelihood that low quality schools exit the market significantly.

Although clearly not a comprehensive review, these important papers demonstrate some striking similarities to the role of quality reporting in healthcare markets. First, there appears to be a substantial response to quality reporting, though this effect is relatively small. Consider the main estimate from Hastings and Weinstein (2008). They find that roughly 1 in 20 parents was responsive to quality information. Comparing this to the response in Culter *et al.* (2004) this is a similar magnitude, though smaller, than the response to quality reporting for CABG in New York State. There hospitals saw a decline in volume in the year following a high mortality flag of 10%. Similarly, the findings that distance seems to weigh very strongly in the choice of schools is quite similar to healthcare demand. Both industries are characterized by local markets but it is striking that the healthcare consumers who generally make far fewer trips to a hospital are so responsive to distance. It is less surprising, given the daily trips to school, that distance has an effect. That said, in both cases one would expect the utility for a good outcome (e.g., lower mortality or morbidity and improved lifetime earnings) to be very high so substantial distance effects are surprising and potentially indicative of information problems that limit the response to high quality.

Conclusion

In this article the basic theoretical underpinnings for quality reporting and demand in healthcare markets have been covered. The rationale for quality reporting is based on the potential for asymmetric information on quality that leads to suboptimal outcomes. It has been seen, in a simple framework, how changes in demand due to information provision can change equilibrium quality. Whether these changes improve welfare depends on a number of features of the market. Ultimately, however, the normative standard is the full information demand curve that would exist. The empirical evidence on the impact of quality reporting on demand suggests small average effects with important heterogeneity in the population. Comparing the estimates to the impact of quality reporting in education suggests the impact of quality reporting in cardiac surgery has been larger.

Despite the many simple empirical studies of quality reporting and demand, the application of econometric tools and field experiments to better understand the precise mechanism by which quality reporting improves quality is an important next step for research. For example, incorporating the supply side response into the evaluation of the policy dramatically alters the way in which quality reporting policies should be evaluated as well as the way in which these interventions should be structured (e.g., should information be simplified to target consumers or made more clinically relevant for physicians?). As health reforms in the USA and the inevitable efforts to address cost and quality in all healthcare systems move forward, there is a key role for addressing information failures. Further understanding of the impact of quality information on demand and on market outcomes should be a key item on the research agenda in economics and health services research and an area of focus for policy makers for many years to come.

Quality-Adjusted Life-Years

E Nord, Norwegian Institute of Public Health, Oslo, Norway

Introduction

The quality-adjusted life-year (QALY) is a unit of measurement for valuing health outcomes. The background for it is illustrated in Figure 1.

In the diagram, length of life is expressed on the X-axis, whereas health status is expressed on the Y-axis on a continuum from dead to full health. The lower line shows the health of some hypothetical person over time with standard treatment. The upper line shows the health over time given some alternative better treatment. The total health gain from moving from standard to better treatment – represented by the area between the two lines – consists in gains both in level of health and length of life. The QALY is designed to capture in one single measure of value both these types of benefits so that they are made comparable and also may be added to each other. How this is done technically, is explained in the section Definition, Operationalization, and Meaning.

The value of an outcome measured in QALYs may be related to the cost of achieving the outcome. This is done in a so-called cost-effectiveness ratio (often called a cost-utility ratio). Cost-effectiveness ratios are indicators of value for money. Cost-effectiveness ratios using QALYs allow comparisons of value for money of different interventions in different areas of medicine – in which outcomes of different kinds are achieved – and may thus be an aid in priority setting and resource allocation decisions.

Definition, Operationalization, and Meaning

In the QALY approach, 1 life year in full health for one person is used as a basic, reference outcome. For brevity, this is referred to as '1 well-year.' One gained well-year is assigned a value of one QALY. The idea of the QALY approach is that any health outcome, whatever its nature and size, may be valued relative to the reference outcome, i.e., as equivalent to gaining some fraction of a well-year or some multiple of well-years.

Health outcomes that include gains or losses in quality of life are made comparable to outcomes consisting in gained well-years through the assignment of values to health states (Figure 2). The values on the Y-axis reflect the quality of life associated with the states – often called health-related quality of life. The values are on a scale from zero – corresponding to being dead or in a state as bad as being dead – to unity – corresponding to being in full health. They are used to weight life years in less than full health. For example, in Figure 2, state A is assigned a value of 0.8. Each gained life year in state A then yields 0.8 QALYs. This means that the gain is deemed equivalent to gaining 0.8 of a well-year.

The number of QALYs in an individual's health scenario over time is calculated by determining the value of each year in the scenario and summing these annual values over the whole time horizon. For example, if a person lives 3 years with values 0.8, 0.6, and 0.5 respectively, the value of the whole scenario is $0.8+0.6+0.5=1.9$ QALYs. In Figure 2, 10 years gained in state B yields 6 QALYs (10×0.6), whereas 12 years in state A yields 9.6 QALYs. An improvement from state B to state A lasting 1 year yields 0.2 QALYs ($0.8-0.6$). If the improvement lasts 10 years, it yields 2 QALYs (10×0.2) and is thus equivalent to 2 gained well-years. In Figure 2, the total value of replacing the first scenario with the second one is $10\times0.2+2\times0.8=3.6$ QALYs.

Values and equivalence of health outcomes may be perceived and judged from different points of view. There is, for instance, a difference between pure self interest of individuals

and judgments of value by societal decision makers when concerns for distributive fairness are taken into account. Estimates of value in terms of QALYs are usually meant to express the personal value of outcomes to the recipients of the outcomes, without regard to distributive issues. Such personal value is commonly referred to as individual utility. An approach to valuing health outcomes from a broader societal perspective was outlined by Anthony Culyer and colleagues as early as in 1971 and later by for instance Erik Nord in 1992 and 1999.

To calculate the area under each curve in Figure 1 requires knowledge of the nature of the health states that are experienced, the sequence of these, the duration of each health state and the value of each health state. The former three kinds of knowledge require medical (clinical and/or epidemiological) data. Valuations of health states, on the other hand, is a psychometric task in which health economists have engaged heavily (together with researchers from other disciplines) with a view to making the QALY approach workable. Valuations are generally elicited from samples of the general population by means of one or more specially designed techniques for preference measurement, thereafter values are assigned based on mean or median responses.

Issues

As noted above, estimates of value in terms of QALYs are usually meant to express personal value. Personal value is commonly referred to as individual utility. There are a number of methodological issues relating to the QALY approach as a way of estimating the individual utility of interventions.

First, health state utilities are usually obtained by asking representative samples of the general population to judge how bad it would be for them to be in different states of illness. This is referred to as decision utility. An alternative is to ask patients and disabled people to value the states they are in themselves. This would yield experience utility. Both approaches have strengths and weaknesses. As noted by Drummond *et al.* (2009), a widely held position in current health economics is that QALYs should be based on decision utilities elicited from people who are well informed about experience utility.

Second, for QALY-calculations to be meaningful and valid, utilities for health states need to have interval scale properties. That is, a change of a given size on the 0–1 value scale must have the same importance wherever it occurs on the scale. For instance, a move from 0.4 to 0.6 must have the same value as a move from 0.7 to 0.9. Techniques for preference elicitation vary with respect to their ability to yield utilities with interval scale properties.

Third, as noted above, the number of QALYs in a health scenario over time is calculated by determining the utility of each year in the scenario and summing these annual utilities over the whole time horizon. This means that the number of QALYs obtained from spending time in some fixed state is directly proportional to the length of that time. In other words, as noted by Bleichrodt *et al.* (1997) in a paper on 'risk neutrality of life years,' utility measured in terms of QALYs is (by definition) a linear function of length of time. In the real world, there is not necessarily a linear relationship between duration and utility. Individuals may, for instance, have diminishing marginal utility of length of life in the same way as they normally have diminishing marginal utility of goods and services. However, it is customary to discount QALYs in future years to take account of individuals' preferences for present consumption over future consumption. The number of discounted QALYs is less than proportional to the length of time in a state.

Fourth, in the QALY approach, each possible health state is associated with a single, fixed value. The value of a state is thus assumed to be constant across all individuals and contexts in which it may occur. Clearly, this single value convention is a simplification. Its rationale is a need to prevent valuation in terms of QALYs from becoming too demanding with respect to data and thus too complicated and time consuming.

The convention is reasonable in many circumstances where QALYs are estimated in groups of people, in which cases individual deviations from standard health state values to a large extent cancel each other out. But the simplification does have some implausible implications that lead to continuous debates about the validity of QALYs. The most salient issues are noted below. Note that they all refer to valuations from a personal perspective. Some similar issues may be raised on grounds of concerns for fairness.

First, the single value convention means that the disutility of a state is considered to be independent of the gender, age, and other characteristics of the person who experiences the state, including the person's attainable level of functioning. For instance, it means that dependence on eyeglasses or a walking stick is counted as equally bad for an elderly person as for an young person. It also means that inability to walk is counted as equally bad when it is occurs in a person with a longstanding incurable disability as when it is due to temporary, curable disease in a person who is normally in full health. These implications have been challenged on the grounds that most people have considerable capacity to adapt to and cope with durable disease and disability. This is particularly true of impairments resulting from normal ageing. So even if a person has health problems that people of medium age and normal health would regard as clearly undesirable, and if the person's functional level is the best that he or she can reasonably hope for, his or her utility will not necessarily be much lower than that normally associated with full health. As noted by Erik Nord, Anja Enge, and Veronika Gundersen in 2012, this dependence of utility on what is to be expected and what one is used to may have important implications for valuations of gains in both length and quality of life in people with disability or chronic disease.

Second, the single value convention implies that the utility of a state to a person is considered to be independent of the person's health in the past. For instance, if two people are dependent on eyeglasses, and one was blind in the preceding years, whereas the other had normal sight, the two will be assigned the same utility in their situation with eyeglasses. Concerns about this assumption led to a proposal by Mehrez and Gafni (1989) of an alternative to the QALY approach in which any scenario over time is valued as a whole instead of as a sum of independent valuations year by year. In the alternative approach, the unit of measurement is called the healthy year equivalent (HYE). The disadvantage of this approach is that valuation must be undertaken on all relevant sequences of health states, which may be numerous. Thus, there has been little use of the HYE approach in economic evaluation hitherto.

Third, the single value convention means that the value assigned to a health state does not depend on the duration over which the state is experienced. For instance, the utility of a state in the first year after the onset of a disability is the same as the utility of that state 5 years later even if the person in various ways may adapt to the state. At a more technical level, independence of duration further means that there are implicit assumptions of so-called mutual utility independence and constant proportional trade-off between quality of life and length of life when preferences for health states are elicited.

Fourth, the single value convention means that the utility of a state is considered to be independent of its cause. For instance, the utility is the same for a congenital problem as for a problem caused by hospital negligence.

The concept of QALYs has been linked explicitly to expected utility theory. In a decision analytic framework, QALYs are used as the unit of account in expected value calculations for decisions under uncertainty. Expected utility theory dictates that in order for these expected value calculations to be consistent with preferences over uncertain streams of health outcomes, QALYs should fulfill certain requirements of 'utility' functions. These requirements take the form of a set of axioms, formalized by von Neumann and Morgenstern in 1944. Although much has been written about empirical violations of the axioms of expected utility theory and various alternatives have been proposed, expected utility remains an important point of reference in many discussions of normative decision theory.

Several techniques are available for eliciting health state utilities from respondents, including the standard gamble, time trade-off, and the rating scale. Empirical studies have found that the different techniques produce values that differ systematically. Debates about the relative merits of the different methods refer both to economic theory and to comparisons of psychometric properties of the different measurement techniques.

It is clear from the points made above that the interpretation of health state values as estimates of individual utility in many ways is questionable. It is furthermore a fact that the second factor in QALY-calculations – the duration of health benefits – is purely a quantitative factor with no personal value judgments related to it. For instance, 10 years is simply counted as twice as much as 5 years, with no value judgment involved. Altogether, some therefore prefer to regard the results of QALY-calculations as indicators of the size of health effects rather than the utility – or personal value – of those effects. This alternative interpretation does not, however, alter the basic purpose of QALYs, which is to yield a quantitative estimate of efficiency in different areas of health care.

The QALY approach has been criticized on ethical grounds for implying priority to those individuals who have the greatest capacity to benefit from health care and for not taking into account concerns for fairness in the distribution of health care resources. Historically, the critique is understandable, given the primacy that cost-effectiveness ratios have been assigned in most of the health economics literature as guidance to priority setting. But a distinction needs to be made between calculations of QALYs and how the calculations are used in decision making. QALY estimates are essentially estimates of the aggregate individual utility of interventions. Although such information may be an important input in decision making about resource allocation, it does not follow that priorities should be set such that QALY gains are maximized as this may run counter to concerns for fairness such as wishes to give priority to the worse off and wishes to secure equal access to people in equal degree of need even if they are of different ages and/or have different potentials for health.

Historical Overview

(Reproduced from the Encyclopedia of Public Health with the permission of the publisher (Elsevier) and the author, Josh Salomon.)

Although the term QALY first appeared in the published literature in 1976, some earlier precedents may be found. Herbert Klarman and colleagues in 1968 compared three options for treating patients with chronic renal disease in terms of life years gained, with and without adjustments for 'differential(s) in the quality of life.' In 1970, Sol Fanshel and James Bush proposed measures of dysfunction-free years in evaluation of a tuberculin skin testing program. In 1971, Anthony Culyer and colleagues proposed a scheme for weighting life years within a social indicator framework. At the same time, George Torrance and colleagues introduced the index day and health day. Finally, the term quality-adjusted life-year was used in two separate publications in 1976, one by Milton Weinstein and William Stason examining policies for control of hypertension and another by Richard Zeckhauser and Donald Shepard in a more general exploration of analytic approaches to evaluating social policies with life-saving or health implications. An article by Weinstein and Stason appearing in the *New England Journal of Medicine* in the following year introduced QALYs to a broad medical and public health audience and is frequently cited as a major milestone in the development of cost-effectiveness analysis in health and medicine. In England, a highly influential early paper applying QALYs to evaluation of coronary artery bypass grafting was reported in an article by Williams (1985) in the *British Medical Journal*.

Researchers have developed a registry of cost-effectiveness studies that report outcomes specifically in terms of costs per QALY. Peter Neumann and colleagues reviewed the literature from 1976 through 2001 and identified 533 original studies meeting their inclusion criteria. Consistent with the earlier reviews of the broader cost-effectiveness literature, a major increase in the volume of studies on costs per QALY was evident, with 228 studies over the two decades from 1976 to 1997, followed by 305 studies over the 4-year period from 1998 through 2001.

Alternatives to QALYs

The disability adjusted life year (DALY) is a summary measure much like the QALY, developed by Christopher Murray and colleagues. The main difference is that it uses a scale of severity of illness from zero (full health) to unity (as bad as being dead) instead of a scale of utility from zero (dead) to unity (full health). The DALY was first developed for the primary purpose of quantifying the global burden of disease. However, the developers of the DALY explicitly intended that the measure could be used also as a metric for health benefits in the denominator of cost-effectiveness ratios. In the present day, the DALY is widely used – in fact much more than QALYs – in economic evaluation of health programs in developing countries.

The QALY procedure focuses on life years and the quality of these. In a paper in the *British Medical Journal* in 1992, Erik Nord argued that the health care system is concerned with providing care for people ('living, breathing, feeling, and thinking individuals'), not with maximizing numbers of abstract time entities. The health care system is also concerned with meeting moral claims on treatment. The concept of claims is related to living subjects. Life years as such are not subjects and therefore do not have moral claims. Nord thus suggested the saved young life equivalent (SAVE) as an alternative to the QALY that focuses on persons rather than years. In the SAVE approach, the reference outcome consists in saving the life of a young person and restoring him or her to full health. The value assigned by society to this reference outcome is called a SAVE. In valuations that have a societal rather than an individual viewpoint, different kinds of health outcomes may all be valued relative to the SAVE, for instance using the so-called person trade-off technique. However, there has been little use of the SAVE in economic evaluation hitherto.

Rationing of Demand

L Siciliani, University of York, York, UK, and Centre for Economic Policy Research, London, UK

Glossary

Asymmetry of information A situation in which the parties in a transaction have different amounts or kinds of information as when, for example, physicians have a greater knowledge than patients of the likely effectiveness of drugs while the patients have greater knowledge of the likely impact of drugs on their family circumstances, or people seeking insurance have more reliable expectations of their risk exposure than insurance companies.

Copayment An arrangement whereby an insured person pays a particular percentage of any bills received for health services, with the insurer paying the remainder.

Creaming A form of favorable selection in health insurance by which the insurer obtains a higher proportion of good risks (people with a low probability of needing care or who are likely to need only low-cost care or both) in their portfolio of clients than is assumed in the calculation of the insurance premiums. It is also called cherry-picking.

Diagnosis-related group (DRG) Diagnoses grouped according to their clinical similarity and the cost of treatment.

Elasticity of demand A measure of the responsiveness of the consumption of a good or service to a change in its price.

Fee-for-service A method of remunerating professionals (especially medical doctors) according to an agreed fee schedule specifying what is payable for each item of service supplied.

Marginal cost The additional cost incurred if the output rate is increased by a small amount.

Moral hazard A risk that can occur when the insurer has imperfect information on the likely behavior of insured individuals. There are two main types. Ex ante moral hazard refers to the effect that being insured has on safety behavior, generally increasing the probability of the event insured against occurring. Ex post moral refers to the possibility that insured individuals will behave in such a way after an insured event has occurred that will increase the claim cost to insurers, partly because the user-price of care is lower through insurance and demand may therefore rise. It is also often related to insurance fraud.

Oregon experiment In 1989 the US state of Oregon initiated a controversial reform of its Medicaid program by simultaneously increasing the number of people it covered but reducing the number of services that were insured. The services included were to be based on an explicitly prioritized list after extensive consultation with the public. A second experiment occurred in 2008 when 10 000 Oregon residents were randomly drawn from the non-Medicaid population to join the scheme. This presented an opportunity for exposing the benefits for these poor residents of membership. While the results did not show health improvements, they did show an increased use of preventive care, increased outpatient visits and increased utilization of health services. A third Oregon Medicaid experiment is still (2013) under way: A reorganization that integrates community services and clinical health care through 'Coordinated Care Organizations', which seek to address the underlying determinants of ill-health in the community.

Prospective payment A method of reimbursing health service providers (especially hospitals) by establishing rates of payment in advance, which are paid regardless of the costs in actual individual cases.

Skimping It refers to providing less intensive or lower-quality care than that specified in some standard or protocol in order to reduce costs in relation to the reimbursement due to the provider.

Introduction

In the presence of health insurance and limited capacity, an excess demand for services remains a permanent feature of several publicly funded health systems. The demand for health care needs therefore to be rationed in one way or another. This article describes three different common types of demand rationing. It distinguishes between (1) direct rationing, (2) rationing by waiting time and quality, and (3) price rationing.

Direct rationing refers to allocation mechanisms which explicitly rule out the provision of certain types of care to patients within the public sector (either by the rules set by the public insurer and/or because the doctor explicitly tells the patient when they demand care).

Rationing by waiting or by quality refers to allocation mechanisms which are implicit: the patient is not explicitly refused care. It is instead the presence of waiting times or low quality of care (either clinical or nonclinical), which induces some patients not to seek care from the public sector and either to opt for no care or care delivered in the private sector.

Finally, the article discusses price rationing, which in publicly-funded health systems takes the form of copayments or coinsurance rates for specific types of care. The article discusses each of these three types of rationing in turn. Although each is discussed in isolation, in practice these coexist in many health systems. The focus is on publicly funded health systems. Demand rationing within private health insurance markets is not discussed.

Direct Rationing

In the presence of complete coverage under public health insurance, patients could potentially demand treatment up to the point where the marginal benefit is zero. In a system with no capacity constraints, this would induce excessive consumption, the well-known issue of 'ex-post moral hazard.' However, most countries do limit the supply of care to a level below the one required to satisfy all potential demand, which results in an excess demand. The demand for health care has to be rationed in one way or another.

The capacity constraint is set by policymakers who decide on the number of hospital beds and doctors working in the health sector. The supply of health care can vary significantly across countries (and even within countries) and so does the size of the excess demand. Lower supply levels will require more demand rationing. Organization for Economic Co-Operation and Development countries vary significantly in their health expenditure per capita, with National Health Service (NHS)-type systems spending less than public insurance ones. Rationing is therefore more prominent in NHS-type systems.

From an efficiency point of view, in the presence of a capacity constraint, a natural way to manage the excess demand is to allocate care according to the highest benefit–cost ratio. Policymakers could rank all possible health treatments by their benefit–cost ratio and assign care to patients in descending order until the capacity is exhausted. To some extent this is in line with how governments operate. Treatments that are perceived or shown to have low benefit–cost ratio are not available within the public-insurance package. This is the case for some type of dental and ophthalmological care, plastic surgery, physiotherapy, or alternative medicine. However, listing all possible treatments to which patients are entitled and to compare them on the basis of benefit–cost ratios would be very costly. Public agencies (like National Institute for Health and Care Excellence) do increasingly encourage an evidence-based approach to resource allocation (Drummond *et al.*, 2005), but these still cover only a selection of treatments. One attempt to rank all possible treatments on the basis of cost-effectiveness criteria is the Oregon Experiment, which shows how drawing such comprehensive lists may generate surprising and counterintuitive results (Tengs, 1996).

Moreover, even if policymakers can exclude certain treatments (rationing 'across' treatments), it is optimal for governments to pursue rationing also 'within' a given treatment. Consider, for example, all patients who could benefit from hip replacement. For some patients costs will exceed benefits: these patients should therefore be optimally rationed. Governments could provide a detailed description for each treatment of the criteria to be used by the provider to ration care. These could be based on severity, patients' characteristics, pain, and overall health status. Providing such detailed descriptions for each treatment would again be very costly. Although governments do provide guidelines for some treatments, these are unlikely to be comprehensive.

The difficulty for governments in designing detailed rationing rules both 'across' and 'within' treatments suggests that doctors will play a critical role not only in providing health care but also in rationing care to patients. It is they who ultimately decide who should receive treatment. The rationing function is indeed (implicitly or explicitly) delegated to doctors in most countries. Doctors therefore act as agents on behalf of governments in implementing optimal rationing rules (McGuire, 2000). Governments can (and indeed do) outline the basic principles to health care entitlement and let doctors implement them. Below, such basic principles are first discussed and, then, the conditions under which doctors act as (im)perfect agents and how different incentive schemes may affect rationing.

Policymakers in several countries often state the general principle that access to care in publicly funded systems should based on need. The word 'need' can be subject to different interpretations. Need could refer to current health status of the patient, expected benefit from treatment, or patient's severity (Wagstaff and van Dooerslaer, 2000). For some types of care, these criteria go hand in hand if patients with worst health (higher severity) also have high expected benefits. But this may not be case for other types of care where patients with worst health (higher severity) have low expected benefits (as for some types of cancer care). In the first instance, it is high-severity/benefit patients who are likely to get the treatment. In the second one, a tension between equity and efficiency arises (Hauck *et al.*, 2002). On efficiency grounds (health maximization), patients with higher benefit should receive the treatment. On equity grounds, the priority may be reversed and patients with higher severity (and worst health) should receive the treatment. It is also worth emphasizing that the principle that access should be based on need offers little guidance on how costs should be taken into account. If patients with higher need are very costly, it does not necessarily follow that those patients should receive the treatment. In summary, general principles are useful but they are open to different interpretations by providers. A large body of the empirical literature suggests that the amount of care offered can differ to a great extent among doctors (Phelps, 2000).

Even if clear allocation rules could be established by policymakers, doctors would have an incentive to implement them only if they act as perfect agents on behalf of the government. Doctors' behavior may be affected by their own preferences and the way they are paid. For example, salaried hospital doctors may put considerable weight on a patient's benefit as opposed to costs. In terms of hospital payment, fixed budgets give strongest incentive to ration because extra patients do not generate additional revenues. Prospective payment systems of the diagnosis-related groups (DRG) type give weaker incentives to ration because additional patients increase revenues. Providers however may still have an incentive to ration high-cost and unprofitable patients (Ellis, 1998). Generous fee-for-service (FFS) systems or cost-reimbursement rules give weakest incentive to ration patients. The incentive to ration depends also critically on the degree of altruism of the doctors, highly altruistic doctors being more reluctant to ration patients. Altruism, therefore, plays a critical role in determining the design of incentive schemes (Ellis and McGuire, 1986; Chalkley and Malcomson, 1998): higher altruism typically requires lower powered incentive schemes because highly altruistic doctors paid with FFS arrangements are unlikely to exert much rationing.

In summary, direct rationing (explicit refusal of treatment to a patient) is a pervasive feature of many health systems.

Rationing occurs both 'within' and 'across' treatments. Some rationing is implemented through government allocation rules, which define the 'package' covered by the public sector. However, most rationing is exerted by the doctors and will be based on their preferences and their payment schemes.

A key issue in devolving the rationing role to doctors, is that 'turning patients down' can be an unpleasant activity. Without clear rules, doctors may feel reluctant to refuse treatment to patients with positive benefits. This will be exacerbated when the capacity constraint is tighter. Moreover, it is the doctors who will need to explain to patients why they are not offered treatment. They may also be liable for taking an unfair or unjust decision, and they may be at risk of breaking laws, which prohibit discrimination among patients.

If doctors are reluctant to explicitly ration patients, they may instead add the patients to a waiting list so that patients will have to wait before they receive treatment. This will generate a different type of rationing, which is described in Rationing by Waiting Times and Quality.

Rationing by Waiting Times and Quality

If direct rationing is difficult to implement, other forms of rationing are needed to allocate the limited capacity. If doctors simply refer for treatment all patients who could benefit (because they are reluctant to turn down patients with low benefit), a waiting list of patients authorized to receive care is likely to build up. If capacity is well below demand, patients' wait could be long. Demand may exceed capacity in every period, implying that in the absence of some way of limiting waiting lists, the length of the list could grow indefinitely. Waiting times may have a rationing effect if they dissuade some patients to seek treatment. Instead of waiting, the patient may opt for the private sector. Longer wait times will discourage more patients. Another possibility is that while waiting the patient may become unfit for surgery or recover. The empirical evidence from the UK suggests that waiting times do act as a rationing device to equilibrate demand and supply. Most empirical studies find that demand for care is inelastic, and that the elasticity is approximately -0.1: a 10% increase in waiting times reduces demand by only 1% (Martin and Smith, 2003; Iversen and Siciliani, 2011 for a review). The result that demand is inelastic implies that waiting times exert only a moderate rationing effect and that low levels of supply will translate into long waiting times.

Although waiting times eliminate the need for doctors to explicitly refuse treatment to patients, rationing by waiting times can be an inefficient form of rationing compared to direct rationing. Long waiting times impose a cost on patients, which is not necessarily recovered by anyone else (Gravelle and Siciliani, 2008). Some (short) waiting times may generate efficiency savings if they reduce the chance of idle capacity (i.e., the probability that supply is not used; Iversen, 1997). However, these efficiencies are fully exploited with short average wait times (Siciliani *et al.*, 2009). Waiting times are in the order of months for many procedures, well beyond those required for such efficiency savings to arise.

To mitigate the cost for the patients generated by waiting, several health systems prioritize patients on the list so that more severe patients wait less than less severe one. This is often done informally by doctors. Some governments have further reinforced this idea by developing policies (mostly in the form of guidelines), which encourage doctors to prioritize patients through the use of formal scoring systems (patients who score higher points in terms of severity, pain, and need wait less).

Other governments have discouraged the use of waiting time rationing through the development of targets or maximum waiting time guarantees, which introduce penalties for hospitals having many patients waiting for a long time. These policies may encourage increases in productivity but may also induce a switch from waiting time rationing to direct rationing.

Waiting times are not the only factor which induces patients to opt for the private sector. Other factors, like amenities and quality of care, also contribute to the choice between the public and the private sector. Besley and Coate (1991) provide a theory that suggests that a government (which has constraints on distributional tools) may find it optimal to distort quality downward to encourage the richer subset of the population to opt for the private sector. The shift of the rich to the public sector helps to bring the demand in the public sector in equilibrium with the limited supply as well as to redistribute income. This theory seems consistent with casual observation that public hospitals offer lower amenities compared to private one (patients may need to share rooms, have less privacy, and overall less comfort). This is not necessarily the case for clinical quality: whether it is higher or lower in public hospitals is less straightforward. On one hand, improving clinical quality is at the core of policy efforts in many publicly funded systems. On the other hand, public hospitals do face large demands, which induce hospitals to keep length of stay to a minimum, a dimension of lower quality (Barros and Siciliani, 2011).

As for direct (explicit) rationing, also under nonprice (waiting time and quality) rationing, the payment rule for providers may affect the incentive to vary quality and waiting times. For example, a DRG-type hospital payment system may induce creaming or skimping, i.e., the incentive to raise quality for profitable patients and reduce quality for unprofitable ones (Ellis, 1998). DRG systems also induce providers to treat additional patients, which should translate into lower waiting times.

In summary, rationing by waiting and quality is also a pervasive feature of many publicly funded health systems. Compared to direct rationing, these are (to some degree) inefficient because for a given capacity they reduce patients' welfare. However, they release doctors from the responsibility of directly rationing patients.

Price Rationing

Demand for health care can also be rationed through prices. In many publicly funded systems, this takes usually the form of a copayment or a coinsurance rate: the patient is asked to pay a fee or a proportion of the medical expenses. The idea is to make the patient cost conscious, who in turn demand less health care and in this way contain moral hazard (excessive consumption).

Countries vary in the use and design of copayments with some countries making more use than others. With few exceptions copayments remain low in publicly funded systems. Large increase in copayments would also imply a significant reduction in the benefit from being insured against the cost of illness. According to theory, the optimal copayment should be designed such that it efficiently trades off the risk spreading benefits of a lower price against the ex-post efficiency benefits of a higher price (closer to marginal cost; Zeckhauser, 1970). The theory implies that the optimal copayment is positively related to the elasticity of demand: copayments should be higher when the elasticity is higher. Copayments are indeed observed for dental care, ophthalmology care, and drugs where the elasticity is arguably larger. They are more rarely observed for inpatient or surgical care, which is free of charge in most (though not all) countries, due plausibly to its more inelastic demand.

Several empirical studies have estimated the elasticity of demand. Early studies found a wide range of elasticities' estimates, which could vary between -0.1 and -2.1 (Cutler and Zeckhauser, 2000). These estimates are potentially affected by selection bias if sicker individuals choose insurance plans with lower copayments and also demand more care. The Rand experiment eliminates such potential bias by randomizing individuals in different plans (Manning, *et al.*, 1987). It suggests that demand is inelastic with an overall elasticity of approximately -0.1 or -0.2. The article by Sinaiko (2012) updates this literature.

The idea that copayments make patients cost conscious relies on the belief that patients are able to influence the choice on the care. Given the asymmetry of information, which characterizes the patient–doctor relationship, the choice of care is (to say the least) mediated through the doctor. Copayments may have little impact on demand of care if doctors base their recommendation only on medical ground and ignore the financial implications for the patient. Copayments will instead play a role only if patients are well informed (which may be the case for some conditions) or if doctors internalize patients' disutility from higher prices. Behavior of the doctors will also be influenced by their financial incentives.

Both waiting times and copayments ration demand. Compared to rationing by waiting, copayments have the advantage that the cost imposed on the patient is recovered by the provider or the insurer in the form of additional revenues. Furthermore, if consumers accurately appreciate the value of health care, a price rations out low-value uses. However, copayments raise equity issues (if they are not income tested) if poor patients are deterred from demanding care compared to richer patients, a criticism that is often raised against their excessive use within publicly funded systems. Finally, the role played by copayments in rationing demand is mitigated by the asymmetry of information, which characterizes the patient–doctor relationship.

Conclusions

Three different types of rationing have been discussed: (1) direct rationing; (2) rationing by waiting time and quality; and (3) price rationing. Direct rationing can in principle allocate care efficiently by giving care to patients with highest benefit–cost ratio compatibly with the capacity constraint. This could be implemented by listing explicitly the treatments covered by public insurance (as well as those not covered) and/or by asking doctors to ration according to a set of established optimality criteria (potential health gains, heath status, and costs).

In practice, drawing an explicit list of eligible treatments is a complex and costly exercise and there are limits to this approach. Delegating the rationing role to doctors is inevitable. However, doctors may vary in the application of a set of rationing rules due, for example, to different interpretation of such rules, generating variations in clinical practice. Moreover, doctors themselves may be reluctant to exercise to a great extent the rationing role because they may find difficult or unpleasant to turn patients down and they may also be held liable for mistakes. This generates the scope for other forms of rationing.

If all potential patients who demand care are referred for treatment, a waiting list will quickly build up with (implicit) waiting time rationing replacing explicit direct rationing. Waiting times may ration public patients by inducing some of them to seek care in the private sector. Similarly, offering limited amenities in the public sector may shift some patients to the private sector. Compared with direct rationing, these forms of implicit rationing will however come at the cost of lower welfare for those patients who seek care in the public sector due to the waiting time or other costs imposed to them.

An alternative to rationing by waiting is to ration by price through the introduction of copayments or coinsurance rates. Its use can be a useful complement to other forms of rationing but needs to be traded off with the lower insurance coverage against the cost of illness. Moreover, large copayments (if not income tested) raise equity issues because poor patients may be discouraged from utilizing care. This can contrast the principle that access to care should not be based on the ability to pay, which is at the core of many publicly funded health systems.

Regulation of Safety, Efficacy, and Quality

MK Olson, Tulane University, New Orleans, LA, USA

Glossary

Asymmetry of information A situation in which the parties to a transaction have different amounts or kinds of information as when, for example, physicians have a greater knowledge than patients of the likely effectiveness of drugs while the patients have greater knowledge of the likely impact of drugs on their family circumstances.

Consumer surplus The difference between what a consumer pays for a good or service and the maximum they would pay rather than go without it.

Cost–benefit analysis A form of economic evaluation by comparing the costs and the (money-valued) benefits of alternative courses of action.

Incidence In epidemiology, incidence is the number of new cases of a disease identified during a time period. In economics, incidence concerns who pays taxes and who bears various other costs, that is, who bears the ultimate distribution of the burden after all effects in the economy have been worked out.

Marginal benefit The increase in benefit, or sometimes willingness to pay, from a small increase in the rate of consumption or utilization of a service.

Present value The value at a particular point in time of a future flow of income, health, etc., normally discounted using an appropriate interest rate or rates.

Introduction

Pharmaceutical regulation is designed to ensure safety, efficacy, and quality of the drugs available to consumers. This is accomplished through a range of regulatory activities over the course of a drug's life cycle including premarket screening and evaluation of new pharmaceuticals, inspection of manufacturing facilities, regulation of drug labeling and promotional activities, and the postmarketing surveillance of drugs following approval. This regulation extends to drugs and biologics that are intended for use in the diagnosis, treatment, prevention, and cure of diseases.

The rationale for pharmaceutical regulation is imperfect or asymmetric information. Evidence about drug safety and efficacy is difficult to observe and evaluate. As a consequence, physicians and patients lack information about a drug's quality. Information about the benefits, risks, and overall performance of new drugs is critical for their safe and effective use. Without accurate information about drug quality, physicians and patients may make inappropriate drug choices and suffer negative health consequences. Asymmetric information could also lead some patients to avoid taking drugs for fear that they are of low quality. Because firms as the developers of new drugs potentially know more about their quality than physicians and patients, particularly before launch, it is possible that firms may underinvest in developing prelaunch information and/or quality may be lowered or cheapened without consumer's knowledge for economic gain. The adulteration of drug products and detrimental effects on public health were motivating forces for developing early pharmaceutical regulations. Pharmaceutical products and their effects have become increasingly complex over time and evaluating those effects requires special expertise. Expert agencies like the US Food and Drug Administration (FDA) and the European Medicines Agency (EMA) regulate the prelaunch data requirements and evaluate the evidence over the life of a drug, to reduce the effects of informational asymmetries and uncertainty in the pharmaceutical market.

Regulators strive to protect and advance the public health by pursuing two goals: ensuring drug safety and effectiveness; and facilitating access to medically useful drugs. The problem facing regulators is that efforts to achieve one goal may in fact reduce the chances of achieving the second goal. Stringent regulations designed to keep dangerous or ineffective drugs off the market may delay patient access to new medicines. Alternatively, efforts to improve drug access by lowering regulatory stringency and accelerating reviews could lead to the approval of some drugs that are either unsafe or ineffective. The trade-off between safety and access is a central one in the regulation of new pharmaceuticals. The challenge for pharmaceutical regulators is balancing an interest for safety and efficacy with an interest for timely access. Finding the right balance, however, requires regulators to weigh the costs of unsafe or ineffective drugs against the costs of delay in the approval of beneficial drugs.

This article begins with an overview of important pharmaceutical regulatory legislation affecting the market access of brand name drugs in the US. It next describes EMA regulation and discusses some similarities and differences between the US and EU systems. It then examines evidence about the cost trade-offs reflected in pharmaceutical policy and concludes with a discussion of recent reforms in FDA regulation.

Overview of Pharmaceutical Regulation

Drug tragedies and safety concerns have motivated increases in pharmaceutical regulations over time. In the US, in the early 1900s, adulterated food and drug products and mislabeled medicines led to the Pure Food and Drugs Act of 1906. This Act banned the sale of misbranded or adulterated drugs and prohibited false labeling. It also required an accurate listing of ingredients on the labels of so-called 'patent medicines,' which were generally unpatented remedies that were heavily advertised and promoted as cures, but did not work as promoted. Although the Act gave government the power to prosecute

 doi:10.1016/B978-0-12-375678-7.01202-5

firms that violated the law, it did not require firms to test products before marketing.

In 1937, a liquid sulfa drug called Elixir Sulfanilamide, which contained a poisonous solvent, was sold to consumers and resulted in more than 100 deaths. This tragedy led to the 1938 Food, Drug, and Cosmetics Act, which required firms to test products for safety before marketing and file that information with the FDA. The burden of proof, however, lay with the agency to reject a drug to prevent it from being marketed. Drugs could be marketed automatically without approval after 60 days (in some cases 180 days) unless the FDA showed them to be unsafe. The Act also gave the FDA the power to regulate drug labels to ensure the accuracy of therapeutic claims and adequacy of instructions for safe use. However, enforcement was challenged by the absence of scientific evidence about drug effects relating to such claims. Because the Act did not require firms to demonstrate that drugs were effective, an important aspect of the informational problem facing consumers and physicians was not addressed.

This changed with the 1962 Drug Amendments to the Food, Drug, and Cosmetics Act. The 1962 Amendments were motivated by the worldwide thalidomide drug tragedy. In 1961, researchers discovered that thalidomide, which was being used as a sedative for pregnant women throughout Europe and in Canada, was responsible for thousands of severe birth defects in which infants were born with missing or truncated limbs. The drug was not being sold in the US because it was held up by an FDA reviewer as reports began to emerge. However, samples of the drug were distributed to US physicians for premarket study. Although Congress was conducting hearings into high prices for drugs of dubious efficacy before the scandal, the near miss of a US tragedy expanded their focus to include drug safety.

The 1962 Amendments required firms to provide 'substantial clinical evidence' of safety and effectiveness for all drugs before they could be marketed. The law eliminated the prospect of automatic approval by removing the time limit within which FDA was required to act to reject a new drug. This shifted the burden of proof to firms to obtain explicit FDA approval before entering the US market. The law also required firms to submit their plans for premarket clinical tests to the FDA and inform the FDA of any serious adverse drug reactions (ADRs) experienced by patients. The FDA was also given oversight of prescription drug advertising and promotion.

Many industrialized countries throughout the world responded to the thalidomide tragedy with increased safety standards and regulation for new drug approval. However, most European countries, with the exception of Norway and Sweden who already required evidence of drug effectiveness, did not establish a mandatory efficacy requirement for new drug approval until several years later. Another way that the US response differed from other countries is the complex set of procedures and requirements governing the premarket clinical development, evidence submission, manufacturing, and approval of new drugs. These procedures continue to be used today by the FDA in drug approval. There has also been a convergence in pharmaceutical regulation relating to a drug's clinical development and good manufacturing processes in recent years as a consequence of efforts toward international harmonization.

The process begins as firms conduct preclinical studies and testing in animals to determine which drug compounds offer promise and are reasonably safe for human testing. In the US, when firms are ready to begin clinical testing in humans, they must submit an Investigational New Drug (IND) application to the FDA. The IND contains the results from toxicology studies, animal studies, and other preclinical tests, plans for clinical testing in humans, details of the manufacturing process, and results from any clinical studies conducted outside the US. The IND allows FDA to provide input into planned clinical tests or reject poorly formulated IND applications. An IND application becomes effective after 30 days unless the FDA places a hold on it.

Once an IND is effective, firms may begin premarket clinical testing with human subjects, which proceeds in three phases. Phase I studies test for drug safety in a small number of healthy human subjects (20–80 subjects). Phase II studies are controlled clinical tests in a small number of human subjects with the target disease to develop preliminary data on effectiveness. If the data from the Phase II trials suggest effectiveness, the firm may begin Phase III studies, which are large-scale, placebo-controlled randomized clinical studies used to confirm a drug's effectiveness (600–3000 subjects on average). In cases where it may be unethical to put clinical trial patients on a placebo, Phase III studies compare the target drug to the current treatment. Clinical studies can take between 2 and 10 years to complete, during which firms collect the data and evidence from these studies. These data, along with samples of the drug, are submitted to the FDA in a New Drug Application (NDA), which includes all the data and results from all clinical and preclinical studies. After accepting an NDA, regulators commence review to analyze the evidence and determine if the drug's benefits exceed its risks. The FDA also negotiates with the manufacturer over the drug's labeling, reviews promotional materials, assesses the need for postmarketing study requirements (i.e., Phase IV studies), and inspects the firm's manufacturing facilities. Phase IV studies expand the safety and efficacy profile of selected drugs in a large population following drug launch and can include formal therapeutic trials or comparisons with existing medicines. Phase IV confirmatory studies are required for drugs approved with limited exposures and/or surrogate endpoints, which are markers (i.e., blood pressure, CD4 cell count, tumor shrinkage) used in clinical trials as an indirect measure of clinically meaningful endpoints (i.e., longer survival or reduced symptoms). Phase IV studies are also sought where questions arise about whether serious adverse events can be attributed to a drug.

To satisfy the requirement for 'substantial evidence' of safety and efficacy, the FDA has generally required two large-scale, controlled clinical studies to demonstrate a drug's effectiveness. The rationale is that the results of any single controlled clinical study must be confirmed by a second such study sufficiently powered to meet the agency's evidentiary standard. This requirement for two Phase III trials, sometimes referred to as the 'gold standard' for approval, has been a subject of debate and controversy over time. Although the requirement has been waived in some cases in recent years, it has greatly added to the cost and length of the FDA approval process. In addition, FDA is the only regulatory authority in

the world that requires companies to submit the raw data collected in clinical trials to assure that results reported by the firm can be replicated from the FDA's own independent analyses of the data. These requirements have increased the size of NDAs as well as the time and effort required to review them.

In the late 1980s and early 1990s, the crisis surrounding Acquired Immunodeficiency Syndrome (AIDS) and growing awareness of delays in the FDA's drug approval process led to new reforms to improve patients' access to new drugs. FDA introduced treatment INDs and a parallel-track program to give patients with life-threatening diseases early access to promising investigational therapies before approval. The FDA also relaxed certain statutory requirements in the testing of AIDS drugs. For instance, Subpart E procedures allowed for the elimination of Phase III studies before approval, whereas accelerated approval permitted sponsors to use surrogate endpoints in clinical studies other than survival or morbidity to demonstrate efficacy. The agency's success in accelerating access to new AIDS drugs led to increased public and industry pressure to reduce regulatory delays for other drugs. FDA argued that they needed more resources to combat delays and Congress responded with new legislation, which introduced industry funding for new drug review.

The 1992 Prescription Drug User Fee Act (PDUFA) initiated the program whereby drug manufacturers ('sponsors') are required to pay fees to the FDA to help finance its review of NDAs. In return, firms receive agency commitments to expedite the review of NDAs and meet a series of performance goals. Two key goals specify review targets for priority-rated drugs, which offer a significant therapeutic advance over existing remedies, and for standard-rated drugs, which offer little to no therapeutic gain over existing remedies. The goals stated that FDA should review and act on 90% of priority drug applications in 6 months and 90% of standard drug applications in 12 months. Another goal directed FDA to eliminate its backlog of NDAs awaiting approval within 24 months of the establishment of the program. Before PDUFA, the average review time was approximately 30 months. To increase accountability, the FDA was required to report annually to Congress on the status of meeting its performance goals. PDUFA was enacted with a 5-year term and its renewal requires new legislation to extend its term. These features allowed stakeholders to assess the agency's performance before renewal and make necessary adjustments in the program. One interesting provision in PDUFA, which became a target for later reform, was that fee revenues could only be used for efforts to accelerate drug reviews and could not be used for other purposes, such as postmarketing drug safety surveillance.

Drug review times began to decline under PDUFA, drug approvals increased, and the program was renewed in the 1997 FDA Modernization Act (PDUFA II) for another 5 years. PDUFA II increased user fees, raised agency revenue targets, and lowered the review deadline for standard-rated drugs from 12 to 10 months. New performance goals were also added to ensure the timeliness of communications between the FDA and sponsors during the clinical development period to further speed-up the process. PDUFA II included timelines for the FDA to schedule sponsor-requested meetings before the submission of INDs or NDAs, resolve disputes with sponsors which arise during clinical development, respond to sponsor questions about study protocols, and develop guidances for industry. To further combat delays in drug development, PDUFA II included a provision allowing the agency to accept a single, large-scale, controlled clinical study as 'substantial evidence' of effectiveness (instead of two), but discretion remained with agency to make that determination. The 2002 Public Health Security and Bioterrorism Preparedness and Response Act (PDUFA III) reauthorized the program, raised fees and revenue targets, and further expanded the FDA's interactions and communication with firms during testing phases and the review cycle.

Drug industry user fees account for 65% of the agency's human drug budget and the time required for the FDA approval phase has been cut by nearly 60% since the enactment of PDUFA. Kaitin and Cairns (2003) report that clinical development times have also declined from a high of 7.2 years in 1993–95 to 5.5 years in 1999–2001 since PDUFA II. However, a series of safety-related drug incidents culminating in the 2004 withdrawal of Vioxx – a Cox-2 inhibitor allegedly linked to thousands of deaths from heart attacks or strokes – raised concerns about the effects of PDUFA on drug safety and the agency's handling of postlaunch drug safety issues. Questions arose about whether the FDA's approval process had become so accelerated that adequate attention was not being given to drug safety issues, especially postlaunch. Questions also arose about the timeliness and effectiveness of risk communications to the public, the transparency of agency decision making, the handling of internal agency conflicts over approval decisions, and the failures by firms to complete required postmarketing safety studies.

Congress responded to these and other safety concerns with the 2007 FDA Amendments Act (PDUFA IV), which renewed the user fee program and provided the agency with new authorities to address drug safety problems that arise after approval. The Act gave the FDA authority to require Phase IV postmarketing studies and clinical trials to address important drug safety questions and power to fine firms that did not complete their studies. It gave the agency new authority to require safety labeling changes (such as new black box warnings) when new serious risks emerged after approval, and the authority to require drug or biologic developers to submit Risk Evaluation and Mitigation Strategies (REMS) as part of a NDA (or for an already approved drug) when deemed necessary by FDA to ensure that the benefits of a drug outweighed its risks. These and other recent FDA reforms will be discussed in detail in the final section.

The European Medicines Agency

By the 1980s, most industrialized countries adopted some form of efficacy regulation in response to increases in the number, complexity, and toxicity of new pharmaceuticals. However, a range of different economic, political, social, and cultural factors in countries resulted in a proliferation of national drug regulatory systems and processes for marketing authorization. Concern about the fragmented regulatory systems in the European Community, uneven drug access among EU countries, and a desire for a single integrated European

market to facilitate the free movement of new medicines led to new policies to standardize the way in which new drugs and biologics were approved and marketed in the EU.

In 1993, the European Commission created the EMA to authorize/approve new drugs and biologics in the EU. The EMA began evaluating new products in 1995 through a centralized procedure in which a drug receives a single marketing authorization valid in all EU countries. The centralized procedure is compulsory for new biotechnology and advanced therapy medicines (i.e., gene therapy) as well as new drugs to treat AIDS, cancer, neurodegenerative disorder, diabetes, autoimmune diseases, viral diseases, and orphan diseases. Firms have the option to use the centralized procedure for other new drugs that offer a significant therapeutic benefit or otherwise serve the public interest. The process has strict deadlines for timely reviews, which include a limit of 210 days for the scientific committees to evaluate drug applications and reach a decision, 30 days for EMA to finalize and then transmit that decision to the European Commission, who grants the marketing authorization (within 90 days).

In a second track, firms can seek approval in a limited number markets through a decentralized procedure based on a process of mutual recognition. Under this track, the EMA receives a NDA from a firm, but then forwards it to a single member country recommended by the firm for review. Following approval, that country refers the drug application to other member countries designated by the firm. If mutual recognition or approval is not granted, firms can pursue arbitration through the EMA.

Both the EMA and FDA share common objectives to protect public health by ensuring the safety, efficacy, and quality of new medicines. Both agencies have special procedures to facilitate the approval of orphan medicines and the accelerated approval of medicines for life-threatening illnesses with few therapeutic options. Both the agencies are also funded by industry user fees. There has been increasing communications, information sharing, and cooperation between the EMA and the FDA over time as well as increasing convergence in regulatory procedures. Along with their Japanese counterparts, the US and EU agencies have worked together with drug firms toward the global harmonization and improvement of international drug regulations through the International Harmonization Conference (ICH).

There remain interesting differences between the EMA and the FDA. (1) Marketing authorization in the EU is valid for 5 years, whereas FDA approval allows firms to market drugs in the US indefinitely. The EU requires sponsors to submit a reevaluation of the risk–benefit balance after 5 years to renew a product's marketing authorization. (2) Marketing authorization is not the final hurdle in the EU because the firm must negotiate a drug's price and reimbursement with the government before marketing. Unlike the US, which does not negotiate drug prices with firms, price negotiations in EU countries can further delay the entry of new drugs into the market (3) The EMA typically requires comparator-controlled clinical trials or three-arm studies, which compare the target drug to a comparator drug and placebo, whereas the FDA is satisfied with placebo control except when it is ethically unfeasible. This amounts to a regulatory standard of comparative efficacy for EU approval and provides one reason why the two agencies might reach different approval decisions or different risk–benefit conclusions for the same drug. (4) Assessments in the FDA are conducted by its own reviewers in a single agency, whereas assessments in the EMA are conducted by the national agencies in different Member States. Unlike the FDA, the EMA is predominantly a coordinating office that depends on scientific input from a large network outside experts from different Member States who participate on its scientific committees. This suggests that differences in culture and practices among the Member States may potentially influence drug authorization decisions. (5) Negative approval decisions along with the accompanying product assessments are published in the EU in contrast to the US where such information is considered proprietary for drugs that are not approved by the FDA. (6) The FDA is responsible for enforcement of its policies, whereas enforcement of marketing authorizations, licensing, control sales, and promotional activities in the EU is left to the Member States, which could potentially create problems of coordination with the EMA. Still EMA has historically possessed more authority to deal with drug safety issues in the postmarket, including the power to suspend marketing authorization while drug safety issues are investigated, and it has access to a wider range of financial penalties for issues of noncompliance with EU requirements.

Evidence about the Effects of Pharmaceutical Regulation

Evaluating pharmaceutical regulation requires evidence about the cost trade-offs of unsafe or ineffective drugs versus delay in the approval of useful drugs. The social costs of approving unsafe or ineffective drugs include deaths or reductions in health experienced by patients exposed to these drugs, including the opportunity costs of wasted time and resources in the ineffective fight against diseases. The incidence of some of these costs may fall on payers/citizens/taxpayers who ultimately pay for medical care as well as firms who pay liability costs. The social costs of delay or increased requirements for drug approval include the health benefits foregone by patients from delayed treatment and any increase in drug development costs due to increased regulation.

Few studies have examined the health effects of pharmaceutical regulation. The social costs of unsafe drugs become visible when drug-related tragedies occur in which patients are harmed. The social costs in terms of forgone health benefits of approving ineffective drugs are also difficult to observe and assess. With little systematic evidence about the health effects of unsafe or ineffective drugs, highly visible drug tragedies have played an important role in shaping pharmaceutical policy and regulator behavior over time. Quantifying the social value of drugs delayed or prevented from the market by pharmaceutical regulation has also proved challenging. Little research has attempted to estimate the gains in patient health arising from faster access to a new drug instead of an older one.

Much of the early research focused on the extent to which regulation affects the number of new drug approvals, the costs and length of drug development, and regulatory delays in the FDA review, with particular emphasis on the effects of the

1962 Amendments. These Amendments constituted the largest single change in the US regulatory policy and hence provide a natural experiment to examine the effects of pharmaceutical regulation.

Studies showed that the time spent on testing new drugs increased substantially after the 1962 Amendments. Wardell *et al.* (1982) found that the period of preclinical and clinical testing increased from 30 months in 1960 to 100 months in 1970 to 120 months in 1980. The cost of developing new drugs also increased since 1962. Hansen (1979) who examined 1963–75 drug approvals estimated a total capitalized cost of US$54 million (in 1976 dollars) per new drug approval. DiMasi *et al.* (1991) who examined 1970–82 drug approvals estimated a cost of US$231 million (in 1987 dollars) per new drug approval. Using more recent drug approvals in 1989–2001, DiMasi *et al.* (2003) estimated a total cost of US$802 million (in 2000 dollars). These studies are also reviewed in this volume. Studies also suggested that the 1962 legislation resulted in a substantial reduction in the number of US drug approvals, but some questioned the relative role of regulation versus other factors in explaining that reduction.

Peltzman (1973) argued that all decline in US new drug approvals following 1962 was due to the new regulations, whereas others, such as Grabowski *et al.* (1978) argued that regulation could explain roughly half of the decline with the rest attributed to other factors, such as the depletion of research opportunities and increased industry restraint after the thalidomide tragedy. Temin (1980) and Wiggins (1984) found that much of the decline in approvals occurred in a few therapeutic areas (i.e., central nervous system tranquilizers, antiinfectives) and concluded regulation may be even less important than other market factors in explaining the trend. Temin further noted that demand as well as supply of tranquilizers diminished after the public became aware of the thalidomide tragedy. Because the purpose of the 1962 Amendments was to prevent dangerous or ineffective drugs from reaching the market, more evidence is needed to conclude that fewer new drug approvals necessarily reduced social welfare.

In one of the first cost–benefit studies of the FDA regulation, Peltzman (1973) used the growth in market shares for new drugs approved before and after the 1962 law to estimate the gains in consumer welfare from the efficacy requirement and compared these to the losses of welfare from reduced drug approvals. He concluded that gains were far smaller than the costs of the law. His estimates have been the subject of much debate and criticism. Peltzman's analysis did not consider the welfare benefits from a possible reduction in unsafe drugs. Temin (1980) argued that Peltzman's estimate of the benefits of the efficacy requirement was not fully captured in the analysis, whereas the costs were overestimated because all of the observed reduction in drug approvals was attributed to the Amendments.

It is difficult to measure the social value of the drugs that were delayed by more stringent regulation. Data from the FDA showed that much of the decline in approvals following 1962 occurred among drugs offering little to no therapeutic gain over existing remedies, known as me-too drugs, whereas other data showed little decline among drug approvals offering important therapeutic gains. Abraham and Davis (2005) showed that drug withdrawal rates were twice as high in the UK as in the US between 1971 and 1992. They argued that more stringent premarket review and testing standards in the US prevented the approval of some unsafe drugs compared to the UK and showed that US regulators had identified the same safety problems upon which drug withdrawal ultimately occurred in the UK. Although the evidence is compelling that FDA regulation prevented the approval of some dangerous drugs, questions remained about the social costs arising from regulatory delays of potentially useful new drugs.

More recent research has examined the effects of PDUFA, which provides another natural experiment to examine how increased drug review speed has affected drug safety and social welfare. Several studies have documented the increase in drug review speed and approval observed under PDUFA. Other research has investigated whether PDUFA and increased drug review speed led to reductions in drug safety.

Measuring drug safety has posed a challenge in research. Some studies investigated whether the rate of drug withdrawals changed under PDUFA. Friedman *et al.* (1999) compared the rates of drug withdrawals by approval year between 1970 and 1999 and found little difference before and after PDUFA. A study by the General Accounting Office (2002) examined the rates of safety-related drug withdrawals between 1985 and 2000 and found that drug withdrawal rates increased under PDUFA. Berndt *et al.* (2005) found no significant difference in drug withdrawal rates pre- and post-PDUFA, but they note results are sensitive to the time periods selected and potential problem of censoring. They also suggest that as safety-related drug withdrawals are relatively rare, it is inherently difficult to detect significant differences in these rates pre- and post-PDUFA. Some have noted that studies focusing on drug withdrawals provide little information about the possible effects of the reform on the safety or risks of drugs that remain on the market.

Other research has examined the rates of black box warnings given to the FDA-approved drugs before and after PDUFA to determine if drug risks have increased. In an National Bureau of Economic Research working paper, Begosh *et al.* (2006) found no significant difference pre- and post-PDUFA in the rate of new black box warnings received after a drug's approval. Carpenter *et al.* (2008a,b), however, found that the new drugs approved before their PDUFA review deadlines had a higher probability of being withdrawn and receiving a postapproval black box warning compared to other drug approvals. They conclude that PDUFA deadline pressures may in some cases compromise drug safety. Although more frequent than drug withdrawals, black box warnings have until very recently been discretionary FDA actions that must be negotiated with firms. Legislation passed in 2007 first gave the FDA statutory authority to require such warnings after approval.

ADR data from the FDA have also been used in studies to investigate the effects of faster FDA drug review times on drug safety. Most ADR reports are submitted by health professionals when patients experience serious adverse reactions to drugs, but anyone can submit an ADR report. ADRs are much more frequent than drug withdrawals or boxed warnings and they provide signals of potential drug safety problems. However, ADRs are generally underreported and the reports do not include evidence of causation. Olson (2002) examined drug

approvals in 1990–95 and found that faster reviews were significantly associated with increased counts of serious ADRs. A subsequent study by Olson (2008), which included more data and additional controls, also found that faster drug review times were significantly associated with increased counts of serious ADRs among the 1990–2001 new drug approvals. Grabowski and Wang (2008) examined drug and biologic approvals in 1992–2002 found no significant effect of the FDA review speed on ADRs. However, Olson (2008) notes that Grabowski and Wang's study excluded drugs approved before the PDUFA, used three annual ADR counts for each drug instead of a single aggregate count, and included ADR reports listing secondary suspect drugs that were weighted equally with reports that listed a primary suspect drug, which Olson argues increases the noise in ADR count measures.

Olson (2004b) assesses the benefits and costs of therapeutically novel drugs, which the FDA targets for faster drug reviews. She found that therapeutically novel drugs had significantly more serious ADRs after approval, including drug reactions resulting in hospitalization and death. Because priority review status is granted primarily to drugs that are novel, there is an inevitable confounding of drug novelty with fast review. With that caveat and after controlling for a drug's review time, the results showed that for an average drug, novelty is associated with a 60% increase in serious ADRs, 45% increase in ADRs that require hospitalization, and 61% increase in ADRs that result in death in the first 2 years after approval. To measure the health benefits of novel drugs, Olson draws on Lichtenberg's (2005) estimate of the increase in life expectancy due to increases in the stock of priority (novel) drugs, 292 000 life years per year. The benefits of novel drugs are then compared to the life years lost from increased ADR deaths over the period. For drug approvals in 1990–95, and assuming no underreporting of ADRs, results showed that ADR deaths (in the first 2 years after approval) reduced the net longevity gains due to novel drug approvals by approximately 8%. This estimate is subject to two potential biases. First, because ADRs are underreported, the number of ADR deaths may be larger than predicted. For instance, Olson's study shows that 30% underreporting of ADR deaths reduces the estimate of net longevity gains of therapeutically novel drugs by 11%. Second, the life years gained from novel drugs may be overstated in Lichtenberg's study because he does not control for increases in the stock of medical devices and other changing health technologies that may have also increased longevity over time. Both biases would result in a reduction in estimated net longevity gains from novel drugs.

Philipson *et al.* (2008) assessed the benefits and costs of the PDUFA by comparing the increases in drug sales due to faster reviews under the PDUFA to ADR deaths reported for the PDUFA-related safety removals. The reform's benefits are measured as the present value of the increase in producer and consumer surplus due to increased review speed for all approved PDUFA drug submissions over each product's 15-year sales life cycle, whereas the reform's costs are measured as the value of the life years lost from reported ADR deaths among the subset of the PDUFA-related drug withdrawals. They examine data for all drug and biologic approvals in 1979–2002 to develop their estimates and use data for drug sales in 1998–2002 and IMS life cycle year to peak percentages from IMS Health to compute drug sales in all other years. They estimate the gains in producer surplus due to the PDUFA to be US$7–11 billion, and the gains in consumer surplus to be US$7–20 billion depending on assumptions about the amount of surplus captured by consumers during patent protection. However, this estimate assumes that the demand curve for drugs measures marginal benefit and hence consumer surplus, which is likely to lead to a large overstatement because it ignores the effect of insurance on drug prices. They also do not account for any offsets in drug sales from the substitution of newer drugs for older ones, which may further bias benefits upward. With these caveats, they estimate that the benefits from faster reviews are 140 000–310 000 life years gained (assuming the value of a life year is US$100 000), whereas the costs of ADR deaths among withdrawn PDUFA drugs are 56 000 life years lost and conclude that the benefits of PDUFA exceed the costs.

Philipson *et al.*'s cost estimates are subject to some potential biases. They assume that all reported ADR deaths among the subset of withdrawn PDUFA drugs are due to the reform and that this set of withdrawn drugs have no benefits, which they argue results in an extreme upper bound on costs. However, they do not include costs resulting from nonfatal hospitalizations associated with the withdrawn drugs, which 'if valued substantially, could potentially lead to offsets larger than the gains of greater speed induced by PDUFA.' They also do not include as part of the reform's costs any reductions in life years due to increased ADR risks among the drugs remaining on the market, which received faster reviews. Olson's (2008) study finds that a 19-month reduction in review time is associated with an increase of 11 ADR deaths in a drug's first 2 years on the market, which translates into an extra 131 501 life years lost among the drug approvals in 1990–2001. Both factors would increase the estimated costs of the reform.

Philipson *et al.*'s study may also not fully capture the dynamic welfare effects of faster drug reviews and increased producer surplus on pharmaceutical R&D and innovation, which would increase the estimated benefits of the reform. Using survey data from seven large pharmaceutical firms, Vernon *et al.* (2009) estimated that the PDUFA increased R&D spending by US$3.2–4.6 billion. By extrapolating to the entire industry, they predict that pharmaceutical industry R&D spending increased by US$10.8–15.4 billion from 1992 to 2002. If the additional R&D results in more drug innovation, then increased R&D could yield additional benefits of the reform. The authors note, however, that sample selection bias could be a serious issue in making industry-wide projections because of a low survey response rate and incomplete surveys. In addition, their study does not control for other important factors that could have increased R&D spending and incentives for R&D, such as the development of the EU's centralized process for drug approval and increasing competitive pressures.

Evidence about the welfare effects of pharmaceutical regulation has increased over time, but important challenges remain, particularly in the estimation of consumer benefits. Studies that use drug sales data to estimate the dollar magnitude of benefit to consumers are subject to some important limitations. Although drug sales are a good indicator of producer benefit, they convey little information about the actual

improvements in patient health arising from faster access to a new drug instead of an older one. Benefits among drugs that are ineffective, equivalent to existing drugs, or those that have serious side effects would be overestimated with this measure. Further, such studies ignore the important effect of third-party insurance on drug prices. With insurance, consumer demand will not reflect the marginal benefit to consumers and consequently estimated consumer welfare is likely to be overstated. *In lieu* of these limitations, future research may want to utilize measures such as life years or other health impacts of drugs to determine more reliable estimates of consumer benefits from reform.

Recent Reforms of Food and Drug Administration Regulation

There continues to be controversy and conflict over pharmaceutical regulation. In the US, drug-related tragedies and concerns about conflicts of interest in the FDA and in its advisory committees have led to increased public and political scrutiny of the agency in recent years. The withdrawal of Vioxx in 2004 and other controversies, which include those relating to pediatric antidepressants and suicide risks in children, called into question various aspects of the agency's oversight structure and processes and reduced the public's confidence in the FDA. In response to calls for reform, in 2005 the FDA asked the Institute of Medicine (IOM) to convene a committee of experts to conduct an assessment of the US drug safety system and make recommendations to improve risk assessment.

The Institute of Medicine Committee (2007) report identified important shortcomings in the US drug safety system including insufficient regulatory authority and tools for addressing drug safety problems that emerge in the postmarketing period after approval, chronic underfunding of postmarketing drug safety activities, organizational and coordination problems among pre- and postmarketing drug safety teams, limited postapproval drug safety data, insufficient monitoring and ineffective communication of new risk information in the postmarket, and insufficient transparency/public access to a drug's benefit and risk information. The committee found that these problems had become more pronounced over time in part due to the pressures created by the PDUFA; increases in the number, complexity, and potency of prescription drugs marketed; increases in drug utilization for chronic conditions; and other changes that affected the way in which drugs were being promoted, used, and prescribed. The report noted that as more people were taking more drugs over extended periods of time, many drug risks were not becoming known until well after approval. In response to these changes, the IOM committee recommended that the FDA be given new duties, authorities, and resources to ensure drug safety, especially in the postmarketing period, and that the agency develop a life cycle approach for the assessment of a drug's risks and benefits.

Many of the IOM report's recommendations were included in the 2007 FDA Amendments Act (PDUFA IV). This Act reauthorized the user fee program and included numerous provisions to strengthen and modernize the US drug safety system. It is interesting to note that the Act does not weaken the agency's policies for accelerating drug approval or improving drug access. Instead, the 2007 Act gave the agency new powers to identify and address drug safety problems that may emerge after approval including the power to require safety labeling changes, postmarketing studies, and Risk Evaluation and Management Strategies. Marking an important change from the past, the PDUFA IV also allowed the agency to more user fee revenues to build the agency's postmarketing drug safety activities and staff. The Act also contains provisions to increase the availability of risk–benefit information for the public, to improve communications of risk information to the public, and to increase transparency of its decision making.

More specifically, the 2007 Act provided the FDA with the new authority to require and enforce the Phase IV postmarketing studies and clinical trials. Before 2007, the FDA lacked such authority. Although the agency could request that firms conduct a Phase IV study as a condition of approval to address unanswered safety questions to help speed up a product to market, the FDA lacked the enforcement tools (other than the most extreme action of withdrawal of approval) to ensure the completion of such studies. Data showed that the completion rate for Phase IV studies of postapproval risks or efficacy studies was low. Among the 88 new molecular entities (NME) approved in 1990–94, Sasich *et al*. (2005) find that 87% had not completed their Phase IV studies 5–10 years after approval by 1999 and none of the 107 NME approved in 1995–99 had completed their Phase IV studies by December 1999. In September 2004, there were 1191 open postmarketing study commitments reported in the Federal Register (2005) of which only 18% were ongoing, whereas 68% were pending or not yet initiated. Failure to complete Phase IV studies, especially those studies agreed to as a condition of approval or accelerated approval, prevents patients and physicians from receiving necessary information about a drug's risk–benefit profile to make informed prescribing decisions. The 2007 Act allowed FDA to require such studies to identify or assess potential serious risks before or after approval and gave the agency power to levy new fines and penalties against firms who did not complete their study commitments. Firms could receive a civil penalty of US$250 000 for each violation and up to US$10 million for an ongoing violation. The FDA was also made responsible for tracking and reporting on the status of these studies annually to consumers in the Federal Register.

The 2007 Act also provided the FDA with new authority to manage risks among marketed drugs through REMS. The REMS are developed by manufacturers with the input of the FDA to ensure that the benefits of a drug or biological product outweigh its risks. They may be required at the time of approval or after approval if new risk information emerges. The REMS may take many forms, but some of the most common include plans to ensure appropriate risk communication (Medication Guides), safe use conditions, adequate prescriber education or training, adequate pharmacy education or certification, and required patient monitoring or patient registries. All REMS must have a timetable for the submission of assessments to determine if the plan has been effective. With the increase in REMS following the 2007 Act, concerns were voiced at the subsequent PDUFA stakeholders meetings about the lack of standardization of REMS.

Pharmacists sought greater involvement in the development of these plans and suggested that the growing number of unique REMS was placing burdens on the health care system. In response, the agency is reaching out to stakeholders and moving toward greater standardization of REMS.

The 2007 Act required FDA to improve its postapproval risk assessments and the timely communication of those assessments to the public. First, the agency must conduct regular, biweekly screening of the Adverse Event Reporting System (AERS) database and post a quarterly report on the AERS website of any new safety information or potential signal of serious risks identified through AERS. The first report was posted in September 2008. Second, the agency must conduct systematic evaluations of the safety of new drug approvals since September 2007, 18 months after approval or after a drug's use by 10 000 patients. These reviews draw upon a range of pre- and postapproval data including the drug's preapproval safety profile, new adverse event reports, other sources of new risk information, trends in drug utilization, etc. to analyze any potential new safety issues involving these drugs. Summaries of the agency's findings are posted on its website to help improve information about emerging drug risks to patients and physicians.

The 2007 Act required the FDA to increase active postmarket risk identification and analysis as a complement to its existing passive AERS. In 2008, the FDA launched the Sentinel program, which is a national electronic system for monitoring product safety that is linked to automated health care data systems, such as electronic health record systems, administrative and insurance claims databases, and registries. The law required the FDA to work with partners from public, academic, and private entities to develop this system. The FDA can use this system to make queries about potential drug safety issues, which can then be explored quickly and securely using these broad data networks. The law set a goal of being able to query data from 25 million patients by 1 July 2010 and data from 100 million patients by 1 July 2012. The agency reported that it met its data access goal for 2010 and is on target to meet the data access goal by 2012 deadline.

In an effort to improve public access to safety data for drugs involved in premarket studies, the 2007 Act requires that firms must register within 21 days of the enrollment of the first patient, all Phases II–IV drug trials in the publically available National Institutes of Health (NIH) online database, www.clinicaltrials.gov. The Act also mandates the creation of a clinical trials results database for approved drugs that, when fully implemented, will include a set of Internet links to key FDA documents, summary tables of primary and secondary outcomes, expanded results, and information about serious adverse events. Clinical trials results must be submitted within 1 year of the trial completion or within 30 days of drug approval. There are few studies of the overall compliance of firms with the new registration requirements although Lester and Godlew (2011) who examine evidence from NIH and FDA suggests that there is a high level of noncompliance.

The recent reforms of FDA regulation reflect a new awareness of the fact that even with stringent preapproval evaluation procedures some drugs that reach the market could potentially harm consumers. The provisions contained in the 2007 Act suggest that current policy makers are not willing to sacrifice the gains made in facilitating drug access to patients under PDUFA or under accelerated approval or fast-track programs to try to prevent future drug tragedies. Instead, policy makers have strengthened the FDA's authorities and resources for addressing drug safety problems that emerge in the postmarketing period. The adoption of REMS, the Sentinel program, and the new postmarketing authorities allow the FDA to limit or reduce risk exposure among patients by gathering and acting on postlaunch risk information more quickly than they have in the past and in some cases by restricting a drug's distribution (through REMS) to those patients who are the most likely to have a positive benefit–risk profile. This appears to be a significant shift from the 1962 Drug Amendments, but puts the FDA more in line with regulators in the EU countries, who already required risk management plans and risk assessments as part of the approval process and generally had more developed postmarketing safety systems and authorities. The success of these reforms for reducing patient exposure to drug-related risks will depend on the effectiveness of the agency's new tools and programs for identifying and addressing new safety problems quickly and efficiently in the postmarket and the effectiveness of the agency's risks communications to the public. Success will also depend on firm compliance with the agency's policies including the completion of required postmarketing study commitments, including confirmatory studies for accelerated approvals. If proven successful, these reforms could allow regulators to further expand programs used to provide early access to important new medicines.

The most recent renewal of the PDUFA program, the 2012 FDA Safety and Innovation Act (PDUFA V), takes a step in this direction with its provisions to stimulate the development and accelerate approval of new antibiotics and drugs serving unmet medical needs for life-threatening or rare diseases. PDUFA V, which also authorizes user fees for medical devices, generic drugs, and biosimilars, increases further prescription drug user fees and allows some of those funds to build the scientific capacity of the agency, to develop standardized, fully electronic application submissions, to standardize REMS, and to use Sentinel to investigate drug safety issues. PDUFA V continues the trend of fostering greater FDA-sponsor communications during the development and review process. It calls for new staff and two new required meetings during the mid and late stages of review to make sponsors aware of required REMS and advisory committee issues earlier in the review process to prevent unnecessary delays later. In a shift from past programs, PDUFA V essentially extends the review targets for NMEs, NDAs, and original biologics license applications by 2 months by adding a 60-day filing period before the review clock begins to give the agency more time to process increasingly complex drug applications and coordinate its interactions with sponsors and advisory committees. The reasoning is that better coordination up front and communication with firms throughout the process will prevent unexpected delays, which might lead to another review cycle, and thus allow for a shorter overall drug review.

Research and Development Costs and Productivity in Biopharmaceuticals

FM Scherer, Harvard University, Cambridge, MA, USA

Introduction

Substantial gains in human health and longevity have been achieved, especially since the 1930s, through the development and introduction of new pharmaceuticals into clinical practice, ranging inter alia from early antibiotics through anti-cholesterol agents to anticancer medicines. Most of the detailed development of new pharmaceutical entities has been conducted, at least in capitalist nations, by private enterprises, typically subject to detailed regulation by government agencies that monitor clinical testing activities and determine whether a proposed new drug is safe and efficacious enough to permit marketing. The pharmaceutical industry is one of the most research intensive of all private industries. During the early years of the twenty-first century, however, there was evidence of sharply rising research and development (R&D) costs underlying the average new pharmaceutical entity introduced into commercial use and hence reduced research productivity. This article explores the evidence and the issues, with a focus mainly on the US, which has played a leading role in drug development and on which the most complete data are available.

Quantitative Overview

Figure 1 presents an overview of inputs and outputs for the drug R&D process. The solid line traces input trends – notably, reported R&D expenditures (right-hand scale, in billions of dollars) by members of the principal US trade association, the Pharmaceutical Research and Manufacturers of America (PhRMA). The data have important limitations. They are adjusted to year 2000 average purchasing power levels using the US gross domestic product (GDP) price deflator, although R&D cost inflation (measured from US National Institutes of Health studies) has probably proceeded slightly more rapidly than general economy-wide price inflation. Most of the leading pharmaceutical producers are multinational firms, but Figure 1 includes only the R&D expenditures of PhRMA members within the US. Counting overseas outlays of the members, many with home bases elsewhere, would add roughly 25% to the cost. Not all private-sector company pharmaceutical R&D outlays are made by PhRMA members. A particularly important exclusion is for biotechnology specialists, many of which do not publicly report their R&D outlays. Several biotech companies were members of PhRMA in 2008, so their data are included in the PhRMA tallies. But most of them joined only after incurring the R&D underlying successful drug developments, and it would appear that the reported PhRMA R&D totals were not recalculated backward to hold membership constant, in which case the addition of new members overstates actual growth rates. Recognizing these limitations, one can estimate from Figure 1 that inflation-adjusted R&D outlays grew between 1970 and 2007 at an average annual rate slightly below 7.4%.

The dash-dash line in Figure 1 estimates the number of new molecular entities (NMEs) (left-hand scale) approved each year for prescription use in the US. The count of NMEs includes new therapeutic organic chemical molecules – the so-called 'small-molecule drugs,' excluding new uses of already-approved molecules and different formulations of pre-existing

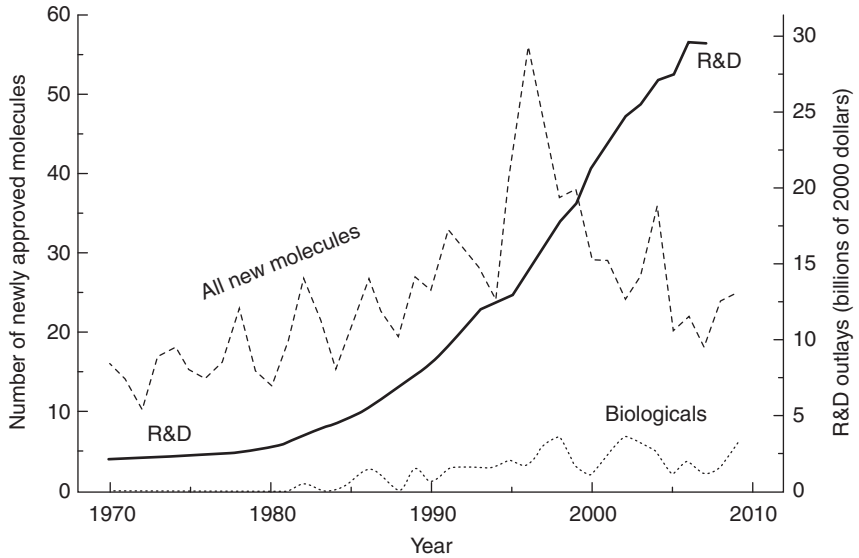

Figure 1 Trends in newly approved molecules and R&D spending US, 1970–2009. Data are drawn from Pharmaceutical Research and Manufacturers of America, *Profile 2008*; Bethan Hughes, 2009 FDA Drug Approvals, *Nature Reviews Drug Discovery* **9**, 89–92 (February 2010); and US Food and Drug Administration, Center for Drug Evaluation and research, statistical tabulations, various years.

molecules, plus the typically much larger molecules derived by gene splicing and related biological processes (but excluding vaccines, blood products, and the like). The large molecule drugs, conveniently called 'biologicals,' are also broken out for separate reporting with the dotted line in Figure 1, beginning in 1982 with the first such new entry, a synthetic human growth hormone. Because source counts vary, a slight estimation error cannot be avoided. It is clear with any set of definitions that the number of new drug approvals varies widely from year to year. The spike around 1996 is artificial, resulting from a sharp fee-induced reduction in the Food and Drug Administration's backlog of drugs awaiting approval. When that peak is redistributed over subsequent years, one finds a modest upward trend of approximately 2.1% per year.

With inflation-adjusted R&D expenditures rising at roughly 7.4% per year and the approval of new pharmaceutical entities increasing at only 2.1% per year, it appears likely that the average R&D cost of NMEs has been rising over time.

The R&D Phases

The discovery and testing of potential new drugs follow a fairly regular sequence of stages characterized in Figure 2. The horizontal time axis is calibrated at zero for the year when testing in humans begins. The vertical axis smooths impressionistically annual spending levels in year 2000 dollars, approximating averages reported by DiMasi *et al.* (2003) for drugs emerging mainly during the 1990s. The costs assumed are those of a project that goes all the way from preclinical work to regulatory approval. No adjustment is made for uncompleted phases, for example, abandonments or failures. There is a long discovery period in which basic and applied research seeks to find and/or synthesize new molecules and identify through theory and *in vitro* testing which drugs might actually work in human beings. In the early years of active pharmaceutical research, the discovery process entailed primarily a random 'try every bottle on the shelf' search, but as scientific knowledge has advanced, theory has come to play an increasingly important role. Once a promising molecule has been identified, it is tested on animals for possible toxicity.

If that hurdle is cleared, a stylized set of human testing phases begins, with appreciable attrition rates at each phase. In Phase I, the drug is administered to a typically small sample of humans to determine the safety of various dosages and in some cases to secure preliminary insight into whether the molecule can alleviate the target disease. If those tests yield promise, targeted Phase II tests for efficacy are conducted in larger cohorts. Success in Phase II is typically followed by considerably more extensive Phase III tests carefully designed with double blinds to infer at reliable levels of statistical confidence whether the drug is safe and effective relative to placebos or, less often, relative to the best-accepted approved drug in the relevant therapeutic category. Phase III tests, typically divided into at least two distinct protocols, may encompass from a few hundred human subjects (only for diseases with no known cures) to more than 10 000 individuals. If the results from Phase III are promising, the drug developer (usually a private pharmaceutical company) applies for marketing approval – in the US, for a new drug approval issued by the Food and Drug Administration; and in Europe since 1995, to the European Medicines Agency. On average, only one-fifth to one-fourth of the small-molecule drugs entering Phase I testing emerge approximately 8 years later with marketing approval. For biological therapies developed during the 1990s, the survival probabilities appear to be higher – for example, roughly 0.3 from a survey by DiMasi and Grabowski (2007) and even higher for the earliest approved biologicals, which mainly emulated naturally occurring substances.

The relevant regulatory agency may after approval insist on additional tests to clarify remaining uncertainties, in which case, further trials continue into a Phase IV. Or the company developing the drug may seek to illuminate more exactly the differences between its drug and existing competitors, embarking on its own initiative into further Phase IV testing.

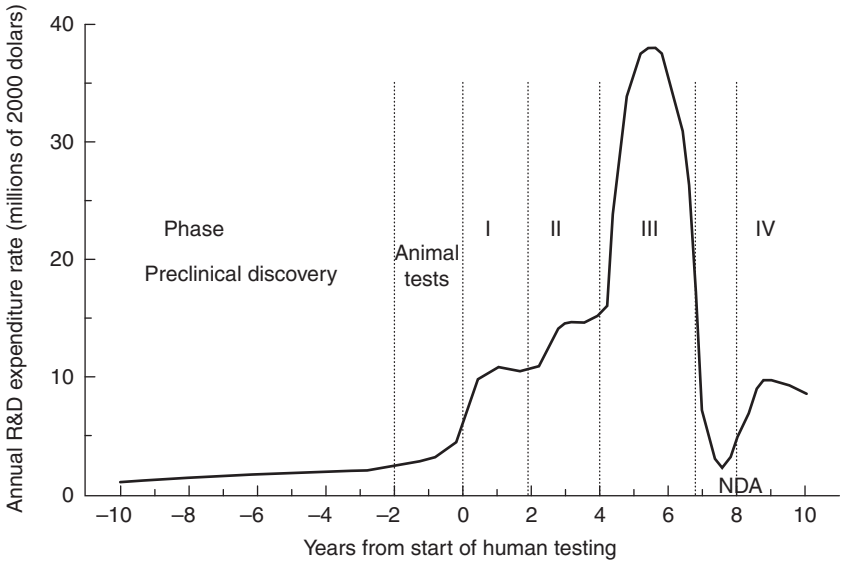

Figure 2 Schematic history of a successful new drug development. Adapted from data in DiMasi *et al.* (2003).

For wholly new vaccines (as compared to minor variants adapted annually to new strains of influenza) even larger human test samples are often needed. The basic problem is, once a subject acquires the target disease, it may be too late for vaccine administration. For preventative vaccines, tests are conducted on populations that might be afflicted in the future, and to keep trial periods within reasonable time bounds, given small probabilities that any given sample member will actually acquire the disease, samples numbering in the tens of thousands may be required to achieve acceptable levels of statistical discrimination along with detecting adverse reactions. To ensure accuracy, subjects might alternatively be injected with the target organism after vaccine administration, as was done, for example, during the eighteenth century in the discovery of the first cowpox-based smallpox vaccine, but this approach violates medical ethics and is now avoided.

Estimating R&D Cost per Successful New Drug

Given this broad picture and its many variations, interest has been focused on the productivity of research and development in yielding new pharmaceutical therapies, i.e., the cost per successful new molecule. There have been numerous quantitative investigations. The leading efforts, and those most highly cited in both the scientific and popular literature, have come from collaborating economists at Tufts University, the University of Rochester, and Duke University (DiMasi *et al.*, 2003). Their methodology, which aims to minimize the proliferation of names will be called the Tufts University studies, enlisted deep cooperation from a handful of major pharmaceutical companies (in the most comprehensive recent effort, 10) operating in the US. The investigators began by identifying a set of clinical testing programs undertaken by the cooperating enterprises on 68 so called 'self-originated' molecules first tested in humans between 1983 and 1994. Their sample excluded 'licensed in' drugs whose early development was performed by companies other than the survey respondents. Once the molecules entered clinical testing, detailed data on individual test program costs and failure rates were obtained so that they could be aggregated into estimates of the average cost per successful molecule, i.e., the actual out-of-pocket cost of the ultimate successes, into which were loaded the probability-adjusted estimates of preclinical and clinical phase failure costs. If, for example, only one molecule out of five entering Phase I testing ultimately secured marketing approval, the cost of an average Phase I test, successful or unsuccessful, was multiplied by $1/0.2=5$ to obtain the average Phase I success cost. Similar probabilistic adjustments were made for later stages. For the most recent of the comprehensive Tufts University studies, the estimated average out-of-pocket cost per successfully approved molecule, including the prorated costs of failed tests, all measured in year 2000 purchasing power levels, were as follows:

Preclinical	$121 million
Clinical testing	$282 million
Total cost per approved drug	$403 million

The mean clinical testing estimates, which are undoubtedly more reliable than preclinical estimates, can be compared with the analogous costs from three earlier studies summarized by Scherer (2010), each adjusted to year 2000 purchasing power levels:

Source	*Test period*	*Average out-of-pocket cost per approved new drug*
Mansfield	Late 1950s	$5.4 million
Clymer	Late 1960s	40.2 million
Tufts I	1970–early 1980s	65.7 million
Tufts II	1983–late 1990s	$282 million

It seems clear that the clinical R&D costs of new drugs have exploded over time. The particularly large multiplier between the estimates of Edwin Mansfield and Harold Clymer is explained by the fact that after 1962, constrained by new and tougher legislation, the US Food and Drug Administration enforced considerably more stringent rules for the evidence it would accept before approving new drug applications. The subsequent sizeable increase between Tufts I and II is now discussed later.

The estimates of success probability-adjusted preclinical R&D costs by the Tufts group are more problematic. For the Tufts II sample, it is seen in the table above, the mean value was $121 million, or 30% of total estimated mean cost per successful molecule. For the Tufts I sample (from the 1970s), it was $90 million (in year 2000 dollars), or 57.8%.

The striking reduction over roughly 15 years in preclinical cost shares, not explained by the Tufts researchers, is probably attributable to radical changes in the way new drugs have been discovered. The science of drug action in the human body advanced by leaps and bounds in the time interval separating the two studies, leading among other things to so-called 'rational drug design,' i.e., the structured synthesis of molecules targeted to interact in particular ways with known receptors in the human body. (A detailed chart of biological pathways is revised and published periodically by the Boehringer-Ingelheim Co. (Michal, 1993).) Much of the research underlying such insights was conducted not in drug company laboratories, but in universities and hospitals supported by grants, most notably, from the US National Institutes of Health. Between 1983 and 2000, the research budget of 'NIH' rose from roughly $2.7 billion (at year 2000 GDP price levels) to $14.4 billion, or two-thirds of US R&D outlays by PhRMA member firms in 2000. Additional research support came from the US National Science Foundation and private philanthropic institutions. An unknown but undoubtedly substantial fraction of such outlays generated basic knowledge helpful in the design of new pharmaceutical entities and in many cases identified specific molecules eventually brought into clinical testing by private sector enterprises (Scherer, 2010; Stevens *et al.*, 2011).

Also, the first drug synthesized using radically new gene splicing methods was introduced commercially in 1982, spurring the explosive growth of a new biotechnology industry, mostly in new companies initially financed by venture capital. Although 90% of the entities comprising the Tufts II sample were small molecules (as compared to biologics), it

cannot be ruled out that the sample companies saved some preclinical R&D expenditures by building on research done inter alia in biotech enterprises. However, DiMasi and Grabowski (2007) report quite similar constant-dollar R&D cost estimates for their Tufts II sample and a slightly later sample covering only biological entities.

Critiques

The Tufts estimates and their predecessors have been widely cited by pharmaceutical industry advocates to argue that drug testing is both risky and costly, and, with additional evidence, that government agencies ought not to intervene in pharmaceutical companies' controversial price-setting process (which in fact many national governments do through various price control mechanisms). Given this, the estimates have been criticized as biased and excessive. Diverse and conflicting critiques are found in Love (2003), Angell (2004), and Light and Warburton (2011). The criticisms have several foci.

Capitalization

More widely cited than the out-of-pocket averages presented above are estimates from the Tufts research of average drug discovery costs, capitalized to 'present value' at the time of product approval to reflect the cost of capital tied up during the R&D period. In the 1983–late 1990s estimates presented above, for example, out-of-pocket costs were capitalized to the time of marketing approval at an implied 11% cost of capital. To illustrate, suppose that 10 years before a new drug's approval date, for example, at year −2 in **Figure 2**, out-of-pocket costs amounting to $5 million (with adjustments for failed trials) are observed. The capitalized figure becomes $5 million $\times (1.11^{10}) = \$5$ million $\times 2.84 = \$14.20$ million, which is the value incorporated into the capitalized R&D cost sums. Here, 1.11^{10} is the amount to which $1 grows over 10 years at compound annual interest. Such adjustments are made for each year to take into account the 'opportunity cost' of companies' investable funds on the assumption that if the money were not invested in R&D, investors could allocate it to other comparably risky assets that over time would yield 11% inflation-adjusted annual returns (derived from standard finance sources using the so-called 'Capital Asset Pricing Model'). For years nearer the time of marketing approval, the adjustment is of course smaller; for example, 5 years out, $1.11^5 = 1.685$ rather than 2.59. When these capitalization adjustments are made, among other things giving relatively greater weight to preclinical as opposed to clinical testing costs, the $403 million Tufts II average successful drug development cost reported above nearly doubles to $802 million. For the earlier Tufts I study, average out-of-pocket costs (preclinical plus clinical) rise in year 2000 dollars from $156 million uncapitalized to $318 million capitalized.

This capitalization assumption, typically reported in the popular press without explanation, has been criticized by, for example, Light and Warburton (2011) on both conceptual and numerical grounds. To ensure correctness, most estimates of investment outlays for research and development as well as physical facilities, advertising, and much else, are typically publicized in unadjusted form for the year of incurrence rather than with capitalization, and consistency in reporting practice would argue for avoiding capitalization, unless the rationale is clearly explained. Nevertheless, it is clear that R&D outlays do have opportunity costs, and in drug discovery and testing, with their long time lags between outlay and the return of profits, the opportunity costs are more significant than for investments with quicker paybacks. Public controversy over the capitalization issue became sufficiently intense in the early 1990s that a specially created US government agency study team focused on it, among other things obtaining consulting assistance from prominent finance theorists. Its report was in US Congress, Office of Technology Assessment (OTA) (1993). The study group concluded that the three most important components of R&D investment are 'money, time, and risk' and that 'the practice of capitalizing costs to their present value in the year of market approval is a valid approach to measuring R&D costs....' Given the lack of public understanding; however, it would undoubtedly be good practice for journalists to report out-of-pocket costs along with capitalized cost estimates.

The higher the interest rate used in capitalization, the larger is the multiple between out-of-pocket and capitalized costs. Light and Warburton (2011) argue that the 11% interest rate used by the Tufts group was too high, given that US Government Office of Management and Budget guidelines in 2003 called for applying a 3% interest rate in evaluating public capital outlays. This criticism is clearly wrong. Governments like in the US (at least up to the year 2012) financed their deficits with what were widely considered 'risk-free' bonds that indeed often bore quite low interest rates. But the common stock with which corporations are financed is riskier and bears considerably higher implicit interest rates. Addressing this issue, finance experts advising the US OTA found (p. 67) that the cost of capital (i.e., the implicit interest rate) for established pharmaceutical companies in the 1980s and early 1990s was on the order of 8–10% after stripping away inflation premia. They also found that R&D-intensive activities were more risky than ordinary corporate investments, calling for interest rate premia on the order of 4.5 percentage points, or approximately 13–14% overall. Recognizing this, the 11% implicit interest rate used by the Tufts group appeared consistent with broader knowledge and perhaps even conservative for the time period covered.

Tax Benefits

Some critics have argued that tax savings realized by corporations as a result of their R&D outlays (treated as current expenses under prevailing tax accounting) ought to be deducted in estimates of what drug development costs. It is true that tax offsets exist. Considering first only the corporate income tax, when a corporation spends an incremental dollar on R&D, that dollar reduces its current pretax profits by a dollar (assuming profits to be positive), and at the 34% US corporate income tax rate prevailing at the time of the most recent Tufts study, a savings of 34 cents is achieved. The problem with adjusting for this saving is that it applies for any incremental expenditure in a positive-income regime – for the cost of hiring an additional worker, for the cost of fuel, for the cost of

environmental cleanup activities, and so on. But to apply such adjustments for each expenditure requires distinctions between optional and mandatory outlays and runs into the difficulty that, if every expenditure were treated as less costly than its out-of-pocket cost, expenditures could rise to exhaust the profits against which savings are claimed. Also, multinational pharmaceutical companies have been adept at shifting their reported profits to nations with low marginal income tax rates, so any attempt to offset R&D outlays by tax savings would have to cope with a multiplicity of savings rates.

A slightly better case can be made for adjusting R&D outlays for tax benefits specific to R&D. These were of two main relevant forms. Under US law since the 1980s, credits against income tax liability have been offered for increases in R&D expenditures relative to the amount expended in specified base years. The provisions of the law have varied from time to time, so adjustments would be complex. Because the credits apply only to incremental outlays above a base year value, it would be difficult to determine which outlays in a large R&D budget are incremental and which are within the no-credit baseline. Special 50% federal income tax credits have also been offered under US law since 1983 for costs incurred testing so-called 'orphan' drugs, i.e., those expected to serve small patient populations. Because the credits are targeted at specific molecules, adjustments to orphan drug R&D costs would be more feasible than adjustment for generalized tax savings. Other complexities of estimating orphan drug R&D costs are considered later.

More generally, the genuine issues posed by capitalization and tax benefits are best judged in policy evaluations of pharmaceutical companies' aggregate net profitability, not with respect to specific drug discovery and testing cost estimates. There too issues arise, although they are beyond the scope of this article. The OTA study concluded (1993) that established pharmaceutical firms' rates of return on net capital averaged 2–3 percentage points higher than their cost of capital, estimated to be roughly 10% after taxes. The OTA group refrained from rendering a clear value judgment as to whether such a premium was problematic, given the risks of new drug development and the desirability of attracting new investment.

Sample Representativeness

Without doubt the most compelling criticism of the Tufts methodology is that their samples may not have been representative of the entire drug development universe. For the Tufts II estimates, the unnamed product sample and cost data came from 10 pharmaceutical firms, 8 of them from the top 20 in terms of sales volume – i.e., the representatives of what many call 'Big Pharma.' It is conceivable that the drugs chosen for development by those companies differed from those developed by smaller firms or even misrepresented the respondents' typical portfolios. In particular, with vast sales pipelines to fill, the companies may have emphasized candidates with a large sales potential – i.e., with luck, the 'blockbusters.' For example, drugs that address widespread health conditions and that are prescribed for chronic as contrasted to acute symptoms tend to have better sales prospects than those targeting relatively rare and/or acute conditions – e.g., those with the mandate, "Take two tablets per day for ten days and if the symptoms persist, see your doctor." Higher sales prospects, both theory and statistical analyses reveal, induce more lavish R&D outlays (Scherer, 2010).

The testing strategies mandated by the Food and Drug Administration or favored by the companies may also have differed. For drugs that will be taken daily for years on end, regulators tend to be more wary of rare and/or cumulative adverse side effects and require larger samples to impart additional statistical confidence on what might otherwise be seen as clinical testing flukes. And for drugs alleviating chronic medical problems of long standing, new drugs will often have to compete with existing therapies that may arguably be less effective, but the differences are foreseen to be sufficiently small that tests are authorized not against placebos, but against established molecules, with unusually large clinical populations to obtain evidence bolstering marketing claims that the new drug is in fact superior to existing alternatives.

A case history at the opposite extreme is seen in the first drugs effective against human immunodeficiency virus/acquired immune deficiency syndrome (AIDS), recognized as a threat by physicians only in the 1980s. The lethality of AIDS was so shocking, and its spread so rapid, that clinicians and regulators accepted major shortcuts to ensure that weapons against the disease were immediately available. The first candidate, azidothymidine (AZT) (also known as zidovudine), was approved by the Food and Drug Administration in March 1987 – only 25 months after the start of human testing, breaking post-1962 speed records. Although comparative placebo tests were conducted, the decisive trial included only 282 patients, and instead of waiting to see whether or how long AZT recipients lived, FDA evaluated the drug's efficacy mainly on the basis of 'surrogate endpoints' – i.e., measures of retroviral levels in trial subjects' blood. Clinical trials were conducted jointly by Duke University, Burroughs-Wellcome, and the National Institutes of Health, with substantial financial support from the NIH. Another AIDS drug, Nevirapine, with the remarkable ability significantly to inhibit transmission of the disease from infected mothers to newborn children, was approved in June 1996 after trials spanning 76 weeks on a total of 549 patients, one branch conducted by the US NIH in parallel with other tests by the drug's inventor, Boehringer-Ingelheim of Germany (Love, 2003).

The initial AIDS drug developments shared two distinguishing bureaucratic characteristics. First, the early AIDS population was sufficiently small that the first therapeutic candidates were ruled at the outset to be 'orphan drugs' – i.e., mainly targeted toward conditions afflicting 200 000 or fewer individuals in the US. Second, they were also accorded 'priority' status by the Food and Drug Administration – i.e., for molecules offering potentially major improvements over already marketed therapies, as distinguished from 'standard' drugs yielding more modest therapeutic gains.

As has been seen, private funds in the US devoted to orphan drug testing have been accorded in the US especially favorable tax status, and clinical testing support by Federal government entities is also common. Recognizing the possibly small market potential of orphan drugs, the Food and Drug Administration has tended to accept smaller clinical trial samples than for drugs targeting wider markets. Also, because

of the tax implications, data are publicly available on the total amount spent for orphan drug testing. For 16 new orphan chemical entities approved in the US between 1998 and 2000, the average clinical trial cost per approved orphan, prorating the costs of failed tests, was $34 million (Love, 2003). This is far below the $282 million out-of-pocket for the most recent Tufts sample, the bulk of whose testing outlays occurred in years earlier and hence were less inflated than those gleaned by James Love. Although DiMasi *et al.* (2003) do not elaborate the point, the OTA reported (1993, p. 232) that roughly two-thirds of orphan drug designations went to companies that were not PhRMA members.

Orphan drugs are also more likely to obtain priority rankings from the Food and Drug Administration than standard drugs. Thus, for new chemical entities approved by the FDA during the first 5 years of the twenty-first century, 89% of the orphans had priority ratings, as compared to 38% for the standard drugs (Scherer, 2010). Since the early 1990s, the Food and Drug Administration has tended to process nonorphan priority drug approval requests more rapidly than standard requests. It is also possible that FDA demands fewer and less costly clinical trials for priority drugs, but on this the evidence is sparse. DiMasi *et al.* (2003) report that in their Tufts II sample, the out-of-pocket clinical testing costs of priority drugs exceeded the average cost of standard drugs by a statistically insignificant amount. The difference was even smaller for capitalized costs, implying that test-to-approval lags were shorter for the priority drugs. DiMasi *et al.* (1991) suggest that priority drugs may have been more costly to test because they break newer scientific ground, requiring more learning-by-doing, and also (p. 172) because "firms have the incentive to do more wide-ranging and costly testing on drugs that have the potential to be both clinically and commercially significant." Whether this inference carries over to the non-orphan priority drugs tests of smaller companies is unknown.

An Independent Test of the Evidence

There are other fragments of evidence suggesting average out-of-pocket costs lower for drugs outside the Tufts sample than for in-group molecules. But now an alternative approach is explored. Several authors, such as Adams and Branter (2010), have pursued more aggregative approaches to the problem of estimating drug development costs. Here the author report the result of his own broad-brush approach. The methodology is simple: dividing annual counts of new therapeutic entity approvals in the US into the reported intra-US research and development spending of PhRMA members. It is bound to be incomplete and inexact for at least four reasons. First, PhRMA's membership includes companies with a home base outside the US, and by excluding overseas R&D outlays, the full costs of their drugs approved in the US are certain to be underestimated. Second, many of the drugs approved in the US come from non-PhRMA members, and although such firms' innovations are included in the denominator of cost/drug calculations, their R&D outlays are excluded from the numerator, again resulting in an underestimate. Over the years 2001–05, the non-PhRMA share of approved new medical entities was 51%, implying a sizeable downward bias. Third, the R&D expenditures of PhRMA members are focused not only on developing and testing NMEs but also testing to see whether existing molecular entities are effective against additional disease conditions, developing vaccines and other biological products, and reformulating inert binders that control the timing of a drug's release into the blood stream. And much Phase IV research undertaken by major pharmaceutical firms is aimed not at complying with regulatory agency mandates, but to strengthen evidence used in field marketing of already approved molecules. By excluding such projects from the denominator count, the cost per drug, new and old, is overestimated. And finally, as we have seen in **Figure 2**, the R&D expenditures underlying new entities precede by as much as a decade the date of approval. Lags must be accounted for, but are inherently variable.

Recognizing that perfection is unattainable, the following methodology was pursued. The **Figure 1** time series of NME approvals for the years 1974–2007, including both small-molecule drugs and some biologicals (but not vaccines and the like) was used as the denominator of the cost calculation. Total reported R&D expenditures of PhRMA members in the US were used, adjusted with the GDP deflator to constant year 2000 price levels, to measure costs. To reflect the fact that approvals lag the incurrence of testing costs, the R&D series was prelagged by 4 years relative to approvals, for example, approvals in the year 2000 were related to 1996 R&D expenditures. This convention reflects in a crude way the central tendency of the outlay flow shown in **Figure 2**, with outlays peaking 3 years before approval but with early outlays weighted more heavily because of attrition.

The Tufts II analysis focused on drugs whose clinical test expenditures were mostly incurred between 1983 and 1999. Within that restricted sample of years, the computed average out-of-pocket cost R&D per lagged NME approved, using the methodology described above, was $306 million in year 2000 dollars (also used as the measuring basis for Tufts group's summary estimates). When the exercise was repeated without the inclusion of biological entities, the average was $390 million. The Tufts II estimate, including seven biologicals (10% of the sample) was $282 million. The difference is small, suggesting that for an intrinsically difficult measurement, the Tufts estimates are both credible and perhaps even conservative.

For the full 1974–2007 molecular approval series, the average growth rate of constant-dollar R&D costs per molecule was found by regression analysis, which smooths year-to-year variations, to be 6.5% per year with biologicals included and 7.2% per year with them excluded. DiMasi *et al.* (2003) estimated the growth rate between their Tufts I and II studies, spanning slightly shorter intervals, to be 7.4%. Again, the conclusion seems inescapable that there has been substantial growth in R&D costs per new approved molecule, or in other words, a decline in research productivity.

Reasons for Change

Several hypotheses vie to explain the apparently continuous increase in R&D costs per molecule approved. Despite advances in the technology of preclinical small-molecule screening, one might suppose that diminishing returns would

set in after seven or more decades of active discovery, among other things forcing companies to focus on more difficult therapeutic targets. During the 1990s it was thought that the perfection of large-molecule gene-splicing techniques would reverse any such tendency and usher in a new golden age of pharmaceutical discovery. However, the observable changes thus far have been less than revolutionary.

There is definite evidence that clinical trial sizes have risen over time, partly as a result of tougher standards established by the US Food and Drug Administration. Also, as individual therapeutic classes became more crowded, companies may have elected to increase sample sizes to improve the statistical significance of results touted in competitive marketing. For three therapeutic categories studied by the OTA (1993), average enrollment in Phase I through III clinical trials rose from 2237 for drugs approved in 1978–83 to 3174 for 1986–90 entities, implying a median year growth rate of 4.7%. The average number of subjects drawn into Phase IV grew considerably more rapidly, from 413 to 2000 (sic), or 21% per year. Using publicly available data, DiMasi *et al.* (2003) estimate that average trial sizes in the 1980s and 1990s rose at a rate of 7.47% per year. In addition, the complexity of trials rose. DiMasi *et al.* (2003) report from an outside data source that the number of procedures administered per trial subject increased between 1990 and 1997 by 120% for Phase I trials, by 90% for Phase II trials, and by 27% for Phase III trials. Weighting the phase growth percentages by the fraction of out-of-pocket costs incurred per phase, this implies an average growth of 50% in 7 years, or 5.8% per year.

Clinical trials are mostly conducted in hospitals and similar medical centers. Over the period 1970–90, a day of hospitalization costs in the US rose at an average rate of 11% per year – nearly twice the rate at which the GDP price index was increasing. It seems reasonable to assume that in-hospital test costs rose commensurately. There is also reason to believe that major hospitals view their clinical testing activities as a 'profit center' and dump some of their soaring overhead costs onto the well-heeled pharmaceutical firms sponsoring clinical trials.

A more speculative hypothesis is that 'Big Pharma' companies have allowed organizational slack to accumulate in their R&D activities, especially after numerous large-company mergers failed to achieve substantial increases in the output of new therapeutic entities (Munos, 2009). A correction against this trend may have begun in the second decade of the twenty-first century as pharmaceutical giants such as Pfizer and Merck, acknowledging disappointment over the lagging productivity of their innovation efforts, cut back their R&D staffs in the wake of major new mergers.

Conclusion

In summary, the research and clinical testing costs underlying pharmaceutical innovations have risen considerably over recent decades to levels measured in hundreds of millions of dollars per approved new molecule. The most widely publicized estimates of R&D costs, sometimes poorly understood, are consistent with alternative estimates. There would probably be less controversy over those estimates if more detailed data on sample composition were disclosed, but confidentiality constraints imposed in exchange for access to company microdata may preclude this. It is clear that clinical success may be achieved at substantially lower cost with alternative models of pharmaceutical development and testing, but embracing those alternatives requires streamlined regulatory and organizational approaches and sacrifices in the richness of the evidence on the basis of which physicians must make subsequent prescription choices.

Resource Allocation Funding Formulae, Efficiency of

W Whittaker, University of Manchester, Manchester, UK

Glossary

Actual allocations The allocations Primary Care Trusts (PCTs) in England receive for the forthcoming financial year.

Allocative efficiency Producing the maximum output subject to a constraint.

Department of Health The ministry responsible in England and Wales for determining PCT allocations for each financial year.

Disability free life expectancy (DFLE) It is the expected years of life with no limiting long-term illness or disability.

Market forces factor (MFF) It is an index used to weight PCTs in accordance to the differing costs of delivering health care across England.

National Health Service It is the provider of publicly funded healthcare in the four countries of the United Kingdom (England, Wales, Scotland and Northern Ireland).

Need Capacity to benefit from additional expenditure, often proxied by utilisation. Additional need represents need over and above the age structure of the population. Legitimate and illegitimate need are often operationalized as utilization that do/do not reflect need. Unmet need represents under-utilization of services by groups of the population. General unmet need affects all groups in the population proportionately. Specific unmet need affects particular groups of the population.

Pace of change The rate at which PCTs are moved toward their target allocations from previous allocations.

Payer The institution or body responsible for distributing the healthcare budget.

Primary Care Trust The geographic organizations responsible for the spending of an area of England.

Production possibility frontier It is the maximum amount of health generated for differing levels of expenditure.

Pure efficiency Allocations made that maximise risk-adjusted health gains.

Resource Allocation Working Party It was set up to attain a resource allocation formula that objectively, equitably and efficiently responded to relative need.

Social welfare function A function that maps from the levels of utility attained by members of society to the overall level of welfare for society.

Target allocations Allocations expected to meet the needs of the PCT in accordance to the PCT population size, age structure, additional needs (over and above age), MFF, and DFLE.

Technical efficiency A given output is produced using no more inputs than are technically necessary – there will normally be a wide variety of different combinations arising out of their substitutability.

Weighted capitation Payment per individual, weighted by risk, more risky populations hence receive higher payments.

Introduction

Publicly funded health care systems require some form of resource allocation funding principles, usually in the form of formulae, to enable the payer (typically a government body) to distribute health care budgets across population groups. Population groups are typically defined by geography and a population within each geographic boundary is likely to have variations across individuals within it both in terms of health and in the utilization of healthcare services.

To distribute health care budgets efficiently requires knowledge of how population groups differ, which in turn relies on up-to-date data on population variations in the need for health care. Need, taken here as the capacity to benefit, is difficult to measure. Poor data availability usually results in need being proxied by service utilization, with the assumption that populations with higher needs will have higher rates of health care services use. Precision is therefore not really to be expected in matching budgets to local needs, because data on neither can be perfect. Perhaps the best that can be expected is that formulaic solutions push the system in the right directions.

Utilization, however, reflects access to care which may be the product of both demand (influenced by an individual's need for care, how affordable care is to the individual and whether the individual is willing to accept care) and supply factors (whether the individual has providers of care in their area and whether care is available). If access varies by geographic population groups, funding formulae using utilization measures alone to allocate budgets could reinforce inequalities and inefficiencies in both health and access to health care.

An alternative way of measuring need is to use demographic and/or health related population characteristics as a proxy (e.g., a mortality ratio, which assumes populations with higher needs have higher mortality ratios). Although such proxies can serve as an alternative to measuring need as utilization, they are most frequently seen as complementary measures, the assumption being that they detect different aspects of need.

Weighted capitation methods are typically used to apply a needs-based approach to resource allocation in health care. These methods weight populations by indices of need and are used to determine each population group's share of the health care budget.

The main challenge in designing resource allocation formulae is that they ought to allocate health care budgets in accordance with the payer's objectives. The payer's objectives typically relate to efficiency, equity, or more likely, a mixture of

 doi:10.1016/B978-0-12-375678-7.00211-X

both. The prime concern lies with whether the funding formulae used to derive allocations is efficient, i.e., pushes the system toward maximizing the health of society given the resources available, or whether there is potential for inefficiencies in the funding formulae such that the push is in the wrong direction. This article investigates how weighted capitation approaches, and the payer's efficiency-equity objective, impact on the efficiency of the resource allocation funding formulae used to distribute health care budgets.

The article is structured as follows. First, what is meant by efficiency in the resource allocation formulae is explained and examples provided of the conflict between efficiency and equity in resource allocation using two population groups. Second, the extent to which the formulae impact or are impacted by technical efficiency is looked at. Examples of how the resource allocation formulae have developed since the introduction of the National Health Service (NHS) in England, and the impacts of these changes on efficiency are then given. Much of the discussion presented on the efficiency of using a weighted capitation approach in England is applicable to other international settings. While the methods for the financing of health care in the developed world vary widely, there has been increasing use of capitation payments. The final section provides the article summary.

Efficiency

A Production Possibility Frontier Approach to Resource Allocation

Economic efficiency consists of two types of efficiency, allocative and technical efficiency. Allocative efficiency concerns producing the maximum output subject to inputs, i.e., it is not possible to increase output simply by reallocating resources, and it is achieved by equalizing the marginal capacity to benefit from additional funds across all inputs, while technical efficiency concerns utilizing a specified combination of inputs to produce maximum output. From a resource allocation perspective economic efficiency concerns maximizing the value of output (health gains and/or prevention) from given resources.

The problem with measuring efficiency in health care is that it is not obvious how to define the output of interest: is it health care use? Access to health care? Or measures of health gains or outcomes? Further, how can such data be obtained? Hollingsworth (2008) provides a review of the literature surrounding the measurement of production frontier efficiency in health care. The answers to these questions are not obvious, and will likely invoke some normative judgment.

Figure 1 gives a graphical representation of a production possibility frontier (PPF) for a public service, that is, the plot of health outcomes associated with spending on a population group (this example, and what follows is adapted from Smith (2007)). The aim is to determine the optimum payment for the population group given the payer's efficiency and equity objectives. The PPF relates expenditure (X) on the population group to the health outcomes (Y), and is a cumulative outcome for all individuals within the population group. The more productive the population group is in generating health,

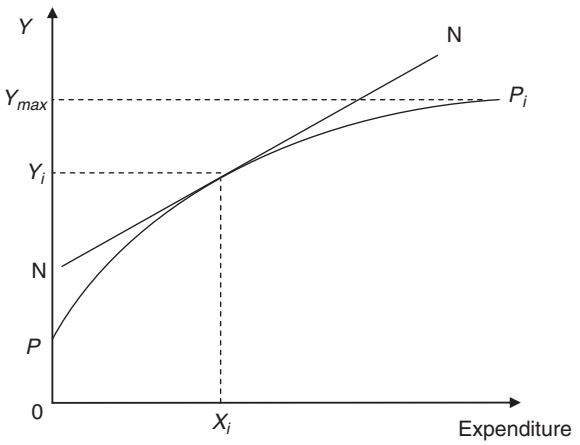

Figure 1 Production possibility frontier (PPF). Adapted from Smith, P. C. (2007). *Formula funding of public services*. London and New York: Routledge Taylor & Francis Group.

the higher the PPF lies. In this simple example it is assumed that no historic spend feeds into present health, and that population groups with zero public health care expenditure may have a positive health outcome. This may be because of private utilization of health care services, for example. This figure, and all subsequent figures are illustrative, and not much should be read into the intercept.

The PPF for population group i (PP_i in Figure 1) represents outcomes for payments where technical efficiency holds (efficient production of the health care by the providers serving the population group). Further assumptions are that there are decreasing returns to expenditure (the PPF is concave), that there is only one input (or alternatively that all inputs can be aggregated to one measure, in this example, budget allocations) and one output (some measure of health such as life-years gained, whose value is independent of the identity of those in whom it is embodied), and that other factors such as different providers, complimentary services, the environment, personal characteristics, and societal influences are exogenous to the shape of the PPF. The time period is assumed to be 1 year (that, in reality, is typically the time frame used for allocated budgets).

The need of population i can be measured as the difference between the level of health at a particular level of expenditure, and the maximum health attainable. In the case with unlimited funds, one may expect to observe expenditure up to the point where the benefit (additional health) of additional expenditure is zero (i.e., where further need is zero). This is where the PPF flattens out (Y_{max}). Unfortunately, resources are scarce, and the available budget allocated to health care (which in itself is also an issue for efficiency at the State level) may not be enough to ensure that maximum health is attained. With an allocated health care budget payers have to determine how to distribute this across geographic populations.

Figure 1 highlights, in this simple example, how determining the amount of expenditure determines the outcome achieved. With this in mind, and with knowledge of each geographic population's PPFs, the payer can optimize a social welfare function.

The payer determines the social welfare function and hence marginal social value (slope of NN in Figure 1), essentially a

cut-off cost above which no more treatment is offered. The payer provides expenditure up until the point where additional expenditure results in less health produced than is valued by society. Only at expenditure X_i does the marginal social value of the payer meet the marginal gain in health outcome (benefit). Expenditure less than X_i corresponds to a higher marginal benefit than marginal social value (the slope of the PPF is steeper than the slope of the welfare function, NN). Expenditure greater than X_i corresponds to a lower marginal benefit than marginal social value (the slope of the welfare function, NN, is steeper than the slope of the PPF). A steeper social welfare function would have a higher marginal social value of expenditure, and this would imply optimum expenditure at a higher marginal gain in health, which would lie to the left of X_i. To be allocatively efficient the payer should equate the marginal social value to the marginal benefit, this would be at expenditure X_i and corresponds to the pure efficient solution to resource allocation. The pure efficient solution maximizes aggregate outcomes, and is where expenditures are allocative and technically efficient. Alternative allocations would result in a reduction in total health produced.

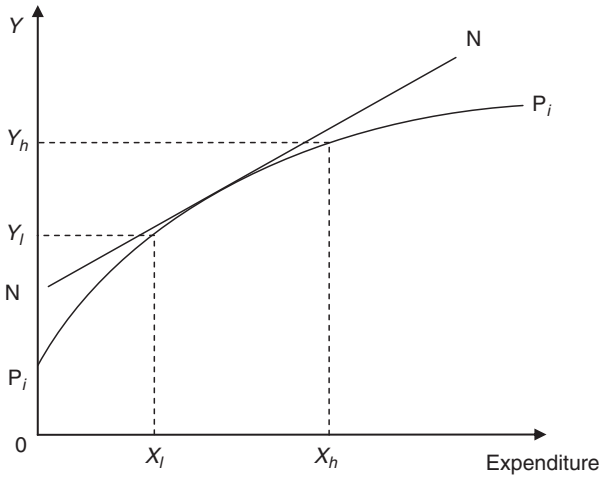

Figure 2 Inefficient allocations of expenditure across two populations with the same PPF. Adapted from Smith, P. C. (2007). *Formula funding of public services*. London and New York: Routledge Taylor & Francis Group.

The Divergence from Pure Efficiency

In reality there are two main reasons why the pure efficiency solution above is never met. First, allocations may not be set at the point where the marginal capacity to benefit from expenditure equals the marginal social value. This may be because of inaccurate needs measurement, differences in the cost of delivering health care across population groups, or as a result of an alternative equity objective held by the payer. Second, although the payer may distribute budgets efficiently, budgets might not be spent efficiently by providers serving the geographic populations (technical inefficiency). This section will look at each case.

Inaccurate needs measurement

Where expenditures do not reflect need, the implication is that populations of equal (risk adjusted) marginal need receive different budgets. Figure 2 gives a graphical example. In this case, two populations have equal need and are equally productive (the PPFs for the two populations are the same and overlap), but receive different allocations, X_l and X_h. One population receives X_l and resulting outcome Y_l, while the other receives X_h and outcome Y_h. Allocative efficiency does not hold here since redistributing funds so each population group receives the same expenditure would increase outcomes in total. This is because the increase in expenditure to the low-resource population (l) results in greater gains in outcome than the loss in outcome from decreasing expenditure to the high-resource population group (h). The four main ways in which inaccuracies arise are described below.

Utilization methods to model need

Utilization data is largely employed in resource allocation formulae to help model the needs of different geographical populations. This assumes that higher utilization of services reflects a higher capacity to benefit from expenditure. There are a variety of methods available to weight geographic populations based on utilization data. For example, one can weight populations based on the share of total utilization, or apply average utilization rates to the age and/or gender breakdown of geographic populations. Detailed econometric methods can also be applied, enabling a multitude of population characteristics to explain variations in utilization across population groups. This approach regresses geographic population level utilization on variables thought to identify needs. The estimates from the regression are then used to weight the geographic population's share of the budget to reflect the differences in need across each geographic population.

Analyzing utilization data to direct budget allocations poses two potential problems, the first being that only observed (met) needs are modeled. Under- (and over-) utilization by population groups will be sustained in this setting. The second concerns the effect of supply-side impacts on utilization. Variations in utilization may be because of differences in provider provision of services rather than need.

Unmet need

Unobserved (unmet) need can either be general or specific. General unmet need is nondiscriminatory across all geographic population groups, such as a lack of health care services for all. This does not bias the formulae since the unmet need represents a common proportionate lack of health care meaning relative needs weights to population groups remain valid. Specific unmet need is discriminatory, affecting certain geographic population groups because of their population makeup. For example, if utilization is lower for minority ethnic groups, population groups with higher rates of minority ethnic groups would receive a lower weighting than would be if the needs of minority ethnic groups had been observed. To control for specific unmet need, estimates with the 'wrong' sign in regressions explaining utilization may be held back from being part of the funding formulae weights (for example, negative estimates for minority ethnic groups where no clinical explanation for an ethnic difference is identified).

Illegitimate supply

Illegitimate supply-side factors are where variations in utilization reflect providers' provision of services rather than the needs of population groups. For example, utilization approaches could reinforce any existing inefficiency in maintaining service provision levels that may in part reflect an access to health care issue (such as differences in waiting times for hospital surgery or in the availability of General Practitioners across geographic population groups). Methods to control for any illegitimate supply-side factors include the addition of geographic population group dummies in a regression to control for group average variations that are over and above the observed variations across geographic population groups.

Age and gender weighting

Age and/or gender weights may be applied to the resource allocation formulae, in addition to, or in place of, utilization modeling. The motive for such an inclusion is the notion that health needs vary over the life cycle and by gender. To be accurate these must fully explain variations in need. This, however, is unlikely, given numerous other factors including socioeconomic status, education, and sociodemographic characteristics have been found to explain variations over and above age and gender.

Incorporating concerns for health inequalities

Geographic populations may differ, in part, because of demographical or epidemiological factors. Differences in geographic populations may mean that the same level of expenditure will result in different health outcomes between geographies. That is, differences in productivity result in different PPFs across geographic populations. How productive a population group is determines the height and/or slope of the PPF. Differences in the height of PPFs across population groups do not alter the allocations made under pure efficiency. However, differences in the slope of the PPF across geographic populations have important implications for the pure efficient allocation. For the payer to maximize outcomes, it has to adjust expenditure and outcomes by marginal need. Needs adjustment will make the marginal social benefit from expenditure equivalent across geographic populations, meaning the same sloped line is applied to all geographic populations, irrespective of their PPF. Applying the same sloped line means across each geographic population the marginal social value and marginal benefit are equal at the allocative efficient levels of expenditure. At these levels an additional increase in expenditure results in the same increase in benefit (health) for each geographic population. This can be seen as the pure efficiency solution. Any variation from this leads to a net reduction in the sum of outcomes.

Assuming needs have been fully captured in the resource allocation formulae, the pure efficient solution is consistent with different geographical populations attaining different levels of health. For example, one population may be less productive, with a lower PPF, shown by P_1 in **Figure 3**. With no funding formulae, the payer may divide the budget into two, say X^*. At X^* the capacity to benefit from expenditure is greater for the less productive population. Utilization rates may reveal that the less productive population has higher utilization because of the population being relatively older than the more productive population. Weighting X^* on the basis of differences in utilization by age may direct allocations to X_1 and X_2. Under the pure efficiency outcome (where N_1 and N_2 have the same gradient), although the less productive population group receives a higher budget allocation than the more productive population, $X_1 > X_2$, there are differences in health outcomes across the two populations, $Y_2 > Y_1$.

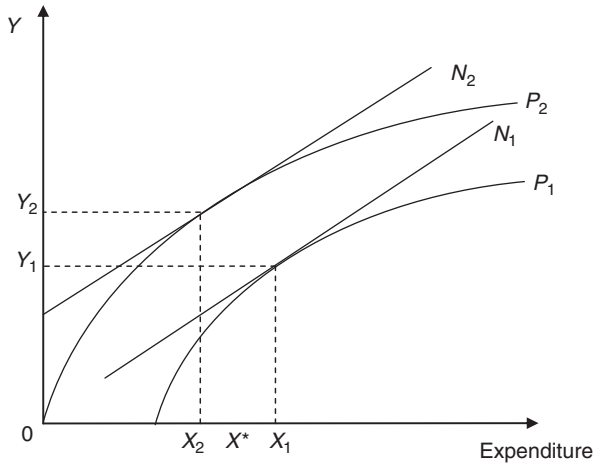

Figure 3 Heterogeneity in PPF across population groups. Adapted from Smith, P. C. (2007). *Formula funding of public services*. London and New York: Routledge Taylor & Francis Group.

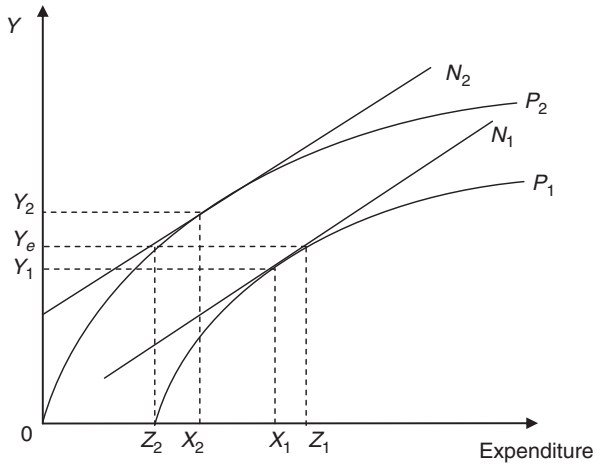

Figure 4 Changes in expenditure to achieve equal outcomes for two populations with different PPFs. Adapted from Smith, P. C. (2007). *Formula funding of public services*. London and New York: Routledge Taylor & Francis Group.

However, differences in health outcomes across population groups may not be seen as equitable. Policy aims have an important impact on how this inequality should be targeted. **Figure 4** gives the expenditure required to ensure both population groups in the example attain the same health, Y_e. The pure efficient solution has differing health outcomes and payments, so to attain Y_e requires increasing allocations to the less productive population ($Z_1 > X_1$), and decreasing

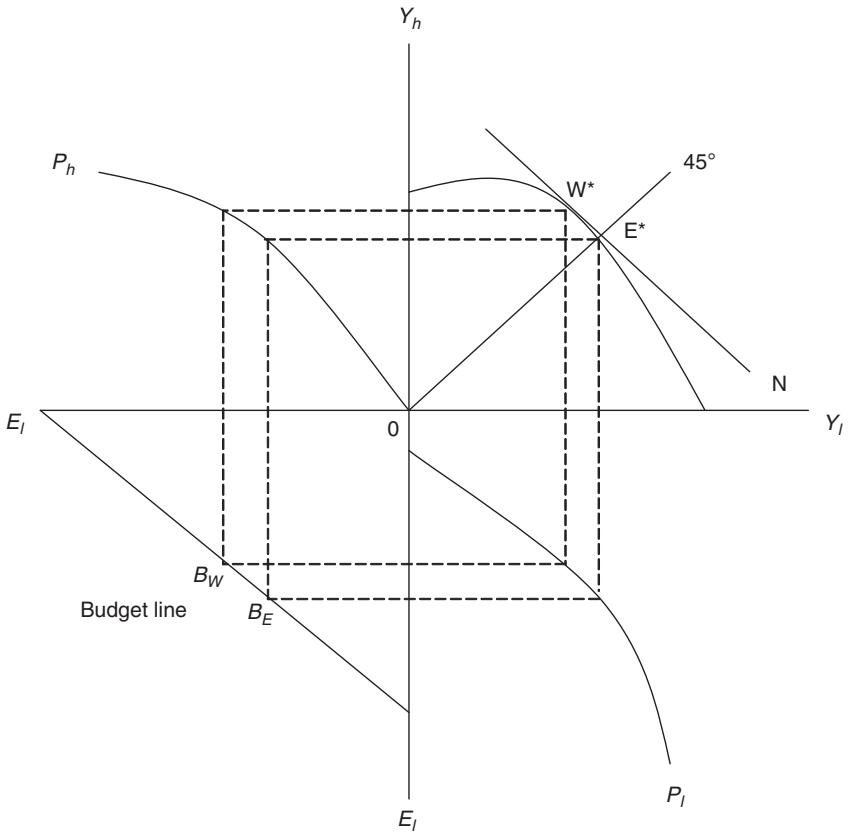

Figure 5 Efficiency-equity trade off. Adapted from Smith, P. C. (2007). *Formula funding of public services*. London and New York: Routledge Taylor & Francis Group.

allocations for the more productive population ($Z_2 < X_2$). As both population allocations are now allocatively inefficient (but still technically efficient), the allocation is less efficient ($Y_1 + Y_2 > 2Y_e$).

Equity versus efficiency

Figure 4 highlights the trade-off in health outcomes when equity or efficiency are maximized. An alternative way to present the trade-off is given in Figure 5. The North-West and South-East quadrants give the PPF for the high productive and low productive populations respectively; the North-East quadrant maps the two production frontiers together to attain total output possibilities between the two populations. The South-West quadrant gives the budget line, with all points on the line sum to the total budget available. Weighted capitation would provide the weight applied to each population. The total outcomes for the two populations are obtained by: allocating expenditure between the two in the south-west quadrant, mapping these to the PPFs for each population in the North-West and South-East quadrants, and finally mapping these to the production possibility frontier in the North-East quadrant. The line N in the North-East quadrant gives the relative marginal social value of each population's outcome. Here it is assumed to be symmetric. The payer's welfare function (and hence slope of N) will dictate how allocatively efficient the allocation is (note it is still assumed technical efficiency holds). The allocations under the pure efficiency solution, where total outcomes are maximized and the marginal capacity to benefit from additional expenditure is equivalent across population groups (W^* in the North-East quadrant), would be point B_W. The alternative equal outcomes objective, where equal outcomes are attained between the two groups (E^* in the North-East quadrant), would be under allocations at B_E. Total outcomes will be inefficient (lower) under the equal outcomes solution (E^*) than the efficient solution (W^*).

Avoidable inequalities in health

One implication of populations having different PPFs is that some populations may never be able to attain a state of health that equals the average across the total population. Figure 6 gives an example where the maximum possible health achievable is lower for one population than the average of the two (Y_e is above the PPF for the less productive group at all points). Figure 7 gives the four quadrant representation. In this example, any attempt to achieve equal outcomes in health will fail (no amount of allocation could ensure the less productive population will reach Y_e). The best the payer can hope to achieve is to ensure the removal of *avoidable* inequalities in health outcomes. In terms of Figure 7, this means allocating at the point where the PPF for the less productive population begins to flatten (the maximum that population group can achieve). Note how, compared to the pure efficiency solution (W^*), the equal health outcome (AE^*) requires a relatively

greater loss in potential health for the more productive population than the negligible gain in health for the less productive population.

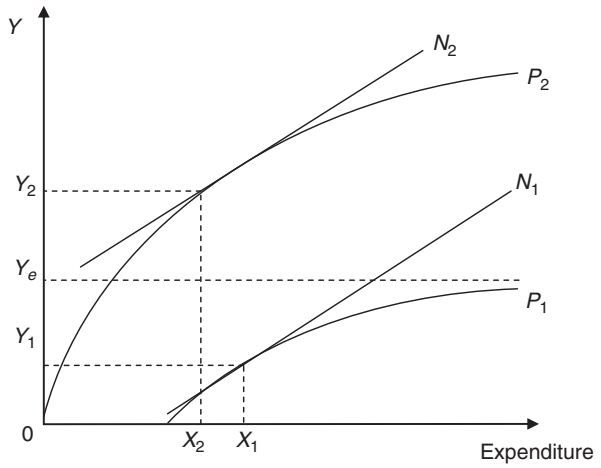

Figure 6 Avoidable inequalities in health. Adapted from Smith, P. C. (2007). *Formula funding of public services*. London and New York: Routledge Taylor & Francis Group.

Differing costs in the delivery of health care

The costs of delivering health care may vary across geographic population groups, and not controlling for this will inflate (deflate) allocations for low (high) cost population groups. Effectively, differing costs mean allocated budgets are worth more (or less) in different geographic populations. This may be seen as a reduction (increase) in the budget allocations for high (low) cost geographic population group, making allocations no longer efficient. This is particularly problematic if there exists a correlation between costs and productivity. For example, if less productive population groups face higher costs then allocations will not be at the level sufficient to reflect the expenditure required to deliver the health care for the respective need.

Measuring allocative inefficiency

The issue concerning the resource allocation formulae is one of determining how to distribute the budget across population groups. Figure 8 gives the four quadrant representation of Figure 3, where it is assumed that the payer's objective is the pure efficient outcome with the resulting maximization of output, W^*. Assume however, that the weighted capitation formulae have failed to identify needs of the population groups accurately. The result is higher payments to the more productive population ($X_{2A} > X_2$) and lower payments to the

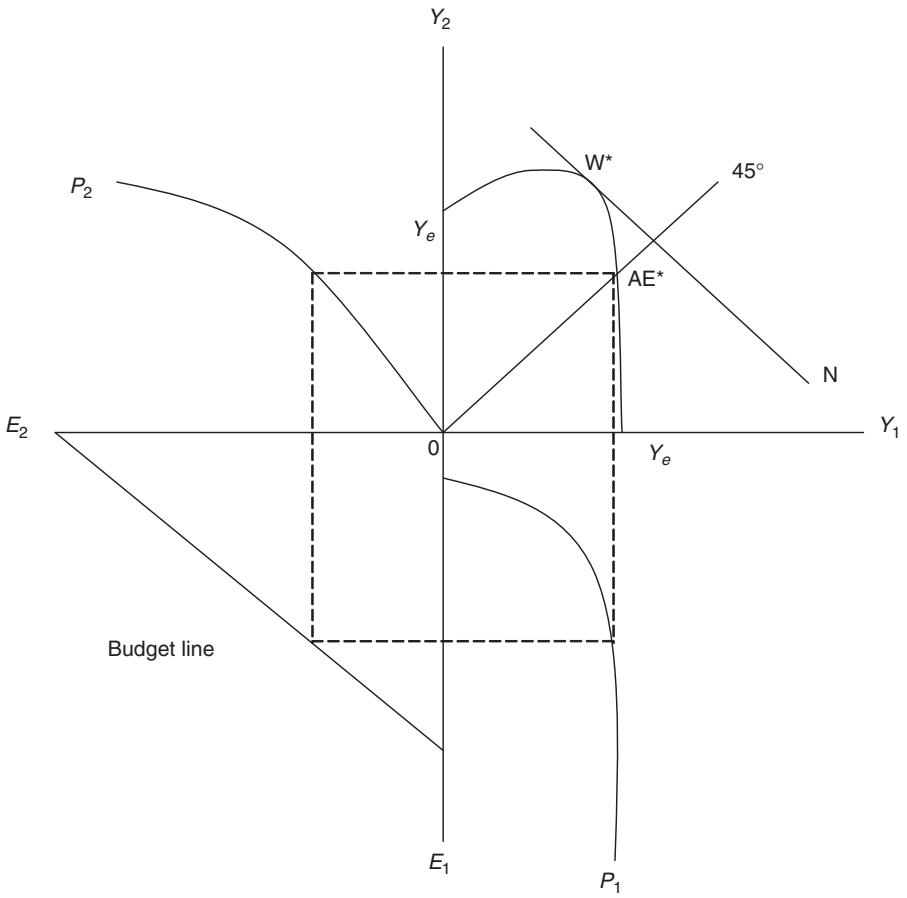

Figure 7 Avoidable inequalities in health. Adapted from Smith, P. C. (2007). *Formula funding of public services*. London and New York: Routledge Taylor & Francis Group.

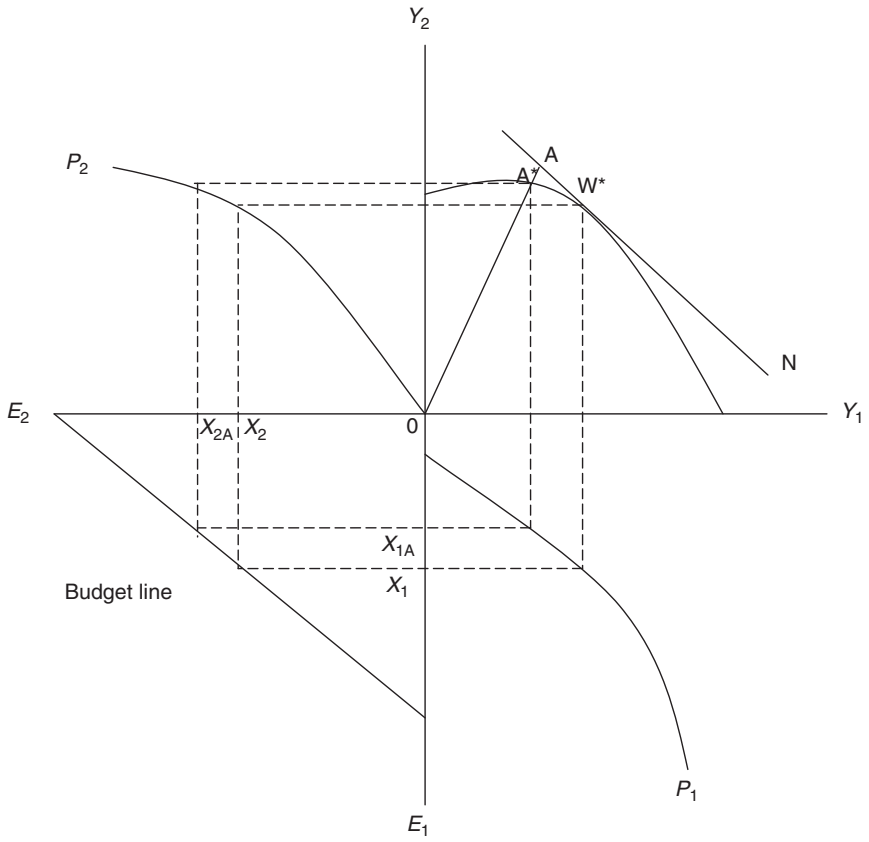

Figure 8 Allocative efficiency in society. Adapted from Smith, P. C. (2007). *Formula funding of public services*. London and New York: Routledge Taylor & Francis Group.

less productive population ($X_{1A} < X_1$) than would have been if needs were correctly identified. The resulting outcome is at A*, where the level of allocative inefficiency is $0A^*/0A$. The failure to identify needs correctly results in a lower output of health $A^* < W^*$.

Assuming the more productive population has lower costs in the delivery of health care, the effect of differences in the cost of delivering health care across population groups could also be seen in Figure 8. Here the differences in costs inflate the budget allocated to the high productive population ($X_{2A} > X_2$), and deflate the budget allocated to the low productive population.

Technical inefficiency

Until now it has been assumed that the budgets allocated to population groups are spent efficiently, utilizing the budget to attain the maximum health possible. There is, however, an ever growing number of studies that investigate the efficiency of providers. Hollingsworth *et al*. (1999) provided a review of methods used to model technical efficiency. The potential for technical inefficiency arises because of factors within the formulae, within the structure of the health care system, and external to health care.

Within the formula: Budget risk

A key issue arising with budgeting health care funds is that of budget risk. Because of uncertainty in the demand for health care, variations in practice across providers, and potential errors in the capitation formulae, health care expenditure is unlikely to match budgets allocated. This may lead to resources being used on the basis of budget availability rather than need. Budget risks are likely to increase the smaller the geographical area used, the shorter the time horizon, and for more limited types of care.

There may be the possibility that the resource allocation formulae present incentives to be technically inefficient. For example, if budgets are directed toward high need populations, this may present an incentive to undertreat populations to sustain high(er) budgets.

Further complications with the budgets arise since any budget underspend is not redistributed. There is an incentive for underbudget providers to behave inefficiently, that is, spend over and above what they (efficiently) need to provide health care to use up the budget.

Since most resource allocation formulae incorporate past usage (as used in utilization models) any inefficiencies in provision is reinforced. The needs weights will be generated from utilization that is potentially inefficient and inequitable. If past allocations were inefficient future allocations based on these prior allocations will also be inefficient. To ensure inefficiencies are not sustained, the causes of the inefficiencies should be targeted, for example, access to services. A potential way forward would be to incorporate measures of within-provider efficiency and equity into the formulae. For example,

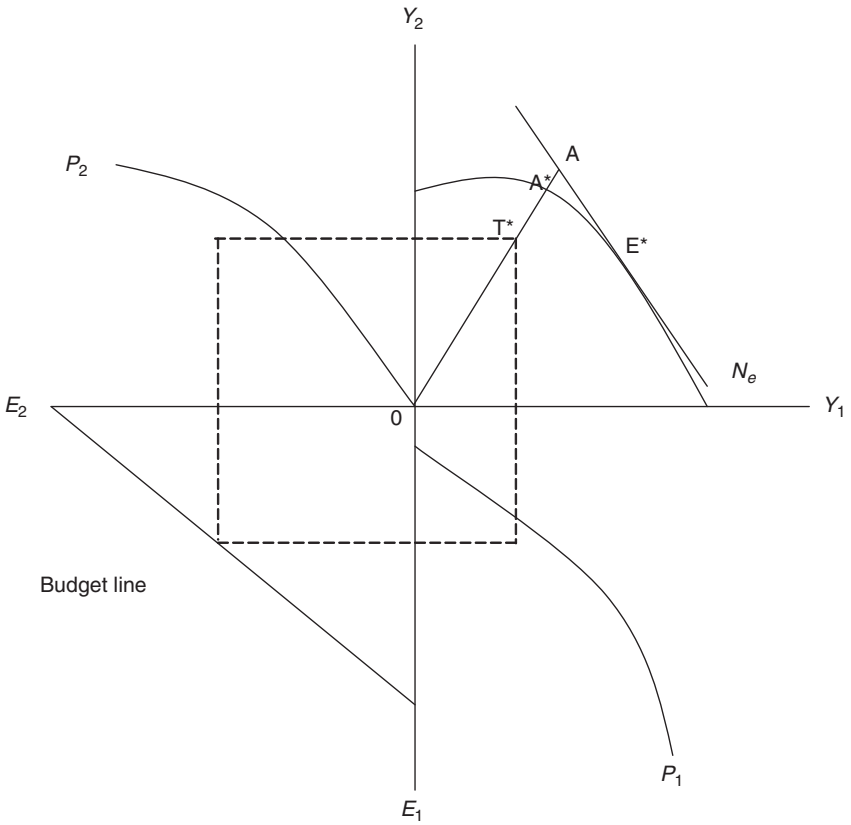

Figure 9 Total efficiency of the resource allocation formulae. Adapted from Smith, P. C. (2007). *Formula funding of public services*. London and New York: Routledge Taylor & Francis Group.

budget allocations may include a weight for relative efficiency (however this is measured) or for relative equity in health (however defined), which could penalize providers who do not channel budgets to target inefficiency and poor access.

Within the health care system: Market failure

The market structure of the health care system could lead to inefficiencies. For example, in England the NHS is essentially a monopolistic employer and provider of health care resources. The NHS is not subject to competitive market forces that may provide pressure to ensure the NHS system works efficiently, at lowest cost with most impact. For example, the frequency of restructuring the administration of the NHS highlights the struggle to streamline NHS administration and 'red tape' present in the system: allocations were originally made to 14 geographic population groups, but this figure has grown over the years: for 1996–97, to 100; for 2003–04, to 303; and since 2006, to 152 geographic population groups.

External factors

There are also economic influences that may affect the overall delivery of health care. The recent recession, for example, has led to pressure on publicly funded health care systems' budgets, which have been cut in real terms. The effects of this could, for example, lead to the encouragement of better (more) efficient procedures and structures both between and within the sectors and services of the health care system.

Impact on efficiency

In terms of the example, Figure 9 shows the implications of technical inefficiency. Now the outcome (T^*) in the North-East quadrant is not on the PPF of both population groups. Relaxing the assumption of technical efficiency would mean allocations do not produce the maximum health for populations. One moves south and/or westwards in the north east quadrant reflecting reductions in output because of technical inefficiency.

The Current NHS Resource Allocation Formulae in England

In England the amount of public funds allocated to health care from taxation is politically determined. The Treasury sets aside a total spend on the NHS health care in the annual Budget. Of this, the Department of Health (DH) then assigns the total budget for the three largest 'programmes' of NHS service. These are Hospital and Community Health Services (79% of the budget), Prescribing (11%), and Primary Medical Services (10%). Within these budgets, weighted capitation methods are applied to generate a target share of the budget for each Primary Care Trust (PCT), of which there are currently 152 across England. PCTs receive a lump sum to spend across the three programmes as they deem fit.

The DH has used variations of weighted (risk adjusted) capitation payments for distributing budgets for NHS health

care across England since 1977–78. The aim of the current formulae used to determine the capitations is to enable PCTs "to commission similar levels of health services for populations with similar need, with the further objective, since 1999, of helping to reduce avoidable health inequalities" (Department of Health, 2011, p.7).

The services provided by the NHS are not free to the user, because, while free at the point of consumption, individuals pay indirectly via taxation. The taxes used to fund the NHS health care services are substantive: the current weighted capitation approach is used to allocate some $132 billion to PCTs for the 2011–12 financial year, and the NHS as a whole accounted for over 8% of UK Gross Domestic Product for 2010–11.

The weighted capitation formula generates target allocations based on PCT populations, adjusted for: the age distribution; additional need over and above observed age structure; and differences in costs of delivering the services across PCTs – the Market Forces Factor (MFF). A separate index is given to each of these three components, and these are multiplied together to give a weighted population for each PCT in each program (see eqn [1]).

$$\begin{aligned}\text{PCT weighted population} = {} & (\text{population}) \times (\text{age index}) \\ & \times (\text{additional needs index}) \\ & \times (\text{MFF index}) \end{aligned} \quad (1)$$

These weighted populations are then combined according to the share of each program to the total budget. The weighted population for each PCT is then multiplied by the total budget to give a target allocation. PCT allocations, however, are not solely determined by weighted capitation methods. Actual allocations are obtained by taking the difference between target allocations and the previous year's allocation (adjusted for any transfers in responsibilities). A 'pace of change' policy then sets the differential growth in allocations that PCTs receive in addition to the previous year's allocation. The growth component is determined by national and local priorities, and the distance between last year's allocations from target allocations.

Different weighted capitation models are used both within and between each program. Within the Hospital and Community Health Services program, for example, the measurement of need is done separately for five sectors: acute care, maternity services, mental health services, human immunodeficiency virus and acquired immunodeficiency syndrome (HIV/AIDS) treatment, and HIV prevention. For prescribing budgets, a MFF is not required because of nationwide prescribing costs. Utilization models account for 90% of each needs index, with the remaining 10% accounted for by an avoidable health inequalities factor.

Changes in the NHS Resource Allocation Formulae over Time

There have been significant changes to the England NHS resource allocation formulae since the NHS inception in 1948.

Geographic population groups (the population index)

The population index provides the basis of the capitation formulae. Population size was introduced into the formulae from 1971, and methods used to obtain these weights have become increasingly more accurate.

First, the differing administrative boundaries for the allocation of budgets have become more refined, from the original allocations across 14 Regional Health Authorities in 1971–95, to: 100 Health Authorities in 1996–02, 303 PCTs in 2003–08, and now 152 PCTs. A higher level of disaggregation increases the accuracy in identifying need by providing greater variations across population groups.

Second, the methods used to obtain population data have also become more advanced. From 1999 population size has been derived from 'constrained' population data. This calculates the number of people registered with General Practitioner (GP) surgeries and unregistered patients living in the area. Constrained population data direct budgets to the population the area serves, reducing the inefficiency of directing budgets on the basis of residence (which had been the main population measure), which may under- or over-estimate the populations served in the area.

From 2006 population projections from the Office of National Statistics (ONS) have been used, which given allocations are based in advance, are thought to better reflect the population served by an area. Population projections incorporate trends in birth, death, and migration.

The changes in the population index would have meant a more accurate measurement of PCT populations. It is important to ensure accurate population modeling since any inaccuracy can divert allocations away from need.

Need measurement (age and additional needs indices)

There have been a number of reviews of the resource allocation formulae, where each has mainly been because of developments in the needs weights. Below the major developments are picked out.

The UK NHS was introduced in 1948, and at the time there was no defined procedure in place to allocate healthcare budgets across the country. The NHS was faced with funding the hospitals, beds, and staff that it had taken over. The initial method for resource allocation was to sustain funding of these services, irrespective of the differing need for healthcare services across populations of England. Funding continued in this way until 1971.

By 1971, a new funding formula, 'The Crossman Formula', was implemented. The formula contained three elements: population size weighted by average bed days by age and gender; bed days weighted by a national cost per bed per year; and cases (inpatient, outpatient and day cases) weighted by the national average cost per year. The inclusion of a proxy measure of need such as bed days meant that resources were being directed toward areas where they were most needed. The inclusion of bed and case volumes, however, still maintained a proportion of the budget that was allocated based on current/inherited supply.

Criticism of the lack of a needs-driven approach resulted in the introduction of the Resource Allocation Working Party (RAWP) formula in 1976. RAWP was set up to attain a resource allocation formula that objectively, equitably and efficiently responded to relative differences in need. The RAWP formula was a weighted capitation approach to allocating resources across the country. The formula now derived

capitation payments weighted by need. Need was measured by age and gender, and noting how age and gender alone would be insufficient to approximate need, 'additional need' was calculated using Standardized Mortality Ratios (SMRs). For the first time, the resource allocation formulae now contained non-utilization measures for need.

The RAWP formula was in place until the 1988 review of the formula was implemented in 1990. For the first time, empirical estimations on the variations of need factors on health care utilization were modeled using regression analysis of hospital utilization. Regression analysis was creating a shift from value judgments on the weighting of needs and permitted the weights on the needs variables to be adjusted for supply factors.

With the release of 1991 Census data, a further review was made in 1994 which was carried out at the University of York (Carr-Hill *et al.*, 1994). To remove the potential endogeneity of supply, significant supply variables were removed from the regression and the regression was then reestimated.

In 1995, a Resource Allocation Group (RAG) was set up to assess resource allocation in primary care. RAG was replaced in 1997 by the Advisory Committee on Resource Allocation (ACRA), an independent expert body to ensure resources for primary and secondary care fully reflect local population needs. The Technical Advisory Group (TAG) was also set up to provide technical support.

In 2002, a further review was conducted. The new formula incorporated more updateable deprivation measures (the Indices of Deprivation), and, for the first time, a measure of unmet need. Unmet need was modeled by maintaining the coefficients with incorrect signs in the models for the descriptive regression analysis but not using these variables as prescriptive weights in the weighted capitation formulae. Supply-side variables were now maintained in the regression but like those measuring unmet need, were not used to obtain weights for need.

There are four key factors in the measuring of need: observing legitimate met and unmet need, controlling for illegitimate need by the modeling of supply-side factors on utilization, and the inclusion of a health inequalities adjustment. Econometric techniques and updates in data availability have improved the accuracy of measuring met need, and the removal of illegitimate supply-side measures of need have arguably lead to greater efficiency in the allocation of budgets.

Unmet need was not modeled until 2002, and is intrinsically difficult to capture, particularly since most resource allocation formulae use utilization data to model need. Even if unmet need is accurately modeled, this may still be inefficient unless procedures are put in place to target the removal of under-utilization of these groups. With no stipulation of how providers should spend their allocated budgets, unmet need 'premiums' could implicitly generate technical inefficiency if these premiums are spent on services that would be relatively less productive in health.

Differing costs in the delivery of health care (the MFF index)

The RAWP formula was amended in 1980–81 to weight capitations on the basis of unavoidable differences in the costs of delivering health care across the country. The MFF was applied to account for differences in staff costs. The introduction of this factor removed the inefficiency of under/over funding because of the differences in the cost of health care by region. The MFF has been updated and expanded regularly. In 2002, the number of pay zones (used to calculate the MFF index) increased from 78 to 117 and a smoothing technique was applied to reduce sharp drops in wage rates for neighboring areas. In 2006, there were further increases in pay zones to 303. In 2008 ,more up- to- date data were used, doctors and dentists were given their own weighting, and further smoothing techniques were implemented. Another review in 2011 updated the MFF with more recent data.

The MFF aims to correct for differences in the cost of delivering services across PCTs. Assuming high cost PCTs serve relatively more productive (in health) populations, the MFF moves budgets to a more efficient allocation, through aiming to be more equitable by adjusting for unavoidable differences in the cost of delivering health care between PCTs. This diverts budgets away from less productive populations, which again, could raise concerns over equity.

Payer's equity concerns

The Department of Health and Social Security (1976) review of the resource allocation formulae set the objective "to secure, through resource allocation, that there would eventually be equal opportunity of access to health care for people at equal risk." This objective is consistent with the pure efficiency solution where equal risk translates to equal marginal benefit from additional expenditure.

In 1998, ministers announced a new objective of the formulae: that of "contributing to the reduction in avoidable health inequalities" (Department of Health, 2011). This was incorporated into the 2002 review of the formula by the introduction of a health inequalities adjustment (based on years of life lost, measured as deviations from the average mortality rate in England). In 2008, ACRA introduced a new health inequalities adjustment, Disability Free Life Expectancy (DFLE). The DFLE combines mortality and morbidity (measured by limiting long-standing illness) data to generate expected years from birth that are free from disability or limiting long-term illness, and is compared to a baseline of 70 years.

The formulae have moved from the pure efficiency solution toward a more equitable solution (from W^* to AE^* in **Figure 7**). The health inequalities adjustment is currently given a weight of 10% in the needs indices, but this has no statistical basis.

Overall Impacts of the Formulae Changes on Efficiency

The improvements in modeling geographic population groups, need and the incorporation of the MFF are likely to have reduced inefficiency in budget allocations enabling a better possibility of maximizing health (the pure efficient solution: W^* in **Figure 7**). The inclusion of an avoidable health inequalities measure from 2002, however, means it is unlikely the pure efficient solution is met. Rather, the best the payer can hope to achieve would be somewhere between W^* and AE^*in **Figure 7**, resulting in relatively lower level of health (the point between W^* and AE^* will depend on how much weight is applied to the health inequalities adjustment). In addition, the inclusion of

past allocations and the pace of change policy to formulate actual allocations make any movement toward the desired outcome slower. Including past allocations also creates issues about technical efficiency, in particular, budget risk. Under spending providers have an incentive to inflate their spending and such activities could become self-perpetuating.

Conclusion

The most efficient resource allocation funding formula requires the relative needs of the populations the payer serves to be identified. Identifying needs accurately enables the weighted capitation approach (commonly used in developed countries to allocate health care budgets) to direct budgets to those areas most efficient in producing health. This approach is consistent with higher budgets allocated to less productive populations on the basis of need, but recognizes that the maximization of health output may lead to inequalities in output between each population group.

There are a variety of reasons why the funding formulae may not be efficient. The reliance on accurately measured needs is a key concern, requiring the ability to disentangle supply-side factors, and understand and recognize the impacts of unmet need. Another key issue surrounds the adjustments that may be included for health inequalities. Equity and efficiency aims do not necessarily have to be in conflict – but they often are. Perhaps the most striking and complex impact on efficiency lies in the activity of the providers of health care. Technical inefficiency may be caused by a number of factors, and each detracts from the resource allocation funding formulae being efficient.

Risk Adjustment as Mechanism Design

J Glazer, Boston University, Boston, MA, USA, and Tel Aviv University, Tel Aviv, Israel
TG McGuire, Harvard Medical School, Boston, MA, USA

Glossary

Managed competition A policy toward individual health insurance markets using both competition among plans and regulation of premia and benefits. Usually includes some risk adjustment of plan payment.

Mechanism design A field of game theory in which a principal tries to motivate an agent by designing a mechanism for rewarding the agent.

Optimal risk adjustment Refers to a risk adjustment system in which a regulator finds the form of risk adjustment of plan payments to maximize some economic objective, such as minimization of efficiency problems due to adverse selection, a form of mechanism design problem.

Service-level selection Action by a health plan to provide more or less of certain services in order to attract or deter potential enrollees who would lead to profits or losses.

Introduction

In many countries, residents choose a health plan or sickness fund through which to receive health insurance benefits. These choices are regulated and at least partially paid for by governments and employers. Collective financing of health care redistributes the burden of cost from the sick to the healthy and from the poor to the rich. At the same time, societies seek the virtues of markets: choice, innovation, and price and quality competition from their health insurance plans. Melding the desires for both a fair yet controlled and efficient yet innovative health insurance sector is a central problem facing all developed nations. A common approach to this problem consists of national governments collecting the funds to pay for health care, but then passing responsibility for the purchasing of health care to a local organization, a private insurance plan as in the federal Medicare program in the US, a local government in the UK, Canada and Australia, or sickness funds as in Germany, Israel, the Netherlands and Belgium. Governmental involvement aims at a fair distribution of the cost burden, and competition among the decentralized participants is intended to promote efficiency. A critical element of the policy is paying more for the sick and less for the healthy as they join plans – the job of risk adjustment.

Defining Risk Adjustment

In this article 'risk adjustment' is referred to as a formula relating payment to a provider or a health plan to observable characteristics of a person (such as age, previous diagnoses). In the Medicare program in the US, Germany, Netherlands, Israel, and other countries, risk adjusted payments flow from governments to health plans when individuals enroll in private plans. Large provider groups are increasingly asked to bear risk, (this is the primary direction of US health policy) and risk adjusted payments come into play there as well. As provider payment and risk bearing become more central in health policies, the statistics and economics of risk adjustment take on increasing importance.

The evolution of health policy has put new demands on risk adjustment. This article reviews the two basic methods for deriving a risk adjustment, one primarily statistical, and a second introducing an economic objective into the statistical analysis. In the second method, finding the right risk adjustment is a problem in mechanism design. The authors begin with the basic model of adverse selection and derive the implications for risk adjustment. They then consider two applications with a close connection to the empirical methods that can be used to estimate risk adjustment weights.

The most common approach to risk adjustment is statistical. Conventional risk adjustment sees the goal of risk adjustment as matching payments to expected cost as closely as possible. If an older enrollee is expected to be twice as expensive as a younger enrollee, conventional risk adjustment would pay twice as much for the older enrollee. Many factors other than age matter for expected costs. Research on conventional risk adjustment is statistical and data oriented. Researchers seek to find the right combination of variables (referred to as risk adjustors) to include in regression models so that the explained variation in health care costs is high, without relying on risk adjustors that are difficult to collect in practice or can be manipulated by providers seeking to increase revenue. There is also discussion of whether certain variables should be recognized as part of risk adjustment, for example, if an individual chooses to smoke, whether he or she should be 'rewarded' by a higher risk adjusted payment. The premise behind this research – sometimes regarded to be so obvious as to not require justification or analysis – is that the healthcare market in question will function better, the better the job the regression model can do in predicting healthcare costs of enrollees.

By contrast, optimal risk adjustment views risk adjustment as a set of incentives to address an economic problem. Calculating the optimal risk adjustment begins with an explicit conception of how the relevant market functions, which relates the risk-adjusted price (e.g., the payment for young and old) to the behavior of payment recipients. The economic objective (usually efficiency) is also stated explicitly. Then, using mechanism design, the optimal risk adjustment is derived as the prices for young and old which maximize the

efficiency of the health care market. Optimal risk adjustment does not refer to particular weights, but rather to a methodology by which the optimal weights are obtained. Optimal risk adjustment also relies on data, however, the optimal weights are not, in general, regression coefficients but a solution to a problem of economic maximization.

The Basic Adverse Selection Problem and the Role of Risk Adjustment

A health plan can underprovide some services and overprovide others, attracting the low risks and deterring the high risks. The basic idea draws on the early analysis of insurance by Rothschild and Stiglitz. Demand for treatment of chronic conditions, for example, may be much better anticipated, and more unevenly distributed in a population, than demand for acute care. In such a case, the health plan has a financial incentive to distort the mix of its care away from chronic care and toward acute illness, in order to deter/attract the high/low risks. Nearly all writers on the efficiency of health insurance markets with managed care, acknowledge this effect, though they vary in the emphasis they put on it. When a plan can set premia as well as quality, a version of this strategy is to provide low quality overall, and set a low price, to attract the low-risks.

This quality distortion problem has received a good deal of attention in health economics literature. The basic adverse selection model is presented here. Suppose that there are two types of individuals, L and H, who can contract two illnesses, a and c. Illness a we call an acute illness and both types of people have the same probability of contracting this illness, $p_a > 0$. The two types are distinguished in their probability of contracting the chronic illness c. Let p_i, $i \in \{H,L\}$ denote the probability that a person of type i contracts illness c. Then, $p_H > p_L > 0$. The proportion of H types in the population is λ, $0 < \lambda < 1$. Let $p_c \equiv \lambda p_H + (1-\lambda)p_L$ denote the (expected) probability that a person randomly drawn contracts the chronic illness. Throughout the analysis it is assumed that each individual knows their type. It is also assumed that each individual must choose one plan.

If a person (of either type) has illness j, $j \in \{a,c\}$, their utility from treatment will be increased by $V_j(q_j)$, where $q_j > 0$ denotes the 'quality' of the services devoted to treat illness j, with $V'_j > 0$ and $V''_j < 0$. If a person has both illnesses, their utility, if treated, will simply be increased by $V_a(q_a) + V_c(q_c)$. Treatment services are provided by health plans. A health plan is characterized by a quality pair (q_a, q_c). Thus, if a person of type i, $i \in \{H,L\}$ joins a plan with a quality pair (q_a, q_c), their expected utility will increase by:

$$U_i(q_a, q_c) = p_a V_a(q_a) + p_i V_c(q_c) \quad [1]$$

Throughout the analysis it is assumed that each plan gets to choose its quality pair and a plan can offer only one quality pair. All plans have the same cost function. A plan's cost of treating a person with illness j, $j \in \{a,c\}$ at a quality level q_j is $C_j(q_j)$, where $C'_j > 0$, $C''_j > 0$. Thus, if a person of type i, $i \in \{H, L\}$ joins a plan that offers a quality pair (q_a, q_c), the plan's costs are expected to increase by:

$$C_i(q_a, q_c) = p_a C_a(q_a) + p_i C_c(q_c) \quad [2]$$

The 'socially efficient' quality pair (q_a^*, q_c^*) equalizes marginal benefit of treatment to marginal cost, thus solving the following pair of equations:

$$\begin{aligned} V'_a(q_a^*) &= C'_a(q_a^*) \\ V'_c(q_c^*) &= C'_c(q_c^*) \end{aligned} \quad [3]$$

High and low risk types have different probabilities of becoming ill, but once ill, receive the same utility from treatment. Thus, the efficient level of quality is independent on the probability of becoming ill and is the same for both types.

It is assumed that the Regulator can enforce an open enrollment policy. The order of moves in our model is as follows: First the Regulator/payer announces r^*, the premium (paid by the Regulator/payer) a plan will receive per enrollee. Next, plans (simultaneously) choose their quality pair (q_a, q_c), then individuals choose plans and plans collect a revenue of r^* per enrollee, finally each individual's health state (whether she has illness a and/or c) is realized and plans pay the costs of treatment. A 'competitive equilibrium' in this market is a set of quality pairs such that, when individuals choose plan to maximize expected utility, (1) no quality pair in the equilibrium set makes negative expected profit, and (2) there is no quality pair outside the equilibrium set that, if offered, will make a positive profit.

Following Rothschild and Stiglitz it is known that if the proportion of the H types in the population is sufficiently large, then a competitive equilibrium exists and is characterized by two quality pairs. H types choose the plan(s) that offer the quality pair:

$$\begin{aligned} (q_a^H, q_c^H) &= \text{argmax } U_H(q_a, q_c) \\ \text{s.t.} \quad & C_H(q_a, q_c) = r^* \end{aligned} \quad [4]$$

and L types choose the plan(s) that offer the quality pair:

$$\begin{aligned} (q_a^L, q_c^L) &= \text{argmax} \quad U_L(q_a, q_c) \\ \text{s.t.} \quad & C_L(q_a, q_c) = r^* \\ \text{and} \quad & U_H(q_a, q_c) = U_H(q_a^H, q_c^H) \end{aligned} \quad [5]$$

The equilibrium is described in Figure 1. The curves r_i^*, $i = H, L$ represent all plans, i.e., pairs of (q_a, q_c), that break even if the plan attracts only individuals of type i, when the premium is r^*. The points denoted by q_i, $i = H$ or L, depict the plan chosen by type i in equilibrium, i.e., $q_i = (q_a^i, q_c^i)$. Curves u_i, $i = H, L$, represent type i's indifference curves that goes through the point q_i. The curve r^* represents all plans that break even if the plan attracts a random sample of the population, and the point q^* depicts the socially efficient levels of quality. It can, therefore, be seen that plans will not offer the socially efficient quality profile in equilibrium.

When the Regulator/payer is using risk adjustment, the premium paid to the plan (often referred to as 'capitation') is conditioned on observable characteristics of the enrollee. The capitation payment might be based, for example, on the enrollee's age, with older enrollees having higher payments associated with them because they are expected to cost more.

It can be illustrated how conventional and optimal risk adjustments are calculated using this model. Assume that the

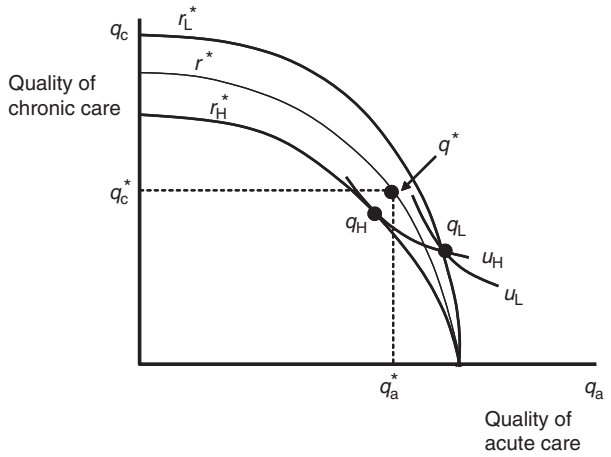

Figure 1 The basic adverse selection result.

Regulator gets a signal s about each consumer's type. The signal could be, for example, the consumer's age. Suppose that s can take a value of 0 or 1 ('young' or 'old'). The signal contains information in the sense that type H person is more likely than type L person to get the signal 1. Let γ_i, i=H or L, be the probability that consumer of type i gets the signal 1. It is assumed that $\gamma_H > \gamma_L \geq 0$. (Note that if $\gamma_H = 1$ and $\gamma_L = 0$, the signal is perfect i.e., the Regulator knows the individual's type.)

Let λ_s be the posterior probability the consumer is of type H given the signal s. Because the signal is informative, using Bayes' rule one can show that $1 \geq \lambda_1 \geq \lambda_0 \geq 0$. Thus, if a person got the signal 1, that person is more likely to be of type H than a person who got the signal 0. Let,

$$P_s = P_H \lambda_s + P_L(1 - \lambda_s) \quad \text{for } s = 0, 1. \qquad [6]$$

and

$$r_s = C(q_a^*) + P_s C(q_c^*) \quad \text{for } s = 0, 1. \qquad [7]$$

P_s is the probability that a person with signal s will contract illness c and r_s is the expected health care costs of such a person at the efficient level of quality of care. Clearly $P_1 > P_0$ and $r_1 > r_0$. One can readily confirm that if plans are paid r_s for each person who got the signal s, and consumers are randomly distributed across plans, plans break even providing the efficient level of care.

The capitation payment r_s is what the authors mean by 'conventional' risk adjustment. It can be shown, however, that conventional risk adjustment does not implement the socially desired outcome, i.e., at the competitive equilibrium, plans do not provide the socially efficient quality. The same forces that break the efficient pooling equilibrium when premiums are not risk adjusted will also break the efficient pooling equilibrium when premiums are conventionally risk adjusted. Market equilibrium under conventional risk adjustment will still be a separating one where the H types and the L types choose different plans with a different quality profile. This separating equilibrium is more efficient (i.e., it induces a higher expected utility) than the one without risk adjustment, but it is not the best the Regulator can do. As demonstrated below, an optimal risk adjustment can be constructed to implement precisely the socially desired quality.

Let

$$C_H^* = C(q_a^*) + P_H C(q_c^*) \qquad [8]$$

and

$$C_L^* = C(q_a^*) + P_L C(q_c^*) \qquad [9]$$

C_i^* is the expected costs of an individual of type i at the efficient quality profile.

The authors are now ready to discuss the conditions under which risk adjustors implement the socially desired contract:

Proposition: Let r_s^*, $s=0,1$ be solution to the following system of equations:

$$\gamma_H r_1^* + (1 - \gamma_H) r_0^* = C_H^* \qquad [10]$$

$$\gamma_L r_1^* + (1 - \gamma_L) r_0^* = C_L^* \qquad [11]$$

then if plans are paid a premium r_s^*, $s=0,1$ for each individual who got the signal s, all plans will offer the socially desired quality in equilibrium.

The left hand side of eqn [10] is the expected premium a plan receives for each enrollee of type H, under the risk adjustment scheme r_s^*. The right hand side of eqn [10] is the plan's expected cost of an enrollee of type H, under the socially desired quality bundle. Equation [10] states the condition for the expected premium for a type H individual to be equal to the individual's expected cost. Equation [11] does the same thing for a type L individual.

It can be easily verified that, if $\gamma_H < 1$ and $\gamma_L > 0$ then $r_1^* > r_1$ and $r_0^* > r_0$. Conventional risk adjustment redistributes some, but not enough, resources from the low-cost to the high-cost types. In Figure 1 this redistribution would appear as a shift in the zero-profit curves relative to the curves in the no risk adjustment case. As the proposition above shows, the Regulator may shift the zero-profit curves even further than is implied by conventional risk adjustment, by 'overpaying' for a consumer who got the signal 1, compensated by 'underpaying' for consumers who got the signal 0, and by so doing, bring the market closer to the socially desired outcomes. 'Overpaying' and 'underpaying' are in comparison to the conventional risk adjustment premiums. Figure 2 illustrates the equilibrium under optimal risk adjustment.

Intuitively, this result can be understood as follows: If the signal is not very precise, the difference in premium conventional risk adjustment pays, for a consumer who got the signal 1 and a consumer who got the signal 0, will be small. Furthermore, the proportion of consumers who got the signal 0 among the L-types is not much larger than the proportion of consumers who got this signal in the entire population. Thus, by offering a quality profile that attracts only the L-type consumers, a plan can reduce its cost by a significant amount relative to the reduction in the premium it is expected to receive. If, however, the premium for an individual who got the signal 0 is significantly lower than the premium for an individual with the signal 1, the plan is severely punished for attracting only individuals of type L.

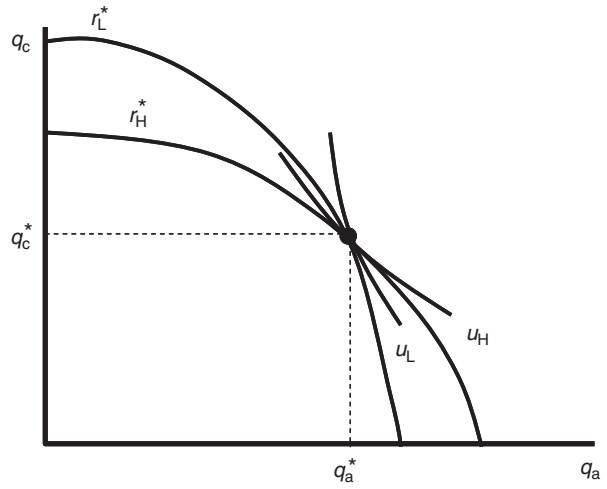

Figure 2 Market equilibrium under optimal risk adjustment.

Multiple Services and Maximizing Fit

The analysis just laid out can be made operational in a more realistic setting in which a plan is providing multiple services (not just two) and in which the Regulator's objective in conventional risk adjustment of 'best fit' is also recognized.

When a plan decreases the stringency of rationing on a service, i.e., increases the level of spending on a service, costs are affected because spending goes up for existing enrollees and spending is incurred on enrollees newly attracted by the spending increase. The idea of optimal risk adjustment is to make sure that for all services a plan is making a decision about, from those used mostly by the healthy and cheap to those used mostly by the sick and costly, these cost increases are balanced against revenue gains to the same degree. This is done by recognizing that enrollees have a payment made on their behalf and the terms of that payment are described by the risk adjustment parameters. There is, thus, a relation between the marginal cost and marginal revenue for each of the services in a plan. Balancing incentives across services essentially amounts to an equation for each service, the level of rationing being the variable and the risk adjustment weights being the parameters.

To equalize incentives in rationing all services, the covariance of the risk adjusted payment with the use of every service must track the covariance of the total predicted costs associated with the increase in use of the service. Intuitively, the optimal risk adjustment formula must have the property that by spending on a service, the cost consequences to a plan relate to the revenue consequences in the same way for all services. It is important to stress that the result for optimal risk adjustment says how a given average payment should be risk adjusted, but does not answer the question of how high or low on average the payment should be.

The optimal risk adjustment emerges as a set of linear equations one for each service, with unknowns equal to the variables available for risk adjustment. An interesting feature of this optimal risk adjustment scheme is that the number of parameters available for risk adjustment could be greater or less than the number of services a plan is deciding about. (Some risk adjustment systems have scores of weights.) If the number of available risk adjustment parameters is larger than the number of services whose quality the plan decides on, there may be many risk adjustors that achieve optimality in the sense of incentive balance across services.

This observation raises the question: Among the ways to set risk adjustment to achieve efficient incentives, which way is best? A natural way to answer this question is to reintroduce the original statistical objective of risk adjustment, best fit. In an earlier paper, the authors show that conditions describing efficient service provision are linear in the risk adjustment weights. These can be introduced as constraints on a least squares risk adjustment regression. This risk adjustor is referred to as the minimum variance optimal risk adjustment (MVORA). It is minimum variance by properties of least squares estimators, and it is optimal because the linear constraints on incentives for efficient service provision are satisfied.

Application to Managed Competition and Enrollee Premiums

Risk adjustment is recognized as an integral part of managed competition policy, with the general objective of making sure plans are willing to accept and serve ailing expensive enrollees as well as healthy low cost enrollees. Managed competition policy also relies on premiums paid by enrollees. If competition is to have its desired effects, plans that are able to provide good care at a lower cost, or provide worthwhile benefit enhancements, need to transmit incentives to consumers through premium competition. If a plan has a better product that consumers are willing to pay for, the logic goes the plan will be able to charge an incremental premium and attract enrollment.

Premium-based incentives are an integral part of health plan payment in the US in two important emerging health policy contexts – the Medicare Advantage (MA) program and Medicare Part D offering private plans in Medicare, and the new state-run 'Exchanges' created as part of the Affordable Care Act (ACA) – plan payments come from two sources at once: risk-adjusted payments from a Regulator and premiums charged to individual enrollees. Premiums also play a role in the Netherlands and Germany, though again important institutional details describe the relationship.

Here the authors consider a general setting of a premium support policy in which a Regulator has a budget to pay plans, and has the ability to risk adjust that budget. In addition to risk adjusted payments, plans must also collect revenue from enrollees through premiums. How should a Regulator set risk adjustment weights if only part of the funding for plans is coming through public budgets and being risk adjusted, and the balance will be set by plans in a managed competition market?

Suppose the Regulator collects some public funds to pay plans, and must risk adjust 75% of costs based on age, gender and previous diagnoses. Enrollee premiums must cover the other 25%, and premiums are conditioned on another,

possibly overlapping set of variables, age, smoking status, and geography. The key insight is that the risk adjustment mechanism adopted by the Regulator affects premiums, because what a plan would want to (from profit-maximization) and would be able to (due to competition) charge enrollees as a premium depends on how the Regulator sets risk-adjusted payments. 'What happens' in this plan market, from a number of perspectives, depends on how these premiums work out. The Regulator needs to consider the effect of the risk adjustment on premiums as part of the answer to how to set risk adjustment weights. The Regulator's problem in the case of premiums conditioned on several variables differs from the case when the Regulator has the same budget but premiums are to be the same for everyone.

The first step is to describe how risk adjustment weights affect premiums. Let the total number of people be N and health care costs of individual i be x_i. People vary in two observable dimensions, according to health status, the basis of risk adjustment, and according to another set of characteristics the authors refer to as personal, the basis of premiums. Health status is indexed by h, $h=1,\ldots,H$; personal characteristics are indexed by t, $t=1,\ldots,T$. For notational simplicity, it is assumed that each of these categorizations is one dimensional and the information is mutually exclusive so that each person is characterized by an (h,t) pair the authors will refer to together as a 'type.'

Define x_{ht} to be the average cost of person of type (h,t), and n_{ht} to be the number of people of type (h,t). Health care costs are plan costs (which must be covered by plan payments) and are fixed (do not depend on risk adjustment or premiums). The risk adjusted payment by the Regulator can only depend on $h{:}r_h$. The premium can only depend on $t{:}p_t$. It is assumed that competition among health plans forces premiums to be zero-profit, meaning, for each premium category, t, the premium for that category is determined by the following condition:

$$\sum_h n_{ht}(r_h + p_t - x_{ht}) = 0 \qquad [12]$$

Equation [12] shows how premiums depend on risk adjustment weights. There are T of these expressions, one for each premium category. In each expression there are H parameters, the risk adjustment weights on category h. The authors now move on to the consideration of a second step in a managed competition context, choosing the risk adjustment weights in light of the presence of premiums in plan payment. There are many applications dependent on the objectives of the Regulator. The authors begin with the most basic.

Suppose the Regulator seeks to maximize fit of the payment system with respect to choice of the risk adjustment weights r_h on the H health status factors, subject to a per-person budget for risk adjustment and subject to how the market will set premiums to be zero profit conditional on risk adjustment, described in eqn [12].

In general, maximizing an objective of the Regulator involving premiums subject to eqn [12] can be addressed as a problem in mechanism design, setting the payment parameters (risk adjustment weights) to maximize the objective subject to the constraints. The budget constraint on risk adjustment is one linear constraint. The set of linear equations in eqn [12] are also constraints. It is important to note in this regard that the constraints in eqn [12] are equivalent to the so-called normal equations in least squares with respect to premium variables. Thus, a least squares regression in which premium categories are added as variables and the Regulator's budget is added as a constraint will find the risk adjustment weights that lead to the best fit (by properties of least squares).

One could also change the objective of the Regulator, introducing concerns for efficient service provision as discussed in the earlier application. Premium support policies raise other issues as well. For enrollees to sort themselves efficiently across plans, the premiums' differences they face should be close to the cost differences they would impose on the plans. This efficiency objective could also be expressed as a set of constraints on premiums.

Final Comment

The most basic implication of economic analysis of risk adjustment is this: When considering design of any mechanism to deal with problems of adverse selection, the nature of the underlying inefficiency and an anticipation of how plans and providers react to the policy should provide the foundation for the analysis. This observation implies that 'conventional' approaches to risk adjustment are not in general optimal, and encourages researchers and policy makers to consider alternatives. To design an efficient risk adjustment payment scheme, one needs to know how plans/providers/patients will react to it. Economic theory can help shed light on this question, but ultimately, plan behavior is a matter of empirical research.

Risk Classification and Health Insurance

G Dionne, HEC Montréal, Montreal, QC, Canada
CG Rothschild, Wellesley College, Wellesley, MA, USA

Glossary

Adverse selection A situation in which high-risk individuals tend to 'drive out' low-risk individuals from insurance when premium averaging leads the former to detect a bargain and the latter no bargain at all.
Asymmetry of information A situation in which one party in a transaction has more or superior information compared to another, for example, physicians have a greater knowledge than patients of the likely effectiveness of drugs while the patients have greater knowledge of the likely impact of drugs on their family circumstances, or people seeking insurance have more reliable expectations of their risk exposure than insurance companies.
Classification risk The possibility of being initially misclassified and later reclassified as high-risk with limited access to or high premiums for insurance as information is revealed overtime.
Community rating Setting health care insurance premia according to the utilization by a broad population (for example, one defined by employer type or geography).
Coverage mandates Regulations requiring insurance policies that cover certain health conditions.
Cream skimming A form of selection in private health insurance markets by which the insurer obtains a higher proportion of good risks (people with a low probability of needing care or who are likely to need only low-cost care or both) in their portfolio of clients than is assumed in the calculation of the insurance premiums also called 'cherry-picking' and 'creaming'.
Death spiral The complete unraveling of an insurance pool by a feedback loop between rising premiums and exit by the healthiest remaining individuals in the pool that forms an extreme adverse selection.
Distributional equity in insurance The notion that a fair insurance system should equalize premiums and insurance access across higher and lower-risk individuals.
***Ex-ante* efficiency** The best outcome from the point of view of an individual behind a notional veil of ignorance, before one knows what risk type or risk class they will belong to.
Financial equity The notion that two individuals facing the same risks and the same coverage should pay the same premium.
Group equity The notion that no identifiable group should be required to cross-subsidize any other identifiable group.
Horizontal equity The notion that two individuals facing the same risks should have access to the same coverage at the same premium. Treating equally those who are equal in some morally relevant sense that commonly meet horizontal equity principles 'equal treatment for equal need' and 'equal treatment for equal deservingness'.
Incentive contracting The contracts designed to mitigate problems arising from informational asymmetries.
Interim efficiency/interim Pareto efficiency The outcomes that cannot be improved on for any risk type within a risk class without harming another individual.
Moral hazard There are two main types. Ex ante moral hazard refers to the effect that being insured has on behavior, generally increasing the probability of the event insured against occurring. Ex post moral hazard arises because being insured reduces price of care to the patient and hence leads to an increase in demand from insured persons.
Perfect risk classification A risk classification based on observable characteristics that generates insurance premiums that fully reflect the expected cost associated with each class of risk characteristics.
Risk adjustment A technique for adjusting a payment to an individual's risk characteristics usually achieved through government-run transfers across insurers that depend on their insurance pool's risk-related characteristics.
Risk classification in health insurance The use of observable characteristics by insurers to group individual risks with expected medical costs while underwriting insurance policies.
Screening insurance The contracts that are designed to induce individuals with different private information to self-sort into distinct contracts.
Underwriting The process of measuring risk exposure of a potential client and determining the insurance premium to be charged.

Introduction

Risk classification refers to the use of observable characteristics, such as gender, race, age, and behavior, to price or structure insurance policies. Risk classification potentially has undesirable consequences, including adverse effects on distributional equity. In dynamic settings, risk classification can also increase classification risk, which refers to the risk that an individual faces of being reclassified into a higher-cost class at a later date.

A perfect risk classification system should, using actuarial rules and principles, generate an insurance premium that

 doi:10.1016/B978-0-12-375678-7.01316-X

reflects the expected cost associated with a given risk. Two clients with the same risk level should pay the same, actuarially fair premium. This is known as the financial equity criteria. In health insurance, premiums are most commonly determined by age, sex, and smoking behavior. Current medical conditions (high cholesterol, diabetes, etc.) and medical histories of older clients are often added as criteria because they can affect the medical expenses covered by the insurance plan. Information on lifestyle, diet, and exercise can also be considered.

Market forces push competitive insurers toward employing risk classification whenever it is legal (and permissible according to social norms) to do so. For example, age is an easily observable characteristic that is often correlated with expected health care expenditures. If insurers do not price their insurance products on the basis of age, they will find that, on average, selling policies to the lower-risk young is more profitable than selling policies to the higher-risk old. Individual firms will therefore have an incentive to cream skim – to offer a lower-priced insurance product only to the young and thereby to attract only the most profitable risks.

Selection and pricing activity based on individual characteristics is subject to concerns about social fairness (or equity) and potential discrimination. This is particularly true in the medical and disability insurance markets. Policy makers who dislike the consequences of risk classification may therefore find it desirable to use regulatory restrictions to limit its use. Indeed, risk classification is restricted or banned outright in various markets, for example, via community rating laws that require insurers to offer all individuals in a given community the same policies at the same premiums, as the compulsory public health system in Canada and several US states.

The policy decision to restrict the use of risk classification often involves a trade-off between financial and social equity. This trade-off is policy relevant because departures from financial equity can lead directly to inefficient insurance provision. For example, risk pooling arising from legal restrictions on risk classification variables may lead to a situation in which lower-risk individuals are faced with higher premiums than those corresponding to their true risk, whereas higher-risk individuals pay lower premiums. Low-risk individuals may leave the pool, driving premiums higher and causing even more individuals to leave the pool. This inefficient market unraveling is known as an adverse selection death spiral.

Understanding the cost and benefits of risk classification more generally is challenging for at least two reasons. First, there are a number of interrelated and overlapping effects of risk classification that are difficult to disentangle. Second, the relative importance of these various effects depends strongly on the institutional details of the insurance market. In some markets, permitting risk classification facilitates efficient insurance provision without compromising concerns about equity. In some others, banning risk classification has beneficial equity effects without imposing any efficiency costs. In others, the decision to ban risk classification involves a nontrivial trade-off between equity and efficiency goals.

This article provides a simple framework for identifying the types of markets in which these three cases arise. One of the key determinants is the presence or absence of residual asymmetric information in the market. This article reviews empirical tests for asymmetric information in health insurance markets.

Potential Welfare Effects of Risk Classification

Public policy typically involves trade-offs between equity and efficiency. Public policy regarding risk classification in insurance markets is no exception. It is further complicated by the presence of several conceptually distinct but overlapping notions of equity and efficiency.

Equity

There are at least four potential notions of equity in the risk-classification context: horizontal equity, financial equity, group equity, and distributional equity.

Horizontal equity refers to the idea that any two individuals facing identical insurable risks should be treated identically: they should, for example, have access to the same policies and at the same prices. Group equity, however, refers to the idea that each identifiably distinct group (e.g., males, 25-year-olds) should not, as a group, be required to cross-subsidize other groups. A desire for this type of equity is sometimes referred to as subsidy aversion. Financial equity is a special case of group equity in which there is no heterogeneity within the group.

The goals of horizontal and group equity are frequently in tension with each other. By way of illustration, consider a population consisting of otherwise homogenous 30-year-old men and women seeking individual health insurance policies. Suppose that there is only one type of policy available; the only question is, what price individuals will be charged for it? Suppose further that the expected cost to an insurer of providing coverage to a woman is higher, on average, than the cost of providing coverage to a man.

If insurers risk-classify using gender, then women in the population will face higher insurance prices. Group equity will be satisfied at the level of gender, as each gender will be charged an appropriate premium. Insofar as not all women in the group are identical, however, financial equity will not be satisfied. Moreover, some women, perhaps those in good health with no interest in bearing children, are likely to have lower than average expected costs and, similarly, some men are likely to have higher than average expected costs. So it is likely that there are some men and some women in the population with exactly the same expected costs to insurers. Because insurers are risk-classifying by gender, these two identical risks will be charged different premiums for identical coverage. This violates horizontal equity. On the other hand if insurers do not risk-classify by gender, then horizontal equity will be trivially satisfied. Group equity will be violated, however, because the lower-on-average-risk men will be charged the same as women, men as a group will effectively be cross-subsidizing women as a group.

Group and financial equity are founded on an actuarial notion of fairness: What is fair to an individual or group is that they be charged prices in relation to their true cost to an insurer. Like horizontal equity, distributional equity is a nonactuarial notion. It refers to the idea that, at least in some

circumstances, two individuals should be charged the same price in spite of the fact that they, or groups they are members of, face different risks. Bans on risk classification on the basis of genetic conditions such as Huntington's disease, or on the basis of preexisting conditions more generally, are primarily motivated by a concern for distributional equity.

Distributional equity also encompasses attempts to use policy for the explicit purpose of redistributing from a historically advantaged class (e.g., males) to a historically disadvantaged class (e.g., females). This is distinct from concerns for actuarial group equity – i.e., that one group should not subsidize another in an actuarial sense. Because riskiness rather than group membership is the more fundamental characteristic vis-a-vis insurance provision, it is not obvious why providing distinct groups of heterogeneous risks actuarially equally would be a desirable policy goal. This article therefore focuses primarily on horizontal, financial, and distributional equity.

Efficiency

There are at least two distinct notions of efficiency that are relevant in the risk-classification context: interim efficiency and ex-ante efficiency. There are two distinct types of interim efficiency: the efficiency of outcomes and the efficiency of institutions.

Insurance outcomes in market A are said to be more interim efficient (or interim Pareto efficient) than insurance outcomes in market B when every individual is at least as happy with the insurance policy they would get in market A as with the insurance policy they would get in market B, and someone is strictly happier. Equivalently, market B's outcomes are interim inefficient if nobody would object to replacing the market with market A's outcomes, and at least somebody would strictly prefer the switch.

The notion of interim efficiency of institutions is applied when there is a range of possible insurance outcomes consistent with different policy institutions. The range of possible outcomes consistent with a policy regime in which risk classification is legal, for example, may depend on the extent to which the government also imposes taxes on the contracts sold to different risk classes. Similarly, there may be a range of insurance outcomes consistent with a regime in which risk classification is banned. Saying that the institution of legal risk classification is interim efficient means that for every potential banned classification outcome, there is some legal classification outcome that makes every individual at least as happy (and some strictly happier).

Interim efficiency involves evaluating insurance markets from the point of view of individuals who know their type (which could include intrinsic riskiness or tastes) and risk class. Because there are typically many types and classes within a given population, there will typically be many different possible insurance outcomes which cannot be compared on interim efficiency grounds, as some individuals would be better-off with one of these outcomes, and other individuals would be better-off with another.

In contrast, ex-ante efficiency evaluates efficiency from the point of view of a representative individual behind a veil of ignorance about their risk type or class. Insurance outcomes in market A are thus said to be more ex-ante efficient than insurance outcomes in market B if a hypothetical individual who did not yet know what risk type or class they will belong to would prefer the market A outcomes.

The notions of distributional equity and ex-ante efficiency are closely related. One might reasonably use the notion of distributional equity to argue that individuals with the gene for Huntington's disease should be able to purchase insurance covering the costs associated with its treatment for the same premium as someone without the gene. One basic argument is that it would be unfair to charge an individual for something entirely out of their control. Alternatively, one could make the same arguments on the grounds of ex-ante efficiency: A risk-averse representative individual behind the veil of ignorance, who did not yet know whether or not they would be born with the gene, would strictly prefer to be born into a world in which premiums do not depend on the presence of the gene.

Distributional equity can potentially be invoked for other unrelated reasons, but this article focuses on the particular distributional equity concerns arising from the point of view of a representative, risk-averse individual behind a veil of ignorance about their type and class. In other words, it regards as beneficial policies which redistribute toward risk types that are relatively disadvantaged from an ex-ante point of view.

Another way of framing the desire for, for example, gene-independent pricing is in terms of a desire for insurance against classification risk. Because individuals are either born with the Huntington's disease or not, individuals cannot directly insure themselves against the risk of having the gene and being in a bad risk class. Preventing insurers from genetic discrimination is potentially desirable insofar as it effectively provides otherwise unavailable insurance against this classification risk.

A similar argument potentially applies more generally to bans on risk classification on the basis of preexisting conditions like cancer or diabetes. The primary conceptual distinction is that one could, in principle, have insured oneself against such classification risk by purchasing a long-term, or guaranteed renewable contract before the condition developed. Insofar as the market for long-term contracts or other forms of insurance against classification risk functions poorly, however, restricting risk classification has potentially beneficial distributional equity effects insofar as it reduces classification risk.

It is important to note that interim inefficiency of outcomes implies ex-ante inefficiency as well. If outcomes in market A are better than market B outcomes at the interim stage for each type, then the representative agent behind the veil of ignorance will necessarily prefer market A. Interim inefficiency in the institutional sense implies ex-ante inefficiency in a somewhat more subtle sense. As a stand-alone policy, for example, a ban on risk classification might reduce interim efficiency (in the institutional sense) yet raise ex-ante efficiency through beneficial distributional equity effects. Nevertheless, interim inefficiency in the institutional sense implies the existence of some alternative intervention, such as government-coordinated risk adjustments, that is even better than a ban from an ex-ante perspective.

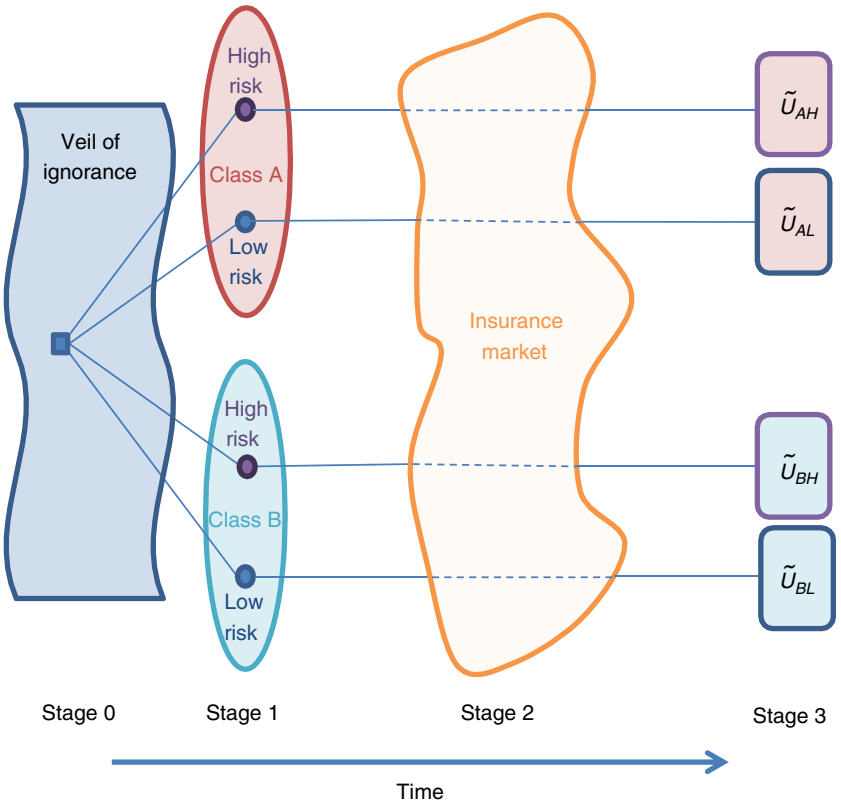

Figure 1 A conceptual framework.

The Equity and Efficiency Trade-offs of Risk Classification

Risk classification will typically have implications for both efficiency and equity. The particular trade-offs between efficiency and equity implied by the decision to allow or ban risk classification in insurance markets are context-dependent. Figure 1 provides a simple framework for sorting these contexts.

Figure 1 depicts the timing of an abstract insurance market. At stage 0, a notional representative individual contemplates the future from behind a veil of ignorance. At stage 1, individuals are born and learn both their true risk type and their class. The diagram depicts a case with two risk types, high and low risks, and two classes, labeled A and B, which might represent male and female, white and nonwhite, or Huntington's positive and negative, for example.

At stage 2, individuals enter an insurance market and potentially purchase insurance. At stage 3, the health outcomes are realized, and individuals with insurance receive their coverage and choose treatment levels. These outcomes result in a random utility, or well-being, level denoted by $\tilde{U}_{ij}$ that will potentially depend on risk type j and class i.

This framework can be used to explore the consequences of risk classification in a variety of situations. For example, if classes A and B are 30-year-old females and males, respectively, then it encompasses the example above illustrating the trade-off between individual and group equity when there is a lower but nonzero fraction of high-risk types within class A and a lower but nonzero fraction of low-risk types within class B. To capture a situation like classification based on the presence of the Huntington's gene in which class is perfectly predictive of risk type, one would simply take the fractions of the high-risk types within classes A and B to be one and zero, respectively.

The framework is best suited for analyzing insurance decisions that take place at one moment in time. It is less well suited to addressing fundamentally dynamic issues, such as the implications of risk classification based on preexisting conditions like diabetes or heart disease. It can be adapted to this application if insurance is sold on an annual basis with no long-term contracting, however. Similarly, it can be fruitfully applied to analyze the implications of age-based risk classification in some contexts.

When this simple framework is applicable, the qualitative implications of risk classification hinge on three basic questions.

Question 1: Is Risk Classification Perfect or Imperfect?

In some cases, as with the BRCA1/2 breast cancer gene, class is only imperfectly correlated with risk: There may be women without the gene who still face a high risk of breast cancer. In other cases, such as the gene for Huntington's disease, class is closer to perfectly predictive of risk type, and all members of either class will have the same risk type. It may then be said that risk classification is perfect.

Whether or not risk classification is perfect is important for two reasons. First, when risk classification is perfect, classes are pools of individuals who are perfectly homogenous from the point of view of health risk. The tension between horizontal and group equity therefore disappears. Second, when risk classification is imperfect, insurers who employ risk classification still face heterogeneity of risks within each class. Employing risk classification therefore reduces, but does not eliminate informational asymmetries. This is important because, in the face of informational asymmetries, insurers may find it useful to employ indirect mechanisms to induce self-sorting of different risks. This is known as screening. Screening can have important implications for efficiency and equity.

Question 2: Are Policies Uniform or Not?

Screening refers to the deliberate attempt to induce self-sorting of individuals through contract design. In the canonical example of screening, insurers offer two types of policies: An expensive comprehensive policy and a less expensive and less comprehensive policy, such as a catastrophic coverage policy with a very high deductible. Individuals who know themselves to be in good health are more likely to find the latter an appealing option, so individuals will be induced to self-sort by riskiness into distinct policies.

Screening relies on insurers' ability to tailor menus of significantly different policy options: it is predicated on nonuniform policies. If regulatory restrictions circumscribe insurers' ability to design such menus, for example, through coverage mandates that require all insurance policies to cover a certain same set of conditions, then screening will be curtailed or eliminated.

To see why the uniformity or nonuniformity of policies can have important implications for the equity and efficiency effects of banning risk classification, consider the effects of banning gender-based risk classification. If insurers find it much more costly to provide health care to women than to men then, absent any coverage mandates, it could potentially circumvent the ban by offering two policies: An expensive and comprehensive policy, and a less expensive one providing comprehensive coverage for everything except childbirth, breast cancer, gynecological examinations, and other gender-specific health care needs. Women faced with such a menu would find it worthwhile to pay the higher premium for coverage of their needs, and men would not. In this case, the insurer would effectively circumvent the risk classification ban, which would consequently have neither efficiency nor equity effects. In contrast, a ban imposed under coverage mandate-induced policy uniformity would likely have welfare effects.

Question 3: Are Insurance Purchases Mandated or Not?

In markets without purchase mandates, individuals who perceive themselves to have the greatest need for insurance, and hence the highest expected costs to insurers, will be differentially more likely to purchase coverage, whereas lower-risk individuals are differentially likely to opt out of buying coverage at all. In this case, the pool of insured individuals is said to be adversely selected relative to the population. An adversely selected risk pool requires higher premiums for firms to break even. In the most severe cases, adverse selection can completely destroy a market via an adverse selection death spiral.

Because purchase mandates and risk classification are two different ways to mitigate adverse selection, the presence or absence of a purchase mandate is crucial for analyzing the equity and efficiency implications of risk classification.

A Quick-and-Dirty Guide to the Equity–Efficiency Trade-offs

The eight distinct answers to the set of three questions above describe eight conceptually distinct institutional contexts. In practice, however, purchase mandates are typically coupled with minimum coverage mandates that limit the degree of policy differentiation: otherwise, individuals could fulfill the mandate by purchasing a low-priced contract providing essentially zero coverage. Therefore the two regimes with mandated purchases and differentiated products are not considered.

Table 1 provides a quick reference guide to the efficiency and equity effects of risk classification in the six remaining institutional contexts. It focuses on interim efficiency and horizontal, financial, and distributional equity, with beneficial distributional equity effects interpreted as those which would be desirable from the point of view of the veiled representative individual at stage 0 in Figure 1.

Consider first environments with a purchase mandate and a uniform contract. Bans on risk classification are the least likely to be controversial in these environments, because they

Table 1 Effect of a ban on risk classification

Institutional context	*Interim efficiency*	*Distributional equity*	*Horizontal equity*	*Financial equity*
Effects of a ban on perfect risk classification				
Mandated purchase and uniform contract	Neutral	Beneficial	Neutral	Detrimental
Optional purchase and uniform contract	Detrimental	Beneficial/neutral	Neutral	Detrimental
Optional purchase and differentiated contract	Detrimental	Beneficial/neutral	Neutral	Detrimental
Effects of a ban on imperfect risk classification				
Mandated purchase and uniform contract	Neutral	Beneficial	Beneficial	Detrimental
Optional purchase and uniform contract	Detrimental (institutionally)	Beneficial/neutral	Beneficial	Detrimental
Optional purchase and differentiated contract	Detrimental (institutionally)	Beneficial/neutral	Beneficial	Detrimental/neutral

improve distributional equity in a horizontally equitable way without harming interim efficiency. This is because only premiums, not insurance coverage, are affected by risk classification, and banning risk classification beneficially (from an ex-ante perspective) redistributes from individuals who were born into the fortunate group with fewer low risks to those who were unlucky enough to be born into the higher-risk group.

When risk classification is imperfect, but purchases of a uniform contract are still mandatory, such a ban also has a beneficial impact on horizontal equity, because it prevents individuals with the same true risk from being charged different premiums by virtue of the group to which they happen to belong. The primary objections to banning risk classification in mandatory-purchase uniform-contract contexts are likely to stem from financial equity effects; some might feel strongly that individuals should not be forced to cross-subsidize others. This objection is likely to be particularly germane for risk classification based on preexisting and preventable conditions, but it may be present more broadly.

In an optional-purchase institutional context, banning risk classification may additionally induce efficiency reducing adverse selection effects. Suppose, for example, that group A consists of people with an expensive-to-treat preexisting condition and group B consists of healthy individuals. With legal risk classification, the market will segment and group B individuals will pay lower premiums. One possibility, if risk classification is banned, is that all individuals will continue to purchase insurance at some intermediate premium. In this case, the welfare effects are exactly as with a mandate. The other possibility is that the market will suffer from a death spiral: Group B individuals will find insurance too expensive at the new premium and will leave the market. Premiums for the group A individuals will then rise to the same as they were before the ban was imposed. In this case, the risk classification ban will be purely efficiency reducing. It will have no beneficial equity effects at all.

Similar adverse selection-driven negative efficiency effects arise with a richer and more realistic set of individual risk types. If the adverse selection is mild, so that only a few of the lowest-risk types are driven from the market by a ban in risk classification, then policy makers will face a genuine trade-off between beneficial distributional equity effects of uniform pricing and the efficiency costs of adverse selection. With sufficiently severe adverse selection, the uniform pricing will have at most mild distributional equity benefits, and ex-ante efficiency will be reduced. If a policy maker wanted to ban risk classification and believed that the adverse selection problem was likely to be severe, introducing a purchase mandate would therefore be essential. This was the primary motivation for policy makers to include a coverage mandate in the Patient Protection and Affordable Care Act passed by the US Congress and signed into law by President Barack Obama in 2010.

A similar trade-off between interim efficiency and distributional equity applies if risk classification is imperfect, but the interim efficiency effects of a ban are detrimental in the institutional sense rather than in the outcome-based sense. In particular, one can show that the outcome with banned risk classification can always be Pareto improved on with legal risk classification and some appropriate risk adjustments, for example, through government-administered transfers across insurers serving different risk classes.

The detrimental interim efficiency effects of banning perfect risk classification are also similar when contracts are differentiated and insurance is not mandated (bottom rows). The mechanism is somewhat different, however: Low-risk individuals will be screened – induced to self-select – into a high-deductible policy providing worse coverage rather than being adversely selected out of the market entirely. There is some disagreement among economists about the precise nature of screening in insurance markets; some widely used models of insurance markets predict the same outcomes with and without risk classification bans, and, consequently, no distributional equity effects. Others predict the potential for beneficial distributional equity effects via pooling of different risk types or cross-subsidies across distinct contracts.

It is clear that even in the simple analytical framework depicted in Figure 1, evaluating the welfare consequences of risk classification is nontrivial and highly context-dependent. Of the three central questions identified above as being useful for understanding these welfare effects, the latter two are observable policy questions. The first question is an empirical one. It can be understood as a question about the presence or absence of asymmetric information: Risk classification is imperfect precisely when there is unused information about risk within a risk class. In these cases, incentive contracting – designing contracts to mitigate the imperfections of the risk classification technology – can play an important role. Screening is the type of incentive contracting that is particularly important when the relevant asymmetric information within a risk class is of the adverse selection type, as has largely been assumed up to this point, but other types are potentially important with other types of informational asymmetries. In part because of its central importance for the welfare analysis of risk classification, the presence or absence of informational asymmetries has been the subject of much recent empirical work.

Risk Classification and Residual Asymmetric Information in Health Insurance Markets

Perfect risk classification should separate individual risks and generate different actuarial insurance premiums that reflect these risks. With actuarial premiums, full insurance should be the optimal contract, and there should not be any correlation between insurance coverage and individual risk. But in the real life of health insurance contracting, there are numerous reasons for imperfections in risk classification. Particularly important among these is the possibility of residual asymmetric information within a given risk class. Recent empirical work has therefore focused on searching for evidence for presence and extent of this sort of residual asymmetric information.

General Tests for Residual Asymmetric Information

Information problems are common in insurance markets. Usually, the insured are better informed about their own

characteristics or actions than are their insurers. The two best-known information problems discussed in the economics literature are adverse selection, discussed above, and moral hazard, where insurance leads individuals to take unobserved actions either before (ex-ante moral hazard) or after (ex-post moral hazard) the realization of health outcomes that raise the costs borne by the insurer. Asymmetric learning over time is a third information problem. Because similar empirical patterns are predicted by these three problems, empirical work on information problems is challenging.

Empirical work has three sequential goals. The first is to determine whether information problems exist, and, if so, how severe they are. The second is to identify which information problem or problems are present when the first test rejects the null hypothesis that there is no information problem. This is important for an insurer because it must implement the appropriate instruments to improve resource allocation. A fixed deductible, for example, efficiently reduces ex-ante moral hazard, but not necessarily ex-post moral hazard. A high deductible can even have an adverse effect and encourage accident cost building.

The third goal is to find ways to improve the contracts and reduce the negative impact of asymmetric information on resource allocation. These resource allocation objectives must take into account other issues, such as risk aversion, equity, and accessibility of services. This last issue is particularly important in health care markets. A decrease in insurance coverage may reduce ex-ante moral hazard because it exposes the insured person to risk, but it also significantly reduces accessibility to health services for sick people who are not responsible for their condition. Although the third goal is ultimately the most important, this article focuses on the first two goals, which have been convincingly tackled in the literature only recently.

Well-constructed theoretical models with carefully established theoretical predictions are essential for achieving these goals. Many theoretical contributions were published in the 1970s which appealed to asymmetric information to account for stylized facts observed in insurance markets. Not all of these accounts were readily adapted to formal tests of information asymmetries, however. For example, partial insurance, such as deductible and co-insurance contracts, can be justified by either moral hazard or adverse selection, but proportional administrative costs can also justify it. So the mere fact that these are common features of real-world insurance policies does not imply the presence of asymmetric information.

The following simple question has motivated most recent empirical work toward the first goal: Do insurers that apply risk classification techniques based on observable characteristics in their underwriting policies also find it useful to employ contract design to further separate risk types within the risk class? In static or one-period contracts, the answer is no unless there is residual asymmetric information within the risk classes. (The reality is, of course, much more complicated because contract duration between the parties can cover many periods, and over time the true risks may become known to both parties.) Finding a residual correlation between chosen insurance coverage and risk within risk classes is therefore a tell-tale sign of asymmetric information. Tests for such a correlation have been the centerpiece of the empirical literature on information problems in insurance markets.

Econometricians analyze two types of information when studying insurers' data. The first type contains variables that are observable by both parties to the insurance contract. Risk classification variables are one example. Econometricians/insurers combine these variables to create risk classes when estimating accident distributions. They can be used to make estimates conditional on the risk classes or inside the risk classes. The second type is related to what is not observed by the insurer (or the econometrician) during contract negotiations or selections, but can explain the insured's choice of contracts or actions. A typical empirical study looks for the conditional residual presence of asymmetric information in an insurer's portfolio by testing for a correlation between the contract coverage and the realization of the risk variable during a contract period. Different parametric and nonparametric tests have been proposed in the literature.

Finding a positive correlation between insurance coverage and risk is a necessary condition for the presence of asymmetric residual information, but it does not shed light on the nature of the information problem. In insurance markets, the distinction between moral hazard and adverse selection boils down to a question of causality. Under moral hazard, the structure of an insurance contract drives the unobserved actions, and hence the riskiness, of the insured. For example, a generous health insurance plan can reduce the incentives for prevention and increase the risk of becoming sick. Under adverse selection, the predetermined riskiness of an individual drives their contract choices: Higher-risk individuals will tend to choose policies providing better coverage. The correlation between insurance coverage and the level of risk is positive in both cases, but the directions of causality in the two cases are exactly opposite.

To separate moral hazard from adverse selection, econometricians need a supplementary step. In insurance markets, dynamic data are often available. Time adds an additional degree of freedom to test for asymmetric information, particularly in the presence of experience rating – whereby future premiums depend on past accident history. Experience rating works at two levels in insurance. Past accidents implicitly reflect unobservable characteristics of the insured (adverse selection) and introduce additional incentives for prevention (moral hazard). Experience rating can therefore directly mitigate problems of adverse selection and moral hazard, which often hinder risk allocation in the insurance market.

The failure to detect residual asymmetric information, and more specifically, moral hazard and adverse selection in insurance data, is often due to the failure of previous econometric approaches to model the dynamic relationship between contract choices and claims adequately and simultaneously when looking at experience rating. Intuitively, because there are at least two potential information problems in the data, an additional relationship to the correlation between risk and insurance coverage is necessary to test for the causality between risk and insurance coverage.

Testing for Asymmetric Information in the Health Insurance Market

Many reviews of empirical studies in different insurance markets have been published, including health insurance and

long-term care insurance. It is observed that the coverage–risk correlation is particular to each market. Accordingly, the presence of a significant coverage–risk correlation has different meanings in different markets, and even in different risk pools in a given market, depending on the type of the insured service, the participants' characteristics, institutional factors, and regulation. This means that when testing for the presence of residual asymmetric information, one must control for these factors as well. Up to now the empirical coverage–risk correlation findings have been equivocal. What characteristics and factors explain the absence of robust coverage–risk correlations in health insurance markets?

Long-term care market and the health care market are analyzed separately, notably because long-term care insurance effectively combines both health insurance and longevity insurance (annuities). It is well documented that private long-term care insurance is very expensive in the US and therefore not very popular. Less than 5% of the elderly participate in this market. Is it due to adverse selection? Those who purchase this coverage do not seem to represent higher risks than the average population. This negative result is explained by a combination of two opposite effects: A pure risk effect and a risk aversion effect. For a given risk aversion, higher-risk individuals buy more insurance under asymmetric information, as do more risk-averse individuals (who are assumed to engage in more prevention to reduce their risk). The net effect on the correlation between risk and coverage is not significant because both high-risk and low-risk individuals buy this insurance. However, it is not evident that more risk-averse individuals put forth more effort. Consequently, the absence of correlation may be explained by factors other than risk aversion.

Many empirical studies in the literature find a positive correlation between poor health condition and generous coverage, whereas other studies do not find this correlation. Some do not reject asymmetric information in the medical insurance market, but do not find evidence of adverse selection. Their results are even consistent with multidimensional private information along with advantageous selection. Indeed, some obtain a negative correlation between risk and insurance coverage. The significant sources of advantageous selection are income, education, longevity expectations, financial planning horizons, and most importantly, cognitive ability.

Other studies offer detailed analyses of health insurance plans. For example, it is shown that when the employer increased the average participation cost of the most generous plan for the policyholders, regardless of the risk they represented, the best risks in the pool with lower medical expenses left this plan for a less generous one with a lower premium. The new insurance pricing clearly generated adverse selection. Even if the age of the insured were observable, the insurance provider did not use this information, and the younger participants abandoned the more generous plan. This is a case in which the absence of a proper risk classification yielded severe adverse selection. This type of constraint, wherein risk classification variables are not used, is often observed in the health care market where the trade-off between efficiency and distributional equity matters.

One potential reason for not observing a significant correlation between coverage and risk is the absence of insured private information on the insured's health status. Young individuals who may not have experienced any health problems may think they belong to the low-risk group. The statistical test should be done within these risk classes, even if the employer does not use age as a risk classification variable. Another reason for the lack of risk–coverage correlation, which may also apply to health insurance, is policyholders' failure to use their private information when selecting insurance policies. It has been found, for example, that the demand for life insurance is not sensitive to insurance price and risk.

It has also been documented that insurance consumption depends on institutions. Moreover, risk classification in the health care market is heavily regulated in many countries. Therefore, the empirical predictions based on the implicit assumption of competitive markets may not be appropriate for many markets, including health insurance. For further discussion on particularities other than efficient risk classification that may generate an absence of correlation between insurance coverage and risk, see the references in further reading.

Conclusion

This article has discussed the complex welfare effects of risk classification in health insurance. The policy decision to permit or ban risk classification may have consequences for efficiency, for equity, or for both. The various relevant notions of efficiency and equity appropriate in health insurance context were reviewed and trade-offs that are likely to arise in various institutional contexts were qualitatively characterized. A key question for this characterization is whether or not there is (or would be) within-class residual asymmetric information when insurers employ risk classification based on observable characteristics. The extensive and growing empirical works on this question were discussed. There remains substantial scope for future empirical work directed toward quantifying the equity–efficiency trade-offs of risk classification.

Risk Equalization and Risk Adjustment, the European Perspective

WPMM van de Ven, Erasmus University Rotterdam, Rotterdam, The Netherlands

Glossary

Equalization payment The compensation per insured that an insurer receives from or has to pay to the equalization fund. For example, the equalization payment could be equal to the insured's risk-adjusted predicted expenses minus the average expenses per person. If the equalization payment is negative, the insurer has to pay it to the equalization fund.

Out-of-pocket premium Premium minus equalization payment.

Premium The price of insurance. In a competitive market the premiums are risk-rated. An insured's premium then equals the risk-adjusted expected expenses of the insured, plus a loading fee (for administrative costs, the insurer's profit, marketing costs, etc.).

Risk adjustment A technique for adjusting a payment to someone's risk characteristics.

Risk equalization A technique for compensating insurers by means of risk-adjusted equalization payments for the composition of their risk portfolio.

Risk selection Actions (not including risk rating) by consumers and insurers to exploit unpriced risk heterogeneity and break pooling arrangements.

Introduction

Since the 1990s an increasing number of European countries permit periodic consumer choice of insurer in their social health insurance schemes (e.g., Belgium, the Czech Republic, Germany, Israel, the Netherlands, Russia, Slovakia, Switzerland, and Russia). It can be hypothesized that such consumer choice provides the insurers with effective incentives for efficiency and innovation. However, an unregulated competitive health insurance market also tends toward risk-adjusted premiums and rejection by insurers of high-risk applicants. Therefore, governments in these countries interfered with regulation to make health insurance accessible and affordable for everyone. Risk-adjusted equalization payments are a necessary component of any efficient intervention. Other potential interventions have unfavorable effects: premium regulation creates incentives for selection (which may have several unfavorable effects) and ex-post compensations to the insurers reduce their incentives for efficiency. However, because risk equalization is technically complex, policymakers are confronted with a complicated trade-off between affordability, selection and efficiency.

Risk equalization is discussed from a European perspective. First its relevance is discussed in the competitive health insurance markets and some technical complications (Section 'Why Risk Equalization, and How?'). Then a historical perspective of the European experience with risk equalization (Section 'The European Experience with Risk Equalization: A Historical Perspective') and future perspectives including its relevance for provider payments and for countries with a National Health Service (NHS) such as England is provided. Finally the conclusions are summarized in the Section 'Conclusion.'

Why Risk Equalization, and How?

The solidarity principle, which is highly valued in Europe, implies that high-risk and low-income individuals receive a subsidy to make health insurance affordable. Therefore a great challenge for policymakers is: how to combine solidarity with consumer choice of health insurer? In an unregulated competitive insurance market insurers have to break even, in expectation, on each contract, because competition minimizes the predictable profits per contract. Insurers can do so by (1) adjusting the premium to the consumer's risk (premium differentiation), (2) adjusting the product, for example, coverage and benefits designed to attract different risk groups per product and charge premiums accordingly (product differentiation), or, if the transaction costs of further premium and product differentiation are too high, (3) by adjusting the accepted risk to the premium of a given product (risk selection), for example, by excluding certain preexisting medical conditions from coverage or by not accepting high-risk people. Given the average expenses per risk group, unregulated competition could result in premiums that can differ a factor of 500 or more once health status and age are taken into account.

Although premium differentiation makes coverage less affordable for the high risks, risk selection (by excluding certain preexisting medical conditions from coverage or by not accepting high-risk people) makes coverage less available to the high risks. In both ways, guaranteed access to affordable coverage for the high risks is jeopardized.

To simplify the analysis, it is assumed that health insurers are bound to an open enrollment requirement. This implies that insurers must accept each applicant for a standard coverage. In practice, open enrollment is required in all countries with a competitive social health insurance market. As long as insurers are free in setting premiums, this assumption is nonrestrictive, because insurers are allowed to risk-adjust the premium for each applicant and can offer each type of policy in addition to the policy with the standardized coverage. By this assumption the problem of unavailability that would occur in case of rejection or coverage restrictions, is essentially transformed into a problem of unaffordability (high premiums for high-risk individuals) to be solved by cross subsidies. In this article the author focuses only on the so-called risk-solidarity, i.e., cross subsidies from low-risk to high-risk individuals (and not on income solidarity).

An effective way to achieve risk-solidarity without disturbing competition among the insurers is to give the high-risk consumers a subsidy out of a solidarity fund that is filled with mandatory solidarity contributions from the low risks. Ideally these subsidies are risk-adjusted, i.e., the subsidy is adjusted for the risk factors that the insurers use. For practical reasons the subsidy can be given directly to the insurers. In a transparent competitive market, insurers are forced to reduce each consumer's premium with the per capita subsidy they receive for this consumer. By giving risk-adjusted subsidies to the insurers the different risks that consumers represent for them are equalized. Therefore this way of organizing risk-adjusted subsidies is referred to as 'risk equalization.' In practice, all European countries that apply risk-adjusted subsidies do this in the form of risk equalization (see Section 'The European Experience with Risk Equalization: A Historical Perspective').

Sometimes the term risk adjustment is used rather than risk equalization. However, risk adjustment can also be applied to, for example, provider payments. The term risk equalization is used to denote the specific case of 'risk-adjusted compensations to (the consumers via) the insurers.'

Complementary Strategies

Although sufficiently risk-adjusted equalization payments can be an effective strategy to guarantee affordable coverage in a competitive individual health insurance market, in practice the risk equalization payments are still insufficiently risk-adjusted (see below). Therefore, in addition government may implement one or more of the following strategies:

1. A system of ex-post cost-based compensations to the insurers. For example, the insurers are fully or partly compensated by government for an individual's expenses in excess of a certain annual threshold. These compensations will be reflected in premium reductions, in particular for the high risk-risk enrollees.
2. Premium rate restrictions. An extreme form of premium rate restrictions is that the premiums must be community rated, i.e., insurers must charge the same out-of-pocket premium for the same product to each enrollee, independent of the enrollee's risk. All European countries with a competitive social health insurance market require the out-of-pocket premiums to be community rated.

However, each of these additional strategies has substantial drawbacks, resulting in serious trade-offs.

Ex-post cost-based compensations are not optimal because they reduce the insurers' incentive for efficiency resulting in an affordability-efficiency trade-off.

Premium rate restrictions have some major drawbacks as well. Although the goal is to create implicit cross subsidies from the low risks to the high risks who are in the same pool, this pooling creates predictable profits and losses for identifiable subgroups in the pool, and thereby provides insurers with incentives for risk selection, which may threaten affordability, efficiency, quality of care, and consumer satisfaction (see Box 1). Therefore, premium rate restrictions confront policymakers with an affordability-selection trade-off. In addition it is questionable to what extent premium rate restrictions are effective in the long term, because product differentiation may result in indirect premium differentiation. Insurers may offer special products for various risk groups, for example, depending on life-stage, lifestyle, or health status. Such risk segmentation across the product spectrum can be observed in, for example, Australia, Ireland, and South Africa, where premiums must be community rated. In this way 'community rating per product' results in low premiums for low risks and high premiums for high risks, which undermines the goal of 'community rating across the market'.

Product differentiation may not only occur in voluntary health insurance markets, but also in mandatory social health insurance markets. For example, in the Netherlands a substantial variation in the health insurance products is allowed. These products may vary, for example, according to the list of contracted providers, the financial incentives to motivate consumers to use preferred providers, procedural conditions (e.g., yes or no preauthorization by the insurer or by the general practitioner) and the list of covered pharmaceuticals.

The relevance of good risk equalization is that if the equalization payments are sufficiently risk-adjusted (see below) there is no need for the other strategies, each of which confronts policymakers with severe trade-offs. The better the risk-adjusted equalization payments are adjusted for relevant risk factors, the less severe are these trade-offs.

Box 1 Unfavorable effects of risk selection

1. Insurers have a disincentive to respond to the preferences of high-risk individuals. For example, insurers with a good reputation for chronic care would attract many unprofitable patients and would be the victim of their own success. Therefore, insurers may structure their coverage to make the plan unattractive to high risks or choose not to contract with providers who have the best reputation for treating chronic illnesses. This in turn may discourage physicians and hospitals from acquiring such a reputation.
2. Efficient insurers who do not engage in risk selection may lose market share to inefficient risk-selecting insurers, resulting in welfare loss to society.
3. If risk selection generates large predictable profits it will be more profitable than improving efficiency in health care production. At least in the short run, if an insurer has limited resources available to invest in reducing costs, it may prefer to invest in risk selection rather than in improving efficiency.
4. To the extent that some insurers are more successful than others in attracting low risks, selection will result in risk segmentation. High risks will therefore pay higher premiums than low risks, undermining 'community rating across the market.'
5. Selection may induce instability in the insurance market because low risks have a permanent incentive to break the pooling of heterogeneous risks by switching to lower-priced insurers.
6. Selection wastes resources because investments purely aimed at attracting low risks through risk segmentation or selection produce no net benefits to society.

Acceptable Costs; S-Type and N-Type Risk Factors

For the calculation of the risk-adjusted equalization payments it is important to determine the costs and the risk factors on which the payments should be based. The costs of the services

and intensity of treatment that are acceptable to be compensated are denoted as the acceptable costs. For example, acceptable costs may be those generated in delivering a 'specified basic benefit package' containing only medically necessary and cost-effective care. Because the 'acceptable cost level' is hard to determine, in practice the equalization payments are mainly based on observed expenses rather than needs-based costs. However, observed expenses are determined by many factors, not all of which need to be used for calculating the equalization payments. Assume that all risks factors X that determine observed expenses can be divided into two subsets: those factors for which solidarity/subsidy is desired, the S-type factors; and those for which solidarity/subsidy is not desired, the N-type factors. Then the equalization payments should only be adjusted for the S-type risk factors and not for the N-type risk factors.

Decisions about which risk factors should be labeled an S-type or N-type factor, reflect value judgments that differ across countries and among individuals. In most societies health status and gender are likely to be S-type risk factors. Other risk factors may be open for discussion:

- Characteristics of the individual such as lifestyle, taste, income/wealth, religion, being self-employed, race, and ethnicity;
- Characteristics of the contracted providers, such as price level, practice style, utilization review, various health management strategies, and (in)efficiency;
- Characteristics of the region where the consumer is living, such as average price and income level, population density, average distance to hospitals, and whether there is an over- or undersupply of providers; and
- Characteristics of the contracts and financial incentives between plans and providers.

All European countries that apply risk equalization use age as a risk adjuster. This reflects the desired level of intergenerational solidarity and the desired way of paying health expenses over the life cycle in these countries. Nevertheless, age might (partly) be considered an N-type risk factor. Young people on average have relatively low health expenses and high expenses on housing, schooling and children, whereas for the elderly the opposite holds. The Affordable Care Act in the USA ('Obamacare') allows the insurers to differentiate their premium by a factor 1:3 for age for products sold via the so-called Exchanges, although the additional age-related variation in health expenses is compensated via risk equalization. In other words, age is partly an S-type risk factor and partly an N-type risk factor.

Region is often a disputable risk factor. It is likely that region captures differences in health status, which most likely are to be compensated. However, region also reflects differences in other risk factors, such as price level, oversupply, inefficiency, practice style, etc., which might not be compensated. The more health related risk factors are explicitly included in the equalization formula, the less will region reflect regional health differences and the more it will reflect regional differences in nonhealth factors.

If it is explicitly decided to adjust the equalization payments only for S-type risk factors and not for N-type risk factors, a logical consequence is that insurers are allowed to ask premiums from the consumers that are related to the N-type risk factors. If not, the insurers have incentives for selection based on these risk factors.

If the equalization payments are based on observed expenses, as is mostly the case in practice, the calculation of the risk-adjusted equalization payments could be as follows. Assume that $E(X)$ is the best estimate of the expected expenses in the next contract period for a person with risk characteristics X. An estimate of the acceptable cost level could then be $E(X)$ with the values of the N-type risk factors set at an acceptable level (e.g., the acceptable level of the price or supply of health care or the acceptable practice style). Because some components of the vector X have been fixed at some specific value, the acceptable cost level can be written as a function that only depends on the nonfixed values. Hence if $X = (Xs, Xn)$ and Xs has the S-type factors and Xn the N-type factors, then the acceptable cost level would be $A(Xs)$. The risk-adjusted equalization payment could then be a function of $A(Xs)$, for example, it could be $A(Xs)$ minus a fixed amount Y (or a certain percentage of $A(Xs)$, as in the USA Medicare). Negative equalization payments imply payments from the insurer to the subsidy fund. If it is assumed that the average premium (excluding surcharges for administration, selling costs, profits, etc.) equals the average predicted health expenses, the national average of the consumers' out-of-pocket premiums (i.e., premium minus equalization payment) equals Y. In countries such as Russia and Israel, $Y = 0$. In these countries the consumers do not pay any out-of-pocket premiums directly to their insurer. In countries such as Switzerland and Ireland, Y equals the average predicted per capita expenses. The Netherlands has an intermediate position, with Y equal to 45% of the average predicted per capita expenses.

Criteria for Risk Equalization

The application of risk equalization in practice is hindered because ideally the following criteria should be fulfilled:

1. Appropriateness of incentives: Insurers should have incentives for efficiency and health-improving activities, and no incentives for selection and for distorting information to be used for calculating the equalization payments.
2. Fairness: Ideally the risk-adjusted payments should only compensate for so-called acceptable costs, and depend only on so-called S-type risk factors. The payments should sufficiently compensate the insurers for their high-risk enrollees ('distributional fairness' and good predictive value), and should be sufficiently stable over time.
3. Feasibility: the required data should be routinely obtainable for all potential enrollees without undue expenditures or time. The data should be resistant to manipulation by the insurers and government should be able to control the correctness of the data. There should be no conflict with privacy and ideally the system should be acceptable to all parties involved. Information that is routinely collected, standardized, and comparable across different insurers and measures that are easily validated have greater feasibility than measures that require separate data collection, validation, and processing.

In practice most potential risk equalization models appear not to fully fulfill these criteria, resulting in complicated trade-offs.

Potential Risk Adjusters

Risk equalization research started in the late 1980s. The calculation of risk-adjusted equalization payments requires a good prediction of each individual's health expenses based on the individual's characteristics, which are called risk adjusters. Because it is clear that age and gender alone are insufficient adjusters, the research efforts in the past two decades focused on developing health adjusters.

The inappropriate incentives related to prior utilization as a risk adjuster ('rewarding high prior utilization') may be reduced by combining it with diagnostic information. Widely known classification systems are the ambulatory care group system and the diagnostic cost group (DCG) models. Diagnosis-based models begin by identifying a subset of all diagnoses that predict subsequent year resource use. The many codes are grouped into more aggregated groups based on clinical, cost, and incentive considerations. Diagnosis-based risk adjusters tend to do well in predictive accuracy and feasibility. Although these models outperform a model based on age and gender only, there still exist subgroups that are substantially undercompensated.

Health status information can also be derived from the prior use of prescription drugs. Lamers *et al.* (1999) developed the so-called pharmacy cost groups (PCGs). They classified drugs into different therapeutic classes and further classified them on the basis of empirically determined similarities in future costs. Although PCGs are good predictors of future health care costs, a point of attention is that if the additional subsidy for a PCG-classified enrollee (far) exceeds the costs of the prescribed drugs that form the basis for PCG-assignment, the insurer has an incentive to (stimulate the physician to) overprovide medication in order to ensure an increase in the future subsidies. To prevent perverse incentives, Lamers *et al.* (1999) used only 10% of all prescriptions to define the PCGs.

Disability and functional health status have been shown to be relatively good predictors of future expenditures, even after controlling for demographic factors and prior utilization. These indicators reflect someone's ability to perform various activities of daily living and the degree of infirmity, and seem to be an almost ideal adjuster.

There are different opinions about the usefulness of mortality as an additional risk adjuster (see e.g., Lubitz, 1987). Van Vliet and Lamers (1998) argued that mortality should not be used as a risk adjuster because most of the excess costs associated with the high costs of dying are unpredictable. Although cause-of-death information is theoretically attractive, practical concerns include reliability, validity, availability, manipulation, auditing, privacy of the data, and perverse incentives.

The only country with a competitive health insurance market that applies mortality as a risk adjuster is Belgium. In countries with a noncompetitive health insurance market it is not unusual to use mortality as a risk adjuster.

Do We Need Perfect Risk Equalization?

It is important to emphasize that in the case of premium rate restrictions the predictable profits and losses need not be reduced to zero. One should take into account an insurer's costs of selection and the (statistical) uncertainty about the net benefit of selection. A bad reputation resulting from selection activities such as keeping patients from the highest-quality care can be a high cost to an insurer. In addition, the information that is necessary for risk selection is not for free. So a 'perfect' risk equalization formula is not necessary. It should be refined to such an extent that insurers expect the costs of selection (including the cost of a bad reputation) to outweigh its benefits. By making the risk groups in the risk adjustment algorithm more homogeneous, the costs of selection increase although on average its profits fall. But it is still an unanswered question how much 'imperfection' is acceptable.

The European Experience with Risk Equalization: A Historical Perspective

The application of risk equalization in Europe started in the early 1990s, when several European countries started to radically reform their social health insurance system. In Belgium, Czech Republic, Germany, Israel, the Netherlands, Slovakia, and Switzerland the regulatory regime was changed such that the consumers have a guaranteed periodic choice among risk-bearing social health insurers, who are responsible for providing or purchasing health care for their enrolees. In some countries the social health insurers are called sickness funds (e.g., in Belgium, Germany, and Israel). In this article they will be indicated as '(health) insurers.'

Risk Adjusters and Ex-Post Cost-based Compensations

Before 2000 all these countries used predominantly demographic risk adjusters, in combination with community-rated out-of-pocket premiums. Some countries used disability and/or region as an additional risk adjuster(s). A disadvantage of predominantly demographic risk adjustment is that community-rated premiums create large predictable profits and losses for subgroups like the chronically sick, resulting in incentives for risk selection.

All European countries experience(d) severe implementation problems. Especially in the first years there was a serious lack of relevant data, in particular at the level of the individual enrollee. All in all the European experience indicates, in accordance with the experience in the USA that even the simplest risk equalization mechanisms are complex and that there are many start up 'surprise problems.'

Several countries used ex-post cost-based compensations as a complement to imperfect risk equalization, for example, Belgium and the Netherlands. In Israel the insurers receive a fixed payment for each person who is diagnosed with one of the following 'severe diseases': end stage renal failure requiring dialysis, Gaucher's disease, talasemia, hemophilia and acquired immune deficiency syndrome. Germany (until 2002) and Switzerland do not have any form of ex-post cost-based

compensations. Consequently, the incentives for selection in Germany and Switzerland are high.

Risk Selection

It is hard to give clear evidence of selection activities in practice. Even if insurers perform risk-segmenting activities, they may argue that it is not 'selection,' but normal commercial behavior because they are specialized in certain segments of the market. In addition, selection activities in the form of 'not investing in better care for unprofitable subgroups' are difficult to detect because it is not known what would have happened if insurers had put in place appropriate incentives. Therefore, rather than hard evidence of selection, the following anecdotal evidences of selection activities reported in the European countries are cited:

- Selective advertising/using the internet;
- Accessibility problems;
- Health questionnaires;
- Delayed reimbursements;
- Offering health insurance via life insurers who make specific selections based on health inquiries;
- Selectively terminating business in unprofitable regions, for example, by closing offices in high-cost areas;
- Opening clinics in healthy regions;
- Employer-related (group) health insurer;
- Via limited provider plans such as health maintenance organizations and preferred provider organizations;
- Offering high rebates in case of a deductible;
- Information to unprofitable enrollees that they have the right to change insurer;
- Turning away applicants on the telephone and ignoring inquiries and phone calls;
- Special bonuses for agents who are successful in getting rid of the most expensive cases by shunting them off to competitors; and
- Voluntary supplementary insurance.

Acceptable Costs

Belgium is the only country in which the distinction between S-type and N-type risk factors is a relevant policy issue in practice. It was decided that medical supply should not be included in the risk equalization system. Schokkaert and Van de Voorde (2003) illustrate the nontrivial impact of this political decision on the health insurers' results.

Although the Dutch government formally announced that the risk-equalization formula should only be based on age/gender/health, in practice the Dutch risk equalization model also contains risk factors such as region and being self-employed. These risk factors partly reflect health status (an S-type factor) and partly other risk factors (N-type factors). A correction for the biased weights in the current risk-equalization formula would have substantial financial consequences for the Dutch insurers.

Improvements of Risk Equalization

An effective way to prevent risk selection is to complement the demographic risk adjusters with health indicators. Then, (1) it is harder for the insurers to define who the preferred risks are; (2) on average the predictable profits/losses are less; and (3) there are less possibilities for insurers to select the preferred risks, than in the case that risk equalization is only based on age/gender. Since 2000 the risk equalization systems in several European countries have been improved by adding relevant health-based risk adjusters.

In the Netherlands the risk equalization model was extended with PCGs in 2002, with DCGs in 2004 and with an indicator of multi prior year high expenses in 2012. In Germany the incentives for risk selection were reduced by the implementation of an ex-post risk pooling for high costs insured in 2002, and by implementing a health adjuster in 2003 (yes/no being registered in an accredited disease management program). In 2009 a health-based adjuster was added that compensates for 80 severe diseases and costly and chronic diseases, based on diagnostic information and/or prescriptions. In Belgium risk adjusters based on inpatient diagnostic information and information about chronic conditions based on outpatient prescribed and reimbursed drugs were added in 2008. In Switzerland prior hospitalization has been included as a risk adjuster in 2012.

However, all these improvements in risk equalization are not necessarily a sufficient guarantee that selection will be reduced. Several arguments explain why selection may not be a major issue in the early stage of the implementation of a risk equalization mechanism in a competitive health insurance market, and why over time selection may increasingly become a problem. First, in the early stage many players, for example, consumers, health insurers, managers and providers of care, may be unfamiliar with the rules of the game. However, over time they will be better informed and can be expected to react to incentives for risk selection. Second, in the early stage the differences among health insurers with respect to benefits package, premiums, and contracted providers are relatively small. Over time they may increase. Third, most risk equalization systems have been implemented in the mandatory social health insurance system. Traditionally these health insurers are driven by social motives rather than by financial incentives. However, over time new insurers and increasing competition can make the market more incentive driven. As soon as one insurer starts with profitable selection, the others are forced to copy this strategy. Finally, one may argue that selection is not so much of a problem because doctors may be reluctant to discriminate among risks because of medical ethics. However, present ethics may change over time if the entire delivery system becomes more competitive.

How Good are the Risk-Equalization Formulas in Practice?

Currently the most sophisticated risk-equalization formulas can be found in the Netherlands, Belgium, Germany, and the USA-Medicare. How good are these formulas?

The results of an evaluation of the Dutch equalization formula 2007 indicates that this formula provides insufficient compensation for groups defined on health status, prior utilization, and prior expenses. These groups can be easily identified by the insurers. In case of an average premium, the average predictable losses per adult in these subgroups are

in the order of hundreds to thousands of Euros per person per year. For example, given an average community-rated premium the average predictable loss per adult for 21% of the population who report their health status as fair/poor, equals €541. The results also indicate predictable losses for groups of insured whose disease is included as a risk-adjuster in the equalization formula, for example, heart problems and cancer. Clearly not all of these patients fulfill the criteria to be classified as a patient eligible for a high equalization payment. It may be expected that other sophisticated risk equalization algorithms, such as the ones used in Belgium, Germany, and the USA-Medicare, yield similar results.

Lessons from the European Experience

In totality the European experience indicates, in accordance with the experience in the USA, that even the simplest risk equalization mechanisms are complex and that there are many start up 'surprise problems.'

In all countries the criterion 'appropriate incentives' did not appear to be a dominant one in choosing among different risk equalization models. On the contrary, redistributive effects among the insurers, feasibility (including acceptability) and fears for complexity were quite dominant criteria. In addition, one should not preclude, especially in the early days of risk equalization, an insufficient understanding of the problem. For example, the decision by the Swiss parliament in 1994 to limit the duration of the risk equalization model to a period of 13 years only can be easily countered. In autumn 2004 the Swiss parliament prolonged the formula for another 5 years, but voted once more against all propositions to improve the risk equalization formula. This decision reflects the compromise between the 49% arguing for further improvement and the 51% defending a deregulated liberal social health insurance.

Another country where risk equalization is a highly political issue is Ireland. Over a period of more than a decade there have been significant obstacles to the introduction of risk equalization because of political, legal, and implementation issues.

Another lesson is that even sophisticated risk equalization formulas currently in practice are not yet sufficiently refined and do not eliminate all incentives for risk selection that are caused by the community rating requirement.

Future Perspective of Risk Equalization in Europe

Given that current risk equalization schemes in most countries are far from perfect, the first priority should be further investment in improvement. Investment is needed both in better data and in research and development of better risk adjusters. In addition policymakers should seriously consider the use of ex-post cost-based compensation and reconsider the use of community rating. Policymakers must understand that risk selection is not inherent to the competitive insurance market, but is primarily the result of one possible form of regulation (i.e., community rating), and that alternative forms of regulation result in other outcomes.

Improving Risk Equalization

Current risk-equalization models in Europe can be improved by adding new health adjusters such as indicators of mental illness, indicators of disability and functional restrictions, multiyear DCGs rather than one-year DCGs, multiyear prior expenses and multiyear prior hospitalization and the enrollee's choice of a voluntary high deductible. In addition insurers might ex-post receive an ex-ante determined fixed amount for certain high-cost events (e.g., pregnancy) or diseases. New research efforts should in particular focus on individuals who are in the top 1% or top 4% of health care expenditure over a series of years because current risk equalization formulas perform worst for these groups.

The more risk equalization is improved, the more chronically ill people are likely to become preferred clients for efficient insurers, because the potential efficiency gains per person are higher for the chronically ill than for healthy persons. However, it is still questionable whether in practice a sufficiently refined risk equalization system is feasible. For example, approximately 6% of the Dutch population suffers from one or more of the 5000–8000 rare diseases for which the current formula does not compensate insurers and for which it is hard to find suitable risk adjusters. Because of the small number of people with each of these rare diseases the coefficients of the risk adjusters may change substantially from one year to the next, which conflicts with an essential precondition for ideal risk adjusters.

Improving Ex-Post Cost-Based Compensation

Ex-post cost-based compensation can be an effective complement to imperfect risk equalization, but also involve a selection-efficiency trade-off because they lower incentives for insurers to operate efficiently. However, the severity of the trade-off can be lowered by replacing existing compensation schemes with other forms of risk-sharing. Countries that currently have a uniform system in which insurers are retrospectively compensated for expenses above a threshold incurred by any enrollee (e.g., Germany), would be better off with a differentiated system in which a retrospective compensation is only given for individuals belonging to a small group of high risks determined in advance, for example, based on expenditures and hospitalization in the previous years. In this way it would be possible to increase insurers' financial risk without significantly increasing their incentives for risk selection.

A Better Understanding of the Regulatory Regime

Regulation of a competitive social health insurance market is a complex issue. Because many policymakers do not have sufficient understanding of the problem and the potential solutions society is often confronted with suboptimal regulatory regimes. An example is community rating. Most (if not all) policymakers confuse community rating as a goal and as a tool. Because their policy goal is that everybody in the community should pay more or less the same premium, they use mandatory community rating as a tool to achieve this goal. However, community rating creates incentives for risk

selection, which may result in the adverse effects outlined in Box 1. Therefore, although community rating has some important advantages (short-term affordability, transparency, and low transaction costs of organizing cross subsidies), it also has serious negative effects in the long term, particularly as a result of insurers' disincentives to provide good quality care to the chronically ill. Nevertheless, all European countries with a competitive social health insurance market require premiums to be community rated (although this most likely is in violation with the European regulation).

The major rationale for a competitive social health insurance market is to encourage insurers to be prudent purchasers of health care on behalf of their enrolees. Policymakers must understand that a condition sine qua non for achieving this aim is that insurers are adequately compensated for each enrolee – that is, they must receive a risk-based revenue related to each enrolee's predicted health care expenses, either from the enrolee in the form of a risk-rated premium or from a risk equalization scheme. Insurers will then focus on efficiency rather than on risk selection, and chronically ill people will become the most preferred clients for efficient insurers, rather than undesired predictable losses. This will in turn stimulate insurers to contract with providers who have the best reputation for high-quality well-coordinated care for chronically ill people.

An alternative for community rating is to allow risk-adjusted out-of-pocket premiums within a bandwidth, for example, a factor of two or four, in combination with subsidies for certain groups to improve affordability. Insurers are then free to charge risk-adjusted premiums provided their maximum premium does not exceed the minimum premium per product, for example, by a factor of two or four. With good risk equalization, the overwhelming majority of the premiums will be within the bandwidth. Policymakers might give this strategy a serious thought. Any information surplus the insurers might have would then be focused on premium differences rather than on selection. If the insurers are required to identify any risk factors they use for differentiation of their premiums, government could try to include the S-type risk factors in the equalization formula in subsequent years. (By definition government does not want to subsidize the N-type risk factors.) In this way the reduction of solidarity that results from the insurers' freedom to differentiate their premiums, may well be a short-term sacrifice to a long-term solution.

A Wider Application of Risk Equalization in Europe

So far most of the risk equalization literature in Europe focused on the social health insurance markets where consumers have a periodic choice of insurer. However, risk-adjusted payments can also be applied to noncompeting purchasers of care, for example, as risk-adjusted budgets for regions within a NHS such as in England, Italy, or Spain.

The recently proposed reforms in England to abolish the primary care trusts, to allocate approximately 75% of the NHS-budget to new general practitioner (GP)-consortia and to give the consumers a free choice of GP make the formula on which resources are allocated in the English NHS even more complicated. The formula must then be calculated at the individual consumer level, rather than at the small-area level. If one individual moves from one GP-consortium to another, this person's budget must follow the consumer. Therefore, the proposed health reforms provide England with a new challenge: how to prevent risk selection by the new GP-consortia? A first version of a person-based resource allocation formula for the NHS has already been developed.

England has a long tradition of research on resource allocation formulas. Therefore, the rich input of this English knowledge about resource allocation formulas, substantially enhances the risk equalization knowledge in Europe. A first issue is the concept of 'health.' In the risk equalization literature traditionally some crude proxies for health are used, such as DCGs, PCGs and other information derived from prior utilization, without much discussion about the validity of these indicators. In England, decades ago the discussion had already started about the concepts morbidity, need and demand, and about the difference between health status and need, or the various concepts of need, such as normative, felt, expressed, and comparative. Second, England has a long tradition of applying the supply of health care facilities as a so-called N-type risk factor in the allocation formula. This English experience may give interesting insights to countries as the Netherlands, Switzerland, and Germany, where supply of health care facilities is (still) considered an S-type risk factor. Third, researchers in England considered supply to be a function of health care needs and utilization, and applied econometric techniques to deal with this endogeneity problem. These insights will enrich the traditional risk equalization literature, where this endogeneity has been overlooked.

Provider Payment

Risk adjustment algorithms can also be used in the purchaser–provider relation. The rationale is that purchasers may give a risk-adjusted capitation payment to (a group of) providers of care to deliver a defined set of services to their enrollees and may try to share some of their financial risk with the providers of care. A simple form of capitation is the payment to GPs for the services they deliver themselves. If consumers have a choice among capitated providers, which mostly is the case, risk selection is an issue. It becomes more complicated if the providers' capitation payment also includes an ex-ante determined budget for several forms of follow-up care, as in the case of GP-fundholders. These follow-up costs may range from care prescribed by the GP, for example, prescription drugs, laboratory, and physiotherapy, to all follow-up costs (the so-called total-fundholder). In the latter case, in fact the GP functions as an insurer.

The functioning and effects of risk-adjusted capitations may strongly depend on the number of persons per capitated entity: for example, 2000 (a GP) or 2 000 000 (an insurer). In case of a small number of persons the conditions of the law of the large numbers are not sufficiently fulfilled, and the capitated provider may be confronted with a substantial financial risk because of large deviations from the statistically expected result. Forms of financial risk-sharing between the purchaser and the capitated provider of care can then be applied.

Risk-adjusted capitation payments and forms of financial risk-sharing ('bonuses') are essential elements of so-called pay-for-performance programmes. In these programmes it is crucial that the physicians' payments are sufficiently adjusted for the case-mix composition of their practices.

It is a great challenge to apply risk adjustment on the level of the physician and to analyze the consequences of the crucial differences and similarities between capitation payments for insurers and for primary care physicians.

Conclusion

Some conceptual issues for understanding the complexity of risk equalization have been discussed and an overview of risk-adjusted equalization payments in Europe has been provided. Most of the experience in Europe is with risk-adjusted payments to insurers in competitive health insurance markets. However, the relevance of risk adjustment for provider payment is increasing.

In practice, the risk equalization algorithms in all countries are imperfect and substantially undercompensate the high-risk enrollees. In addition, all European countries also implemented premium rate restrictions in the form of community rating. Consequently, the health insurers are confronted with incentives for risk selection, which may threaten affordability, efficiency, quality of care, and consumer satisfaction. There is evidence that risk selection is a serious issue in European countries. Some countries reduced the insurers' incentives for selection by giving them ex-post cost-based compensations. But these compensations also reduce their incentives for efficiency, resulting in a selection-efficiency trade-off. An alternative option that European countries may consider is to allow insurers to differentiate their premiums within a bandwidth, in combination with subsidies for certain groups to improve affordability.

The conclusion is that good risk equalization is an essential precondition for reaping the benefits of a competitive health insurance market. If insurers are confronted with substantial financial incentives to be irresponsive to the preferences of the chronically ill, the disadvantages of consumer choice of health insurer may outweigh its advantages. However, (also) the European experience indicates that in practice the implementation of even the simplest risk equalization scheme is very complex. This holds even more for the implementation of health-based risk equalization.

Risk Selection and Risk Adjustment

RP Ellis and TJ Layton, Boston University, Boston, MA, USA

Glossary

Base period The period from which information is used to predict costs or other outcomes.
Community rating When insurance premiums are not allowed to vary across individuals.
Concurrent risk adjustment The use of variables measured in the prediction period to predict outcomes in the same period.
Conventional risk adjustment Risk adjustment models that focus solely on unbiasedness and statistical properties such as maximizing the models explanatory power (R^2).
Optimal risk adjustment Models of risk adjustment that incorporate behavioral objectives in setting plan premiums or other outcome targets, potentially allowing biased predictions.
Prediction period The period for which the regulator would like to predict an outcome.
Prospective risk adjustment The use of variables measured in a prior base period to predict outcomes in the prediction period.
Risk adjustment The use of information to explain variation in health-care spending or other outcomes such as resource utilization, mortality or health over a fixed interval of time, such as a quarter or year.
Risk selection When an individual's choice of insurance or a service is correlated with her cost (risk) to the insurer.
Service-level risk selection The act of distorting the level of services offered in an insurance contract in order to attract low risks; for example, the exclusion of diabetes specialists in an insurer's network to dissuade high-risk diabetics from enrolling in the plan.

Introduction

The problem of risk-based sorting often referred to as risk selection, and the use of risk adjustment to offset it are central concepts in health economics. After briefly defining risk selection and risk adjustment, this article provides an overview of the theoretical and empirical literatures that analyze these concepts. The issues covered here touch on numerous entries in this book, including health insurance, adverse selection, health plan competition, and death spirals, among others.

What is Risk Selection?

Risk selection occurs in health-care markets whenever consumers differ in expected cost (risk) that cannot be priced and make choices based on differences in risk, shifting the risk from the individual to the supplier. This choice can result in potentially inefficient or unfair sorting by average cost, quantity of visits, or quality. The most common reason for unpriced variation in risk is asymmetric information, in which consumers have private information about their health status, environment, or tastes for health care that insurers are unable to use when setting premiums. Incentives for risk selection can also be created even with full information when pricing is regulated, such as when regulators restrict the information that health plans are allowed to use when setting premiums or benefit features.

What is Risk Adjustment?

Although risk adjustment is defined in many ways, we offer one broad definition that includes almost all of the myriad ways the term is used: the use of information to explain variation in health-care spending, resource utilization, and health outcomes over a fixed interval of time, such as a quarter or year. Although it is not discussed, the term risk adjustment is also used in the health services research literature to refer to methods of explaining variation in a particular procedure or episode of treatment.

Theory of Risk Selection

Almost all theories of risk selection center on the choice of health insurance plans. In the classic Rothschild and Stiglitz model of risk selection, there are two types of consumers (high risk and low risk) and two states of the world (healthy and sick). The consumers differ in their probabilities of realizing the sick state, resulting in different expected costs in each potential state of the world. There is no moral hazard, so full insurance is optimal. Yet, under the assumptions of the model, a pooling equilibrium is either infeasible (when the low-risk types are unwilling to purchase the plan priced at a pooled premium) or inefficient. This model is recreated in graphical form in Figure 1. The two axes measure available consumption in each of the states of the world. If there is no insurance, available consumption is lower in the sick state due to health-care spending; hence, the initial endowment with no insurance is at a point such as E for both consumers. Because the two consumers differ in the probabilities of the two states of the world, their indifference curves between different levels of spending will diverge, with low-risk types having steeper indifference curves than high risks at every point. For risk-averse, utility-maximizing consumers, indifference curves between income in the two states of the world will be convex, and efficient consumption requires that insurance be provided until each type has equalized income in both states of the world (i.e., is on the 45° line). A possible outcome may be that

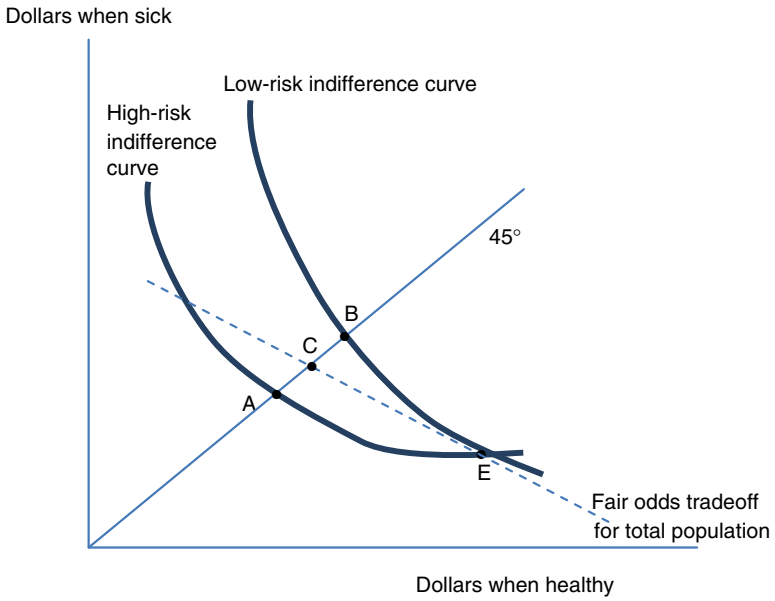

Figure 1 Indifference curves between consumption in two states of the world using the Rothschild and Stiglitz (1976) framework. Reproduced from Cutler, D. M. and Zeckhauser, R. J. (2000). The anatomy of health insurance. In Culyer, A. J. and Newhouse, J. P. (eds.) *Handbook of health economics I*, pp. 563–637. Amsterdam: Elsevier.

the break-even pooled full insurance point in this framework is at a point such as *C*, which is preferred to no insurance by high-risk types but less preferred than no insurance by low risks, making it infeasible and inefficient. Moreover, even if a sponsor (the government or an employer) forces this option to be offered, the health plan will strongly prefer enrolling the low-risk types and may either distort plan offerings so as to be less attractive to high risks (high deductibles or cost sharing) or take costly efforts to avoid high risks.

Although the Rothschild–Stiglitz model is quite nice for describing risk selection among traditional indemnity health insurance plans, selection in the real world is more complex. In the US, managed care organizations (MCOs) such as Health Maintenance Organizations (HMOs), and Preferred Provider Organizations (PPOs) have captured a large share of the market for health insurance from the traditional indemnity plans. These plans often offer much lower cost sharing in return for much more tightly rationed health-care services. However, because consumer risk is still unpriced due to asymmetric information or regulation, the incentives for risk selection by profit-maximizing health plans are still quite strong, but the methods by which the selection occurs are likely to be quite different due to the low levels of cost sharing that are a hallmark of MCOs. The classic model for describing risk selection among managed care plans was formulated by Glazer and McGuire.

The Glazer and McGuire model of risk selection moves away from selection on the level of cost sharing offered by a plan toward a theory of 'service-level selection.' Because high-cost and low-cost individuals demand different services, MCOs can induce the high-cost individuals to avoid their plans by rationing the services demanded by these individuals more tightly than other plans. Likewise, they can attract low-cost individuals by rationing the services these individuals demand more loosely than other plans. For example, a profit-maximizing MCO may have incentives to ration care for a chronic condition like diabetes by including few or no diabetes specialists in its network. However, the MCO may want to provide easy access to acute services or alternative medicine like acupuncture or chiropractic services in order to attract the low risks. In equilibrium, MCOs offer less than the efficient quantity of some services and more than the efficient quantity of others.

Both types of models of risk selection describe inefficient equilibria due to a correlation between demand and unpriced risk. These inefficiencies lead to welfare losses. Note that the correlation does not have to be positive (high risks demand more, or adverse selection) to induce a welfare loss. If risk and demand are negatively correlated (high risks demand less, or advantageous selection), welfare losses still occur, but now the losses are due to plans offering 'too much' of something rather than too little. Also note that selection does not have to be limited to selection on cost sharing or to service-level selection. Selection can occur on any attribute including health plan quality (or service-level quality), through special offers such as gym membership discounts, etc. The key result, however, is that when unpriced risk is correlated with demand, inefficiencies and welfare losses are likely to occur.

Empirical Models of Risk Selection

Empirical models of risk selection are important for two reasons. First, they help us to determine where selection exists and on what characteristics selection occurs. If one knows where selection is a problem, one can implement solutions such as risk adjustment to fix the problem. If one knows what characteristics selection occurs on, one can use regulation to limit its effects. Second, they allow one to measure the welfare losses from selection. With a measure of welfare loss, one can

analyze trade-offs between inefficiencies caused by selection and inefficiencies caused by regulations intended to limit selection such as risk adjustment, reinsurance, and mandates.

A major difficulty involved with developing empirical models of risk selection is the confounding presence of moral hazard in health insurance. If there were no moral hazard, one could compare the average cost of individuals in Plan A with the average cost of individuals in Plan B and conclude that the plan with higher average cost is adversely selected. However, if Plan B has lower cost sharing or looser rationing of services and higher average cost, it is not clear whether the higher average cost is due to increased utilization due to the lower level of cost sharing (moral hazard) or to fundamentally higher cost individuals choosing Plan B because of the lower cost sharing (adverse selection). This problem can be solved with panel data and exogenous variation in health plan premiums, however. Essentially, moral hazard and adverse selection can be isolated by observing shifts in demand and corresponding shifts in average cost following a price change (see Einav and Finkelstein, 2011, for a graphical description of this method). Further complexity arises if adverse selection and moral hazard interact with one another. Individuals may choose a plan with lower cost sharing because they have a higher elasticity of demand rather than due to their higher risk (Einav *et al.*, 2013)

The method described above nicely allows for straightforward estimation of welfare losses. This method has produced estimates of welfare losses that are surprisingly small. These estimates are important because they allow researchers to use simulations to determine the welfare effects of various regulations such as incremental cost pricing, plan subsidies, or mandates. However, one strong assumption is necessary for the estimate of welfare loss to be complete: fixed contracts. The welfare losses being measured are really only those stemming from inefficient pricing of contracts. But the theoretical models of selection described above focus not just on pricing but also on the nature of the contracts themselves. The assumption of fixed contracts is likely valid in the context of employer provided insurance because the employer often chooses the plan parameters. However, in the context of a less regulated (or completely unregulated) market for insurance where insurers choose the majority of the parameters of the contracts they offer, the assumption of fixed contracts is likely to break down. In this unregulated environment, welfare losses occur not only through inefficient pricing of efficient contracts but through equilibria where only inefficient contracts are offered.

It is possible (and highly likely) that the welfare losses from distorted contracts are much larger than losses due to inefficient pricing. For example, coverage for mental health care in the US has been highly rationed in many health insurance plans because it attracts high risks. This is effectively a 'death spiral' that has occurred in a plan characteristic rather than of an entire plan. When contracts are not fixed, it is important for empirical models to be able to highlight the characteristics that selection occurs on because, as the Glazer and McGuire model of service-level selection points out, these are the characteristics that will be inefficiently rationed, and, thus, these are the services that regulators must focus on in order to achieve efficiency and minimize welfare losses. However, empirical models that can quantify the welfare loss due to these inefficient contracts are few in number due to the fact that these contracts are extremely complex due to the seemingly infinite number of parameters firms can vary (network size, cost-sharing parameters, in-network hospitals, etc.). Nevertheless, there is empirical evidence that inefficiencies such as service-level selection by MCOs exists, just no easy way to determine how much welfare is lost due to these inefficiencies.

Instead of trying to quantify welfare losses due to inefficient contracts, the empirical literature has sought to answer the question of why the welfare losses due to inefficient pricing are so low. This has resulted in interesting new theories and empirical evidence for interactions between selection and market frictions such as imperfect competition and switching costs and behavioral issues such as inertia and other mistakes.

The discussion of risk selection so far has focused primarily on the US setting where numerous, diverse health plans compete in multiple dimensions (premiums, benefit features, cost sharing, and selective contracting) with an important goal of attracting profitable enrollees. Similar structures of competition exist in Chile and Colombia. Several other countries also have multiple competing health plans (e.g., Belgium, Germany, Japan, Netherlands, Switzerland, and Israel), however benefit features, cost sharing, and premiums are regulated much more tightly in these countries, and selective contracting is relatively rare. Although selection incentives exist in these other competing health plan settings, the plans typically do not control providers and have relatively few tools available for influencing selection. Selection problems are typically even less of an issue in countries with a single social insurance plan (e.g., Canada, France, Denmark, Italy, Sweden, and the UK), although selection issues can still arise through competition among individual providers or geographically, where consumers get to choose among alternative local market areas. Selection concerns are also common when there are private complementary or supplementary insurance policies alongside of a single, publicly funded plan, as in Australia and Ireland.

Theory of Risk Adjustment

Remarkably, there is no unified or widely adopted theory of risk adjustment. Instead, there are models of risk selection that point to desirable features of risk adjustment models, and statistical models of risk adjustment that develop empirical risk adjustment models that satisfy various statistical properties (unbiasedness, minimum variance, robustness, and fair payment for subpopulations). One underlying reason why there is no unified theory of risk adjustment is that an important motivation for risk adjustment is usually equity, not just efficiency. With regard to efficiency-based arguments for risk adjustment, the appropriate risk adjustment model depends on the market and regulations in which competing health plans (or providers) operate. If premiums, cost sharing, and benefit plans are allowed to vary across consumer attributes that are observable to the health plan, then there will be no unpriced variation in costs or selection problems, and only fairness and equity concerns will remain. Once regulators

restrict premiums, cost sharing, and benefit coverage variation, risk adjustment is the classical tool for combatting risk selection.

Though there is no unified theory of risk adjustment, the literature has essentially assumed that the welfare loss from the distortions caused by selection are proportional to the sum of the squared differences between individuals' expected costs and the revenue a plan receives for those individuals. This assumption leads to the convenient result that the main goal of any risk adjustment system should be to minimize this sum of squared differences, or to maximize the fit of the payment system as measured by the R^2 statistic. Other theoretical models of risk adjustment have built on this assumption.

Glazer and McGuire were the first to develop theoretical models characterizing 'optimal risk adjustment,' which they distinguish from the existing statistical models that do 'conventional risk adjustment.' The central objectives of conventional risk adjustment are unbiasedness (paying each plan so that predicted costs equal actual revenue for each individual) and maximizing predictiveness (minimizing deviations between payments and expected costs). The essence of optimal risk adjustment is to allow biased risk adjustment models which optimally correct for identified incentive problems in health-care markets. Glazer and McGuire, (2000) choose to model the service distortion selection problem, in which competing health plans oversupply services that attract the healthy (e.g., acute care), and undersupply services that disproportionately attract the high cost, relatively sick (e.g., chronic care services). Since the signals used for risk adjustment are never perfect, even with conventional risk adjustment paying the expected costs it will be optimal for health plans to distort service offerings so as to attract the relatively healthy within a payment category, and deter the relatively sick. The solution Glazer and McGuire devise is to overpay on signals predicting a greater likelihood of being high cost, and underpay on signals predicting low cost, so as to undo the incentive to undertreat the high-cost enrollees. For example if only half of patients with asthma in a plan have their diagnoses recorded in the base period, and the incremental cost of the observed asthma patients is $500 higher than expected, then the plan should be paid twice this increment, or $1000 to compensate the plan for the under-reported patients with asthma. Conversely, one should pay less than the observed average cost for healthy signals in order to keep overall payments neutral. This twist in payments can in theory undo incentives to undertreat in capitated payment systems.

The service distortion problem that Glazer and McGuire model is a particular problem in the US, because many plans use selective contracting to increase or reduce the availability of specific types of services or providers, thereby influencing the attractiveness of their plan. Similar incentives and concerns arise in other countries, such as Australia and Ireland, where private insurance plans are allowed to choose the extent of coverage for services or copayments not covered generously by the public system. Other selection problems can require different optimal risk adjustment adjustments. For instance, in the US and several European countries (Germany and Belgium) there are concerns about intentional distortion of the signals used for paying competing health plans, or 'upcoding' the observed severity of patients.

Recent literature has explored risk adjustment in a setting where enrollee sorting on expected costs may not be as strong as sorting on the degree of risk aversion or other preferences. Two recent papers, (Bundorf *et al.*, 2012; and Glazer and McGuire, 2011) introduce the possibility that the demand for insurance is determined by both risk and taste and that there is not a perfect correlation between the two. This is especially relevant in the current environment in the US where an integrated HMO may be able to provide care for a chronically ill patient at a lower cost than a PPO but the chronically ill may prefer the PPO due to its wider selection of providers. Both papers show that in this environment consumers will have different incremental marginal costs, but the only way to get consumers to sort efficiently across plans is to charge each consumer her particular incremental marginal cost. Thus, if premiums are uniform across individuals, individuals may not sort efficiently across plans, even with perfect risk adjustment. Glazer and McGuire examine the market equilibria that occur under different regulatory arrangements, analyzing the tradeoff between efficiency and fairness. They show that if taste can be used as the basis of payment, both efficiency and fairness can be achieved using a tax. However, when taste cannot be used as a basis of payment (because it is not observed) and health status must be used instead, subsidies and taxes based on health status are required to achieve both efficiency and fairness. In other words, a uniform payment along with perfect risk adjustment is not enough.

Recent theoretical work is beginning to examine how to implement risk adjustment in the presence of imperfect community rating, which is to say that insurance plan premiums are allowed to vary within specified limits across certain individual attributes (such as age and smoking status). Further work is also examining how risk adjustment models can accommodate intentional benefit plan variation, such as is being allowed in the US health insurance exchanges where substantial variation in cost sharing is being permitted. This theoretical work is important because, as explained, the welfare loss from the distortions caused by selection incentives is proportional to the sum of squared differences between individuals' expected costs and the total revenues a plan received for those individuals. In the US, health insurance exchanges the total revenues can come from multiple sources: premiums, risk adjustment transfers, reinsurance payments, and risk corridor payments. It is clear that these sources of payments will interact with each other and those interactions need to be identified in order to determine how well they will fix the problems of risk selection and what other distortions they may cause.

Empirical Risk Adjustment Models

Early work in developing risk adjustment models focused on the statistical problem of maximizing the amount of variance in total spending that can be explained with available information (Ash *et al.*, 1989; Newhouse *et al.*, 1989). Even in this early work it was recognized that if lagged utilization or spending variables are used as explanatory variables, then the model is not only capturing the underlying illness burden, but also consumer taste for treatment, provider practice variation,

or differences in the underlying efficiency of treatment, which may lead to incentive problems. European risk adjustment implementation has been more precise than most US studies in distinguishing 'acceptable costs,' viewed as appropriate for risk adjustment, and 'unacceptable costs' which are viewed as ineligible for payment differentiation. Early work focused on self-reported measures from surveys that capture health status, however these measures are relatively expensive to gather and update, and not as highly predictive as insurance claims-based measures. In most modern risk adjustment models, diagnosis- and pharmacy-based information is used to predict spending. The extent to which each set of information is used in the models varies by country. The consensus view among risk adjusters and policy makers is that diagnoses and pharmacy signals, although not fully exogenous, are less endogenous than many other variables (such as health plan, provider type, access, taste, and consumer lifestyle), justifying their widespread use for risk adjustment.

From the onset, it has been recognized that health status information (whether self-reported, diagnoses, or pharmacy) from the base period can either be used to predict outcomes from the same period or the subsequent period (i.e., the future). The former is called concurrent (or sometimes retrospective) risk adjustment, whereas the latter is called prospective risk adjustment, and the two vary only in the prediction period. Most payment systems use prospective risk adjustment, due to concerns about endogeneity of the signals as well as the practical reason that it means that risk factors on which payments are based can be measured a year earlier than the spending being predicted. Concurrent models always have higher explanatory power than prospective models. For quality measurement or normalization of many other performance or outcome measures, a concurrent framework is widely used. Careful comparisons of predictive power from the two frameworks are provided in a US Society of Actuaries study authored by Winkelman and Mehmud, and in a series of studies conducted at York University in the UK.

A useful early contribution in the risk adjustment literature used fixed effects in panel data to calculate a 'lower bound on the upper bound' of what is potentially explainable at the individual level using time-invariant, prospective information. This method suggested that between 15% and 20% of the variance in spending was explainable using prospective variables. More recent studies suggest that the potentially achievable prospective R^2 is on the order of 25–35% of total health-care spending and varies with the population, year, and data quality.

To illustrate the importance of using more information than just age and gender to predict costs, consider **Figure 2**, which plots average 2009 covered health-care costs for each of the 65 one-year age cohorts in the US Truven MarketScan commercially insured claims and encounter data. **Figure 1** illustrates the importance of using relatively flexible specifications even for capturing age and sex adjustment of total health spending. The figure highlights that babies are disproportionately expensive, that women cost more than men through their childbearing years, and that in childhood males are slightly more expensive than females. These patterns are poorly captured by including a linear age term or even when using third or fourth degree polynomials of age. Most

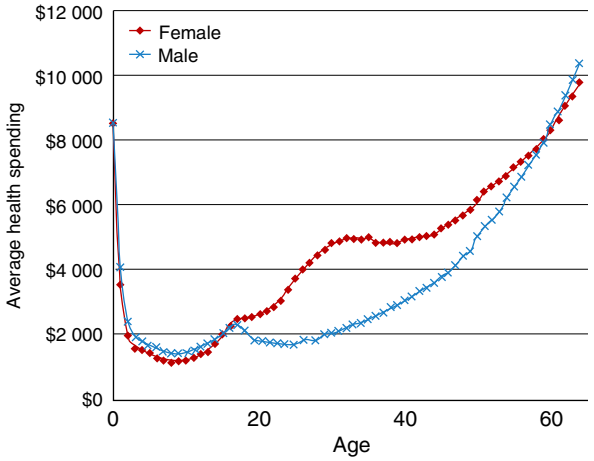

Figure 2 Actual spending by age and gender, 2009. Sample used is the US 2009 Truven MarketScan commercially insured claims and encounter data. All plan types and individual with a valid sex and age < 65 were included, although persons without pharmacy coverage were excluded. Each point plotted is the 1-year average total covered health spending per capita (medical plus pharmacy spending, including deductibles and copayments, but excluding dental and vision spending) for that 1 year age and gender group.

sophisticated risk adjustment models calibrated on large samples use 30 or more age–sex dummy variables to capture this nonlinear pattern.

Rather than only using (exogenous) age and gender, the most common approach used for risk adjustment is to use the rich information appearing on insurance claims as a proxy for individual health status. The most widespread information used is diagnoses, although pharmacy information is also common. Utilization measures (e.g., spending, hospitalizations, and counts of visits) are also highly predictive of future spending, although they contribute relatively modestly to the predictive power once a rich diagnostic model is used. Although claims-based information is only recorded when a visit to a health-care provider is made, and is potentially 'gameable' or amenable to manipulation, its strong predictive power and availability make it highly attractive.

Careful reviews of alternative risk adjustment models of total annual spending have been conducted in the US, Germany, and the UK, and are included in the recommended further readings section at the end of this entry. **Table 1** contains a few highlights of five diagnosis-based risk adjustment models used for payment by public insurance programs in the US (Medicare and Medicaid), as well as large numbers of private health plans. The interested reader can view further details at the references noted in the table.

A glimpse at the dimensions along which many risk adjustment models vary is summarized in **Table 2** from a Dixon *et al.* (2011) study using UK data. Looking first across the rows, age and gender alone only explain approximately 3–5% of total variation in spending at the individual level. Once diagnostic and prior utilization information are included in model (b), surprisingly little further variation is explained by including geographic variation (as captured by 152 geographical primary-care trust (PCT) dummies), 135 need

e.	Model (c) plus 7 attributed need and 3 supply variables	355	0.2671	0.2622	0.8254
f.	Age/gender, 152 diagnosis groups, 151 geographic dummies, 7 attributed need and 3 supply variables	351	0.1272	0.1229	0.7738

Notes: Diagnosis groups use only inpatient diagnoses from a two prior years. Utilization variables include inpatient episode count, outpatient visit count, dummy = 1 if any priority referral, and dummy = 1 if any outpatient visit; all measures are for prior two years. Estimation sample is a 10% random sample of the UK population. Validation Sample #1 is a different 10% random sample of the UK population drawn without replacement. Validation Sample #2 is a 100% sample of patients at 10% of primary-care practices. All results are from Dixon *et al.*, 2011, especially Table 7.4 and Appendix 13, Table 9. http://www.nuffieldtrust.org.uk/sites/files/nuffield/document/Developing_a_person-based_resource_allocation_formula_REPORT.pdf

variables (e.g., income, education, and prevalence of selected chronic conditions in the area), and 63 supply side variables (e.g., numbers of providers of various types and distances). Explanatory power at the individual level as measured by the R^2 differs only in the third or fourth decimal. The final row reveals that dropping the four prior utilization variables has a more significant effect on the model's predictive power, reducing the model's explanatory power by approximately half. Many would argue that the four lagged utilization variables are not only picking up health status heterogeneity,

but also patient and provider taste variation. (Key 'need' and supply side variables are still included in the model.)

Looking across the columns of Table 2 reveals that with 5 million observations in the estimation sample, there is no overfitting problem, even with more than 500 right-hand side explanatory variables. The final column shows that despite having only modest explanatory power at the individual level, where there is a great deal of individual patient randomness, the models do enormously better at the practice level where much of this randomness averages out. The third column sums up patients' actual and predicted spending to the level of 797 primary-care practices (averaging 6500 patients per practice) before using the conventional R^2 formula to calculate predictive power. The explained variation in spending at the practice level starts at 34% for the age–gender model, and increases to just more than 80% once geographic dummies are added in. Even the final model, which does not use the four utilization variables capturing patient and provider taste variation, explains 77% of practice-level variation in spending.

Risk adjustment has been used for more than three decades for the US Medicare Advantage (Part C) program, which offers diverse, competing private health plans to elderly and disabled individuals in the US as a voluntary alternative to conventional Medicare. The risk adjusted payments to health plans from 1985 to 1999 used only age, gender, Medicaid eligibility, institutional status (i.e., whether in a nursing home), and the county of residence of the enrollee to determine the payment amount. Since 2000 risk adjustment in the US Medicare program has used diagnostic information, initially using only inpatient diagnoses, but since 2004 diagnoses from outpatient clinician claims have also been used. After considering numerous alternative classification systems for diagnostic information, the Medicare program chose to implement the CMS Hierarchical Condition Category (CMS-HCC) classification system using 70 diagnostic groups for prediction. As of 2011, up to 86 HCCs are used, and the system is also used for Medicare Part D which includes prescription drug plans. Recent research has suggested that more sophisticated risk adjustment has led to less risk selection in the Medicare Advantage market, but insurance companies still have some ability to select low risks. They show that plans can still select on the individuals' risks, given risk adjustment. A more complete risk adjustment model that compensates plans for the average risk of as many targetable groups as possible might mitigate this problem.

In the UK, risk adjustment has been used for many years to allocate funds between geographically defined 'PCTs' using need, utilization, and health status variables, and done at the group level. More recent efforts in the UK have considered using individual information for risk adjusting payments not only to the geographically defined PCTs, but also to individual general practitioners. The main difficulty of using individual-level diagnostic information has been the process of obtaining this information from office-based physicians who are not required to record diagnoses as a condition of service payments, leading to exploration of models that use only inpatient diagnoses and counts of office and facility visits.

Risk adjustment models using a variety of adjusters are also used in all European countries with multiple, competing health plans, as well as in Chile and Colombia.

Econometric Issues

Risk adjustment models have been an active area for testing and developing new econometric methods. Early models used primarily linear models in part because the very large sample sizes and large number of explanatory variables made estimation of nonlinear models time-consuming if not infeasible. Since the 1990s and 2000s, there has been a surge of interest in building robust nonlinear models that are less sensitive to the outliers that are common in highly skewed expenditure data. The two-part log linear model used so widely in the Rand Health Insurance Experiment has been largely laid to rest by several studies that demonstrated the severe problems caused by uncorrected heterogeneity in such models. Among nonlinear models, Cox Proportional Hazard models, and Generalized Linear Models are the most widely used.

A central finding in the recent literature is that although nonlinear risk adjustment models may be superior for hypothesis testing, by creating test statistics for hypothesis tests that have well-behaved properties, the nonlinear models generally do worse than simple least squares models when used to predict sample and subsample means. Prediction of dependent variable means in levels in nonlinear models is seriously confounded by heteroskedasticity, which can be so multidimensional that it is very difficult to correct in medium-sized samples, and estimation of rich nonlinear models in mega samples needed to capture all of this heteroskedasticity are still hampered by the complexity of estimating precise models with hundreds (or even thousands) of parameters on multiple millions of observations. In sum, although nonlinear models can potentially produce better estimates, this improvement only comes through making various parametric assumptions. When these assumptions are not satisfied (as is probably often the case because they cannot be tested), simple least squares estimates are better because they do not require any parametric assumptions in order to be unbiased.

In recent years there has been a return of support for least squares models, as signaled by their use by researchers in Australia, Germany, the UK, and the US as well as for practical implementation in Belgium, Israel, Netherlands, and Switzerland. The preferred approach since 2000 for the US Medicare program has consistently been to use weighted least squares regressions of annualized spending on the risk adjusters, where annualized spending is actual spending divided by the fraction of the year a person is eligible, and this annualized amount is weighted by the fraction of the year a person is eligible to generate unbiased means. Such an approach replicates the mean exactly in disjoint groups, and is the only demonstrated approach that easily accommodates individuals with partial year eligibility. The mega-samples of multiple millions of observations, used to develop Figure 2 and Table 2 in this article, largely alleviate concerns about overfitting of outliers even with great skewness.

Future Directions in Risk Adjustment

Risk adjustment figures prominently in the US Affordable Care Act of 2010, notably in the proposals for establishing insurance exchanges to serve the individual and small group

insurance markets. To keep insurance affordable, premium subsidies will be offered by the government, and premium rate bands will limit premium variations across age and gender groups to be no more than three to one. It is readily seen from Figure 1 above that in the absence of regulation, plans would choose to charge 64-year-old males a premium that is approximately 10 times that of a 10-year-old male. Such regulated premiums can only be feasible if premium subsidies to plans are risk adjusted so that plans are paid for enrolling the aged and relatively unhealthy.

The US Department of Health and Human Services has developed new risk adjustment models for use in the insurance exchanges. The biggest changes between the new models and the CMS-HCC model are separate models for adults, children, and infants and the use of a concurrent rather than prospective framework. There are also different weights depending on the 'metal level' of the plan due to differing plan liability, which labels plans according to whether they are expected to cover 90% or more of health-care spending (platinum), 80% or more (gold), 70% or more (silver), or 60% or more (bronze). Because plan differences are explicit in terms of what is covered, selection incentives are strong, and aggressive risk adjustment is needed, which may explain the use of a concurrent rather than a prospective framework. The proposed concurrent models have R^2s from 0.289 to 0.360, much larger than the typical prospective model which typically has an R^2 approximately 0.12. The concurrent framework also accommodates the lack of previous diagnostic data for new enrollees. Although a concurrent framework solves this problem and substantially improves prediction, it also represents a payment system that begins to look similar to cost-based reimbursement. It will be interesting to see if it will bring some of the moral hazard problems (i.e., upcoding and increased utilization) that come with that type of payment scheme.

The exchanges have also introduced new questions about how risk adjustment interacts with other forms of plan payment. In the exchanges, plans will be paid through age-rated premiums and through risk adjustment, reinsurance, and risk corridor transfers, so the revenues a plan receives for an individual will be the sum of these payments, not just the risk adjustment payment. In the exchanges premiums can vary by age, and this age-based premium variation can lead to improvements in welfare by causing more efficient sorting of individuals to health plans. However, as risk adjustment and reinsurance payments compensate plans for age-based differences in cost, competition will cause the plans to vary premiums less and less. In the extreme (an extreme which is easily achievable) risk adjustment and reinsurance will fully compensate plans for age-based cost differences and premiums will not vary by age. This will lead to inefficient sorting. Hence, it is clear that when premium rating is allowed, there is a trade-off between minimizing selection incentives by maximizing the fit of a payment system and inefficient sorting caused by a lack of variation in premiums. It also remains to be seen how risk adjustment, premiums, and reinsurance will interact with taste heterogeneity.

New areas that are also receiving a great deal of attention are customized risk adjustment models that predict outcomes other than total spending. Predicting hospitalizations, length of stay, hospital resource use, readmissions, mortality, performance measures, and primary-care service needs are all examples of specific risk adjustment models that have been calibrated and are increasingly being used. Value-based payment is another example of a US reform that benefits from risk adjustment. With the new emphasis on detecting and rewarding good performance, risk adjustment is destined to see further expansion in use for these new outcomes globally.

Another important current area for risk adjustment in the US is in bundled payments to Accountable Care Organizations (ACOs), which are moderate-size health-care provider networks willing to receive a bundled payment in exchange for taking responsibility for providing all care to a panel of patients. Given the modest size of these panels, risk adjustment will be critical for ensuring that both healthy and sick enrollees are welcomed in the ACO. Comparing actual to risk-adjusted predictions of various performance outcomes within the ACO is also a key concept in these organizations.

A final important area for risk adjustment is in bundled payment for primary care, particularly as part of the Patient-Centered Medical Home (PCMH). In this CMS initiative, the Medicare program is encouraging primary-care providers to take responsibility for providing comprehensive primary care for patients from all payers (Medicare, Medicaid, and private) and offering increased primary care 'base payments' for the extra effort this will take (beyond what they will be reimbursed for via fee for service). These base payments will be partial capitation amounts, not fee based. Sizable bonus payments are also being considered to reward primary-care practices for achieving specified quality, cost, and patient satisfaction targets. If either the base payments or bonus payments are not risk adjusted, then primary-care practices could potentially act like insurance companies, striving to attract the healthy and avoid the relatively sick, undermining the potential of the PCMH initiative.

To date, risk adjustment models in the US have relied primarily on demographic and claims-based (usually diagnostic) information to adjust payments, utilization, and outcome measures. Occasionally self-reported information is used, although the relatively high cost of surveys and consumer input limit the widespread use of such information. A potentially huge source of information for the future are electronic health records, which capture not only what treatments are done, but also the results of various biometric and laboratory tests and imaging procedures. Health records will be challenging to use, but offer rich possibilities for improved prediction of diverse outcomes of key interest to researchers and policymakers.

Sample Selection Bias in Health Econometric Models

JV Terza, Indiana University-Purdue University Indianapolis, Indianapolis, IN, USA

Introduction

This article examines empirical models in health economics and health services research aimed at providing causal inference regarding the effect of a particular variable (the causal variable – X) and outcome of interest (Y). Such models are typically used to explain (predict) past (future) economic behavior, test an economic theory, or evaluate a past or prospective policy intervention. Common to all such applied contexts is the need to infer the effect of a counterfactual *ceteris paribus* exogenous change in X on Y, using statistical results obtained from survey data in which observed differences in X are neither *ceteris paribus* nor exogenous. The current article focuses on a particular survey context in which such lack of exogenous (and *ceteris paribus*) control in sampling can lead to bias in causal inference and prediction. In these cases, values of the outcome Y are not observable for all members of the relevant population and sampling preclusion is not random. Instead, it is governed by a systematic sample selection (SS) rule which is determined by both observable and unobservable factors. If the unobservable (and, therefore, uncontrollable) factors in the SS rule are common to (or correlated with) unobservable determinants of the outcome, then econometric methods that fail to take account of such correlation will likely produce biased estimates of causal effects. Selection bias will also plague predictions of the outcome obtained from such naive methods. For example, suppose a particular prescription (Rx) drug (henceforth, the drug) is under consideration for future deregulation and over-the-counter (OTC) sale, it would be of interest (e.g., to the producer of the drug) to know the deregulated (OTC) price elasticity of demand for the drug. In this example, Y is OTC consumption (demand) and X denotes drug price (or out-of-pocket (OOP) per unit payment for the drug). Until the drug is cleared for OTC sales (deregulated), only data on on Rx drug prices (or OOP payments) and Rx consumption can be obtained. Would-be OTC purchases cannot be observed because, before deregulation, the drug in question can only be purchased by prescription. In this case, the requirement that a prescription be obtained from a physician serves as a systematic selection rule precluding would-be OTC purchasers from consuming the drug. Suppose that

(a) physicians tend to prescribe the drug in question for the more severely ill,
(b) illness severity is unobserved and positively correlated with OTC demand for the drug, and
(c) price negatively affects physician prescribing behavior, then applying a method that ignores these facts (e.g. ordinary least squares (OLS)) to a sample of patients for whom the drug has been prescribed, and who are, therefore, consuming the drug, will likely produce a price elasticity estimate that understates the truth (i.e., is less negative than it should be).

As another example, suppose one seeks to predict the would-be utilization of a particular type of healthcare by currently uninsured individuals, if they were to become insured. One might consider OLS estimation of a health care utilization regression using a sample of insured individuals. The OLS results would then be used to predict utilization for the uninsured as if they were instead insured. Suppose, however, that the following are true:

(d) unobserved health status influences the probability of being insured (adverse selection or cream skimming)
(e) unobserved health status affects healthcare utilization, and
(f) the true predictor model differs between the insured and uninsured, then applying a prediction method (e.g., best linear prediction via OLS) that ignores these facts, to a sample of insured individuals, will likely be biased when used as a predictor of healthcare utilization for the uninsured if given coverage.

The remainder of the article is organized as follows. In the following section, a more formal discussion of SS bias is presented. In Section Using Control Functions to Correct for Sample Selection Bias, a commonly implemented remedy for such bias is discussed. The discussion therein begins with linear models. The role of instrumental variables (IVs) in this context is also discussed. More commonly, encountered (in health economics and health services research) nonlinear models and estimation methods are then considered. The final section summarizes and concludes.

Sample Selection Bias Because of Unobserved Confounders

At issue here is the presence of confounding variables which: (1) serve to mask the true causal effect of X on Y (TCE); (2) or bias predictions of Y that ignore them. Define a confounder as a variable that is correlated with both Y and: X; sample inclusion ($S=1$ if included, $S=0$ if not); or both. Confounders may be observable or unobservable (denoted C_o and C_u, respectively – in the current discussion both are assumed to be scalars (i.e., not vectors)). Here it is also assumed that there are no unobservable confounders for X (or for C_o) – that is, these variables are assumed to be exogenous. Observations on C_o can be obtained from the survey data, so its influence can be controlled in the modeling of Y and S and, therefore, in the estimation of the TCE. Clearly, C_o can be directly implemented in the prediction of Y. It may be assumed, however, that the correlation between C_u and Y, and between C_u and S cannot be ignored (e.g., unobserved factors that are correlated with OTC drug demand are also correlated with physician prescribing behavior). Moreover, one cannot directly control for C_u because it is unobservable. If left unaccounted for, the presence of C_u will likely cause bias in statistical inference regarding TCE and prediction. This happens because

 doi:10.1016/B978-0-12-375678-7.00908-1

estimation methods that ignore the presence of C_u will spuriously attribute to X (and C_o) observed differences in Y that are, in fact, because of C_u. Such bias is referred to as SS bias (or bias because of SS on unobservable confounders). SS bias can be formally characterized in a useful way. For simplicity of exposition, the true causal relationship between X and Y can be cast as linear and be written as

$$Y = X\beta + C_o\beta_o + C_u\beta_u + e \quad [1]$$

where β is the parameter that captures the TCE, β_o and β_u are parametric coefficients for the confounders, and e is the random error term (without loss of generality, it may be assumed that the Y intercept is zero). The SS rule determining the observability of Y can be modeled as

$$S = I(X\alpha + C_o\alpha_o + W\alpha_W + C_u > 0) \quad [2]$$

where the α's are parameters, W is an IV (i.e., an observable variable that is correlated with neither C_u nor Y – more on this later), and $I(A)$ denotes the indicator function whose value is 1 if condition A holds and 0 otherwise. In the naive approach to prediction and the estimation of the TCE (ignoring the presence of C_u), the ordinary least squares method (OLS) would be applied to

$$Y = Xb + C_o b_o + \varepsilon \quad [3]$$

using only observations for which values of Y are observed, where the b's are parameters and ε is the random error term. The parameter b is taken to represent the TCE and $Xb + C_o b_o$ is the relevant Y predictor. Correspondingly, $\hat{b}$ (the OLS estimate of b) estimates the TCE, and $X\hat{b} + C_o\hat{b}_o$ (with $\hat{b}_o$ being the OLS estimate of b_o) is the estimated predictor. It can be shown that OLS will produce unbiased estimates of b and b_o (here and henceforth, when unbiasedness is referred to it is done so in the context of large samples). It is also easy to show, however, that under general conditions

$$b = \beta + b_{X\lambda}\beta_u \quad [4]$$

and

$$b_o = \beta_o + b_{C_o\lambda}\beta_u \quad [5]$$

where $b_{X\lambda}$ is a measure of the correlation between X and λ (a function of $X\alpha + C_o\alpha_o + W\alpha_W$ – more on this later), and $b_{C_o\lambda}$ is similarly defined. As is clear from eqn [4], the bias of the naive OLS estimate of the TCE ($\hat{b}$) is $b_{X\lambda}\beta_u$. Moreover, it can be shown that the sign of $b_{x\lambda}$ is opposite that of the parameter α in eqn [2]. Consider the OTC drug demand example discussed in the introduction. Here, the TCE of price on OTC demand is β and under hypotheticals (a), (b), and (c), both β_u and $b_{X\lambda}$ are positive (the latter because α is negative). By the law of demand, β should be negative and, because $b_{X\lambda}\beta_u$ (the bias) is positive, the OLS estimate of the price effect on OTC demand will likely understate the true price effect (in absolute value). By a similar argument, in the insurance coverage and healthcare utilization example discussed earlier, hypotheticals (d), (e), and (f) imply that the bias of the OLS predictor $X\hat{b} + C_o\hat{b}_o$ is $X(b_{X\lambda}\beta_u) + C_o(b_{C_o\lambda}\beta_u)$.

An approach to estimation is needed that, unlike OLS applied to eqn [3], does not ignore the presence of, and potential SS bias because of, C_u. In the following section, methods that correct for selection bias through the inclusion of a control function which accounts for C_u are discussed. Such control functions also exploit sample variation in the IV (W) to eliminate SS bias because of correlation between C_u and S (more on this later).

Using Control Functions to Correct for Sample Selection Bias

As eqn [1] demonstrates, if C_u were observable then unbiased estimates of β and β_o could be obtained by applying simple OLS to (1) using the selected sample (i.e., the subsample with observable data on Y). As it turns out, if C_u (albeit unobservable) is assumed to follow a given probability distribution then, based on eqn [2], it can be shown that the following is true for the subset of the population with observable data on Y

$$Y = X\beta + C_o\beta_o + \lambda\beta_u + \nu \quad [6]$$

where λ is a function of $X\alpha + C_o\alpha_o + W\alpha_w$ and ν is the random error term possessing all of the requisite properties for unbiased regression estimation. This control function, which may be more explicitly stated as $\lambda(X\alpha + C_o\alpha_o + W\alpha_w)$, is the λ which is referred to in eqn [4] and eqn [5]. Its direct inclusion as a regressor in eqn [6] would serve to eliminate the SS bias plaguing regression estimation based on eqn [3] – made explicit in eqn [4] and eqn [5] for OLS. Strictly speaking, however, this is not feasible because λ involves the unknown parameters α, α_o, and α_W. Remainder of this section considers feasible linear and nonlinear estimators designed to circumvent the nonobservability of λ while producing unbiased estimates of the TCE of X and an accurate predictor for Y.

Unbiased Estimation of β and β_o in Linear Models

Despite the fact that λ is not directly observable, the parameters of linear models like eqn [1] can be estimated via the following two-stage method. First, estimate α, α_o, and α_W using the appropriate binary response model for eqn [2]. For example, if C_u is standard normally distributed, then estimates of the parameters of eqn [2] can be obtained by applying conventional probit analysis to a sample comprising observations with and without observable values of Y (i.e., both 'selected' and nonselected observations). The control function λ can then be estimated as $\lambda(X\hat{\alpha} + C_o\hat{\alpha}_o + W\hat{\alpha}_W)$, where $\hat{\alpha}$, $\hat{\alpha}_o$, and $\hat{\alpha}_W$ are the first-stage parameter estimates. In the second stage, unbiased estimates of β and β_o can be obtained by applying OLS to

$$Y = X\beta + C_o\beta_o + \hat{\lambda}\beta_u + \upsilon \quad [7]$$

using the subsample of observations for whom Y is observable ($S = 1$), where $\hat{\lambda}$ is the first-stage estimated value of the control function λ. If C_u is assumed to be standard normally distributed, then λ will have the familiar inverse Mill's ratio form and the two-stage estimator described here coincides with the Heckman-type SS model.

The inclusion of W (the IV) in eqn [2], and in the formulation of λ, warrants some discussion. Note that if the need

to control for the unobservable (C_u) in eqn [1] could be eliminated, the main source of selection bias would be neutralized and unbiased estimates of β and β_o could be obtained by applying OLS to

$$Y = X\beta + C_o\beta_o + e^* \quad [8]$$

where $e*$ is a random error term that fulfills the conditions for the unbiasedness of OLS. Note that it would not be required to control for C_u in eqn [1] if it were, indeed, NOT a confounder; in which case one could legitimately set β_u equal to zero. One way to break the confounding link between C_u and S would be to randomize the SS rule. Unfortunately, in applied health economics and health services research, as in other social sciences, explicit randomization (experimentation) is often prohibitively costly or ethically infeasible. A form of pseudorandomization is, however, possible in the context of survey (nonexperimental) data. If, for instance, a variable that is observed as one of the survey items is highly correlated with S but is correlated with neither Y nor C_u, then the sample variation (across observations) in the value of that variable can be viewed as providing variation in S that is not correlated with C_u – a kind of pseudorandomization for S. The IV W which was included in eqn [2] serves this purpose.

In the context of the OTC example discussed earlier, any variable that affects physician prescribing behavior, but is not correlated with OTC demand for the drug would be an IV candidate. For example, measures of individual physician overall preference for prescribing the drug have been used as IVs in similar empirical contexts. Likewise in the insurance coverage healthcare utilization prediction example, any observable variable that influences the likelihood of coverage that is not directly correlated with the type of healthcare usage in question can be used as an IV. For example, the existence and features of state-level government programs aimed at facilitating the acquisition of health insurance coverage have been used for this purpose.

It should be noted here that the inclusion of W in eqn [2] (and by implication in λ) is not required for the technical legitimacy, feasibility, or unbiasedness of the two-stage estimator described earlier. Notwithstanding this fact, applications of the two-stage estimator that do not include an IV – so-called identification solely via functional form – are generally viewed as lacking.

Unbiased Estimation in Nonlinear Models

The linear model (as specified in eqn [1]) does not conform to most empirical contexts in health economics. In most applied settings, the range of the outcome is limited in a way that makes a nonlinear specification more sensible. For example, the researcher is often interested in estimating the TCE of X on whether or not an individual will engage in a specified health-related behavior. In this case, the outcome of interest is binary so that a nonlinear specification of the true causal model would likely be more appropriate. In the OTC drug demand model discussed earlier, the outcome of interest (drug consumption) is nonnegative. An exponential regression specification of the true causal model is more in line with this feature of the data than is the linear specification in eqn [1]. Another common example of inherent nonlinearity in health economics and health services research, is in the modeling of healthcare expenditure or utilization (E/U). It is typical to observe a large proportion of zero values for the E/U outcome. In this and similar empirical contexts the two-part model (2PM) has been widely implemented. The 2PM allows the process governing observation at zero (e.g., whether or not the individual uses the healthcare service) to systematically differ from that which determines nonzero observations (e.g., the amount the individual uses (or spends on) the service conditional on at least some use). The former can be described as the hurdle component of the model, and the latter is often called the levels part of the model. Both of these components are nonlinear – binary response model for the hurdle; nonnegative regression for E/U levels given some utilization.

To accommodate these and other cases, the generic nonlinear version of the true causal model in eqn [1] can be written as

$$Y = \mu(X, C_o, C_u; \theta) + e \quad [9]$$

where $\mu(X,C_o,C_u;\ \theta)$ is known except for the parameter vector θ. It is very often assumed that $\mu(X,C_o,C_u;\ \theta) = M(X\beta + C_o\beta_o + C_u\beta_u)$, where $M(\ )$ is a known function and $\theta = [\beta\ \beta_o\ \beta_u]$. In this linear index form the true causal models corresponding to binary and nonnegative outcomes are commonly written, respectively, as

$$Y = F(X\beta + C_o\beta_o + C_u\beta_u) + e \quad (Y = \{0,1\}) \quad [10]$$

and

$$Y = \exp(X\beta + C_o\beta_o + C_u\beta_u) + e \quad (Y \geq 0) \quad [11]$$

where $F(\ )$ is a function whose domain is unit interval. It is to be noted here that for the generic nonlinear model characterized by eqn [9] the TCE is not embodied in any particular parameter (e.g., β) as in the linear models defined by eqn [1]. Instead, the TCE will be a nonlinear function of all parameters (θ) and all of the right-hand side variables (X, C_o, C_u) of the model. Moreover, the exact form of the TCE in nonlinear settings will differ depending on the researcher's policy relevant analytic objective(s). These issues will not, however, be discussed here and are the subject of other articles of this encyclopedia. The current discussion focuses on estimation of the vector of parameters θ.

The nonlinear generality of eqn [9] brings with it considerable, though not insurmountable, complications in the formulation of the nonlinear analog to eqn [6]. In the generic nonlinear model, although the SS rule is still defined as in eqn [1], the relevant control function is implicit and does not have a closed form, as did $\lambda(X\alpha + C_o\alpha_o + W\alpha_w)$ in the linear case. In light of this, accounting for the presence of C_u in eqn [9] does not involve a simple substitution of the control function, as was the case in moving from eqn [1] to eqn [6]. With these issues in mind, the nonlinear analog to eqn [6] can be written as

$$Y = \mu^*(X, C_o, C_u, W;\ \alpha^*, \theta) + v \quad [12]$$

where $\mu^*(X, C_o, C_u, W; \alpha, \theta)$ is a known function derived from eqn [9] and $\alpha^* = [\alpha\ \alpha_o\ \alpha_w]$. Unbiased estimates of the

parameters of eqn [12] can be obtained via the following two-stage protocol. First, estimate α^* as in the linear case. In the second stage, estimate of θ by applying the nonlinear least squares method to the following version of eqn [12].

$$Y = \mu^*(X, C_o, C_u, W; \hat{\alpha}^*, \theta) + \upsilon \quad [13]$$

where $\hat{\alpha}^* = [\hat{\alpha} \ \hat{\alpha}_o \ \hat{\alpha}_W]$ is the first stage estimate of α^*. It should be noted that the only case in which eqn [12] has a closed form is when it is derived from eqn [11] – the exponential regression model. In that case, eqn [13] can be written

$$Y = \exp(X\beta + C_o\beta_o)\hat{\lambda}^* + \upsilon \quad [14]$$

where the estimated control function $\hat{\lambda}^*$ is a function of $X\hat{\alpha} + C_o\hat{\alpha}_o + W\hat{\alpha}_W$.

Summary

Often sample inclusion is not random. Unobservable determinants of sample inclusion may also influence the outcome of interest. Naive regression estimates that ignore such latent correlation are subject to a kind of endogeneity bias – so-called SS bias. SS bias in regression parameter estimation is also manifested in corresponding causal inference and prediction. In this article the general circumstances in which SS bias is likely to be a problem is detailed and examples are given. Most empirical studies that confront potential SS bias are cast in a linear framework and implement a relatively simple two-stage method to correct for it. This method, and also the sources and implications of SS bias in linear models, are discussed in detail. Linear models and methods are not, however, compatible with most empirical contexts in health economics and health services research which often involve outcomes that are qualitative or otherwise limited in range. For this reason, a general nonlinear framework for modeling potential SS is also discussed, and a recently developed two-stage estimation approach (details of which can be found in the references for Further Reading) is outlined.

Searching and Reviewing Nonclinical Evidence for Economic Evaluation

S Paisley, University of Sheffield, Sheffield, South Yorkshire, UK

Glossary

Bibliographic databases Electronic database of bibliographic information organized, indexed, and searchable by subject descriptors, authors, title, and abstract keywords and other fields. Medline is an example of a bibliographic database.

Citation pearl growing or snowballing A search method using as a starting point a single, known, index source of information. This source is used to find related items (e.g., items citing and cited by the index source) and sources with similar characteristics (e.g., by the same author or containing similar subject terms).

High yield patch or rich patch Any source containing a high proportion of relevant information (e.g., clinical experts, existing economic evaluations).

Indirect retrieval or secondary retrieval Retrieval of information on one topic while searching for information on another topic.

Investigative searching A search method whereby information is identified in a piecemeal fashion rather than using a single, predefined search query. Sources of relevant information are used as leads or links to further relevant sources.

Precision A measure of the quality of a search. It is the proportion of items identified by a search strategy that is relevant.

Proximal cues A source of information that prompts a search for other similar or related, potentially relevant information.

Reference sources Source of information accepted or used on the grounds of its authority in the context of decision-making (e.g., drug formulary, classification of disease, and clinical guideline).

Routine data sources Source of information compiled primarily for administrative rather than research purposes (e.g., prescribing rates).

Search filters A predefined search strategy aimed at restricting search results to studies with specific methodological or clinical characteristics.

Sensitivity A measure of the quality of a search. It is the proportion of relevant items identified by a search strategy from all the relevant items that exist.

Outline

Economic evaluations in the form of decision-analytic models draw on many different types of secondary evidence in addition to costs and effects. The additional types of information used include natural history, epidemiology, quality of life weights (utilities), adverse events, resource use, and activity data. This information is drawn from different sources which can be research and nonresearch based.

Methods for identifying and reviewing evidence on randomized controlled trials (RCTs) of clinical effectiveness are well established. Some methods, many of which have not been validated, have been developed for other types of research-based information. Little guidance is available on identifying and assessing nonresearch based sources of information. On the whole, searching and reviewing methods have been developed in the context of systematic reviews and do not necessarily take into account factors specific to the task of developing decision-analytic models. This article considers how evidence is used to inform decision-analytic models and the implications of this for the methods by which evidence is identified and assessed.

The article considers the following:

- The types of information used to inform decision-analytic models for cost-effectiveness analysis.
- How to search for and to locate these types of evidence.
- How to select and to review evidence to inform a model.
- Factors specific to searching and reviewing in the context of decision-analytic modelling.

Introduction

Decision-analytic cost-effectiveness models aim to inform resource allocation decisions in health care. Evidence is assessed within a framework that reflects the complexity of the decision problem. A broad range of evidence, in addition to evidence on costs and effects, is required to support this approach. Important additional types of information include epidemiology, quality of life weights, natural history, and resource use. This information is drawn from different types of study design including experimental and observational research and from nonresearch based sources including routinely collected data, administrative databases, and experts.

A range of information retrieval methods is required to identify the diversity of information used to inform a decision-analytic models. Methods for identifying and reviewing evidence of clinical effectiveness from RCTs have been developed by organizations such as the Cochrane Collaboration. To a lesser degree, methods for the identification and review of other types of study design, such as observational studies, have been developed, although these have generally not been subject to validation and are not so well established. Very little guidance exists to support the systematic identification and assessment of nonresearch-based sources, including, for

 doi:10.1016/B978-0-12-375678-7.01403-6

example, sources of routinely collected data such as prescribing rates. Such sources can be difficult to locate and to access, and the navigation and interrogation of their nonstandard, often complex format, can be challenging.

On the whole, searching and reviewing methods have been developed in the context of systematic reviews of clinical effectiveness. As such they have been designed to identify and to assess experimental evidence with high internal validity in order to address single, focussed questions on the effects of treatment. Systematic review search methods require extensive searching in an attempt to identify all studies that match the characteristics of the focussed review question (typically defined by the populations, interventions, comparators, and outcomes of interest). The quality of a search is defined according to its sensitivity (that is, the extent to which it has identified all studies that match the review question). The systematic review search approach has become the benchmark approach to searching in all types of health technology assessment (HTA), including decision-analytic modelling, and the concept of sensitivity has become the defining characteristic of a high quality search. Such methods, however, do not necessarily take into account factors specific to the task of developing decision-analytic models such as addressing issues of complexity, drawing on a wide range of different types of evidence and assessing effectiveness in the absence of direct or good quality evidence. This article explores how evidence is used in models and the implications of this for the methods by which evidence is identified and assessed.

Types of Information and Forms of Evidence: The Classification of Evidence

Types of Information

The need for a range of information to inform model parameter estimates is well understood. Information on clinical effect size, baseline risk of clinical events, costs, resource use, and quality of life weights have been identified as the five most common data elements required in the population of decision-analytic models.

Information is also used to support a number of modelling activities in addition to parameter estimation. An analysis of the sources of evidence cited in the reporting of models identified a range of different types of information, drawn from different information sources and used for a variety of modelling activities (see Table 1). These included, in addition to model parameters, the definition of the model structure, the overall design and scope of the model, and various analytical activities and modelling methods.

The types of information used in models can be grouped into five broad categories. The first category relates to the condition or disease area of interest and includes information on natural history, epidemiology, and prognosis. Typical uses of such information include the specification of the model structure through the definition of the disease pathways and of health states within the pathway. Information is also used to provide estimates of baseline population characteristics and baseline risks of clinical events. Some evidence on costs, resource use, and utilities will also be included here.

Further information is required to inform the specification of the available treatment options and the management of the condition or disease. A range of information including clinical practice guidelines and policy documents, expert advice, prescribing rates, and other activity data can be used to inform the definition of management options including relevant comparators, treatment strategies and procedures, and management options at various stages of the disease pathway.

Category three relates to the costs and effects of the clinical interventions of interest. The types of information required include effectiveness evidence, comprising clinical outcomes, adverse effects, and quality of life weights. Adverse effects and quality of life weights often constitute additional, separate requirements where trials provide no or insufficient evidence on these outcomes. As such, searches focussing on these types of evidence might be undertaken in addition to searches for RCT evidence. Other types include information on the cost and resource use implications of delivering the interventions.

Some models might take into account factors that affect the uptake of treatment and that might impact on costs or effects outside the controlled environment of an experimental setting. Potentially relevant information includes patient

Table 1 Classification of evidence used in models of cost-effectiveness by type, source, and use of evidence

Types of information	*Types of source of evidence*	*Uses of evidence within model*
Adverse effects	Evidence synthesis	Design and specification of model framework
Compliance	Expert judgment	Model validation
Current practice	Methodological theory and empirical evidence	Modelling and analytical approach
Epidemiology	Observational research	Population of model parameters
Modelling methods	RCT (clinical and economic)	Sensitivity and uncertainty analysis
Natural history	Reference sources	
Patient preferences	Routine data sources	
Prescribing rates		
Prognosis		
Resource use		
Results and methods from other models		
Clinical outcomes		
Unit costs		
Utilities		

preferences, adherence, or acceptance of treatment as a function of the mode of delivery of an intervention such as homed-based versus hospital-based delivery, or oral versus infusional delivery.

The final category provides analytical rather than clinically related information. This is used to support choices relating to the modelling approach and analytical methods. It can include methodological standards and guidelines, empirical, theoretical methodological research, and modelling approaches used in existing economic analyses.

Formats of Evidence

The range of information used in decision-analytic models is drawn from a number of different forms of evidence. Examples are listed in Table 1. Although it is difficult to devise a definitive classification of the different evidence formats, it is possible to identify several study designs and formats which can be categorized broadly as research-based and nonresearch based evidence.

Research-based sources take the form of a number of different study designs, reflecting the different types of information used in models. These include evidence syntheses, including meta-analyses, systematic reviews, and cost-effectiveness models, RCTs, primary economic evaluations and observational study designs in the form of cross-sectional surveys and longitudinal cohort studies, and theoretical and empirically based methodological studies.

The use of nonresearch based sources reflects the need for models to address real world issues and to take account of the context of the decision. Such sources include expert opinion, both published and in the form of expert advice, routinely collected data and 'reference sources.' Routine data sources cover, for example, national disease registers (although some disease registers will be classed as observational research), life tables, and health service activity data. The category of sources referred to as 'reference sources' describes standard sources often providing generic information, including drug formularies or disease classifications, or sources that have some inferred authority due to consensus on their reliability or relevance to the context of the decision. Examples of the latter might include policy guidance and practice guidelines.

To some extent it is possible to associate the different types of information with the different forms of evidence. For example, it is well established that evidence of clinical effectiveness should ideally be taken from RCTs. Members of the Cochrane and Campbell Economics Methods Group (C-CEMG) have devised a useful hierarchy of evidence for the most important model data inputs, although it should be borne in mind that this does not cover all the types of information used to inform a model.

For those outcomes where there might be insufficient trial evidence, quality of life weights might be taken from cross-sectional observational studies, and evidence of adverse effects can be found in observational cohort studies and post-marketing surveillance data. Epidemiological information can be drawn from longitudinal studies, including long-term routinely collected data. Observational studies can provide information on factors impacting on the uptake of the intervention. Information on the latter might also be found in qualitative studies. This is useful where an issue is considered sufficiently important to warrant some form of discussion but where quantitative data for incorporation in a model are not available.

Evidence to inform the specification and estimation of costs and resource use can be difficult to categorize. In terms of the specification of a cost analysis (i.e., the identification and definition of relevant cost and resource groups) observational costing studies, previous economic analyses, expert opinion, and documentation of how a condition is managed, such as clinical guidelines, are useful. In terms of data with which to populate a model, routinely collected data such as prescribing costs and reference sources such as drug formularies and widely accepted compilations of unit costs are preferable. Where an overall estimate of the costs and resources associated with being in a particular health state are required (e.g., the cost of managing a stroke), it is necessary to use an existing cost analysis, for example, from a previous economic analysis. It is important, however, that consideration is given to the reliability of such a summary estimate.

The type of evidence used to inform the specification for the management of the condition of interest is also difficult to categorize. The definition of disease management and the specification of current practice are complex information needs requiring information on, for example, treatment options, disease management pathways, and clinical decision-making rules or policies. This is unlikely to be satisfied using a single source of information, particularly when a model is required to reflect the variations in disease management in different countries. To represent current practice it is necessary to draw together a range of different types of information to form an overall picture or description of how a disease or condition is managed. The sources from where this information can be found might include, but will not be restricted to, treatment and practice guidelines, activity data, and expert opinion.

In addition to the different types of evidence used to inform a model, it is also important to consider the scope of evidence, within each type, that will be relevant to the model. For example, it is likely that the scope of relevant clinical effectiveness evidence will not be restricted to that which relates to the intervention(s) of interest. In the absence of direct, head-to-head trials, evidence relating to the comparator(s) of interest should also be sought in order that indirect comparisons can be undertaken. This scope of evidence will be further extended where mixed treatment comparisons are undertaken. Here, a network of evidence, including trials of treatments that are not formal comparators, is required. The scope of relevant evidence will be further determined by the breadth or scope of the framework within which a decision problem is analyzed. Although the purpose of some models is to assess the cost-effectiveness of an intervention or interventions at a specific point in the disease pathway, this is done in the context of the whole of the disease pathway. Therefore, the effectiveness and cost-effectiveness of an intervention may need to be considered in terms of its impact on the whole of the disease pathway. For example, the effectiveness of a diagnostic intervention will be considered not just in terms of its diagnostic accuracy but on the extent to which it

impacts on the longer term management of a condition and, ultimately on the clinical endpoints relevant to the condition, including survival and quality of life. As such, evidence on, for example, treatment effects, quality of life weights, costs, and resource use is required not just for the intervention of interest at the point of the decision but for all important management options and health states at all stages of the disease pathway. This is an important consideration in defining the scope and range of searches to be undertaken.

Searching for and Locating Evidence

Models have multiple information needs that cannot be satisfied by a single search query. A series of focussed, iterative search activities should underpin the development of a model. To identify the diversity of evidence required, it is necessary to access a range of different types of information resources and to adopt a number of different information retrieval techniques.

Search methods for the retrieval of RCT evidence of clinical effectiveness are well documented by organizations such as the Cochrane Collaboration and are not covered in depth here. Bibliographic databases remain important sources, particularly for the identification of research-based evidence. However, given the diversity of information required, the totality of the evidence base used to inform any single model will be fragmented. In particular information from nonresearch based sources is scattered and the location and format of these sources can make retrieval difficult.

General biomedical bibliographic databases such as Medline and Embase provide access to a substantial volume of published information and can be interrogated using subject-specific keyword search techniques. Search filters, which are predefined combinations of keywords designed to identify specific study designs or types of information, are useful in identifying the individual types of information required for a model. For example, a number of filters exist for the retrieval of RCTs and cost information. Filters exist for many types of information. Most have been designed pragmatically and few have been validated. Nonetheless, filters are widely used to improve the relevance of search strategies. The Information Specialists' Sub-Group of Inter Technology Assessment Consortium, the UK academic network undertaking HTA for the National Institute for Health and Clinical Excellence (NICE), have developed an extensive resource of critically appraised search filters. In terms of non-RCT evidence, the Campbell and Cochrane Economic Methods Work Group provides advice on searching for economic evaluations and on quality of life weights. Research on the retrieval of evidence on adverse events is currently being undertaken at the University of York in the UK. These sources provide advice both on searching general biomedical databases and on specialist resources particular to specific topic areas.

Some useful specialist databases and resources exist for the retrieval of research-based non-RCT evidence. The Centre for Reviews and Dissemination at the University of York provides access to the National Health Service Economic Evaluation Database (NHS EED) and the HTA database, with the latter including the register of projects and publications of the member organizations of International Network of Agencies for Health Technology Assessment (INAHTA). The TUFTS Cost-Effectiveness Analysis Registry extracts utilities data from systematically identified cost-utility analyses. The Health Technology International (HTAi) Vortal is an extensive searchable repository of resources relating to the field of HTA.

Routine data and reference sources are disparate and cannot easily be brought together as a single reliable resource that can be interrogated using a uniform search approach. Compilations of resources have not been developed to any great degree, although some of the sources aforementioned can provide some coverage. Part of the value of this type of information is its relevance to the decision-making process in terms of geographical context or relevance to a specific decision-making authority. For example, the British National Formulary, the Office for National Statistics and NHS Reference Costs constitute three highly relevant sources for informing model parameter estimates in England and Wales, but do not carry the same authority in other decision-making jurisdictions. It would, therefore, be difficult to develop an international, generic, and comprehensive resource. Organizations such as the World Health Organization and the Organization for Economic Cooperation and Development can provide access to useful country-specific information. International resources such as HTAi and the International Society of Pharmacoeconomics and Outcomes Research (ISPOR) also provide useful starting points. At a national or more local level, harnessing knowledge and skills in order to provide access to compilations of information sources relevant to specific, local decision-making is an important area for development.

In the absence of such resources, the systematic identification of routine and reference sources of information cannot rely on the traditional keyword searching approach commonly associated with systematic review search methods. An alternative approach to retrieving information is to follow systematic lines of enquiry. This investigative search approach is similar in principle to citation pearl growing and snowballing references, used as supplementary search techniques in systematic reviews. Investigative searching does not attempt to identify everything in one search attempt using a single, catch-all, search query. Rather, the objective is to retrieve information in a systematic, auditable, and piecemeal fashion. This is done by identifying one or more relevant starting point(s), to search and to use these to identify relevant leads which can be followed up systematically and iteratively until sufficient information has been identified. A search starting point could be a known publication, advice from an expert or highly focussed exploratory searches using a bibliographic database (e.g., Medline) or an internet search engine (e.g., Google). The repeated following up of leads, known as proximal cues, in the form of new relevant keywords, references and names of authors and organizations will form a network of sources for further investigation. An illustration of a brief investigative search is given in **Figure 1**.

In terms of obtaining information from experts, the potential for bias is high and it is important to demonstrate a transparent and systematic approach to gathering this type of information. Formal methods of eliciting information from

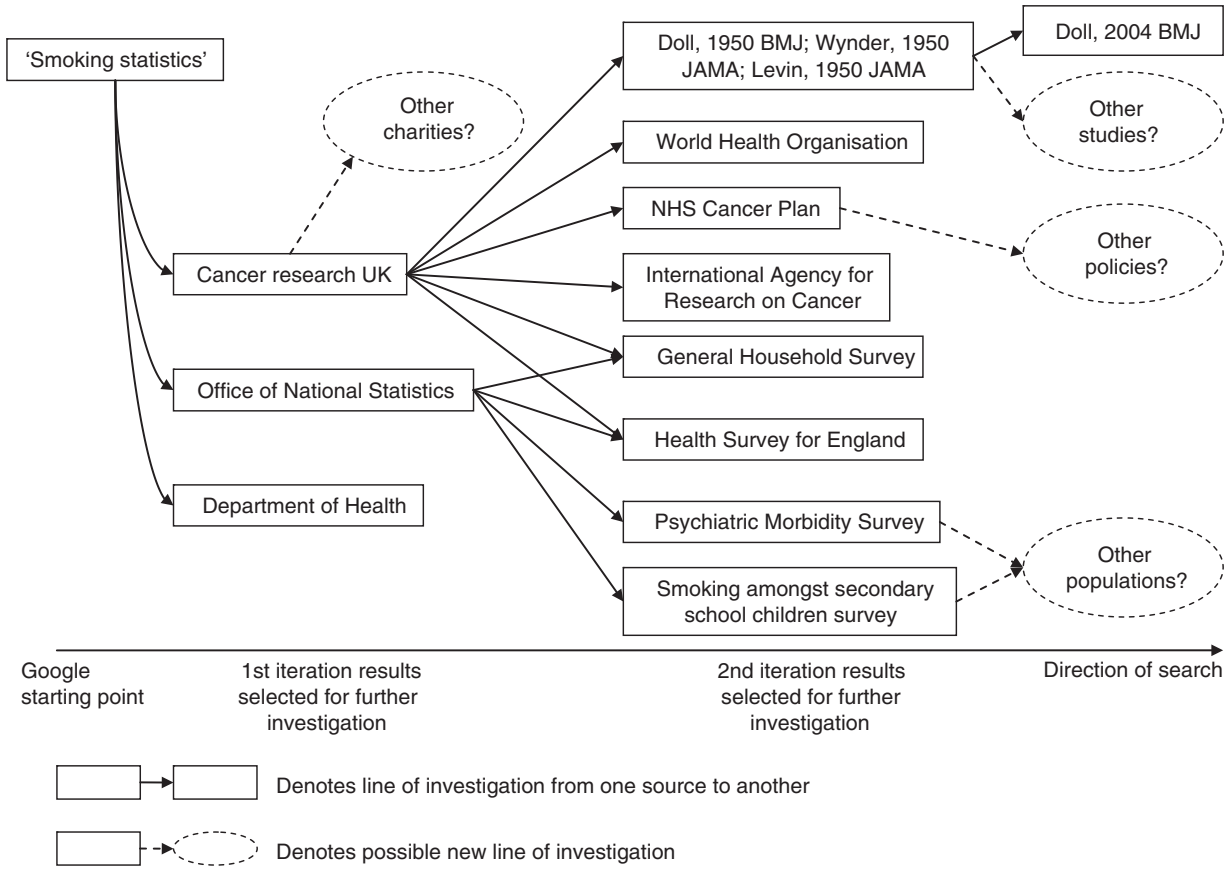

Figure 1 Example of investigative search.

experts include Bayesian elicitation methods, qualitative operational research techniques, and consensus methods. Other forms of good practice include the use of a range of experts in order to capture variation in opinion and in clinical practice. Precautions should also be taken to ensure that the full range of clinical expertise relevant to the decision problem is represented.

How to Search Efficiently

Searches using a systematic review search approach typically attempt to achieve a high-level sensitivity. That is, they are designed to maximize the retrieval of evidence that matches a prespecified and focussed topic. This often necessitates the retrieval of a large volume of irrelevant information in order to ensure that relevant evidence is not missed by the search. Exhaustive searching, aimed at high sensitivity, is considered difficult in the context of modelling. Limited time and resources are frequently cited as constraints when undertaking searches for models. The process of model development generates multiple, interrelated information needs that have, to some extent, to be managed simultaneously and iteratively rather than sequentially. This is very different from the single focussed question scope of typical systematic review searches.

To progress the process of model development it is necessary to assimilate a broad range of information as efficiently as possible. Using techniques that focus on precision, rather than sensitivity, might provide a more efficient approach to searching. Precision is defined as the extent to which a search retrieves only relevant information and avoids the retrieval of irrelevant information. Search techniques that focus on precision can provide a means of maximizing the rate of return of relevant information. The objective of such techniques is to front-load the search process by attempting to capture as much relevant information as early as possible, and to assess the diminishing returns of subsequent, broader, search iterations. Such techniques do not preclude further iterations of extensive searching where a more in-depth approach is required. All the techniques described aim to maximize precision. They are suggested with the caveat that when used on their own without subsequent broader iterative searching there is an increased risk of missing potentially relevant information.

A search process aimed at maximizing the rate of return of relevant information and at minimizing the opportunity cost of managing irrelevant information can adopt widely used information retrieval techniques. Restricting searches to specific fields within bibliographic databases is a commonly recognized technique aimed at maximizing precision. For example, searching for relevant terms within the title of journal articles should minimize the retrieval of irrelevant information. Depending on the nature and amount of information retrieved, a judgment can be made as to whether to extend the search across other fields, such as the abstract, with

a view to increasing sensitivity. A similar technique can be adopted when using search filters to restrict search results to specific study designs. Search filters can be designed to maximize either the sensitivity or precision of this restriction. The choice of high precision filters, sometimes referred to as one-line filters, can be used to maximize relevance. The Hedges project at McMaster University in Canada has developed and tested a set of filters, including one-line filters.

A highly pragmatic approach is to restrict the number of sources or databases searched. If a decision is made to extend the search, the results of the first iteration can be used to select and follow up highly relevant lines of investigation, for example, by carrying out focussed searches of newly identified keywords or by following up key authors.

Existing cost-effectiveness models in the same disease area may be important sources of information, and can be used to gain an understanding of the disease area, to identify possible modelling approaches and to identify possible evidence sources with which to populate a model. This can be described as using a 'rich patch' or 'high yield patch' of information whereby one source of information (i.e., the existing economic evaluation) is drawn on to satisfy multiple information needs. The use of high yield patches can provide useful shortcuts or can help cover a lot of ground quickly in terms of gaining an understanding of a decision problem. However, it is important that consideration is given to the limitations or reliability of a potentially rich source and to ensure that the weaknesses of existing economic analyses are not simply being replicated.

It has already been stated that information needs do not arise sequentially but that multiple information needs might be identified at the outset of the modelling process or might arise simultaneously during the course of developing the model. A useful way of handling multiple information needs is to consider information retrieval as a process of information gathering alongside a more directed process of searching. The pursuit of one information need might retrieve information relevant to a second or third information need. The yield of this secondary or indirect retrieval can be saved and added to the yield of a later more directed retrieval process. For example, a search for costs might also retrieve relevant quality of life information. This would constitute secondary or indirect information retrieval. It could be retained and added to the yield or results of a later search focussing specifically on quality of life.

Sufficient Searching

There is some debate as to what constitutes sufficient searching in the context of decision-analytic modelling. In particular, the need to achieve a high level of sensitivity when undertaking searches is open to question both on practical and theoretical grounds. The NICE has developed useful principles for the searching and reviewing of evidence for decision-analytic models. In terms of searching, this advice states that "the processes by which potentially relevant sources are identified should be systematic, transparent and justified such that it is clear that sources of evidence have not been identified serendipitously, opportunistically or preferentially." To uphold this principle it is important to consider the factors that might influence decisions to stop searching and that might inform judgments as to whether a sufficient search process has been undertaken.

This section summarizes some of the factors that could contribute to a definition of sufficient searching in the context of modelling and that might be used to support a judgment that sufficient searching has been undertaken.

In practical terms, it is often argued that there is not sufficient time or resource to undertake exhaustive, systematic review-type searching for every information need generated by the model. This supports the need for efficient methods such as those described in the previous section. It also requires pragmatic decisions on when to stop searching. Such decisions should be transparent in order that users of a model can judge the perceived acceptability or limitations of the scope of the searches undertaken.

Models are usually required to inform decision-making in the absence of ideal evidence. A decision to stop searching might be driven by an absence or lack of relevant evidence. If a relatively systematic search process exploring a number of different search options has retrieved no relevant evidence, it could be considered acceptable to assume that further extensive searching would not be of value.

One-way sensitivity analysis can be used to explore the implications of decisions to stop searching and of using a range of alternative sources of evidence on the outputs of a model. This type of analysis is widely regarded as a useful means of supporting judgments underpinning the identification and selection of evidence and is stated as a requirement in the Methods of Appraisal issued by NICE.

An extension of this idea would be to undertake some form of value of information analysis to understand the impact of uncertainty in the model and ultimately on the decision-making process. The process of bringing together, within one framework, multiple and diverse sources of evidence bring with it unavoidable uncertainty that cannot fully be understood or removed by comprehensive searching on every information need within the model. On theoretical grounds, therefore, it could be argued that exhaustive searching would not fully inform an understanding of uncertainty. Value of information analysis might be useful in assessing the value of undertaking further searching for more evidence and in determining where search resources should be focussed. It could act as a device to prioritize areas for further rounds of searching during the course of a modelling project or to develop research recommendations for more in-depth searching or reviewing on specific topics to inform future models. It is important to note, however, that the usefulness of this approach is dependent on timing and the extent to which the priorities for searching are revisited during the course of a project. A particular parameter which appears unimportant during the early stages of model development may become more important as the model is further refined over time.

Reviewing and Selecting Evidence

Reviewing techniques used in systematic reviews are, in principle, applicable in the context of reviewing and selecting

evidence for decision-analytic models. However, due to certain factors, gold standard systematic review methods such as those of the Cochrane Collaboration, are not directly transferable and consideration has to be given to adapting these useful and well established methods for modelling. These factors include time and resource constraints, the need to balance quality of evidence with relevance to the context of the decision and the frequent need to accommodate a lack of available, relevant evidence.

Time and Resource Implications

As in the case of searching for information, reviewing the breadth and diversity of evidence used in models is typically constrained by limited time and resources. The value of in-depth reviewing for every information need in the model, such as the use of strict inclusion criteria, extensive quality assessment procedures, and independent reviewing by two reviewers, is also open to question. Various pragmatic rapid review methods can be applied including reduced levels of data extraction, quality assessment, and reporting. In addition, important aspects of the model can be identified and prioritized as requiring a greater proportion of the available reviewing resource.

Assessing the Quality of Evidence

The systematic assessment of the quality of studies considered for inclusion in a systematic review is one of the many mechanisms aimed at checking for and minimizing the risk of bias. Quality assessment tools, sometimes in the form of checklists, exist for many different types of study design including RCTs, observational studies, and economic evaluations. The tools provide a series of questions on the conduct and design of individual studies allowing the systematic consideration of the strengths and weaknesses in terms of reliability, validity, and relevance. Many different checklists exist. Organizations such as the Centre for Reviews and Dissemination at the University of York provide access to a range of checklists. The Cochrane Collaboration, however, recommends against the use of checklists arguing that this leads to an oversimplification of the quality assessment process. The Collaboration has developed the Cochrane Risk of Bias tool, which can be applied to both RCTs and nonrandomized studies.

Given the diversity of information used to inform models it is highly likely that quality assessment tools do not exist for every type of evidence used. In such circumstances it might be possible to generate a number of questions, possibly based on existing tools, to guide the process of assessment. Members of the Cochrane and Campbell Economic Methods Working Group suggest a number of issues for consideration in the assessment of evidence on quality of life weights. The absence of standards for quality assessment is a particular problem in the assessment of routine data sources and reference sources. The quality of commonly used sources, such as national statistical collections, classifications of disease, and drug formularies might be regarded as sufficiently authoritative to be accepted without in-depth quality assessment. The ISPOR has created a Task Force on Real World Data to consider issues, including quality, relating to the use in models of routinely collected data and data not collected in conventional RCTs.

Two tools have been developed that can be used to support the process of quality assessment specifically in the context of decision-analytic models for cost-effectiveness. The tool devised by members of the Cochrane and Campbell Economic Methods Working Group is a series of hierarchies of evidence for five important model data inputs: clinical effect sizes, baseline clinical data, resource use, unit costs, and quality of life weights. Although the hierarchies do not allow the assessment of the quality of each individual study, they form a useful tool for some form of assessment between studies. The Grading of Recommendations Assessment, Development, and Evaluation (GRADE) system provides an 'economic evidence profile'; a framework and criteria for rating the quality of evidence collected from all potential sources relating to all components that may be used to populate model parameters, including research-based and nonresearch-based sources.

Assessing the Relevance of Evidence

The relevance of evidence to the context of the decision is a crucial consideration in assessing evidence to inform decision-analytic models. This is an important distinction in the assessment of evidence for models compared with assessment for systematic reviews. Although standard quality assessment tools used in systematic reviews often include questions relating to relevance, the focus, in reality, is on the assessment of scientific rigor and internal validity. In its consideration of the role of routine data sources the ISPOR Real World Data Task Force emphasizes that 'context matters greatly' in determining the value of available sources. The C-CEMG hierarchies and the GRADE system both place emphasis on factors of relevance directly alongside the assessment of scientific quality. In assessing the value or usefulness of nonclinical sources of evidence, the trade off between contextual relevance and internal validity is often a particularly important consideration.

The tension between relevance and scientific quality is highlighted by the role of expert judgment as a source of evidence. As a basis for parameter estimates, expert judgment is placed at the bottom of the evidence hierarchy, as in systematic reviews. However, the role of expert judgment in interpreting the available evidence and in assessing the face validity or credibility of a model as an acceptable representation of the decision problem is recognized as an important source in the validation of the model.

Selecting Evidence for Incorporation in the Model

The assessment of quality and relevance plays an important part in the selection of evidence for use in a model. Although some initial form of eligibility criteria might be used to select references from a list of search results, this does not take the form of strict, predefined inclusion and exclusion criteria. This may be for a number of reasons. The incorporation of nonclinical evidence in a model tends not to involve the synthesis of data from a number of studies to generate a single pooled estimate. Rather, a range of estimates may be derived or selected from a number of possible options all of which might

be relevant for different reasons. In addition, there is often an absence of 'ideal' evidence. Although a clinical effectiveness review can remain inconclusive due to there being no available evidence, this is not an option for decision-analytic models which have to support a decision-making process regardless of the available evidence base. In doing so, the purpose of a decision model is to identify what might be, on average, the best option and to quantify the uncertainty surrounding the decisions. In the absence of ideal evidence the application of more flexible selection criteria allows the identification of the best available evidence from which the best or closest match can be judged and selected.

Therefore, evidence is not defined as being eligible or ineligible. Rather, the various characteristics of individual sources can be seen as offering different attributes by which eligibility might be judged. These attributes may be different to those of another source; that is, sources will be judged as being useful for different reasons. The quality-relevance tradeoff is an example of this.

The application of more flexible selection criteria allows the identification of a relatively varied set of potentially relevant or candidate evidence from which final selections can be made. The selection of evidence for incorporation in a model is made through a process of weighing up the attributes of each source against each other. The assessment of quality and relevance, sometimes supported by some level of data extraction to aid comparisons between studies, supports this process. This is different to the process of quality assessment and data extraction in standard systematic reviews which take place after evidence has been selected for inclusion. Moreover, the selection of one source of evidence over another does not necessarily lead to the exclusion of evidence as the implications of selecting alternative sources can be explored through sensitivity analysis.

The use in a standard systematic reviews of predetermined, strict selection criteria is another mechanism aimed at minimizing the risk bias in the review. The more flexible approach used in modelling incorporates choices based on weighing up and trading off the relative merits of alternative sources of evidence. This avoids the need to label evidence as being relevant or not relevant, allows the inclusion and exploration of a range of sources of evidence and, in the absence of ideal evidence, permits the incorporation of the best available evidence. In adopting this approach it is important that the process of selecting evidence is transparent, that the choices made are justified and that the extent and impact of uncertainty caused by possible bias resulting from the selection process is accounted for through sensitivity analysis.

A number of procedures can be used to systematize the process of selection. The use of quality assessment and data extraction can help systematize the choices being made. The reporting of the process, including the tabulation of key characteristics of the candidate sources of evidence, can improve transparency. The process of selection can be done through systematic discussion within the modelling project team in order that joint decisions are made. Finally, sensitivity analysis can assess the impact of uncertainty generated by the process of selection, including exploration of alternative sources not used in the base case analysis.

Conclusion

Decision-analytic models assess cost-effectiveness within a complex analytic framework. A broad range of information, in addition to evidence on costs and effects, and including both research- and nonresearch-based information, is required to inform this approach.

Information retrieval and reviewing methods, developed for the conduct of systematic reviews of clinical effectiveness, can be used for the identification and assessment of evidence used to inform decision-analytic models. To make the best use of these methods it is necessary to adapt them to the specific requirements of the task of developing decision-analytic models. This includes employing a range of information retrieval techniques in order to access and exploit diverse formats of evidence and adapting quality assessment and data extraction procedures to support systematic and transparent judgments in the selection of the best and most relevant available evidence.

Decision-analytic models permit an evidence-based approach to decision-making that takes account of the complexities and factors of specific relevance to the context of the decision problem. The collective grouping and interplay of diverse sources of evidence brings with it inevitable uncertainty. This cannot wholly be addressed by minimizing the risk of introducing forms of bias that might be associated with individual sources of evidence. Searching and reviewing methods used in the context of developing a model can provide an efficient means of capturing and understanding a broad range of information and can be used to address systematically and transparently the limitations of the best available relevant evidence such that a full account of the uncertainty associated with that evidence base can be supported.

Sex Work and Risky Sex in Developing Countries

M Shah, University of California, Los Angeles, CA, USA

Introduction

The literature on the economics of commercial sex in developing countries has been a burgeoning area of recent growth for various reasons. First, unprotected commercial sex is a major human immunodeficiency virus (HIV) transmission vector. Sex markets play an integral role in the spread of sexually transmitted infections (STIs) including HIV/acquired immunodeficiency syndrome (AIDS). Each day 20 000 people become infected with HIV (UNAIDS, 2002), and many of these new infections occur in the developing world. In developing countries, sex workers play a central role in the spread of HIV and other STIs as they generally have higher infection rates and more sexual partners relative to the general population. **Table 1** displays HIV prevalence for adults, pregnant women, and sex workers across the developing world. In almost every country, sex workers have significantly higher HIV prevalence than the general population. In countries like Kenya, 85.5% of sex workers are HIV positive relative to 8.3% for the general adult population. Although condoms are an effective defense against infection, and despite the large amounts of financial aid channeled into educating sex workers about the importance of condom use, many sex workers are risking infection by not using condoms. Research in economics has sought to understand this issue because HIV/AIDS and other STIs have potentially devastating implications for economic development.

Table 1 HIV prevalence (per hundred) among adults, pregnant women, and sex workers

Country	*Adult*	*Pregnant women*	*Sex workers*
Benin	1.2	0.4	53.3
Burkina Faso	6.7	12.0	60.4
Cameroon	3.0	1.9	21.2
Congo, DR	3.7	4.6	30.3
Congo, Republic	7.2	7.1	49.2
Ivory Coast	6.8	11.6	67.6
Ethiopia	2.5	4.9	67.5
Ghana	2.3	2.2	30.8
Kenya	8.3	13.7	85.5
Malawi	13.6	32.8	78.0
Mali	1.3	3.5	55.5
Nigeria	2.2	3.8	22.5
Rwanda	7.2	25.3	87.9
South Africa	3.2	10.4	3.2
Uganda	14.5	21.2	86.0
Zimbabwe	17.4	35.2	86.0
Argentina	0.4	2.8	4.2
Brazil	0.7	1.7	11.2
Dominican Republic	1.0	2.8	7.0
El Salvador	0.6	0.0	2.0
Haiti	4.4	8.4	41.9
Honduras	1.6	1.0	20.5
Jamaica	0.9	0.7	24.6
Cambodia	1.9	3.2	43.0

Second, the sex market is a large source of employment for many women in poor countries, which has both microeconomic and macroeconomic implications. Vandepitte *et al.* (2006) estimate the percentage of females who make their living from sex work to be 12% in Diego-Suarez, Madagascar; 4.3% in Ouagadougou, Burkina Faso; 2.8% in Phnom Penh, Cambodia; 1.4% in Jakarta, Indonesia; and 7.4% in Belize. Obviously these are significant numbers and constitute a large number of women earning their living by performing potentially risky work. In addition, these numbers are increasing as more women enter the sex market due to lack of outside labor market opportunities in most developing countries. On a macroscale, the amount of revenue associated with the sex sector is considerable. For example, revenue from the Indonesian sex sector was estimated at between US$1.2 and 3.3 billion, or between 0.8% and 2.4% of the country's gross domestic product (Lim, 1998). In Thailand, close to US$300 million is transferred annually from urban sex workers to rural areas in the form of remittances (Lim, 1998). Therefore, both the financial turnover and the sheer number of women involved in the sex industry are strong motivators for further economics research.

Lastly, from an economics perspective, very little is known about the commercial sex sector, as demonstrated by the numerous policy failures. For example, many interventions aimed at teaching sex workers the alternate skills necessary to get them out of the sex industry have failed. The simplest explanation for this failure is that sex work pays well and most alternative low-skilled jobs do not, so getting women out of the sex industry is incredibly difficult. As another example, despite all the international funding that has been spent on educating sex workers about the risk of diseases such as HIV/AIDS, high rates of risky behavior (i.e., noncondom sex) are still observed in many developing countries.

This article investigates the following questions in the context of developing countries using recent studies from the economics literature:

1. Why might women enter the sex market?
2. Why do female sex workers engage in noncondom use?

To properly set the stage, this article begins with a brief description of sex workers' sociodemographics and transaction characteristics from three different countries: Mexico, Ecuador, and Kenya.

Table 2 Sex worker summary statistics

	Mexico, 2001	*Ecuador, 2003*	*Kenya, 2005–06*
Age	27.82	27.9	28.43
Age of first compensated sex	21.79	23.6	18.67
Very attractive (=1)	0.21	0.27	N/A
Has children (=1)	0.62	0.86	0.76
Can read and write (=1)	0.84	0.92	0.88
Had HIV test (=1)	0.89	0.85	0.60
Had sexually transmitted infections (STIs)/vaginal[a] problems (=1)	0.17	0.52	0.34
Civil status			
Single (=1)	0.41	0.47	0.44
Married/civil union/cohabitating (=1)	0.22	0.48	0.13
Divorced/separated/widowed (=1)	0.38	0.06	0.43
Used condom (=1)	0.91	0.88	0.82
Average transaction price[b]	44.75	7.20	6.40
Number of women	1029	2902	192

[a]A self-reported STI problem in last 3 months for Kenya, ever for Ecuador, and last year for Mexico.

[b]Denotes price in 2003 USD.

Note: This table reports the mean characteristics for sex workers from Mexico (Reproduced from Gertler, P., Shah, M., and Stefano, B. (2005). Risky business: The market for unprotected commercial sex. *Journal of Political Economy*, University of Chicago Press **113**(3), 518–550), Ecuador (Reproduced from Arunachalam, R. and Shah, M. (2008). Prostitutes and brides? *American Economic Review Papers and Proceedings* **98**(2), 516–522; Arunachalam and Shah, (2013) data), and Kenya (Reproduced from Robinson, J. and Yeh, E. (2011). Transactional sex as a response to risk in Western Kenya. *American Economic Journal: Applied Economics* **3**(1), 35–64).

Sex Worker Characteristics

Table 2 presents summary statistics of samples of sex workers in Mexico, Ecuador, and Kenya. The Mexican statistics are constructed from the dataset used in Gertler *et al.* (2005), the Ecuadoran statistics from the dataset used in Arunachalam and Shah (2008, 2013), and the Kenyan summary statistics from data used by Robinson and Yeh (2011). Please see the papers for more detailed information on sampling techniques and data collection activities. Interestingly, sex workers across all these three countries appear to be quite similar in terms of their sociodemographics. They are on average 28 years old, and the vast majority can read and write. Almost 50% are currently married or in civil union partnerships or were married and now are divorced, and more than 60% have children.

The majority of these women have taken HIV tests (89% in Mexico, 85% in Ecuador, and 60% in Kenya). In the past year, 17% of sex workers in Mexico self-reported having STI-related problems, 52% of women in Ecuador reported having an STI problem in the past, and 34% of women in Kenya reported STI-related problems in the past 3 months. Although HIV/AIDS rates tend to be much lower in Mexico and Ecuador (approximately 1% among sex workers), STI rates are relatively high, especially compared to the general adult population in these countries. High STI rates in a population are a risk factor for a potential HIV/AIDS epidemic because untreated STIs facilitate easier transmission of the HIV virus. Condom use rates range on average from 80% to 90% in the last three sexual transactions. The average transaction price varied from approximately US$45 in Mexico to US$7 in Ecuador to US$6.50 in Kenya.

Why Might Women Enter the Sex Market?

Understanding why women enter the sex market is crucial, especially if effective policies related to the sex market are to be implemented. There is obviously no one single reason that women and girls become prostitutes. Some have hypothesized that women enter because sex work pays well (Edlund and Korn, 2002), or because they face economic shocks in a world of poverty (Robinson and Yeh, 2012), or due to lack of outside options in the labor market, and of course there are those who enter due to force, kidnaping, and/or trafficking. Issues related to trafficking have not been discussed too much in the economics literature. This is likely due to the illegal, hidden nature of this market, which makes it difficult to collect good microdata, as well as the fact that many models in economics tend to implicitly assume some semblance of free choice. Without the intention of understating the importance of trafficking and dangers faced by many girls and women who enter the sex market via this channel, this article will not cover this area.

Edlund and Korn (2002) introduce a puzzling stylized fact that prostitution is "low-skilled, labor intensive, female, and well-paid." There is no other occupation like it that is female dominated and pays so well (although it is low skilled), and the authors offer a provocative explanation for this puzzle: sex workers draw a compensating differential due to the foregone opportunity to sell their fertility in the marriage market. Edlund and Korn (2002) not only provide the first formal model of occupational choice involving prostitution but also draw an intriguing link between the labor market and the marriage market that holds for only one occupation. When a woman chooses to become a sex worker, she relinquishes the compensation she would otherwise receive in marriage, because taboos prevent prostitutes from marrying. Thus, even in settings where prostitution is legal, it must draw an earnings premium. Beyond drawing considerable media attention, the richness of the Edlund–Korn model has made it the starting point for economists' discussions of sex work (e.g., Giusta *et al.*, 2004). An especially attractive feature of the paper is that it generates a number of testable predictions.

Arunachalam and Shah (2008) test the Edlund–Korn model. They utilize two large-sample datasets on sex workers, collected in Ecuador and Mexico, which they match to national labor survey data in the respective countries. They corroborate the existence of a sizable earnings premium for sex work, but fail to find support for the marriage-based explanation for this premium. Sex workers are actually more likely to be married than nonsex workers at younger ages when the earnings premium for sex work is highest. Furthermore, they find that the premium to male sex work is even larger than that for women. They hypothesize that the earnings premium would be better explained as a compensating differential, akin to that observed in other risky professions.

Although Robinson and Yeh (2012) agree that that sex work pays much better than other available jobs especially in poor countries and that this level difference in average income is clearly important, another key consideration is the variability of consumption. In Africa, as in much of the developing world, shocks are quite common and formal safety nets are often missing. In addition, insurance through informal systems of gifts and loans is rarely, if ever, complete (Townsend, 1994). Robinson and Yeh (2012) show that women enter the transactional sex market in western Kenya because clients send transfers in response to negative income shocks. These women develop relationships with regular clients who then become the primary source of interperson insurance that women receive. For example, transfers from regulars increase by 67–71% on the days around one's own illness and by 125% on the days around the death of a friend or relative.

Why Do Sex Workers Engage in Noncondom Use?

Much of the health policy literature argues that in many cases sex workers engage in unprotected sex because they are uninformed of the risks and that they would protect themselves if they fully understood the risks (World Bank, 1999; Lau *et al.*, 2002). In the cases in which sex workers are aware of the risk, others hypothesize that noncondom use occurs because condoms are either very expensive or not available at all (Negroni *et al.*, 2002), implying there are serious supply-side constraints. Alternatively, others have argued that sex workers are forced to have unprotected sex (Karim *et al.*, 1995; World Bank, 1999), and because they face physical or economic threats, they engage in noncondom use.

Although ignorance does exist and the forced exploitation of sex workers does occur, another possible explanation is that sex workers are willing to risk infection by not using condoms with clients if they are adequately compensated. Indeed, economic theory has long posited the general principle of compensating wage differentials (Rosen, 1986), and a number of authors have documented wage differentials that compensate for risky work activities in other labor sectors such as mining, police work, and firefighting (Viscusi, 1992; Siebert and Wei, 1998). Although there is anecdotal evidence that sex workers charge more for sex without a condom (Ahlburg and Jensen, 1998), there was little empirical evidence testing this claim before research from the economics community. In addition, it has been widely documented that men have strong preferences for noncondom sex. Therefore, if men are willing to pay more for sex without a condom, then sex workers might simply respond to these market incentives.

Understanding why sex workers do not use condoms is critical for the development of policy that is effective in increasing condom use and consequently in reducing the transmission of STIs, including HIV. The usual policy recommendations are to intervene on the supply side (World Bank, 1999). These policies include (1) educating sex workers about the risks, (2) increasing access to inexpensive condoms, (3) reducing environmental barriers to condom use by working with gatekeepers such as brothel owners and the police, and/or (4) empowering sex workers by improving their negotiating skills and fostering self-help organizations. Additionally, governments are urged to implement and enforce laws against human trafficking, rape, assault, and indentured servitude. However, if some clients are willing to pay substantially larger sums for unprotected sex, supply-side interventions alone are less likely to sufficiently reduce unprotected commercial sex. Even knowledgeable sex workers with condoms, who are free to turn down clients, might be willing to supply unprotected sex if the price is right. In this case, complementary interventions on the client side that reduce the demand for unprotected sex are also necessary in order to increase condom use.

Gertler *et al.* (2005) investigate whether sex workers are rationally responding to market incentives by testing whether sex workers charge more to take the risk of providing unprotected services. However, selection is an issue due to both sex worker heterogeneity as well as client sorting. For example, in terms of sex worker heterogeneity, better educated sex workers might charge higher prices and also be more likely to use condoms. Similarly, better educated, wealthier clients who value condom use and have a higher willingness to pay may select these sex workers. This will create a positive correlation between price and condom use, which is not necessarily causal or related to compensation for taking a risk. To control for the endogeneity of condom use, they collect information on the last 3–4 transactions for each sex worker to create a panel dataset. They estimate a model with sex worker fixed effects to control for bias from both unobserved sex worker heterogeneity and client selection where the dependent variable is log price. Additionally, they control for client characteristics using sex worker reports of clients' looks, wealth, cleanliness, and risk preferences.

Gertler *et al.* (2005) begin by constructing a simple bargaining model of commercial sex that has a number of empirically testable predictions. The model predicts that a condom will not be used when the client's maximum willingness to pay not to use a condom is greater than the minimum the sex worker is willing to accept to take the risk. Surprisingly, however, the model also predicts that when the client is worried about the risk of infection from unprotected sex, he may be charged more for using a condom than for unprotected sex. Similarly, when the sex worker prefers not to use a condom, the client is given a discount for not using a condom. The price differential between protected and unprotected sex is a weighted average of the maximum the client is willing to pay for not using a condom and the minimum the sex worker is willing to accept to take the risk of infection by not using a condom. The weights are a function of the relative bargaining power of the client and the sex worker.

Table 3 Sex worker risk premium for noncondom sex

Risk premium for noncondom sex (%)	*Noncondom sex (%)*	*Country*	*Source of risk premium*
13	10	Mexico	Gertler *et al.* (2005)
12	12	Ecuador	Arunachalam and Shah (2013)
66	47.2	India	Rao *et al.* (2003) Dandona *et al.* (2006)
9.3	17	Kenya	Robinson and Yeh (2011)

Note: This table reports both risk premium for noncondom sex and noncondom sex rates by country from various studies.

Gertler *et al.* (2005) test these predictions using a panel dataset collected in 2003 from the Mexican states of Michoacan and Morelos. They find that Mexican sex workers receive a 23% premium for unprotected sex from clients who requested not to use a condom, and this premium jumps to 46% if the sex worker is considered very attractive. They also find that clients who requested condom use paid 9% more for protected sex, and sex workers who requested not to use a condom gave clients a 20% discount. The results are completely consistent with the theoretical predictions.

Studies in other developing countries have found similar results with male clients paying a premium for noncondom use in India (Rao *et al.*, 2003), Ecuador (Arunachalam and Shah, 2013), and Kenya (Robinson and Yeh, 2011). **Table 3** summarizes the main results from all these studies. Arunachalam and Shah (2013) and Robinson and Yeh (2011) use a similar sex worker fixed effects empirical strategy as Gertler *et al.* (2005).

Interestingly, Arunachalam and Shah (2013) show that the premium men pay for noncondom sex in Ecuador is approximately 12% but that this premium increases in locations with higher disease rates. A one percentage point increase in the local STI rate increases the premium for noncondom sex by 33%. This is the first paper in this literature to have biological STI outcomes for sex workers. Therefore, the authors are able to identify this source of the risk premium as directly linked to STI rates. These results suggest that market forces may curb the self-limiting nature of STI epidemics exacerbating the spread of disease. To a greater extent than other epidemics, economists argue that the spread of STIs is shaped by individuals' behavioral responses. For example, with an increase in awareness of the risk of contracting disease, individuals substitute away from risky sex toward abstinence (Kremer, 1996), toward protected sex (Ahituv *et al.*, 1996; Dupas, 2011), or away from sex with men toward sex with women (Francis, 2008). Viewing risky sex much like other commodities in the market, economists anticipate that demand declines as the expected cost increases (Posner, 1992). Hence, economists tend to see behavioral responses to STI prevalence as generating a self-limiting incentive effect of epidemics (Geoffard and Philipson, 1996). Evidence from the commercial sex sector, however, suggests that market forces may dampen the self-limiting feature of STI epidemics be cause sex workers draw a premium for engaging in risky unprotected sex.

Robinson and Yeh (2011) use a panel dataset constructed from 192 self-reported diaries of women who provide transactional sex in Busia, Kenya. They find that women who engage in transactional sex increase their supply of risky, better compensated sex to cope with unexpected health shocks, particularly when another household member is ill. More specifically, they find that women are 3.1% more likely to see a client, 21.2% more likely to have anal sex, and 19.1% more likely to engage in unprotected sex on days in which another household member (typically a child) falls ill. These behavioral responses obviously entail significant health risks for these women and their partners, and suggest that women are unable to cope with risk through other consumption smoothing mechanisms. This is an extremely critical issue in a place like Busia, where the estimated HIV prevalence was 9.8% in 2004 (CBS, 2004).

In India, Rao *et al.* (2003) use 2003 data from Songachi, Kolkata's oldest and best established red-light district, with more than 4000 sex workers working in 370 brothels that service approximately 20 000 clients a day. Rao *et al.* (2003) use an instrumental variable strategy to estimate the premium for noncondom sex and correct for unobserved heterogeneity. They use exposure to an HIV/AIDS intervention targeted at sex workers as the instrument because this intervention is highly correlated with a sex worker's propensity to use condoms, but the authors claim it is uncorrelated with a sex worker's income. They estimate that when sex workers use condoms, they earn between 66% and 79% less.

The loss in earnings associated with condom use clearly represents a major disincentive to safe sex. The problem comes from the fact that clients, most of whom do not want to use condoms, are able to exploit competition among sex workers. If a sex worker insists on having sex with a condom, the client can simply go to the next brothel or another sex worker in the same location where he will find a sex worker who is more willing. The solution to this can come either from educating clients about safe sex or creating an agreement among sex workers to collectively agree to refuse condom-free sex (Rao and Shah, 2012).

Conclusion

The scope for research on the sex sector remains large given how little economics work has been done in this area to date. For example, still very little is known about how regulating this market might affect public health outcomes. Different countries apply distinct regulatory techniques to their own sex markets. In some countries sex work is illegal, in other countries it is decriminalized, and in other places it is legal. However, very little is known about how these different regulatory procedures affect things like public health outcomes or the welfare of women involved in the sex industry.

Gertler and Shah (2011) show that regulating the sex market in Ecuador can have some unintended consequences. They find that increasing enforcement of regulation in the street sector significantly decreases STIs. However, increasing enforcement in the brothel sector increases the probability that a sex worker will be infected with an STI. This is because increasing enforcement in the street shifts sex workers on the margin from the more risky street into the less risky brothels, thereby increasing street prices and reducing the overall number of street clients. As a result, overall infection rates fall. In contrast, increasing enforcement in the brothel sector can exacerbate public health problems by inducing some unlicensed brothel sex workers into the riskier street sector. This example and this entire article illustrate that sex workers clearly respond to economic incentives, which is an important lesson for policy implementation.

Savings behavior is another area calling for future research. Unlike most other professions, sex workers earn more at younger ages and their income decreases with age and experience (Arunachalam and Shah, 2008). Because of this inverted earnings to age profile, saving at younger ages should be a priority for these women. However, data show that young sex workers do not save much of their earnings. Whether this is due to lack of access to banks, lack of demand on their part, or some other reason is still unclear. This question is a much needed topic for future research.

Smoking, Economics of

FA Sloan, Duke University, Durham, NC, USA
SP Shah, John Hopkins University School of Medicine, Baltimore, MD, USA

Glossary

Activities of daily living limitations Limitations in basic activities in which individuals must engage in their daily lives, such as bathing, feed oneself, toileting.
Behavioral economics A branch of economics that incorporates psychological insights into economics.
Commitment devices Various methods individuals use to be sure that they follow through on prior decisions.
Compensatory behavior Behavioral response to a regulated outcome, for example, an increase in the tax on cigarettes increases the amount of the cigarette that is smoked.
Endogenous Arising from within a system, for example, in a system describing health and health behaviors, health may be endogenous to smoking and conversely.
Excise tax A tax on the manufacture or sale of a product.
Forward-looking An individual who considers future benefits and costs in making a decision.
Marginal utility of consumption The gain in utility from an increase in one unit of a (composite) good.
Marginal utility of wealth The gain in utility from an increase in one dollar of wealth.
Over-the-counter Term often used for drugs that are sold without a prescription.
Price elasticity or elasticity of demand Minus the percentage change in the quantity demanded divided by the percentage change in the product's price.
Randomized controlled trial An experiment in which subjects are randomly assigned to a treatment or control group.
Reverse causation A dependent variable influences an explanatory variable and conversely.
Risk averse A willingness to pay positive amounts to reduce risk while not changing the expected outcome, i.e., tastes when the certainty equivalent (the utility review obtaining a given amount for sure) exceeds the expected utility of a gamble, i.e., the sum of products of the probability of each outcome and the value associated with the outcome.
Risk tolerant Not risk averse.
Shifting The increase in price of a good following an increase in the tax imposed on the good.
State Attorneys General The state attorney general in each of the 50 US states and territories is the chief legal advisor to the state government and the state's chief law enforcement officer.
Utility function A function that represents tastes by ranking consumption bundles.

What is the Economics of Smoking and Why Should One Care?

Economists divide markets into demand and supply. Demand reflects individual preferences, relative prices, income, and other factors. Supply differs according to market structure; prices depend on whether the market is competitive or not and the extent of government intervention in the market. On the demand side, decisions about whether or not to smoke are referred to as the extensive margin. Conditional on smoking, the frequency, and intensity of smoking refers to the intensive margin. The decision to smoke is particularly interesting given the addictive properties of cigarettes and the delayed consequences of smoking. Given such consequences, perceptions of risk of future adverse effects, and the discount rate applied to the future cost of smoking have a key role in decision-making. Additionally, government interventions prompt individuals to take externalities into account in their demand decisions.

On the supply side, much emphasis is placed on the cigarette industry's advertising practices. Governments seek to offset such promotion by publicizing the adverse effects of smoking. In the USA, the Master Settlement Agreement (MSA) limits the industry's ability to promote its products and the settlement has increased production costs in the USA which, coupled with substantial increases in excise taxes on cigarettes, has further increased cigarette prices.

The economics of smoking is worthy of attention for several reasons. First, smoking is among the most harmful behaviors to personal health and longevity. Considering the combined cost of internalities and externalities, the societal cost per pack of cigarettes was US$37 in 2004. The main internalities relate to adverse health effects to the smoker. This raises a question about why someone would engage in such behavior. Second, the topic raises issues of fundamental importance to economics, including whether or not people are rational in their decision-making, the accuracy of risk perceptions, preference heterogeneity (e.g. in risk and time preference), and the role of addiction in explaining consumption patterns over time. Third, from a public policy perspective, the track record includes some successes, but effects of many public policies are below initial expectations. Even after decades of policy intervention, in the USA more than 20% of adults continue to smoke. Fourth, even though the share of the US population that smokes has declined, in other countries, especially in lower-income countries, this share continues to increase.

This review will mainly focus on recent economic literature and focus on the USA, where most studies have been conducted. The authors do not discuss important research conducted outside economics.

The Section Alternative Frameworks provides an overview of theoretical frameworks by economists and direct empirical tests of the implications of these models. In the Section Direct Empirical Tests of the Alternative Frameworks, other empirical tests of these frameworks are turned to. In the Section Other Empirical Evidence to Explain Continued Smoking, the empirical evidence on continuing smoking is reviewed. Sections Price: Effect of Cigarette Taxes and Effects of Other Cigarette Demand Determinants review findings on price and other determinants of cigarette demand. In Sections Effects of Smoking on Longevity and Health and Other Effects of Smoking, the authors summarize empirical evidence on the consequences of smoking on health, wages, labor force participation, and expenditures on personal health care services. The Section Effects of Policy Interventions evaluates evidence on demand- and supply-side public policies that have the goal of reducing cigarette consumption.

Alternative Frameworks

At the risk of oversimplification, empirical analysis of the economics of smoking is guided by three alternative frameworks: rational addiction, imperfectly rational addiction, and irrational addiction.

Rational Addiction

At least at first glance, addiction seems to be the last place one would find rational behavior. By 'rational,' economists mean that agents use all available information to weigh benefits and costs before making a decision. 'Available' does not mean that the agent has perfect information because the cost of search is nonzero and not trivial. For decisions with consequences over many periods, the rational agent considers downstream and current effects, which are discounted to present value. These implicit calculations reflect subjective beliefs about probabilities of various outcomes and utilities associated with each outcome with choices based on relative expected utilities.

Smoking is addictive and addiction has the special property that consumption in one period affects future marginal utility and, hence, future consumption of the good. The seminal contribution to the theory of addiction using a rational framework is Becker and Murphy (1988). In this model, the agent is a rational, forward-looking individual with stable preferences. Becker and Murphy give precision to the concept of addictive behavior as consisting of these properties: Tolerance – higher levels of past consumption reduce the marginal utility of consumption in the current period; withdrawal – there is disutility associated with cessation in consumption of the good; reinforcement – higher consumption of the addictive good yields higher marginal utility which leads to higher consumption of the good.

In their model, the rational agent maximizes finite lifetime utility with consumption of the addictive good, a composite nonaddictive good, and the stock of the addictive good (how addicted the agent is). The model implies that consumption of the nonaddictive good is set where marginal utility of consumption of the good equals the discounted marginal utility of wealth – a standard result. For the addictive good, the marginal utility of consumption equals the discounted marginal cost of consuming a unit of the good. Hence the agent anticipates adverse future health effects of consuming the addictive good now as well as future prices of the good.

Imperfectly Rational Addiction

In an imperfectly rational addiction framework, some assumptions underlying the rational addiction model are relaxed: consistency of time preferences, and accuracy of risk perceptions about the harms potentially caused by addictive behaviors or the probability that consuming addictive goods will lead to the person becoming addicted. Under hyperbolic discounting the person's discount rate, which applies to both gains and losses, increases as the time for implementing the change becomes closer. The discount rate is constant and exponential (the usual assumption about discounting in economics) for decisions occurring in the future, but is higher for decisions occurring in the present. Thus, if the person considers quitting smoking in 10 years, they use exponential discounting. If the issue is quitting smoking today, they use a higher rate. This has the effect of reducing the present value of the benefit of quitting, i.e., reducing the future cost of adverse health effects. To the extent that the expected benefit is lower, there is less incentive to quit. Because the discount rates depend on the timing of the decision, this behavior is said to be 'time inconsistent.'

Various studies have used this approach and made many modifications to the basic theory, for example, by distinguishing between sophisticated and naïve hyperbolic discounters. The sophisticates know that they will be time inconsistent, so they employ self-control devices, for example, they may not have cigarettes around the house. Also, people may favor smoking bans or higher excise cigarettes as methods of self-control. Others, the naïfs, do not realize that they have time-inconsistent preferences, and so do not consider that at the later time they will discount the benefits of quitting highly, and so not quit early.

Irrational, Cue-Triggered Addiction

In an irrational framework, individuals do not base decisions on objective comparisons of costs and benefits of specific choices, but rather are swayed by emotions. Addictive goods' consumption may result from visceral urges provoked by external cues, which lead to impulsive consumption that would not have occurred in the absence of these cues. More generally, decision-making often follows pattern matching rather than an explicit weighting of benefits and costs. Behaviors that cues elicit are part of the pattern matching process.

Characteristic 'irrational' assumptions are that consumption among addicts is considered by the addicts themselves as a mistake; that environmental cues based on past experiences trigger consumption; and that addicts understand and manage their susceptibility, i.e., they are 'sophisticates'. In one model (Bernheim and Rangel, 2004), a person can be in either a 'cold' or a 'hot' state. When cold, the person is rational. However, when exposed to certain environmental

stimuli, for example, places where the individual has often smoked in the past, the person switches to the hot state in which emotions supersede rational decision-making. The person can control the probability of receiving an environmental stimulus by altering their lifestyle activity. However, the utility from a lifestyle that provides a high probability of a stimulus (e.g. attending parties) is higher than the utility from another activity (e.g. in the extreme, rehabilitation).

Direct Empirical Tests of the Alternative Frameworks

Rational Addiction

Chaloupka (1991) used data on individuals from the second National Health and Nutrition Examination Survey to test the rational addiction model. He regressed daily cigarette consumption on cigarette prices, past, present, and future, and lagged and future cigarette consumption. The price parameter estimates were not statistically significant, providing weak support for the rational addiction model.

Becker *et al*. (1994) used cross sectional data on US states to test the rational addiction model. A key implication of the model is that people are forward-looking in making decisions about consumption of an addictive good. They found that, as cigarette prices rise, current consumption of the good falls, which is what the rational addiction model predicts.

Auld and Grootendorst (2004), using annual aggregate data on milk and the rational addiction model as the underlying conceptual framework, found that milk is the most addictive of all commodities evaluated, including cigarettes! The literature contains other critiques of the models and tests as is, perhaps, to be expected given the relative youth of the topic and its difficult 'fit' with standard economics.

Imperfectly Rational Model

Even if people are not rational and forward-looking, they may be simply forward-looking. Gruber and Köszegi (2001) tested whether cigarette consumption was negatively related to announced cigarette excise tax increases. They found that it was, which they interpreted as evidence for the notion that people are forward-looking but not necessarily time-consistent in their preferences.

There is some empirical evidence on hyperbolic discounting by smokers in particular. Indicators of hyperbolic discounting include: the use of commitment devices, discount rates that vary according to the time horizon with short-terms exceeding longer term ones, and actual behavior not matching stated plans. Odum *et al*. (2002) evaluated discounting on the part of small samples of current, former, and never smokers using two nonlinear decay models, one for exponential and the other for hyperbolic discounting. They found the hyperbolic model provided a better fit between the two. Current smokers discount health gains and losses more than never smokers do using both exponential and hyperbolic functional forms. Several other studies, however, have produced conflicting results, and strong empirical support for a key role of hyperbolic discounting in the smoking decision is not yet available.

Irrational Mode

There is a large literature on the relationship between advertising and smoking. Two reviews are in the Further Reading section. However, the vast majority of studies have used aggregate data, which do permit a direct test of the effect of cues on smoking. There is some evidence that teen exposure to TV advertising has a positive and significant impact on the probability of smoking. However, most direct testing of the effects of cues has been conducted by noneconomists.

Other Empirical Evidence to Explain Continued Smoking

Overview

A fundamental reason why some people smoke and others do not may simply be that their preferences differ. Also, persons who believe that they have a lower life expectancy may be more prone to smoke. Persons smoke because they underestimate the probability of adverse consequences of smoking. Now each of these hypotheses will be examined.

Heterogeneity in Preferences

There is empirical evidence that preferences differ between smokers and others. For example, it seems that willingness to pay to be in good health is considerably higher for never smokers than for current smokers, implying that one reason people continue to smoke is that they value being in good health less.

Smokers select riskier jobs but receive lower risk-adjusted compensation than nonsmokers. This seemingly anomalous result can be predicted from a model in which employers' offers and workers' utility depend on wages and the probability of injury on the job. Smokers and nonsmokers appear to be segmented labor groups having distinctive preferences and distinctive labor market curves. Smokers are more risk tolerant and more impatient. Moreover, heavy smokers tend to be more impatient and less risk averse than never smokers whereas former smokers are more patient and risk averse than never smokers.

Biased Risk Perceptions

Youth risk perceptions are particularly relevant for the initiation of smoking as almost all initiation occurs before age 22, whereas adult risk perceptions are important for what they tell us about cessation. A common assumption appears to be that youths start to smoke because they are overoptimistic about life outcomes.

The empirical evidence reveals a more complex picture. Youths are extremely pessimistic about the probabilities of lung cancer due to smoking or, indeed, dying for any reason by age 20 (Sloan and Platt, 2011).

Overall, for adults, comparing subjective with objective risk, subjective beliefs are quite close on average to their objective counterparts. However, there are differences by smoking status. Even though subjective beliefs about the probability

of dying tend to be higher for current smokers than for never smokers, current smokers tend to be relatively optimistic and never smokers relatively pessimistic in assessments of their own mortality. However, risk perceptions seem not to be important in the decision of adults aged 50–70 to continue smoking. The evidence on relative optimism and pessimism is consistent with a more general finding that low-risk groups tend to overestimate and high-risk groups tend to underestimate their mortality risks. Overestimation of risk reduces the probability that a person will be a current smoker, a result found in several studies from various countries.

Price: Effect of Cigarette Taxes

Another explanation of continued smoking is that although real cigarette prices have risen, cigarette prices may remain too low to deter much smoking. There is a basic distinction between the extensive margin and the intensive margin. The former refers to a decision to smoke or not to smoke and the latter refers to the amount, conditional on whether the person smokes at all.

Extensive Margin

At the extensive margin, the tax responsiveness of youths and adults depends on two separate types of behaviors – initiation and cessation. A higher cigarette tax affects initiation decisions for youths and cessation decisions for adults. The general consensus is that the price of cigarettes in the USA is negatively related to smoking participation. However, the magnitude of these negative price elasticities and whether youth smoking is more sensitive to price than adult smoking has been the center of much recent controversy.

Studies alternatively measure price responsiveness with data on cigarette prices or excise taxes. The effect of a given increase in the excise tax on prices depends on the amount of shifting that occurs. The amount of shifting of an increase in a state excise tax on retail prices of cigarettes might be less near a state border if state B does not follow state A's excise tax increase.

Conventional wisdom suggests that youth cigarette consumption is highly sensitive to price and is greater than price sensitivity for adults. This is not borne out by empirical studies that control for other determinants, or else only weakly. There is little evidence that higher taxes prevent smoking initiation in adolescence but some that taxes influence decisions regarding cessation and at the intensive margin. Initiation decisions may, after all, be driven by noneconomic and unmeasured determinants such as peer acceptance and many studies have not included direct measures of 'smoking sentiment' amongst peer groups or in localities, which may be correlated with taxes and prices.

Carpenter and Cook (2008) used repeated cross-section data from 1991–2005 and controlled for antismoking sentiment, finding that price elasticities for smoking participation range from -0.23 to -0.56. For adults, the general consensus has been that price elasticities for adults fall within the -0.3 to -0.5 range. Higher taxes appear to reduce smoking participation by older adults, especially for those who are less educated and from low-income households. Associated with a $1 increase in the excise tax are participation elasticities ranging from -0.29 to -0.31 for the 45–59 age group, just above -0.2 for persons aged 60–64. These elasticities appear to be lower in other countries (e.g. Russia and China). The price elasticity of smoking varies with other demographic factors, including education and gender. Among Irish women, for example, cigarette taxes have the greatest negative effect on initiation for women with intermediate levels of education. For cessation, cigarette taxes have the greatest effect for women with the lowest level of education. However, the pathway through which educational attainment affects the propensity to smoke remains unidentified. Although there is no established theoretical reason that would explain differences in smoking by gender, historically men have had higher rates of smoking than women but the gender gap has narrowed in recent decades. Research findings on the impact of cigarette prices on smoking participation by gender are mixed. It seems that women are nearly twice as responsive to cigarette taxes as men.

Intensive Margin

At the intensive margin, an increase in the cigarette tax results in a decrease in the number of cigarettes consumed daily; however, one study showed that smokers often compensate either by extracting more tar and nicotine from each cigarette (Adda and Cornaglia, 2006) or by shifting to a cigarette brand with more tar and nicotine content (Farrelly *et al.*, 2004) with the result that tar and nicotine consumption is not reduced and for one group (18–20) appears to have increased. More recently, Abrevaya and Puzzello (2012) reexamined Adda and Cornaglia's (2006) evidence on the compensatory behavior of smokers who, facing higher taxes, reduced cigarette consumption although maintaining their cotinine (a biomarker for nicotine) levels. They used (1) appropriate clustered standard errors, (2) a larger sample from the same years and survey than the data in Adda and Cornaglia's (2006) analysis, (3) cigarette-prices instead of and in addition to cigarette-taxes, and (4) sampling weights. Abrevaya and Puzzello (2012) found that the Adda and Cornaglia (2006) results were not robust. They find little empirical support for compensatory behavior found in subsamples of smokers. Stehr (2007) reported elasticities of intensity for adult men and women of -0.09 and -0.12, respectively, which implies that most of the effect of an increase in the excise tax is from a reduction in the fraction of adults who smoke.

Effect of Cigarette Prices on Smuggling

Cigarette price differentials cause changes in buying patterns, both across geographic areas, such as US states, and across selling modes, such as internet sales versus sales from bricks and mortar stores. Two studies focus on tax avoidance through internet purchases of cigarettes. Lower cigarette prices for cigarettes obtained over the internet have two major potential effects. First, they may increase aggregate cigarette consumption. Second, they may shift purchases from other retailers to internet vendors. Internet penetration increases the

negative effect of an excise tax increase on taxable cigarette packs per capita sold.

Effects of Other Cigarette Demand Determinants

Educational Attainment

Two important stylized facts are pertinent for describing the relationship between educational attainment and smoking. First, more highly educated persons tend to be healthier than others and, second, on average more highly educated persons smoke less. Although the associations are indisputable, there is controversy about causation and, if there is causality, the magnitude of the effect. Moreover, the relative importance is not clear of the various pathways through which educational attainment influences smoking.

Although the correlation between education, health behaviors, and health is well established, the notion that additional schooling affects health behaviors and causes health improvements is not. Reverse causality from health in general, and health behaviors in particular, to years of schooling completed, and/or the presence of third factors correlated with schooling and smoking but omitted from the analysis may cause educational attainment, health behaviors, and health to vary in the same direction. In high-income countries, but not necessarily in other countries, there is little reason to expect reverse causation from health to years of schooling because generally the temporal lag between the completion of formal education and the time at which health declines is several decades.

Possible omitted third variables is a more likely source of bias. Among these variables are: native ability, time preference, including at the time schooling choices are made, genetic factors, poor health in early life which may be positively correlated with poor health in adulthood (and which may also affect educational attainment in early, low income in early life which similarly may affect educational attainment and, independently, health in later life (Jayachandran and Lleras-Muney, 2009).

One's ability to make valid causal inferences depends on the quality of the identification strategy. Various strategies have been used. For example, de Walque (2010) constructed panels based on smoking histories, finding that among women, college education has a negative influence on the probability of smoking and more educated persons' smoking responded more quickly to diffusion of information on smoking. He offered explanations for differences by gender. Other identification strategies were based on availability of high school and college openings, draft avoidance during the Vietnam War and abolition of secondary school fees. In general, studies find causal effects, but there are exceptions. Most empirical evidence on effects of educational attainment comes from the USA and other high-income countries. However, empirical evidence from other countries supports the finding of a negative effect of educational attainment on smoking.

Peers

Peer effects have different potential roles depending on the stage of the life cycle. For adolescents, peers may encourage smoking. In the past, in adult life, smoking may have been seen as useful in promoting business or social interactions. Also, spouses may influence a person's smoking patterns. Isolating peer effects is difficult in particular because choice of peers is endogenous. People who enjoy being around smokers are likely to associate with smokers and conversely for persons who suffer from being around smokers. The conventional wisdom is that peer effects are important in influencing adolescents to start smoking.

Powell *et al.* (2005) analyzed peer effects on smoking. Peer effects were measured as behavior of all students in a school less the student in question. The instrumental variables were characteristics of other students in the school. They found that peer effects have an important role in influencing individual adolescents to smoke. In particular, moving from a school in which no students smoke to one in which a quarter of the students smoke increases the probability that a youth smokes by 14.5% points. Although the specific estimates vary, virtually all studies in the USA and elsewhere, have found positive effects of peer group smoking.

One type of peer effect reflects interactions of siblings and spouses within a household, where the expectation is that the effect would be strong. The relationship between decisions about smoking of spouses may reflect several underlying influences: correlation due to matching in the marriage market; bargaining within marriage; and social learning.

Health Shocks

Surviving a major health shock, such as a heart attack, may affect continued smoking for at least two reasons. First, the shock may reveal inherited susceptibility, i.e., new information about the personal effects of a life style including smoking. Second, the person may seek to forestall further health damage to self. However, the health shock may serve to increase unhealthy behaviors if it leads to thinking that they will gain little or no benefit from cessation given that they do not have much time to live. The onset of smoking-related health shocks other than cancer, nonsmoking related health shocks, onset of activities of daily living limitations, and onset of fair/poor health all increase the probability of smoking cessation. Smoking-related health shocks may generate new information on the effects of smoking to the individual. But the nonsmoking-related health shocks must be affecting smoking though another mechanism.

Health shocks to spouses as well as their smoking behavior may influence an individual's smoking decision. Among never smokers, but not for current and former smokers, spousal smoking has a negative effect on a person's longevity expectations. Spousal smoking-related health shocks also reduce longevity expectations of never smokers for reasons that are not understood because they have no effect on such expectations for current smokers. This might occur through three channels: Consumption externalities – one spouse's welfare affects the other spouse's welfare; altruism – one spouse reduces smoking in response to the other spouse's bad health; and learning about risks of smoking from the health experience of the other spouse. There is some evidence suggestive that consumption externalities are at work.

Stress

Even though there is a substantial amount of noneconomic literature on the effect of stress on smoking, the economic literature on the topic is quite limited, and only some results support an effect of stress on smoking. Job-related stress seems to increase smoking at the extensive margin, but the relationship is not generally statistically significant at the intensive margin. Death of a parent within the previous 2 years increases the probability of continuing to smoke. Without fixed effects, being separated, divorced, widowed in the past 2 years leads to continued smoking, but with fixed effects included, these relationships disappear.

Effects of Smoking on Longevity and Health

The effect of smoking on health is well documented in the epidemiologic literature. Economists have made some contributions as well showing that smoking is very harmful to personal health. The authors review three types of economic studies here – effects of smoking on: the smoker's health, nonsmoker's health, and neonate's health.

Between one third and three quarters of excess US veteran deaths are attributed to heart disease and lung cancer caused my military-subsized smoking. Smoking significantly contributes to inequality by income in predicted mortality.

A mother's decision to smoke involves balancing the utility of smoking against the disutility of adversely affecting the health of her child. Agee and Crocker (2007) assumed that a mother has three arguments in her utility function – her consumption, her health, and her child's health. Using data from the National Maternal and Infant Health Survey, they found that a mother values the health of her child more than her own health. The authors conclude that antismoking messages should mention health benefits to children from mothers not smoking.

Smoking is particularly harmful when done by pregnant women. The effect of smoking on birth weight is in the range of negative 100–150 g.

Compared to the 1950s when epidemiological studies on the health harms of smoking were just beginning to appear, people have become far more knowledgeable about the adverse effects of smoking. Thus, women who smoke during pregnancy in recent years are a much more select group than women who smoked while pregnant in the mid-twentieth century. Using data from three sources, the National Child Development Study, the British Cohort Study, and the Millennium Cohort Study, approximately half of the reported effects of smoking on the probability of low birth weight is due to unobserved maternal characteristics that are correlated with prenatal smoking.

Other Effects of Smoking

Wages

Empirical evidence indicates that smokers have lower wages than nonsmokers. The issue is not whether or not there is a difference in wage rates by smoking status but rather whether or not the relationship from smoking to wages is causal. In particular, smoking may be systematically related to omitted factors that also affect worker productivity.

Expected lifetime contributions to Social Security are US$3800 lower for smokers than never smokers among men and approximately US$200 lower among women (US$2000). A study using Canadian General Social Survey data to determine the effect of smoking on wages found a loss in earnings due to daily smoking of 24%. One reason why Social Security contributions are lower for smokers is that they may have been out of the labor force for longer periods. For example, smoking affects labor market participation indirectly through its effect on diabetes (through its effect on blood sugar levels and insulin resistance) and cardiovascular disease onset.

Expenditures on Personal Health Care

Although smokers tend to be sicker on average, they also live shorter lives. The fewer years of exposure to health expenditures may offset higher expenditures smokers incur per year that they are alive. However, it is probably correct to conclude that, overall, smoking raises expenditures per smoker, though by a trivial amount. Approaches which evaluate smoking-related expenditures at a point in time rather than over lifetimes yield much higher estimates of smoking cost (Sloan *et al.*, 2004).

Effects of Policy Interventions

Advertising

Cigarettes are one of the most advertised and promoted products in the USA, at least historically, in spite of the fact that government-imposed limits on such advertising also have a long history, beginning with a ban on advertising of cigarettes on television and radio implemented in 1970. The focus here is on effects of cigarette advertising bans and of promotion of smoking cessation products.

Heckman *et al.* (2008) criticize much past research that infers advertising has a causal influence on smoking initiation. Specifically referring to the Cochrane Review studies, but applying more generally as well, the authors have three specific criticisms. First, the studies do not develop adequate models on which to base the empirical analysis. Second, they do not adequately account for endogeneity of advertising exposure. Third, there may be insufficient variation in advertising exposure to generate statistical differences in responses.

Overall, evidence on the effects of advertising bans is mixed. Advertising restrictions mainly influence the smoking rate through their impact on concentration of the cigarette product market. With fewer sellers, people smoke less. The effects of both limited and comprehensive bans seem to be greater in developing countries than in developed countries.

Another strategy to reduce cigarette consumption is to promote products that reduce smoking behavior. Avery *et al.* (2007) investigated a policy in which the Food and Drug Administration (FDA) allowed all cessation products to be sold over-the-counter (OTC) immediately. They projected that

this policy would increase advertising of smoking cessation products by 80%. In a second simulation, they assessed the effect of offering each product available OTC a year earlier. They found that this change would increase advertising of smoking cessation products by 9%. As the number of competitors in this market increases initially, the effect on advertising is positive. However, the effect of adding competitors diminishes with entry of new sellers and eventually becomes negative.

Smoking Bans

Smoking bans may have desirable intentions in terms of reducing smoking rates and environmental tobacco smoke, but whether or not in fact they do reduce them is an empirical question. The evidence from the literature on the effectiveness of smoking bans is mixed.

Local laws restricting workplace smoking in Ontario, Canada reduced environmental tobacco smoke for blue-collar workers but not for other workers. Smoking bans in Norway have made smokers more considerate of others in areas where smoking is not banned but it has not been established that the smoking bans cause changes in social norms.

Poutvaara and Siemers (2008) theorized about the role of social norms in smoking. If the social norm is that smokers may smoke at will they argued there would be too much smoking – nonsmokers are hesitant to ask smokers not to smoke in their presence even though the disutility of the other person's smoking exceeds the utility gain from the social interaction. In this type of situation, smoking bans may represent a second-best policy. Others have found that bans reduce smoking among persons who frequent bars and restaurants but not among the population overall.

There is also research on unintended adverse side effects of smoking bans. One such effect may be that people travel further to get to locations where they can both smoke and consume alcoholic beverages, which may increase the prevalence of drunk driving and some evidence supports this view. Another perverse effect may arise in the form of increasing exposure of nonsmoking family members because bans in public places increase smoking at home.

Master Settlement Agreement

The MSA reached between 46 state attorney generals and the four major cigarette manufacturers in November 1998 represents the largest single public intervention in tobacco control in US history (Sloan and Chepke, 2011). The MSA settled numerous lawsuits filed by individual states against cigarette manufacturers, which alleged that the manufactures had promoted smoking, thereby increasing the smoking rates in the USA, which in turn increased medical costs incurred by the states, mainly through Medicaid.

The MSA included an assessment on cigarette companies that resulted in a substantial increase in cigarette price. The price increase and MSA antismoking provisions reduced smoking rates by 13% for persons aged 18–20 and 65+ and by 5% for others. For the first 15 months after MSA implementation, the effect of the MSA is estimated to have reduced prenatal smoking by 2.4%. The MSA appears to have led states to increase the excise tax on cigarettes, presumably because the MSA weakened cigarette manufacturers' political power in opposing such increases.

Another explanation for the increase in state cigarette excise taxes post-MSA is that publicity immediately before and after the MSA was implemented affected voter preferences about the cigarette companies and issues related to tobacco control policies with the result that voters were more favorable to such policies after the MSA was implemented.

Although the MSA imposed costs and various restrictions on large cigarette manufacturers, it also reduced the uncertainty about outcomes of legal disputes that existed before MSA implementation. The MSA led to a decrease in manufacturers' cost of capital by at least 2.2%. Overall, the MSA has been a mixed success. Cigarette price increases can be accomplished more efficiently by excise tax increases, which do not involve the high legal expense of litigation. Moreover, the MSA was a 'cash cow' for states rather than a source of revenue dedicated to public programs to reduce smoking and improve population health. Of course, there is no guarantee that additional excise tax revenue from cigarettes would not be spent in the same way.

Behavioral Economics Solutions

As indicated in the Section Alternative Frameworks, some aspects of smoking are consistent with predictions of behavioral economics. There is a limited amount of research on policy interventions whose designs reflect insights of behavioral economics. An experimental product (CARES) offers smokers an opportunity to invest in a savings account in which they deposit funds for 6 months. After this, if they pass a urine test for cotinine and nicotine, they are returned the money. Otherwise, the money goes to charity. Although the results suggest that the program was effective in inducing successful quitting, the possibility remains that participants were more motivated to quit. Further, as the authors acknowledge, only a minority of smokers successfully quit.

Volpp *et al.* (2009) evaluated a randomized controlled trial of a smoking cessation intervention at one firm. 878 employees were randomly assigned to two groups: (1) a group that only received information about benefits of smoking cessation; (2) the other group received this information plus financial incentives to stop smoking. There was an immediate payment of US$100 for completing the education program, US$250 for cessation within 6 months, and another US$400 for abstaining from smoking for an additional 6 months. An insight of behavioral economics is that immediate payments and implementation of self-control devices are important motivators for behavioral change. The latter group had significantly higher rates of smoking cessation than did the control group – 14.7% versus 5% quitting after 9–12 months following enrollment, which was somewhat lower than the quit rate at 6 months.

In spite of the amount of economic research that has been conducted, several controversies remain, including the magnitude of effects of cigarette prices and taxes on smoking initiation and youth smoking more generally and the causal

effect of educational attainment on smoking. The theory of rational addiction made an important contribution in showing that smoking and other addictive behaviors may reflect an explicit choice by informed individuals. A body of empirical research supports some of the model's predictions.

However, the introduction of psychological concepts into economics by behavioral economics has helped explain important stylized facts about smoking decisions that are not well explained by the fully rational framework. Empirical tests of the imperfectly rational and irrational frameworks are still in their infancy. Furthermore, it is one thing to state that people derive utility from such behaviors as smoking; but what really motivates people to smoke in a point in time, given that they know that smoking is very bad for personal health? Certainly virtually everyone knows that smoking is costly in the long run, but many people smoke and continue to smoke.

In the end, what makes smoking interesting to study is not only its relevance to human health, but also that understanding smoking behavior requires us to draw on a variety of disciplines as well as fields within economics.

Social Health Insurance – Theory and Evidence

F Breyer, University of Konstanz, Konstanz, Germany

The Concept of Social Health Insurance

Unlike private health insurance (PHI), 'social' health insurance (SHI) is characterized by three distinguishing features:

- Compulsory membership, at least for the great majority of the population.
- Community rating, i.e., premiums unrelated to individual risk.
- Open enrollment, i.e., even if the insurance market is competitively structured, an applicant cannot be denied coverage by an insurer.

The theory of SHI has two distinct branches. In the normative branch, the main questions are: (1) What are the efficiency and equity reasons for introducing and maintaining such a compulsory institution in a market economy; (2) How should SHI be designed so as to optimally attain the respective goals, both with respect to the benefits covered and to the way how it is financed; and (3) How should a competitive market for SHI be regulated to achieve its targets? The positive branch explains why SHI exists in most democracies and why certain observable features are characteristic.

Normative Theories of Social Health Insurance

Possible Efficiency Reasons for Social Health Insurance

According to neoclassical welfare economics, the violation of one or more assumptions of the First Welfare Theorem (Mas-Colell *et al.*, 1995) in a particular market is necessary (but by no means sufficient) (for sufficiency, it must be shown that government can create an institution which is suitable to bring about a better allocation) to justify government intervention in this market on efficiency grounds. In the case of SHI, the assumptions typically alluded to are market transparency (which may be violated in the cases discussed in the Sections Asymmetric information in the health insurance market and Insurance against reclassification risk) and independent preferences (for violations see Sections Altruism and free riding and Externalities from medical care).

Asymmetric information in the health insurance market

If competitive insurance markets are best described by the assumptions of the Rothschild and Stiglitz (RS) model, then asymmetric information of the 'hidden information' type (i.e., absence of transparency) may lead to an inefficient market equilibrium. If the insured has more precise information on his individual risk distribution than the insurer, the only possible RS equilibrium is a separating one (a separating equilibrium is an equilibrium in which each risk type is offered a contract which is not bought by other risk types.) in which only the highest risk types are offered complete coverage at actuarially fair premiums. Lower risks obtain more favorable terms but are rationed in terms of coverage. They would prefer to have more but this would make their contract attractive to unfavorable risks. Relative to such an equilibrium, SHI which forces all individuals into a pooling contract with partial coverage can achieve a Pareto improvement: high risks are made better off because they pay lower premiums for the mandated part of their coverage, whereas low risks benefit from improved total (social plus private) coverage (Newhouse, 1996).

However, several objections can be raised against this defense of SHI: first, it is unclear to what extent asymmetric information on health risks is really a problem as medical examinations can be used and are used to determine the risk of an insured. Second, the assumptions of the RS model are highly unrealistic: firms can neither cross-subsidize one insurance plan by another nor anticipate their competitors' reaction to their own market entry. If these possibilities are taken into account, then the inefficiency of the competitive market equilibrium vanishes and so does the justification of SHI.

Insurance against reclassification risk

In contrast to the adverse selection by Rothschild and Stiglitz (1976) model mentioned in Section Asymmetric information in the health insurance market, private health insurers charge different premiums according to health status. As this may change over time in an unpredictable way, individuals face the risk of uncertain premiums ('reclassification risk'). As before, the existence of a problem does not per se justify government intervention. Indeed, private insurers may cover this risk in two ways. First, they can offer 'guaranteed renewable contracts' that provide a premium guarantee to individuals in exchange for a prepayment (Pauly *et al.*, 1995). Second, Cochrane (1995) proposed to insure premium risk by a separate insurance that pays an indemnity to individuals who become a high risk ('premium insurance'). However, both of these market solutions suffer from problems. Guaranteed renewable contracts lock consumers in, which means that they will be unable to switch to another insurer in case they are dissatisfied with the service. (Thus, the case for government intervention ultimately rests on the assumption of nontransparent product quality.) Premium insurance contracts are likely to be incomplete because it is difficult to define the risk type with sufficient precision. Thus, SHI with community rating may be the only appropriate solution for the problem of reclassification risk.

Altruism and free riding

Altruistic rich members of society may be willing to subsidize the provision of healthcare to the poor if they are more interested in the health than in the subjective well-being of the poor – a case of interdependent preferences. Private charity is not suitable to achieve an efficient allocation as donations to the poor, whether in cash or in kind, have a public-good

 doi:10.1016/B978-0-12-375678-7.00907-X

characteristic because they increase the utility not only of the donor but also of other altruistic members of society. The free rider problem of potential donors could be solved either by a tax-financed National Health Service or a specific system with free healthcare for the poor (such as Medicaid) or an SHI with compulsory membership and contributions according to the ability to pay.

Externalities from medical care

Besides the 'psychological' externalities described in Section Altruism and free riding, there are physical externalities involved in some types of medical care, in particular in the treatment and isolation of patients with contagious diseases as well as in vaccination services. However, given the limited extent of infectious diseases, it is questionable if these effects are a sufficient rationale for SHI or if there is a weaker interference in free markets such as the subsidization of vaccines.

Optimal taxation when health and income are correlated

A related justification of SHI is derived from the theory of optimal taxation. If abilities cannot be observed by tax authorities, the extent to which income taxation can be used for redistribution from the high skilled to the low skilled is limited because the high skilled can always 'mimic' the low skilled by reducing their labor supply. However, if there is a negative correlation between ability and the risk of illness, a mandatory SHI with community rating implicitly redistributes between the ability groups in the desired fashion and thus improves social welfare. It must be emphasized, however, that this justification departs from Paretian welfare economics by postulating a specific redistributive goal.

Social Health Insurance and Equity

A further and perhaps the most compelling justification, also known as the 'principle of solidarity' relates to the achievement of equality of opportunity: people differ in their health risk already at birth, and some indicators of risk are readily observable. Moreover, with the rapid progress of genetic diagnostics and the spread of tests during pregnancy, the ability to measure individual health risks of newborns will become more and more pronounced. In PHI, these differences in risk immediately translate into differences in premiums so that those persons who are endowed by nature with a lower stock of 'health capital,' and are thus already disadvantaged, have to pay a higher price for the same coverage on top of this. Behind the veil of ignorance, one would desire at least an equalization of the monetary costs of illness.

There are in principle two ways to achieve solidarity in health insurance. First, PHI premiums can be subsidized for those who would have to pay excessive contributions. The transfer could be on a current basis or a lump sum, equal to the estimated present value of future excess premiums over the whole expected lifespan of beneficiaries. Both have the important advantage of permitting full competition in PHI (or SHI), including insurers acquiring information about true risk. Besides means testing and the need to define a benchmark contract to determine the amount of the subsidy, the second variant has the disadvantage of shifting the risk of longevity to beneficiaries. The second alternative is a compulsory SHI scheme with open enrollment and community rating that prevents differences in health risk from being translated into differences in contributions but, if combined with a competitive structure, induces cream skimming and therefore requires risk adjustment schemes (RAS; see Section Competition in Social Health Insurance) as a secondary neutralizing regulation.

The Design of the Benefit Package of Social Health Insurance

The efficiency reasons given above for the existence of SHI with compulsory membership can be convincing only if the design of the SHI contract is in some sense 'optimal' from the point of view of some 'representative' consumer. The most important design feature is the depth of coverage or, more precisely, the use of copayment provisions in SHI design. What are the main reasons justifying deviations from full coverage?

Administrative costs

Copayment provisions can be called for to keep administrative costs low such as costs of handling claims. For this reason, and assuming expected utility maximization on the part of consumers, it is optimal to exclude partially or entirely expenditures on healthcare items that occur frequently but in limited amounts such as minor medications. More specifically, if administrative costs are proportional to the expected volume of health expenditures, a feature of the optimal insurance contract is a fixed deductible, which serves to equalize marginal utility of disposable income in all insured states of the world. Only in the absence of administrative costs would the optimal deductible be zero. However, in some SHI systems such as the German one, doctors and hospitals are paid directly by the sickness funds and the payment is only weakly related to the volume of services provided so that the handling of individual claims from the insured person by the sickness fund is not necessary and thus this reason is irrelevant.

Noninsurable loss

Illness typically involves not only monetary costs but also nonmonetary losses such as pain and suffering. Optimal health insurance equalizes marginal utility of wealth in all states of nature but this is not equivalent to full coverage if there are complementarities between nonmonetary and monetary losses. In particular, if marginal utility of wealth is lower in case of illness than in good health (e.g., due to reduced ability to enjoy expensive types of consumption), optimal health insurance does not fully reimburse the monetary loss. Although some papers find that marginal utility of consumption is higher in case of sickness, the bulk of the evidence points in the opposite direction, thus supporting the use of copayments for this reason.

Ex ante *moral hazard*

If the insurer cannot observe preventive effort on the part of the insured, a high degree of coverage reduces the incentive for prevention. Hence, there is a trade-off between risk spreading through insurance and maintaining incentives to keep the risk

of illness low. This trade-off leads to a premium function which is convex in the degree of coverage, such that full coverage should be particularly expensive. In SHI such a premium function is nowhere observed, although it could be easily administered because consumers cannot circumvent the convex schedule by purchasing many insurance contracts with limited coverage and low premiums. One reason may be that this type of moral hazard is small due to the nonmonetary costs of illness. Moreover, empirical evidence suggests that people with health insurance live healthier lifestyles, although this may be due to a selection effect. Finally, a system of taxes on harmful and subsidies on healthy consumption goods may be a better alternative (Arnott and Stiglitz, 1986).

A different reasoning applies for prevention through medical services, whose costs can themselves be included in an insurance contract although their occurrence is not a random event. Ellis and Manning (2007) showed that it is efficient to include at least partial reimbursement for preventive services in SHI coverage to align privately optimal demand for these services with the social optimum, which considers the effect of prevention on the premium. In particular, the coverage rate for preventive services should be higher the lower the coinsurance is on treatment (so insurance for treatment and prevention are complementary) and the more risk-averse consumers are.

Ex post *moral hazard*

If the insurer could observe the health status of the insured, the optimal type of health insurance would provide indemnity payments, i.e., the insurance payment would not depend on the insured's healthcare expenditure. With asymmetric information, however, linking reimbursement to expenditure is inevitable. Still, copayment provisions are needed to fend against overconsumption of medical care. The optimal copayment rate is higher the more price elastic is the demand for the particular type of medical services. Empirical evidence, for example, from the research and development health insurance study, shows that there is a small, albeit statistically significant, price elasticity of demand for most medical services.

Competition in Social Health Insurance

In an unregulated PHI market, high risks pay higher premiums for the same level of coverage than do low risks. Community rating in SHI prevents this, making 'cream skimming' attractive, which in turn runs counter to the aim of open enrollment.

Risk selection can take different forms. Health insurers perform direct risk selection if they influence directly who signs a contract. For example, insurers may 'lose' the contract form handed in by a person deemed expensive. Individuals who can be expected to be profitable for the insurer can be encouraged to sign a contract by offering them supplementary services at a discount or, in the extreme case, outright payments.

Indirect risk selection, however, consists in designing benefit packages or by contracting with service providers who are attractive for low risks but unattractive for high risks. In particular, insurers may design their benefit package to attract low but not high risk. An example is a contract with a deductible. This is more appealing for low than for high risks as they face a lower probability of becoming ill and, therefore, of having to pay the deductible. The same reasoning applies to the design of the benefit package in general. For instance, an insurer who covers only few services for patients suffering from diabetes can expect these high risks to prefer another insurer. A straightforward counterstrategy is to impose a maximum deductible and a minimum benefit package. This may not be sufficient, however, because insurers can still try to attract low risks by writing policies with ample coverage of athletic medicine and well-baby care. If these benefits are included in the mandatory package, they will also have to be financed by high risks who have no interest in them (Kifmann, 2002). It may therefore be necessary to specify a maximum benefit package as well.

There are a number of options for complementary regulation designed to limit risk selection. The first is a central fund running an RAS, which pays to the insurer the difference between the expected healthcare cost of the insured and of the average of the respective population. *Ex ante* equalization of expected healthcare expenditures has the crucial advantage of preserving incentives for cost control but is restricted by the availability of data needed to determine payments from the fund. An alternative are cost-reimbursement schemes. These can be based on total cost, costs by service type, and individual healthcare expenditure. In the latter case, the individuals whose healthcare expenditure is reimbursed can be determined prospectively or retrospectively. Various functional forms of reimbursement can be employed. For example, regulation may prescribe a high-risk pool, in which expenditures of the x% most expensive insured (which are identified on the basis of past experience) are covered by the central fund (Van Barneveld *et al.*, 1996). By contrast, Kifmann and Lorenz (2011) found with data of a Swiss health insurer risk selection can most effectively be prevented if costs are reimbursed only up to a limit.

Income-Related versus Flat Contributions

A second feature of SHI which is under scrutiny is the base on which contributions are levied, where the choice is:

1. between income-related and flat contributions, and, in the first case;
2. on which types of income should be included:
   a. only earnings, or
   b. income from all sources,

and whether or not an income ceiling shall apply.

Presently, all countries with an SHI system except Switzerland levy contributions only on the basis of labor income. (In the Netherlands, the employer's share of 50% is levied on labor earnings, whereas the employees pay a flat fee.) Historically, this was an application of the principle of equivalence between contributions and benefits as long as the majority of benefits consisted of income replacement in times of sickness. In the meantime, with the rise in scientific medicine throughout the twentieth century the percentage of income replacement in total health insurance expenditures has dropped to the single digits so that this justification is no longer valid.

Nowadays, health insurance benefits are virtually the same for all members (except for differences in risk discussed in Section Social Health Insurance and Equity), and thus income-related contributions constitute pure income redistribution between high and low earners. A possible justification would be the principle of ability to pay. But this is very imperfectly measured if only labor income is taken into account, in particular with the declining share of labor earnings in national income in recent years. Moreover, wage-related contributions imply a significant additional tax on labor, and therefore distort the labor-leisure choice as well as the decision whether to work in the official sector or in the shadow economy. These important disadvantages have to be weighed against a single argument in favor of this particular contribution base, viz. the low costs of collecting the contributions at the source, i.e., as a payroll tax from the employer.

Besides the efficiency reasons just mentioned, there are additional arguments for uncoupling health insurance contributions from income. In particular, the decision making on copayments and other features of the benefit package is distorted if contributions are differentiated according to income: low-income persons have an incentive to opt for 'too much' insurance coverage whereas the opposite is true for high-income voters.

The only European country with flat contributions is Switzerland, whereas the Netherlands have a mixed system in which the employer's contribution is wage related and the employee's contribution is flat. However, even in Switzerland, effective contributions are not completely independent of income from the point of view of the insured, because low-income households receive a so-called 'premium subsidy.' This subsidy varies from canton to canton and covers that part of the total premium of household members which exceeds x% of household income (where x is usually between 7 and 10). Thus effectively, the total contribution amounts to x% of income up to an income ceiling that depends on the number and age of household members and can be calculated as total contribution divided by x. Thus, this system has the same effects like an income-dependent contribution in which total income from all sources is taken into account.

It is sometimes argued that the volume of premium subsidies, which have to be financed from general taxation, will place an enormous stress on the government budget and will therefore be a constant matter of political debate.

Therefore, a better and politically more stable method for compensating the losers from a transition to flat contributions could be a general reform of the tax transfer system, in which social assistance transfers and child allowances are increased and the income tax schedule is appropriately changed (higher initial tax exemption and higher marginal tax rates) so that the pure income redistribution, which is now implicit in the system of health insurance contributions, is performed within the general budget but now with a broader tax base.

Positive Theory: The Political Economy of Social Health Insurance

Having discussed normative theories of the design of SHI, it is important to assess what can be expected from political decisions in democracies. In particular, the theory should explain:

1. the apparent lack of generosity of the benefit package of SHI, characterized by the massive use of nonprice rationing methods and the simultaneous presence of private financing of supplementary healthcare services; and
2. the widespread phenomenon of financing SHI with income-dependent contributions (or taxes) and no risk-rated premiums, in which there is a twofold redistribution from the low to the high risks and from high to low earners.

As to the first point, several models have been put forward (e.g., by Breyer, 1995; Gouveia, 1997), which show that under plausible assumptions on preferences, the majority of voters will support a two-tier system in which citizens can top up their SHI coverage with PHI (for an opposite result, cf. Hindriks and De Donder, 2003). This is a typical 'ends-against-the-middle' result because the groups of voters who are in favor of a small SHI system are members of the lowest and highest income brackets, whereas middle- and high-income earners end up buying supplementary coverage.

To the second point, Kifmann (2005) showed that there can be majority support for a system with income-dependent contributions if the choice of regime is taken at the 'constitutional stage,' i.e., before the individuals know their health risk, whereas the details of SHI are decided at a later stage after risk types have been revealed. Then even a high earner can vote in favor of a redistributive SHI if the alternative is private insurance with risk-rated premiums and no insurance against a deteriorating risk type over time. This is particularly likely if individuals are sufficiently risk averse and the premiums in a system with risk rating sufficiently dispersed, whereas income inequality in the society should not be too extreme to make the implicit income redistribution too expensive for the high earners. This may explain why in many countries with SHI, contributions are levied only on labor incomes and even on those only up to a ceiling to limit the volume of income redistribution. However, separating 'pure' income redistribution from SHI through flat premiums may be more efficient, but not politically feasible because in such a system the political support for SHI with a generous benefit package, which comes only from the high-risk group, may be too small.

Spatial Econometrics: Theory and Applications in Health Economics

F Moscone and E Tosetti, Brunel University, Uxbridge, UK

Glossary

Cross-section dependence This is the dependence among population units, such as individuals, households, cities, industries or countries, in a given cross-section.

Panel data A panel data set is one that follows a given sample of individuals over time, and thus provides multiple observations on each individual in the sample.

Introduction

Spatial econometrics is concerned with measuring and modeling the correlation of observations generated by the inherent spatial structure of the data (Anselin, 1988). Such correlation, known as spatial dependence, may arise from local interaction of individuals, or from unobserved characteristics that are concentrated across space and that affect the variable of interest.

In health economics, spatial dependence may occur, for example, because individuals seek advice by speaking with neighbors regarding a variety of decisions concerning their health: the treatment to be purchased, the hospital wherein to be admitted, the diet to be undertaken. Local interaction can thus lead to an emergent collective behavior that empirically translates into a structure correlation among statistical units in the data. Spatial dependence may also arise if health providers engage in some forms of local strategic interactions, perhaps due to oligopolistic positions or agglomeration economies, when deciding the price to charge or the quality of health services to supply. At aggregate level of analysis, spatial correlation is likely to be present in the data if the investigator cannot observe important risk factors affecting the variable of interest, such as air pollution, migration, and criminality, which could be linked to regional rather than simply local trends, influencing prevalence and need across a wide geographical area. Spatial correlation can also be caused by a variety of measurement problems often found in applied work, or by the particular sampling scheme used to select units. An example is the lack of concordance between the delineation of observed spatial units, such as the region or the country, and the spatial scope of the phenomenon under study (Anselin, 1988). When the sampling scheme is clustered, potential correlation may also arise between respondents belonging to the same cluster. Indeed, units sharing observable characteristics, such as location or industry, may also have similar unobservable characteristics that would cause the regression disturbances to be correlated (Moulton, 1990).

This article provides a survey of econometric methods that are proposed to deal with spatial dependence in the context of linear panel data regression models. It then illustrates the application of spatial econometric methods to tackle problems in health economics. The discussion on these techniques is confined to linear panels with continuous dependent variable, whereas spatial discrete choice models will not be reviewed. Further, owing to space limitations, nonparametric methods for estimation of spatial models will not be discussed.

The plan of the remainder of the article is as follows. Section Spatial Weights and the Spatial Lag Operator introduces the notions of spatial weights and spatial lag. Sections Spatial Dependence in Panel Data Models, Estimation and Heterogenous Panels provide a review of spatial models and discuss their estimation under strictly exogenous regressors, whereas dynamic spatial models are treated in Section Dynamic Panels with Spatial Dependence. Section Testing for Spatial Independence introduces testing for spatial independence. Applications in health economics problems are reviewed in Section Applications of Spatial Econometrics in Health Economics, and Section Concluding Remarks concludes the article.

Spatial Weights and the Spatial Lag Operator

In spatial econometrics, the neighbor relation is typically expressed by the means of a nonnegative matrix, known as spatial weights matrix. In a spatial weights matrix, often indicated by W, the rows and columns correspond to the cross-section observations (e.g., individuals, regions, or countries), and the generic element, $w_{ij,}$ can be interpreted as the strength of potential interaction between units i and j. The specification of W is generally arbitrary, typically based on some measures of distance between units, using, for example, contiguity or geographic proximity, or more general metrics, such as economic, political, or social distance. To avoid nonlinearity and endogeneity problems, spatial weights should be exogenous to the model, a condition that is not guaranteed when using more general distance metrics. By convention, the diagonal elements of the weighting matrix are set to 0, implying that an observation is not a neighbor to itself. Further, to facilitate the interpretation of estimates in spatial models, W is typically row-standardized so that the sum of the weights for each row is 1, ensuring that all the weights are between 0 and 1. Finally, although most empirical works assume that weights are time-invariant, these can vary over time.

An important role in spatial econometrics is played by the notion of spatial lag operator. Let z_{it} be the observation on a variable for the ith cross-section unit at time t for $i=1, 2,\ldots, N$; $t=1, 2,\ldots, T$. Let $z_t=(z_{1t}, z_{2t},\ldots, z_{Nt})'$, and $W=\{w_{ij}\}$ be a time-invariant $N\times N$ spatial weights matrix. The spatial lag of z_t is given by Wz_t, with generic ith element

$$\sum_{j=1}^{N} w_{ij}z_{jt}$$

Hence, a spatial lag operator constructs a new variable, which is a weighted average of neighboring observations, with

weights reflecting distance among units. The incorporation of these spatial lags into a regression specification is considered in the next section.

Spatial Dependence in Panel Data Models

Spatial Lag Models

Several problems in the social sciences require the inclusion in the regression model of spatial lags of the dependent variable among the regressors. Under this specification,

$$y_{it} = \alpha_i + \rho \sum_{j=1}^{N} w_{ij} y_{jt} + \beta' x_{it} + u_{it}, \quad i = 1, 2, \ldots, N; \quad t = 1, 2, \ldots, T \qquad [1]$$

where x_{it} is a $k \times 1$ vector of observed regressors on the ith cross-section unit at time t, u_{it} is the error term, and ρ and β are unknown parameters to be estimated. The group effects, α_i, could be either considered fixed, unknown parameters to be estimated, or draws from a probability distribution. Section Estimation will discuss estimation under these two alternative frameworks. For the time being, it is assumed that regressors are strictly exogenous, and nonstochastic.

It is often convenient to rewrite eqn [1] in stacked form:

$$y_t = \alpha + \rho \mathrm{W} y_t + X_t \beta + u_t \qquad [2]$$

where $y_t = (y_{1t}, y_{2t}, \ldots, y_{Nt})'$, $\alpha = (\alpha_1, \alpha_2, \ldots, \alpha_N)'$, $X_t = (x_{1t}, x_{2t}, \ldots, x_{Nt})'$, and $u_t = (u_{1t}, u_{2t}, \ldots, u_{Nt})'$. Under certain asymptotic conditions on the spatial weights matrix, the correlation between the spatial lag of the dependent variable, $\mathrm{W}y_t$ and the error term, u_t, is nonzero, if $\rho \neq 0$. For this reason, conventional estimators of parameters ρ and β are inconsistent, and alternative estimation approaches, such as maximum likelihood (ML) and generalized method of moments (GMM), are needed.

Spatial Error Models

Another way to incorporate spatial dependence in the regression equation is by allowing disturbances to be spatially correlated. Consider the simple linear regression in stacked form:

$$y_t = \alpha + X_t \beta + u_t \qquad [3]$$

where the notation is as above. There exist few main approaches to assign a spatial structure to the error term u_t (as seen in Section Fixed effects specification, if α is assumed to be random, then a spatial structure could also be assigned to it); the intent is to represent the covariance as a simpler and lower dimensional matrix than the unconstrained.

One way is to define the covariance between two observations directly as a function of the distance between them. Accordingly, the covariance matrix for the cross-section at time t is $E(u_t u_t') = f(\theta, \mathrm{W})$, where θ is a parameter vector and f is a suitable distance decay function, such as the negative exponential. The decaying function suggests that the disturbances should become uncorrelated when the distance separating the observations is sufficiently large. One shortcoming of this method is that it requires the specification of a functional form for the distance decay, which is subject to a degree of arbitrariness.

An alternative strategy consists of specifying a spatial process for the error term, which relates each unit to its neighbors through W. The most widely used is the Spatial Autoregressive (SAR) specification. Proposed by Cliff and Ord (1969), the SAR process is

$$u_t = \delta \mathrm{W} u_t + \varepsilon_t \qquad [4]$$

where δ is a scalar parameter, and $\varepsilon_t = (\varepsilon_{1t}, \varepsilon_{2t}, \ldots, \varepsilon_{Nt})'$, with $\varepsilon_{it} \sim IID(0, \sigma_\varepsilon^2 \mathrm{I}_N)$. Other spatial processes suggested to model spatial error dependence, although less used in the empirical literature, are the Spatial Moving Average (SMA) and the Spatial Error Component (SEC) specifications. The first, proposed by Haining (1978), assumes that

$$u_t = \delta \mathrm{W} \varepsilon_t + \varepsilon_t \qquad [5]$$

where ε_t is as above. According to the SEC specification, introduced by Kelejian and Robinson (1995),

$$u_t = \delta \mathrm{W} \psi_t + \varepsilon_t \qquad [6]$$

where $\psi_t = (\psi_{1t}, \psi_{2t}, \ldots, \psi_{Nt})'$ and $\psi_{it} \sim IID(0, \sigma_\psi^2)$. A major distinction between the SAR and the other two specifications is that in the first there is an inverse involved in the covariance matrix. This has important consequences on the range of dependence implied by its covariance matrix. Indeed, even if W contains few nonzero values, the covariance structure induced by the SAR is not sparse, linking all the units in the system to each other, so that a perturbation in the error term of one unit will be ultimately transmitted to all other units. Conversely, for the SMA and SEC, the only off-diagonal nonzero elements of the covariance matrix are those corresponding to nonzero elements in W. Under certain invertibility conditions, spatial processes eqns [4]–[6] can all be written as special cases of the following general form

$$u_t = R \varepsilon_t \qquad [7]$$

where R is a $N \times N$ matrix. For example, for an invertible SAR process $R = (I_N - \delta \mathrm{W})^{-1}$, whereas in the case of an SMA, $R = I_N + \delta \mathrm{W}$.

Conventional panel estimators such as the fixed effects (FE) or random effects (RE) estimators of slope coefficients in eqn [3] with spatially dependent errors are $\sqrt{NT}$-consistent under broad regularity conditions and strictly exogenous regressors. However, these estimators are in general not efficient because the covariance matrix of errors is nondiagonal and the elements along its main diagonal are not constant.

Estimation of spatial models is considered next.

Estimation

Maximum Likelihood Estimator

The theoretical properties of quasi-ML estimator in a single cross-section framework have been studied by Anselin (1988) and Lee (2004), among others. More recently, considerable work has been undertaken to investigate the properties of ML

estimators in panel data, in the presence of spatial dependence and unobserved time-invariant heterogeneity.

Fixed effects specification

For ML estimation of spatial regression models, it is convenient to consider the general case of a spatial lag model having SAR errors:

$$y_t = \alpha + \rho W_1 y_t + X_t\beta + u_t \quad [8]$$

$$u_t = \delta W_2 u_t + \varepsilon_t \quad [9]$$

where the spatial lags in the dependent variable and in the error term are constructed using two (possibly different) spatial weights matrices, W_1 and W_2. Suppose that the group effects are treated as fixed and unknown parameters, and that $\varepsilon_{it} \sim IID(0,\sigma_\varepsilon^2)$ Lee and Yu (2010a) propose a transformation of the above model to get rid of the FE, and then use ML to estimate the remaining parameters, ρ, β, δ, and σ_ε^2. Specifically, the authors suggest to multiply all variables by a $T\times(T-1)$ matrix, P, having as columns, the $(T-1)$ eigenvectors associated to the nonzero eigenvalues of the deviation from the mean transformation, $M = I_T - 1_T\left(1_T'1_T\right)^{-1}1_T'$, where 1_T is a T-dimensional vector of 1. It is easily seen that $1_T'P = 0$ so that such transformation removes the individual-specific intercepts. After the transformation, the effective sample size reduces to $N(T-1)$, and because $P'P = I_{T-1}$, the new error term has uncorrelated elements. Under some identification conditions, the estimator of the unknown parameters, obtained by maximizing the transformed model's log-likelihood function, is consistent and asymptotically normal when either N or T, or both, are large.

Random effects specification

This formulation assumes that the group effects, α_i, are random and independent of the exogenous regressors. In this case, following Baltagi *et al.* (2009), a general specification can be suggested by assuming that spatial processes apply both to the random group effects and the remainder disturbances:

$$y_t = \rho W_1 y_t + X_t\beta + v_t \quad [10]$$

$$v_t = \alpha + u_t \quad [11]$$

$$\alpha = \gamma W_2 \alpha + \mu \quad [12]$$

$$u_t = \delta W_3 u_t + \varepsilon_t \quad [13]$$

where $\mu = (\mu_1, \mu_2, \ldots, \mu_N)'$, and it is assumed that $\mu_i \sim IID(0,\sigma_\mu^2)$ and $\varepsilon_{it} \sim IID(0,\sigma_\varepsilon^2)$. The above model, by distinguishing between time-invariant spatial error spillovers and spatial spillovers of transitory shocks, encompasses a variety of econometric specifications that are proposed in the literature as special cases. If the same spatial process applies to α and u_t (i.e., $\delta = \gamma$ and $W_2 = W_3$), this model reduces to that proposed by Kapoor *et al.* (2007); if $\gamma = 0$, it simplifies to that considered by Baltagi *et al.* (2003).

Consistency of estimator for the unknown parameters based on maximization of the model's log-likelihood is established in Baltagi *et al.* (2009). A set of joint and conditional specification Lagrange Multiplier (LM) tests for spatial effects within the RE framework are proposed by Baltagi *et al.* (2009). These statistics allow testing model (10)–(13) against their restricted counterparts: the Anselin model, the Kapoor *et al.* models, and the RE model without spatial correlation.

Instrumental Variables and GMM

In the presence of heteroskedasticity, the ML estimator for spatial models under the incorrect assumption of spherical disturbances is generally inconsistent. As an alternative, instrumental variables (IV) and GMM techniques have been suggested.

In a single cross-section setting, Kelejian and Prucha (1998) propose a simple IV strategy to deal with the endogeneity of the spatially lagged dependent variable Wy_t that consists of using as instruments, the spatially lagged (exogenous) explanatory variable WX_t. The IV approach can be easily adapted in the context of spatial panel data models with either FE or RE. Hence, the Hausman's specification test can be used to choose between FE and RE specification (Mutl and Pfaffermayr, 2011).

GMM estimation of spatial regression models for a single cross-section has been originally advanced by Kelejian and Prucha (1999). The authors focus on a regression equation with SAR disturbances and suggest the use of three moment conditions that exploit the properties of disturbances implied by a standard set of assumptions. Estimation consists of solving a nonlinear optimization problem, which yields a consistent estimator under a number of regularity conditions. Considerable work has been carried to extend this procedure in various directions. Liu *et al.* (2010) suggest a set of moments that encompass Kelejian and Prucha conditions as special cases. Kelejian and Prucha (2009) generalize their original work to include spatial lags in the dependent variable and allowing for heteroskedastic disturbances. This setting is extended by Kapoor *et al.* (2007) to estimate a spatial panel regression model with group error components and by Moscone and Tosetti (2011) for a panel with fixed effects. One advantage of the GMM procedure over ML is that it is computationally simpler, especially when dealing with unbalanced panels.

Heterogenous Panels

For panel data studies with large N and small T, observations are usually pooled and homogeneity of the slope coefficients is assumed. The latter is a testable assumption, which is often rejected in practice. A recent literature argues in favor of heterogenous estimates and suggests the following specification with heterogenous slopes

$$y_{it} = \alpha_i' d_t + \beta_i' x_{it} + u_{it} \quad [14]$$

where $d_t = (d_{1t}, d_{2t}, \ldots, d_{nt})'$ is a $n\times 1$ vector of observed common effects (e.g., a time trend), x_{it} is a k-dimensional vector of strictly exogenous regressors, and β_i follow the random coefficient model $\beta_i = \beta + v_i$, with $v_i \sim (0,\Omega_v)$. It is further

assumed that errors are generated by a spatial process having form (7), such as SAR, SMA, or SEC, where ε_t follows a covariance-stationary process. Pesaran and Tosetti (2011) focus on estimation of the cross-section means of parameters, $\beta = E(\beta_i)$, by conventional FE estimator, and by the following mean group estimator

$$\hat{\beta}_{MG} = N^{-1} \sum_{i=1}^{N} \hat{\beta}_i \qquad [15]$$

where

$$\hat{\beta}_i = \left(X_i' M_D X_i \right)^{-1} X_i' M_D y_i$$

$y_i = (y_{i1}, y_{i2}, \ldots, y_{iT})'$, $X_t' = (x_{i1}, x_{i2}, \ldots, x_{iT})$, $M_D = I_T - \mathrm{D}(D'D)^{-1} D'$, and $D' = (d_1, d_2, \ldots, d_T)$. The authors show that under some regularity conditions, as N and T tend to infinity, $\hat{\beta}_{MG}$, the asymptotic distribution of $\hat{\beta}_{MG}$, (as well as that of the conventional FE estimator) does not depend on the particular spatial structure of the error, u_{it}, but only on Ω_v. Robust estimators for the variances of $\hat{\beta}_{MG}$ can be obtained following the nonparametric approach employed in Pesaran (2006). One advantage of this method is that it does not require *a priori* knowledge of the spatial arrangement of cross-sectional units. Indeed, misspecification of the spatial weights matrix may lead to substantial size distortions in tests based on the quasi-ML estimators of β_i (or β).

Temporal Heterogeneity

Temporal heterogeneity may be incorporated in a spatial version of the Seemingly Unrelated Regression Equations (SURE) approach, as suggested by Anselin (1988). This approach, suitable when N greatly exceeds T, permits slope parameters to vary over time, and errors are allowed to be both spatially and serially correlated. In its more general form, the spatial SURE is

$$y_t = \rho_t \mathrm{W}_1 y_t + X_t \beta_t + u_t \qquad [16]$$

$$u_t = \delta_t W_2 u_t + \varepsilon_t \qquad [17]$$

where β_t, ρ_t, and δ_t are time-varying parameters, and ε_t satisfies $E(\varepsilon_t \varepsilon_s') = \sigma_{ts} I_N$. Let Ω be a $T \times T$ positive definite matrix with elements σ_{ts}. ML or GMM techniques can be used to estimate the above model.

Dynamic Panels with Spatial Dependence

In the recent years, considerable work has been undertaken on estimation of panel data models that include both spatial and temporal dynamics. A variety of spatiotemporal models have been proposed in the literature. Consider the following general dynamic spatial panel:

$$y_t = \alpha + \gamma y_{t-1} + \rho \mathrm{W} y_t + \lambda \mathrm{W} y_{t-1} + X_t \beta + u_t \qquad [18]$$

The above model can be classified into different cases depending on the eigenvalue matrix of its reduced form. In particular, eqn [18] is stable if $\gamma + \rho + \lambda < 1$; spatial cointegration takes place when $\gamma + \rho + \lambda = 1$; whereas under the explosive case, $\gamma + \rho + \lambda > 1$. Under $\gamma + \rho + \lambda < 1$, Yu *et al.* (2008) derive the ML of the FE specification, showing that when T is large relative to N, the estimators are consistent and asymptotically normal, whereas when $N/T > 0$, the limit distribution is not centered around 0, in which case, the authors propose a bias correction. Under $\gamma + \rho + \lambda = 1$, the ML estimator is consistent and asymptotically normal as in the stationary case, although spatial cointegration yields a singular asymptotic covariance matrix for the ML estimator. When $\gamma + \rho + \lambda > 1$, the ML is not tractable, although it turns tractable after applying a transformation that renders stable, the explosive variables (Lee and Yu, 2010b).

Testing for Spatial Independence

Spatial econometrics literature proposes a number of statistics for testing the null hypothesis of spatial independence, i.e., $H_0 : E(u_{it} u_{jt}) = 0, \; i \neq j$ in Model (3). The majority of these tests have been studied only in the case of a single cross-section. One of the most commonly used is the Moran's statistic (Kelejian and Prucha, 2001), which, when extended to a panel set up, takes the form

$$CD_{\mathrm{Moran}} = \frac{\sum_{t=1}^{T} \hat{u}_t' \mathrm{W} \hat{u}_t}{\left(T \hat{\sigma}_\varepsilon^4 \sum_{i=1}^{N} \sum_{j=1}^{i-1} \left(w_{ij} + w_{ji} \right)^2 \right)^{1/2}} \qquad [19]$$

where $\hat{\sigma}_\varepsilon^2$ is a consistent estimator for σ_ε^2, and $\hat{\mathrm{u}}_t$ is a consistent estimator of regression errors. The CD_{Moran} is asymptotically normally distributed.

The information on the distance among units can also be used to build 'local' versions of some statistics as proposed in the panel literature to test against generic forms of cross-section dependence. For example, the local CD_P test proposed by Pesaran (2004) is

$$CD_{P,\mathrm{Local}} = \sqrt{\frac{T}{S_0}} \left(\sum_{i=1}^{N} \sum_{j=1}^{N} w_{ij} \hat{\rho}_{ij} \right) \qquad [20]$$

where $S_0 = \sum_{i=1}^{N} \sum_{j=1}^{N} w_{ij}$, and $\hat{\rho}_{ij}$ is the sample pairwise correlation coefficient computed between FE residuals of units i and j. The $CD_{P,\mathrm{Local}}$ test is asymptotically normally distributed. The reader is referred to Moscone and Tosetti (2009) for a review of this literature.

Applications of Spatial Econometrics in Health Economics

The methods described in this article have been employed to study a variety of problems in regional and urban sciences, geography, economics, crime analysis, environmetrics, epidemiology, and public health. The recognition of a marked geographical concentration for many health indicators has encouraged a wide use of spatial methods to analyze health economics issues. This section first illustrates empirical evidence on spatial concentration for a number of health indicators, and then considers works on local interaction among healthcare providers.

Health Outcomes, Risk Factors, and Health Needs

There exists a growing literature adopting spatial econometric methods to model geographical clustering of various health conditions such as health status and mortality, obesity, and diseases, both communicable, like poliomyelitis, influenza, and HIV, and noncommunicable, like diabetes, cardiovascular problems, and mental health disorders. Lorant *et al.* (2001) study the impact on mortality of deprivation, measured by the Townsend index, and of a set of socioeconomic indicators, in Belgium at municipality level from 1985 to 1993. The authors estimate a spatial lag model and find evidence of high significant spatial effects ($\rho = 0.6$) in mortality and of positive influence of deprivation on mortality. Chen *et al.* (2010) investigate the impact of access to chain grocers on body mass index (BMI) in Indiana (USA) in 2005. The authors estimate a spatial lag model by ML to control for possible 'obesity epidemic' effects, allowing the influence of access to chain grocers on BMI to differ depending on whether or not, a person lives in a low-income community. Empirical results suggest that improvement in access to chain grocer access significantly reduces the average BMI, in low-income communities. Congdon (2002) studies geographical variations in mental health outcomes proxied by hospital and community referrals for a set of diagnostic categories, using data on people living in a London health authority over the period 1994–99. Using Bayesian methods, the author derives an index of needs for mental health problems that includes spatial dependence and a set of sociodemographic variables, such as deprivation, community integration, and ethnicity. Hence, the author compares the forecasting performance of the developed index with that of traditional needs indices and shows that the forecast performance in predicting referrals improves consistently when accounting for spatial effects. One policy implication of the above studies is that formulae used to allocate healthcare resources across geographical areas could be ameliorated by incorporating spatial correlation.

Health Expenditure

Recent works in health economics and in the medical literature indicate that one important element explaining variations in health expenditure is represented by the spillover effect, that is, expenditure on health services in one locality can have beneficial or harmful effects across a wider geographical area. A number of factors can justify such wider effects. For example, a municipality may choose a particular course of action so as to persuade individual service users, families, or indeed service providing bodies, to migrate into or out of their area. Such flow can be encouraged by ensuring that health expenditure, clinical activity, or health policy is more (or less) attractive than that offered in neighboring authorities. Politicians may adopt this strategy as voters perhaps judge them relative to those in nearby localities. A municipality good (or bad) performance may encourage neighboring municipalities to mimic (or avoid) the activities and expenditure patterns associated with such performance.

A large number of papers have empirically tested the above hypotheses. One influential example is the work by Baicker (2005) that explores the extent to which health spending in one state is influenced by the spending in neighboring states. The author adopts IV and GMM approaches to estimate a spatial lag model for 48 contiguous US states, in the years from 1983 to 1992. One conclusion of this work is that states, in response to $1 increase in neighbors' expenditure, raise their own expenditure by almost a full dollar. The reader is referred to Revelli (2006) and Moscone *et al.* (2007) for studies on the UK. Recent studies investigate the long-run dynamics of health spending. For example, Moscone and Tosetti (2010), using a panel of 49 US States over the period 1980–2004, estimate a regression equation for health spending assuming that errors are spatially correlated and also depend on a set of unobserved common factors. The authors find evidence of sizeable spatial correlation in health spending even after controlling for unobserved effects.

A number of works look at healthcare resources consumption and utilization rather than expenditure. For example, Filippini *et al.* (2010) study the demand of antibiotics in 240 Swiss regions in 2002. The authors estimate a spatial error model to account for infection spreading and find that dispensing practices induce higher rate of antibiotic consumption, even after controlling for patient characteristics, epidemiological variables, access to drug treatment, and spatial dependence. Joines *et al.* (2003) investigate the determinants of hospital admission rates in California and find significant spatial effects in hospitalization rates.

Hospital Competition and Agglomeration

Mobley (2003) adopts spatial econometric methods to study hospital competition under managed care in the State of California in the years 1993 and 1998. The author considers a SURE model with spatial lags of the dependent variable and estimates it by ML. Empirical results show that the price charged by a hospital is affected by the price set by neighboring hospitals, suggesting that such information may be used to design antitrust policies. Moscone *et al.* (2011) study hospital competition exploring the determinants of patients' hospital choices, using 144 Italian hospitals in the years from 2004 to 2007. The authors conclude that the likelihood of choosing an hospital by an individual is significantly influenced by the experience in utilization of health services by patients living in the same postal code. However, the use of neighborhood information on average does not seem to lead patients to high quality hospitals. Cohen and Paul (2008) investigate why hospitals concentrate across territory, using data on 93 Washington state hospitals during 1997–2002. The authors estimate a system of cost function and input demand equations, which include an agglomeration variable as a cost shift factor, measured by the spatial lag of labor forces in neighboring hospitals. Results show significant agglomeration economies, perhaps due to cost saving generated by knowledge sharing with adjacent hospitals, labor market pooling, or lower employment search costs.

Concluding Remarks

This article has surveyed the most recent econometric methods for panel data dealing with spatial effects. Recent developments in spatial econometrics offer new methods for

representing the spatiotemporal dynamics of many health economics phenomena. However, the range of spatial techniques adopted until now in health economics is rather limited, when compared to the methods developed in the literature. For instance, only few works have incorporated in their specification time-invariant unobserved heterogeneity and/or temporal dynamics. The use of recently developed techniques in spatial econometrics may offer insights and raise new questions in several areas of health economics.

Specialists

DJ Wright, University of Sydney, Sydney, NSW, Australia

Introduction

Specialists have a unique position in the health system as they provide health-care services to patients and so are agents of patients, but in addition, they provide patients to, and order services from, other health-care providers (e.g., hospitals) and so are agents of other health-care providers as well. In the economics literature this situation is known as common agency. These two agency relationships are characterized by asymmetric information, in that patients have limited medical knowledge about the type of specialist to visit, the quality of any particular specialist, or the appropriate treatment, whereas hospitals have limited knowledge about the preferences of specialists over income and patient welfare.

In addition to having a unique position in the health-care system, specialists operate in a unique market. Patients' health-care expenditures are often covered by public or private insurance and so the demand for specialists' services is often not rationed by price. The payment that specialists receive for their services is either regulated by the public purchaser, the private insurer, or a private purchaser such as a Preferred Provider Organization or a Health Maintenance Organization. As a result, the quality and the quantity of services specialists provide depend very much on the incentives contained in their payment schemes.

In this environment, some interesting questions are: (1) what factors lead to particular specialty choices by doctors, (2) how are patients allocated between general practitioners and specialists, (3) is the quality and quantity of services provided by specialists efficient, and (4) how are specialists allocated between hospitals. These questions are addressed below.

The Allocation of Doctors

An important result in economics is the First Fundamental Theorem of Welfare Economics that states that competitive markets are efficient. A fundamental characteristic of competitive markets is free entry. However, entry into the medical profession is not free as places at medical schools are restricted by governments and entry into specialties is restricted by various professional bodies. As a result, the allocation of physicians between specialties is often inefficient. For example, in many countries, the market for specialties is characterized by excess supply, whereas the market for general practitioners is characterized by excess demand.

These inefficiencies have led researchers to investigate what factors are important in the specialty choice decision of doctors as these factors can then be manipulated to achieve a more efficient outcome. A number of US and Canadian studies have found that graduates of medical schools are more likely to choose specialties with less demanding workloads and higher expected income. In the US, the income elasticity of a particular specialty choice has been estimated to be 1.4, where the income elasticity of a particular specialty choice was defined as the percentage increase in the number of medical students who rank a particular specialty first associated with a 1% increase in expected income. In Canada, the income elasticity of any specialty choice (relative to general practice) has been estimated to be 0.2, where the income elasticity of any specialty choice was defined as the percentage increase in the number of physicians who chose any specialty (relative to general practice) associated with a 1% increase in the fee-per-consultation. Specialty choice is quite responsive to expected income. Therefore, policy makers can influence specialty and general practitioner choice through income differentials and by changing the work environment.

The Allocation of Patients

Patients with a medical condition have limited medical knowledge and so do not know whether a general practitioner (GP) or a specialist is needed to treat the condition. Even if patients knew they need to see a specialist, they do not know which type, for example, does a patient with chest pain need to see a cardiologist or a thoracic surgeon? To analyze the first situation, consider a model in which treatment by a specialist is more expensive than by a GP, but for some conditions treatment is only successful if completed by a specialist. In this latter case, if the GP treats the patient, the patient suffers a waiting loss as specialist treatment is delayed. To determine which type of condition the patient has required the GP to expend effort. In this environment, if specialist costs and patient waiting costs are high, then a gate-keeping system, in which patients must get a referral from a GP before seeing a specialist, is more efficient than a system in which referrals are not needed. Under gate-keeping, a GP payment scheme, which involves a bonus for nonreferral and another bonus for not providing treatment provides GPs with an incentive to undertake effort and only refer those patients with the condition that only specialists can treat. This saves on patient waiting costs and ensures that patients with the condition which is treatable by GPs are not referred to specialists. GP fund-holding, whereby GPs are given a budget from which they pay for a range of elective procedures for their patients, also provides incentives for GPs not to refer patients to specialists and hospitals as it acts like a bonus for nonreferral. However, this is at the cost of not referring patients who should be referred.

The second situation is similar to the first. In a gate-keeping system the GP makes a diagnosis and makes an informed decision about which type of specialist the patient should see. However, in a non gate-keeping system, the uninformed patient chooses which type of specialist to see and if they make an incorrect decision, they waste scarce specialist time and delay appropriate treatment. Where specialist costs are

high and delay in treatment is costly, a gate-keeping system dominates a non gate-keeping system.

Specialist Quality and Quantity of Care

The benefit a patient, who seeks diagnosis or treatment from a specialist, receives depends on the quality of care provided by the specialist, Q, the quantity of medical services delivered by the specialist, q, and the quantity of medical services the specialist orders from other health-care providers such as hospitals, q_0. Let this benefit be given by $B=B(Q,q,q_0)$, where benefit is increasing in all three variables. Patient benefit also depends on the quality of the services provided by other health-care providers, but this is outside the domain of the specialist. The cost of the specialist providing services is given by $C=C(Q,q)$ and the cost of the services provided by other care providers is $C_0=C_0(q_0)$. Both these costs are increasing in all variables. The efficient provision of quality occurs where the extra patient benefits a unit of quality generates equals the extra cost of providing that unit. A similar condition applies for the efficient provision of the quantity of specialist services and the quantity of services ordered from other health-care providers.

Illness is an uncertain event and potential patients are often covered by either private or public health insurance for any health expenditures they incur. The terms of these insurance contracts affect the decision to seek care from a specialist and then the specialist determines the quality and quantity of care once care has been sought. Therefore, the payment scheme that the public or private insurer offers to specialists and the incentives it contains will be a major determinant of the quality and quantity of specialist care.

If quality and quantity were observable and verifiable by courts, a contract between the public or private purchaser and the specialist could be written in which payment was conditional on a particular quality and quantity of service. Competition between private purchasers or maximization of welfare by the public purchaser would then ensure the efficient provision of quality and quantity of health care. However, although the quantity of services is observable and verifiable the same is not true of quality. The quality of a medical service has many dimensions, for example, the appropriate diagnosis of a patient's condition, the appropriate treatment given diagnosis, and appropriate pain management. These dimensions are likely to vary from condition to condition and from patient to patient and so are not easy to specify in a contract in a verifiable manner. Therefore, efficiency cannot be achieved by the writing of conditional payment contracts.

Although quality is not verifiable in courts, it nevertheless maybe be observable to patients. If patients can observe the quality of provider care and the demand for a particular provider is increasing in quality, it is well known that a prospective payment (a payment per patient) coupled with fee-for-service (a payment per service) can achieve efficient provision of provider quality and quantity of service. Essentially the fee-for-service is set to achieve the efficient provision of quantity and the prospective payment is set to achieve the efficient quality as providers compete for valuable patients.

For specialist services, the assumption that patients can observe quality is problematic. Patients in general have little or no information concerning what is the appropriate treatment. In addition, their relationship with specialists is often once-off and so they cannot use past experiences as an indicator of quality as they might do with other health-care providers with whom they have long-term relationships. As competition for patients cannot be relied upon to ensure efficient quality what institutions or avenues exist which might?

Institutions

Specialists need to be licensed to practice, but given evidence from the US that current specialist licensing arrangement guarantee nothing more than minimum specialist expertise and little specialist learning postmedical school, licensing does not provide an indication of specialist quality. In addition, specialist quality is not ensured through selfregulation as review boards fail to respond to patient complaints, and when they do, they rarely impose serious disciplinary sanctions.

Tort law is a vehicle through which specialists who are negligent are liable for any damage that results from not exercising due care. This gives specialists an incentive to maintain quality, but not a very strong one as evidence suggests patients are not very good at detecting negligence when it occurs.

Unlike patients, gate-keeping GPs do form long-term relationships with specialists. As a result, over time, they are able to monitor many patient outcomes from treatment by particular specialists and base referral decisions on these outcomes. This is an imperfect mechanism for ensuring specialist quality as GP referral decisions are not only based on past patient outcomes, but on other factors, for example, friendship. Furthermore, where GPs perfectly observe specialist quality and base their referrals only on quality, specialists have an incentive to overprovide quality to receive more referrals. This incentive to overprovide quality is mitigated if specialists are paid by a combination of a prospective payment and fee-for-service.

In summary, licensing, tort law, and GP gate-keeping provide only limited incentives for specialists to provide quality efficiently.

Specialist Preferences

An avenue for the efficient provision of quality and quantity exists if specialists not only value income, but also the welfare of their patients. Such altruism on the part of providers is thought to be an important characteristic of medical services. Therefore, it is assumed that specialist utility is given by $U=\alpha B(Q,q,q_0)+I-C(Q,q)$, where α is the weight the specialist attaches to patient welfare and I is income. Under the assumption that specialist payments are regulated in most countries by public or private purchasers, specialist income is assumed to consists of a prospective payment, P, and cost reimbursement of $r\cdot C(Q,q)$, where r is the proportion of cost that is reimbursed, that is, $I=P+r\cdot C(Q,q)$. It is assumed that cost is observable.

If the payment scheme involves only full-cost reimbursement, so that $P=0$ and $r=1$, specialist utility is $U=\alpha B(Q,q,q_0)$. The specialist maximizes utility by choosing quality so that the extra benefit the patient gets from an extra unit of quality is zero. The specialist is not concerned with the extra cost involved in providing an extra unit of quality as costs are fully reimbursed. Therefore, relative to the efficient quality, the specialist provides 'too much' quality. Similarly, the specialist provides 'too many' services and orders 'too many' services from other providers relative to the efficient quantities.

However, if the payment scheme involves only a prospective payment, so that $P>0$ and $r=0$, specialist utility is $U=\alpha B(Q,q,q_0)+P-C(Q,q)$. The specialist maximizes utility by choosing quality so that the extra benefit the patient gets from an extra unit of quality weighted by α equals the extra cost of providing that unit of quality. If the specialist values patient benefit and income equally, that is, if $\alpha=1$, then the specialist provides the efficient quality. However, if the specialist values patient benefit less than income, $\alpha<1$, then the specialist provides 'too little' quality relative to the efficient quality. Similarly, the specialist provides 'too few' services relative to efficient provision, but orders 'too many' services from other providers relative to efficient provision as the specialist bears none of the costs of the other providers' services.

Finally, if the payment scheme involves both a prospective payment and some cost reimbursement, so that $P>0$ and $r<1$, specialist utility is $U=\alpha B(Q,q,q_0)+P-(1-r)C(Q,q)$. The specialist maximizes utility by choosing quality so that the extra benefit the patient gets from an extra unit of quality weighted by α equals the extra cost of providing that unit of quality weighted by $1-r$. If r is chosen so that $r=1-\alpha$, then the specialist provides the efficient quality and also the efficient quantity of services. It is still the case that 'too many' services are ordered from other health-care providers.

So even though quality is not observed, a payment scheme, which is a mix of a prospective payment and partial cost reimbursement (supply-side cost sharing) is able to induce the specialist to provide the efficient quality and quantity of own services. Having patient welfare in the specialist utility function provides an incentive for the specialist to provide quality and reimbursing some of the cost of quality provision reinforces this incentive.

The costs of the specialist not only depend on quality and quantity, but also on the amount of unobservable cost reducing effort the specialist expends. In this case, specialist costs are given by $C(Q,q,e)$, where costs are decreasing in cost reducing effort e. The cost of this effort to the specialist is $v=v(e)$ and is increasing in effort. If the specialist payment scheme depends only on q and contains no cost reimbursement, specialist utility is $U=\alpha B(Q,q,q_0)+P(q)-C(Q,q,e)-v(e)$ and the specialist has strong incentives for cost reduction, but weak incentives for quality provision. However, if the specialist payment scheme involves some cost reimbursement, then specialist utility is $U=\alpha B(Q,q,q_0)+P(q)-(1-r)C(Q,q,e)-v(e)$, and the specialist has weak incentives for cost reduction, but strong incentives for quality provision. The optimal payment scheme involves some cost reimbursement as long as $\alpha<1$.

Different specialists have different degrees of altruism, different α's. In this case, it is optimal to offer a menu of payment schemes to specialists and allow each specialist to choose the one that is best for them. These payment schemes involve a fixed payment component and a cost reimbursement component with a greater fixed payment component being associated with a smaller cost reimbursement component. Specialists who are more altruistic choose a scheme with a greater fixed component and a smaller cost reimbursement component. This has intuitive appeal as more altruistic specialists have a greater incentive to provide quality and so are given strong incentives for cost reduction.

The consensus from this theoretical literature is that quality provision above some minimum amount ensured by licensing requirements, malpractice liability, or GP referral decisions requires specialists to value the welfare of patients. If specialists value patient welfare equivalently to their own income, then a prospective payment with no cost reimbursement attains efficient provision of quality and quantity. However, if specialists value patient welfare less than their own income, then regardless of whether costs depend on cost-reducing effort or not, the optimal payment scheme involves some degree of cost reimbursement. Full-cost reimbursement is not optimal as 'too much' quality is provided and 'too little' cost-reducing effort is undertaken.

Given the specialist values patient benefit, the specialist orders 'too many' services from other health providers. This is because the specialist bears none of the cost of these services. However, if the specialist values the welfare of patients and the other health provider's profit, then efficiency can be achieved. To help clarify the exposition, let the other health provider be a hospital. Assume the hospital is paid with a prospective payment and some cost reimbursement, then hospital profit is $\Pi=P-(1-r)C_0(q_0)$. Specialist utility is $U=\alpha B(Q,q,q_0)+\Pi$. If $\alpha<1$, and if the proportion of cost reimbursement is chosen so that $r=1-\alpha$, then the specialist orders the efficient quantity of services from the hospital. Here it is not how the specialist is paid that is fundamental, but rather how the hospital is paid. Once again, some cost reimbursement is optimal.

It should be noted that little has been written about an environment in which insured patients do not know specialist quality and specialist payments are unregulated.

Empirical Evidence Concerning Specialist Payment Schemes

Although the theory above suggested that efficiency of quality provision required at least some cost reimbursement, this is not how specialists are usually paid. In practise, specialists are paid in a number of ways including salary, fee-for-service, and combinations of both salary and fee-for-service. Salary is similar to a prospective payment in that it does not depend on the quantity of services delivered to a patient. Theory suggests it will induce 'too little' quality and 'too few' services relative to efficient provision. Fee-for-service involves a payment for each service delivered so depending on the level of the fee 'too little' or 'too many' services will be provided relative to efficient provision. If the fee is set greater than the extra benefit of an additional service at efficient provision weighted by $(1-\alpha)$, then too many services relative to efficient

provision will be provided. Fee-for-service will also induce 'too little quality.'

It is useful to think of Q and q as the amount of time the specialist devotes to quality and quantity provision, respectively, where quality is increasing in the time spent gaining and retaining expertise and quantity is increasing in the time spent delivering services. That is, the specialist devotes time to two tasks. The time devoted to both tasks in total is $Q+q$. Salary provides 'weak incentives' for quality and quantity provision, whereas fee-for-service provides strong incentives for quantity. Relative to payment by salary, with payment by fee-for-service the specialist provides a higher quantity as it is strongly rewarded and a lower quality as its marginal cost of provision has increased. Because quantity is higher and quality is lower, it is not clear whether the patient is better-off.

A number of empirical studies have examined quantity choices under various payment schemes. The usual finding is that the quantity of services provided by specialists is greater under payment by fee-for-service than under payment by capitation (a prospective payment, where the specialist receives a fixed payment per patient) or salary.

The predictions of the multitasking framework have also been examined empirically in an environment in which specialist have a choice between being paid by fee-for-service or by a mixed payment scheme (salary plus fee-for-service). As the mixed scheme has a smaller fee-for-service component, multitasking theory suggests specialists who choose it will provide less services (lower quantity), but the services will be of a higher quality. Empirical evidence indicates that specialists who switched from being paid by fee-for-service to the mixed scheme reduced their volume of services by 6.2%, but increased the average time spent with patients by 3.8%. This indicates a substitution from quantity to quality as theory suggests. The welfare implications of the policy change are unclear.

Theory and the empirical evidence suggest that pay for performance initiatives should be viewed with caution if not all aspects of performance can be measured and rewarded. This is because specialists will substitute into tasks that are measurable and rewarded and out of task that are not measurable and not rewarded. In such an environment 'weak incentives' such as those provided by salary or a mixed payment schemes can be optimal.

Specialist and Patient Selection

If specialists are remunerated through a prospective payment, they have an incentive to refuse treatment to patients who require many services as these services are costly to provide and these costs are not reimbursed. That is, specialists have an incentive to 'dump' high-cost patients. In addition, specialists have an incentive to attract low-cost patients and they do this by overproviding services. That is, specialists have an incentive to 'cream skim' low-costs patients.

In addition to specialists providing services to patients, specialists provide patients to hospitals and order hospital services for these patients. If hospitals are paid full-cost reimbursement plus a profit margin per service, then they have an incentive to employ specialists that value patient welfare highly (a high α) as they will order many services for their patients. However, if hospitals are paid a prospective payment, then they have an incentive to employ specialists who do not value patient welfare highly. Therefore, the manner in which hospitals are paid has implications for the type of specialists hospitals employ.

It turns out that the way specialists are paid also has implications for the type of specialists hospitals employ and the type of patients they service. Assume there are two types of patients who differ in their length of stay in hospital. There are two types of hospitals, private and public. Private hospital profit increases with length of stay though at a decreasing rate, that is, the second day a patient stays in hospital generates less profit than the first day. Therefore, the private hospital makes more profit with many short stays than with fewer long stays and so prefers to treat short length of stay patients. The public hospital is benevolent and is indifferent between the type of patients it treats. All specialists value income, but differ in their preference for fairness, where fairness is defined as treating all patients equally regardless of type.

In this setting, if private hospitals pay specialists by fee-for-service and public hospitals pay specialists by salary, then (1) specialists who place a relatively high value on income work in private hospitals and treat short stay patients as this maximizes the number of patients they treat, maximizes their utility, and also maximizes the profit of the private hospital and (2) specialists who place a relatively high value on fairness work in public hospitals as this maximizes their utility and the utility of the benevolent public hospital. As healthy short stay patients are treated in private hospitals, public hospitals treat unhealthy long stay patients. Hospitals have selected the type of specialists that they employ through the payment scheme offered and this payment scheme induces these specialists to select the type of patient the hospital prefers. The result is consistent with the empirical observation that specialist physicians are paid by either salary or fee-for-service, with salary being more common in the public sector than the private sector.

Specification and Implementation of Decision Analytic Model Structures for Economic Evaluation of Health Care Technologies

H Haji Ali Afzali and J Karnon, The University of Adelaide, Adelaide, SA, Australia

Introduction

In countries such as Australia, the UK, and Canada, public funding decisions for health technologies (e.g., pharmaceuticals) are based predominantly on cost-effectiveness data. National reimbursement bodies in these countries, such as the Pharmaceutical Benefits Advisory Committee in Australia and National Institute for Health and Clinical Excellence in the UK, provide guidance to the government, which form the basis of decisions around public funding of new health technologies. Most often, this process involves using decision analytic models to inform reimbursement approval at the national level.

Decision analytic models are now an expected part of economic evaluations and are used to synthesize data from a variety of sources, link intermediate outcomes to final outcomes (e.g., quality-adjusted life-years), and extrapolate beyond the data observed in a clinical trial.

The process of developing a model requires three key choices to be made regarding (1) model structure (e.g., health states included in the model, transitions between them, and the choice of a modeling technique), (2) analytical methods such as the perspective taken (e.g., government and society) and the discount rate assumed, and (3) model input values (e.g., incidence of disease and costs of treatment). Recommendations to address uncertainty around the choice of analytical methods and model parameterization (values assigned to the model inputs) (i.e., (2) and (3) above) are generally well established and continually refined in the guidelines developed by national reimbursement bodies. Although the impact of uncertainty around the choice of model structure and making incorrect structural assumptions on model outputs, and hence on funding decisions, is acknowledged, relatively little attention has been paid to address these issues in guidelines.

The article focuses on the processes required to specify a model structure and on the uncertainty specifically arising from the choice of a model structure (i.e., structural uncertainty). The specification of a model structure involves the choice of health states or events to include in the model, and the relationships to be represented between those states.

There are a range of issues to be addressed; firstly defining an appropriate model structure, and subsequent considerations around the feasibility or applicability of the appropriate structure. Key issues include the transparency of the model to end users and the potential effects of model complexity on the process of establishing the internal and external validity of the model. In some cases, model structure may be amended on the basis of the time available to implement, validate, and analyze a model, and/or the data available to populate a model.

Another key part in the development of a model is the choice of modeling techniques, which provide an implementation framework that is used to implement a defined model structure. Inappropriate choice of modeling techniques may influence the outputs of a decision analytic model, and hence needs to be taken into account.

Decision trees are not generally applicable to the process of extrapolation, and so the major area of choice for models that estimate long-term costs and benefits is around the use of cohort-based models (predominantly cohort state-transition models), and individual-based models (generally, either state-transition models or discrete event simulation (DES)). Individual sampling models allow attributes to be assigned to patients that reflect baseline characteristics of patients and/or events experienced within the model. Such characteristics can only be represented in a cohort model by increasing the number of health states included in the model structure. Individual-based models require more analysis time as individuals rather than cohorts are run through the model.

The preceding elements of model-based studies represent the structural features of a decision analytic model. Although concerns have been raised regarding assumptions incorporated into model structures, there is a lack of clarity around the choice of model structure.

The article unfolds as follows: The first section outlines issues around the choice of an appropriate conceptual framework. This framework should reflect the natural history of the condition under study, and defines the states/events to be represented, the relationships between them and the effect of patient characteristics on the probability and timing of events. The second section discusses the development of an appropriate modeling technique (i.e., the choice of an appropriate implementation framework). The third section briefly provides a guide to the terminology used in defining different types of uncertainty around decision analytic models with a focus on structural uncertainty. Then the methods that can be used to deal with structural uncertainty are explored. The concept of reference models and their potential benefits are discussed in section five. Thereafter, the authors illustrate the application of the proposed framework for defining an appropriate model structure, taking major depressive disorder as a case study. Conclusions are formed in the final section.

Choice of an Appropriate Model Structure: Conceptual Framework

All valid models are based on an appropriate conceptual framework. The specification of an appropriate conceptual framework involves two key features, that is, the structural assumptions that inform the choice of health states/events to include in the model, and the relationships to be represented between those states (i.e., transitions between clinical events). The International Society for Pharmacoeconomics and

 doi:10.1016/B978-0-12-375678-7.01401-2

Outcomes Research – The Society for Medical Decision Making Joint Modeling Good Research Practices Task Force reports on the conceptualization of a model provides guidance for the development of an appropriate model structure.

A realistic model structure should comprise key clinically relevant events relating to the natural history of the condition being evaluated. To develop an appropriate conceptual framework, a thorough review of the clinical literature related to the condition under study should be undertaken. This review will document the progression of the condition and summarize a set of main clinical events and their interrelationships, as well as relevant patient's attributes that influence disease pathways and/or response to treatment. A review of the existing models should also be undertaken to inform the importance of identified states/events from the economic perspective. The clinical events identified will be disaggregated where there are likely to be important differences between events with respect to expected disease progression, associated costs, or associated outcomes (e.g., quality of life). If the current evidence is conflicting, more than one plausible model framework can be proposed.

There are additional issues to consider during the specification of a model structure. The choice of model structure should balance the potential value of additional model complexity, that is, increasing the likelihood of identifying important differences in the costs and benefits of the alternative health care interventions being compared, against the potential for reduced transparency, and ease of implementation, which may affect internal validity (i.e., the likelihood of undetected errors in the model). Another issue to consider is the availability of data to populate and externally validate the model (e.g., the extent to which predicted model outputs replicate the observed data, or correspond with outputs from other models in the same area). These issues are related, and all concern the credibility of model outputs.

Transparency and Validity of the Framework

Transparency refers to the ability of the end user (or a delegate of the end user, i.e., an independent reviewer) to understand and assess the implemented model. Where a specific end user is identified, the importance of this issue should be established in consultation with the end user.

The importance of model transparency may be ameliorated if the analyst can clearly demonstrate the face validity of the model. This may take the form of an expert review of the implemented model by an analyst who was not directly involved in the implementation of the model, or who was independent of the entire evaluation. Inputs from experts will be sought as to whether the proposed model structure(s) sufficiently reflects the relevant disease process and disease management pathways. Alternatively, a set of analytic checks may be defined that demonstrate the internal accuracy of the model, for example, using extreme parameter values. In defining the final model structure, the analyst should consider the extent to which they will be able to meet transparency criteria and/or demonstrate the validity of the model.

More complex model structures generally require the estimation of a greater number of input parameters, which may preclude the estimation of particular parameter values or require the use of less reliable data sources, such as data elicited from experts. Alternatively, more complex models may provide greater flexibility with respect to identifying targets for calibration or external validation.

Data Sources for Model Population

A systematic review of the literature and a thorough investigation of relevant data sources (e.g., published literature, national registries, or patient-level database) should be undertaken to identify all potentially useful sources of data, to which appropriate analytic methods can be applied to populate and validate the model. However, if this fails to identify relevant and sufficiently valid data to inform the estimation of all the required input parameters to construct the model, an expert elicitation process can be undertaken to explore the possibility of using expert opinion to fill gaps in data.

It should not be assumed that all missing parameters can be elicited from experts, as there is evidence that experts are sometimes unable or unwilling to estimate parameters about which they are too uncertain.

Expert elicitation is subject to a range of biases; both intentional and unintentional (e.g., recall bias). Before a decision is made to use elicited parameter values, and thus maintain the preferred model structure, values elicited from experts should be validated by asking additional questions in which elicited parameter values can be compared with empirical data. Elicited parameter values can also be cross-checked, that is, comparing expert data from independent sources. It is also important to represent the certainty with which different parameters can be estimated by experts, for which established methods can be applied that also provide transparency.

Missing parameter values may also be estimated using calibration techniques, by identifying sets of input parameter values that produce model outputs that are similar to target values (i.e., observed estimates of the output parameters). Calibration is a useful process even when empirical estimates for all input parameters are available, especially for complex models with many uncertain parameters.

If specific input parameters cannot be directly estimated, and relevant calibration targets cannot be identified (i.e., targets that are part-determined by parameters for which direct data is absent), potential modifications to the model structure should be considered. Decisions around data-related structural modifications should be informed by the importance of the parameters that would be omitted from a modified model structure.

Ideally, the importance of parameters with missing values would be established by implementing and populating the originally specified model structure and testing the sensitivity of the model's outputs to extreme values for the missing parameters. The paradox of this process is that the more complex model is likely to be used regardless of the outcome of this testing process – if the model is not sensitive to these parameters then a less complex model would suffice, but the analyst has already built the more complex model.

Time Constraints

In some cases, it may also be necessary to consider the timelines for the economic evaluation. If a model is being developed to inform a national reimbursement body, which has requested results from the evaluation in a time period that precludes adequate processes for the population, validation, and analysis of a preferred model structure, it may be advisable to reduce the complexity of an ideal model structure.

In all cases where a preferred model structure is modified on the basis of any of the above considerations, the process and rationale for making such decisions should be documented and reported. Here, the 'art of modeling' may be used, whereby the modeling team use their combined clinical and analytical experience to consider and report the potential effects of any structural modifications on the estimated costs and benefits, and in particular on the differences in cost and benefits between competing interventions.

Choice of an Appropriate Modeling Technique: Implementation Framework

There are various modeling techniques that can be used for the economic evaluation of health care interventions. Full details of different types of modeling techniques are beyond the scope of this article and need not be rehearsed here. In this section, the authors briefly present the key features of the three techniques commonly being used in the literature, that is, decision trees, cohort state-transition models, and individual-based models.

Decision Trees

Decision trees (DTs) are the simplest modeling techniques and are most appropriate for modeling interventions in which the relevant events occur over a short time period. The main limitation of decision trees is their inflexibility to model decision problems, which involve recurring events and are ongoing over time. In general, DTs are constructed with three types of nodes, namely decision nodes, chance nodes, and terminal nodes. A simple illustrative decision tree is presented in Figure 1. The tree flows from left to right starting with a decision node (square) representing the initial policy decision (alternative interventions in Figure 1). Each management strategy is then followed by chance nodes (circles) representing uncertain events (i.e., 'disease free' or 'dead' in Figure 1), which will have probabilities attached to them. Finally, endpoints of DTs are represented by a terminal node (triangle) at the right of the tree. The outcome measures (e.g., utility value) are generally attached to these endpoints. Costs, however, are attached to events within the tree, as well as to endpoints. The expected values (costs and effectiveness) associated with each branch are estimated by 'averaging out' and 'folding back' the tree from right to left.

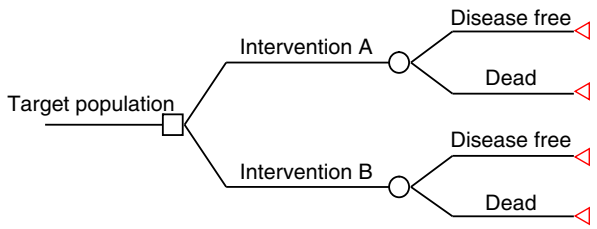

Figure 1 An illustrative example of a decision tree.

Cohort State-Transition Models

Cohort state-transition models (CSTM) are the standard technique used to model the economic impact of health care interventions over time. Using these models to capture long-term costs and benefits (e.g., lifetime), disease progression is conceptualized in terms of a discrete set of health 'states' and the 'transitions' between them. In health technology assessment, most state-transition models are discrete-time models in which the time horizon of the analysis is split into cycles of equal length (Markov cycles).

A CSTM assumes a homogenous population cohort moving between states (or staying in the same state) in any given cycle. Transitions between states during cycles are based on a set of conditional probabilities (i.e., transition probabilities). These probabilities are conditional upon the current health state. The movement between discrete health states (such as depressive episodes or remission) continues until patients enter an absorbing state (e.g., 'death') or up to the end of the specified time horizon. Costs and outcome (e.g., utility weights representing quality of life) are attached to each health state (i.e., state rewards) and transitions (i.e., transition rewards if appropriate) in the model. Expected costs and quality-adjusted life-years (QALYs) are estimated over the time horizon of the model as the sum of the time spent in each health state multiplied by the respective cost and utility weights for each health state.

CSTMs, however, suffer from the lack of memory (i.e., Markovian assumption) in which transition probabilities are not influenced by pathways taken to a particular health state. By creating separate states in a Markov model, it is technically possible to address the above issues. However, this can result in an unwieldy number of events/states and may make model implementation, checking, and analysis difficult.

Individual-Based Models

Individual-based state-transition models

These models are able to carry histories whilst remaining a manageable size. These models include all the key features of the cohort Markov family. However, assigning relevant attributes to individuals rather than to health states within a model means that the effect of the Markovian assumption is removed. They transit individual patients through the model rather than proportions of a cohort. If and where the patient moves during cycles is determined by random numbers drawn from a uniform distribution. A large number of patients are run through the model and the mean costs and QALYs gained across all patients are estimated. The principal advantage of these models is that patients' treatment and/or disease history can be captured, and used to inform subsequent transition probabilities applied to each patient within the model.

A limitation of individual-based state-transition models, however, is that time is managed through a fixed cycle length (e.g., monthly) by which the model moves forward. This may not reflect accurately the length of time spent in certain states as patients can only experience one event within each cycle. It is possible to address this issue by selecting shorter cycles (i.e., weekly) or linking separate models each with different cycle lengths. However, it may be easier to use a more flexible individual-based technique, i.e., discrete event simulation (DES).

Discrete event simulation

DES is a very flexible model that describes the flow of individuals through the treatment system. In DES, patients can be assigned attributes such as age, gender, or disease history which are assumed to influence patient's pathways through the model.

DES can accommodate differing cycle lengths more easily and with greater accuracy than state-transition models. DES uses a stochastic process to simulate events for an individual by sampling probabilities from survival distributions. Times (to next possible events) are sampled and the earliest time represents the next event for a particular individual. These events are added to a calendar and probability distributions are updated conditionally on patient history. This means that the time spent in a particular state can be estimated exactly.

Uncertainty in Decision Analytic Models: Structural Uncertainty

Given the lack of complete information about the key aspects of a decision analytic model (e.g., choice of the health states/events or true values of costs and effects of a particular intervention in a given population), uncertainty is inherent within any model-based evaluation. Uncertainty (or sensitivity) analysis is necessary so that policy-makers can incorporate information on the accuracy of model outputs into decisions around funding of the competing interventions being evaluated, as well as decisions regarding the need for additional information.

To illustrate different types of uncertainty associated with decision analytic models, the authors present a simple state-transition depression model (Figure 2). The model presented in Figure 2 consists of three states: 'well,' 'depression,' and 'dead.' The aim is to estimate differences in the time spent in each state by patients receiving alternative technologies, over a defined time horizon (e.g., patients' lifetime). Costs and outcomes are then attached to the time spent in each state to estimate the costs and benefits of alternative technologies. In state-transition models, time progresses in equal increments (e.g., monthly) known as cycles. The arrows represent possible transitions between states, for which transition probabilities are estimated. Relevant attributes (which influence disease pathways or response to treatment) can be assigned to patients, and updated during the course of running the model. For example, the probability of recurrence (i.e.,'well' to 'depression') increases with the number of previous depressive episodes that patients experienced.

Three broad forms of uncertainty have been distinguished: parameter, methodological, and structural. Parameter uncertainty concerns the uncertainty around the true value of a given parameter within the model (e.g., probabilities of moving between 'well' to 'depression'). Methodological uncertainty relates to the choice of analytic methods such as the perspective taken (e.g., society and government) with an impact on, for example, the process of identifying resource items. Issues around parameter and methodological uncertainties are generally dealt with, for example, by using probabilistic sensitivity analysis and by prescribing a 'reference case,' respectively. Structural uncertainty arises from the assumptions imposed by the modeling framework and refers to the structural features of the chosen model, that is, the choice of clinical events represented in a model (e.g., adding a 'partial response' state to the model presented in Figure 2), and the possible transitions between them.

It is recognized that the choice of model structure can lead to different results, hence different reimbursement decisions. Although concerns have been raised regarding assumptions incorporated into model structures, and that structural uncertainty may have a greater impact on the model's results than other sources of uncertainty, relatively little attention has been paid to the representation of structural uncertainty. Different ways to address structural uncertainty are discussed in Section 'Uncertainty in Decision Analytic Model.'

Addressing Structural Uncertainty

Like uncertainty around methodological issues and the value of input parameters, structural uncertainty cannot be eliminated, and needs to be handled appropriately. Different approaches are used to characterize structural uncertainty.

The simplest approach to representing structural uncertainty is to implement and analyze a range of alternative model structures, and to present the results from each model as scenario analyzes. However, this approach puts the burden of assessing the relative credibility of the alternative structures on the end user, which may result in only a superficial and subjective assessment that will not reflect the full value to the

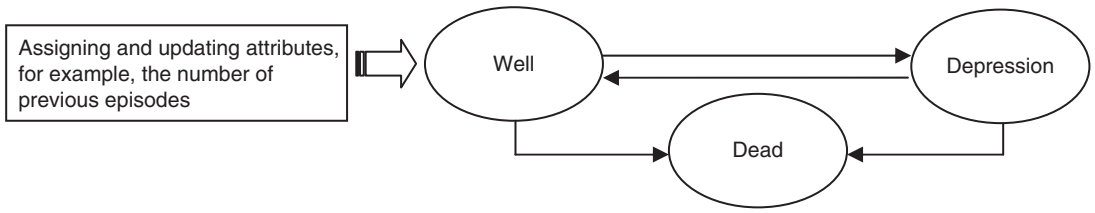

Figure 2 A simple state-transition depression model.

decision-making process of implementing multiple model structures.

For the characterization of structural uncertainty, two techniques have been identified: model selection and model averaging. Both techniques involve developing a set of plausible models using different structural assumptions.

The 'model selection' approach ranks alternative models according to some measure of prediction performance or goodness of fit, and selecting the single model that maximizes that particular criterion. This approach does not represent structural uncertainty, rather it identifies the model that is believed to be the most likely to be the correct model. The effect of selecting a single model will depend on the relevance of the criterion used to select the model and the magnitude of the difference in the predictive power of the alternative model structures. Moreover, given the effort required to build and analyze a range of alternative model structures, it would appear wasteful to report results based only on a single model when there is a likelihood that the other models could be a more correct model.

'Model averaging' methods assess structural uncertainty by assigning weights to a range of alternative model structures according to some measure of model adequacy. Weighted model outputs are then estimated across all model structures included in the model averaging process. The weightings should reflect the probability that each model is the correct model, based on some measure of predictive power (e.g., Akaike's information criterion). The main limitation of the quantitative approach to model averaging is the necessary restriction of the process to represent the elements of structural uncertainty that are linked to outputs for which observed data are available.

Other model averaging applications have elicited weights to be applied to each of the defined model structures. Here, the analyst must consider the potential for biased responses and superficial assessment of the relative merits of the alternative models.

Alternatively, a discrepancy approach has been applied to represent the uncertainty around an implemented model structure. Unlike model averaging, the discrepancy approach does not assess the adequacy of the model structure in relation to alternative structures. Rather, the joint effects of structural and parameter uncertainty are estimated, i.e., the estimated distribution of the costs and benefits of the competing interventions reflects structural and parameter uncertainty.

The application of the discrepancy approach requires the identification of points of discrepancy (i.e., structural uncertainty) within a model structure, and the subjective estimation of the magnitude and variance of the discrepancy between predicted outputs from the model using true values for each input parameter and the true values of the predicted parameters.

Improving the Accuracy and Consistency of Model-Based Evaluations: The Case for Reference Models

One of the main consequences of structural uncertainty is that alternative economic evaluations for a specific disease use alternative model structures (e.g., alternative model structures to evaluate different pharmaceuticals for treating depression). In addition to the structural uncertainties around each model structure, indirect comparisons of the cost-effectiveness of these interventions are further hindered by the diversity in model structure. Using different model structures in evaluations of alternative technologies for the same condition in submissions to national reimbursement bodies can lead to inconsistent public funding decisions because changes in model structure and analysis can produce substantially different results. This increases the likelihood of incorrectly identifying a new technology as being cost-effective (and vice versa).

There is potential for strategic behavior when defining a model structure, by focusing on aspects of the disease process that are targeted by particular technologies, for example, if drug A reduces risk of event X but not event Y and event Y has significant costs and/or quality of life effects, if the model structure represents only X then important aspects of the disease are not included and the results are biased.

To address these concerns, there is a need for a detailed and transparent framework for developing an appropriate common model structure (reference models) for specific diseases (e.g., depression, colorectal cancer, etc.) for economic evaluations to inform public funding decisions. The structure of a reference model defines the clinical events to be represented, the relationships between the events, and the effect of patient characteristics on the probability and timing of events. The model should accurately represent both the knowledge and uncertainty about states/events relating to the disease progression on the basis of the best available evidence. Reference models can be applied to a wide set of interventions for a specific disease (e.g., drugs and procedures that may target alternative mechanisms or stages of disease). For example, a reference model for depression could be used to estimate the costs and benefits of competing antidepressants, as well as evaluating the costs and benefits of alternative models of care (e.g., usual care vs. enhanced care).

By reflecting the natural history of the condition under study more accurately, reference models can improve the accuracy, comparability, and transparency of public funding decisions for new health technologies. However, we emphasize that reference models are not intended to replace structural sensitivity analyzes, and approaches to address structural uncertainty might be still required if there is insufficient evidence (or conflicting evidence) to support an appropriate model structure.

A national reimbursement body could commission the development of reference models for key disease areas, which are then developed according to best practice (as outlined in the preceding sections). The resulting models could be subjected to a thorough process of structural uncertainty analysis, and would ultimately provide a comprehensive and unbiased representation of the disease, including all important clinical and economic aspects (e.g., costs and quality of life effects), which may affect the long-term estimation of costs and benefits of the alternative health care interventions being compared. In terms of the feasibility of using reference models, one of the possibilities will be, for example, to provide the reference model to any industry applicant intending to submit a technology in the relevant disease area by national

reimbursement bodies. Applicants could update the inputs used to populate the model, but would be expected to revalidate the model. Likewise, applicants would be free to use an alternative model structure, but it would have to be fully justified. The outputs of alternative models can be compared against the reference model, which provides a basis for confirming any claimed advantages of new model structures.

Case Study: Major Depressive Disorder

After reviewing the course of depression, this section discusses the issues surrounding structural assumptions used to inform a preferred model structure and the choice of modeling techniques, using examples from published model-based economic evolutions of interventions from the treatment of depression.

Background to the Course of Depression

Major depressive disorder (referred to as depression henceforth) is the most common mental health disorder. Depression is associated with a considerable functional impairment, morbidity, and premature mortality. It is increasingly recognized as a chronic disease characterized by multiple acute episodes/relapses.

A common set of terminology describing different stages of disease progression has been proposed. 'Response' represents a significant reduction (50% or more reduction from baseline scale scores) in depressive symptoms. 'Remission' represents a period during which the patient is either symptom free or has no more than minimal symptoms. 'Recovery' is defined as an extended asymptomatic phase, which lasts for more than 6 months. 'Relapse' is a flare up of the depressive episode, which occurs after remission, whereas recurrence is a new depressive episode that occurs after recovery.

Chronic depression is one of the clinically meaningful structural aspects of depression and is defined as a persistent depressive episode, which is continuously present for at least 2 years, or an incomplete remission between episodes with a total duration of illness of at least 2 years. High-risk patients and those who have not responded adequately to outpatient treatment can be admitted to hospitals. Finally, all patients can die, with an increased risk of death due to suicide while in a depressive episode.

Patients with depression may be treated with different classes of antidepressant drugs, including selective serotonin reuptake inhibitors and serotonin norepinephrine reuptake inhibitors. After a successful short-term treatment, antidepressants need to be continued for a period to prevent relapse (continuation therapy) and to prevent recurrence (maintenance therapy). Psychotherapy or more commonly a combination of pharmacotherapy and psychotherapy are other options in treating patients with depression.

Choice of an Appropriate Conceptual Framework

The choice of health states/events included in the model is considered as a key part in developing decision analytic models. An appropriate model structure should reflect a number of key clinically relevant health states relating to the course of the disease under study. Over recent years, various model structures were used in depression studies.

Some model-based studies of depression included only response as a primary outcome measure in their model. This model structure is not appropriate as it is likely to bias results in favor of treatments with higher rates of response, which may be the more or less effective treatment overall.

In some studies, the possibility of relapse (i.e., remission to depressive episodes) and/or recurrence (i.e., recovery to depressive episodes) was not considered. By excluding these clinical events, studies implicitly assume that the incidence of such is unlikely to differ between competing management strategies. As a recurring illness, this simplification in the model structure in depression studies will favor treatments with higher remission rates. A more appropriate model structure is to represent both levels of treatment success (i.e., response and remission) and treatment failure (i.e., relapse and recurrence).

Hospital admission for high-risk patients or those who have not responded adequately to outpatient treatment is another relevant clinical event. A realistic model of depression should represent this event as it represents clinical practice more accurately.

'Chronic depression' is another relevant event that is important from both clinical and economic perspectives. Approximately 20% of patients with acute episodic illness will develop a chronic course of depression. It has been noted that chronic depression, compared with nonchronic depression, is associated with increased health care utilization, more suicide attempts, and greater functional impairment requiring a longer duration of treatment.

Finally, given a baseline increased risk of suicide at rates 10–20 times above general population rates, the omission of such a state from a depression model will likely bias the model in favor of less effective interventions.

Accepting the above course of disease, the model structure and relationships between events are presented in Figure 3. In this model, depressive episodes represent relapse or recurrence.

Choice of an Appropriate Computational Framework

Some studies of depression used DTs to evaluate costs and effects of alternative management strategies. Given that depression is a chronic illness with recurrent episodes, the main limitation of DTs is their inflexibility to model long-term events. The likely impact of the choice of a DT with a short time horizon on the cost-effectiveness results, and hence policy decisions, will vary according to the short-term cost-effectiveness results. If a more effective treatment (i.e., fewer deaths and/or more remission) can demonstrate cost-effectiveness within a short time horizon, it may be reasonable to expect that this result would not change over an extended time horizon. The likely magnitude of potentially underestimated cost differences should be considered, but a DT may be appropriate in this scenario. Where the more effective treatment is not shown to be cost-effective using a DT, it may be possible to imply the likely cost-effectiveness over a longer

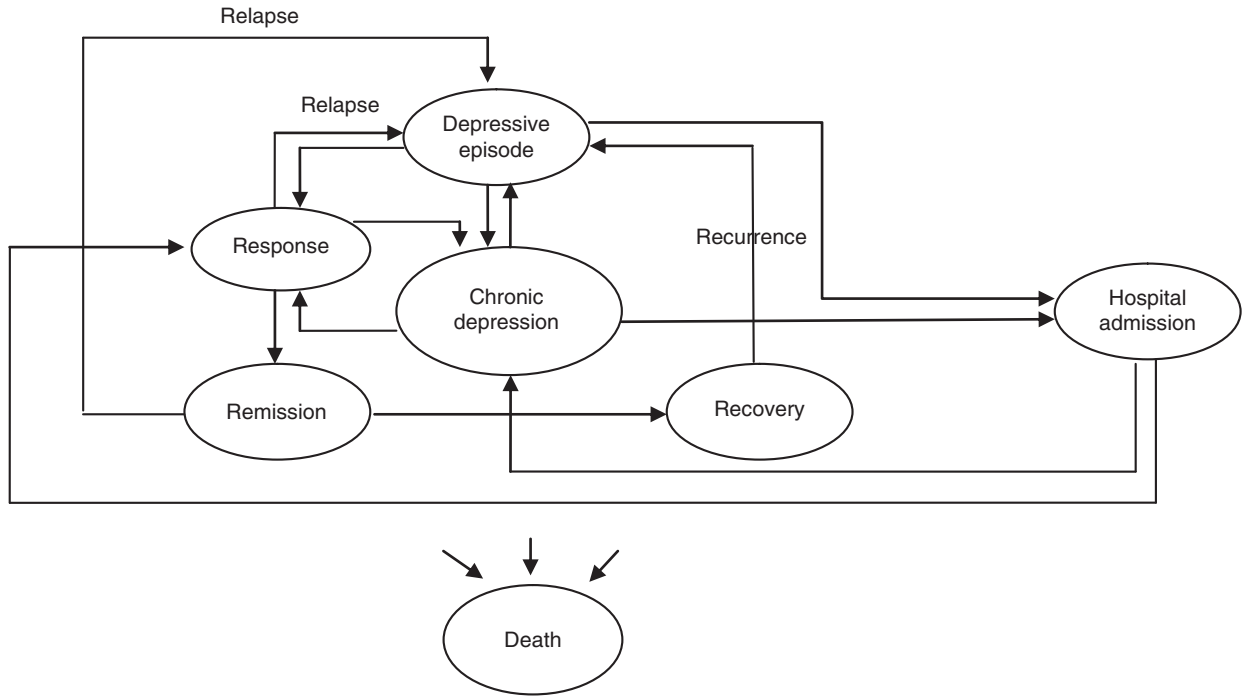

Figure 3 The conceptual framework. (a) Bubbles show the states/events included in the model, and arrows indicate the relationships between the events. (b) There is always a possibility of dying (absorbing state).

time horizon, though a modeled extrapolation provides a more explicit and transparent process of estimation.

By including recurring events and breaking up a decision tree to sequential time periods, it is technically possible to capture recurring events over longer time periods. This, however, progressively increases the size of the model and the use of an alternative modeling technique might be preferred.

To address the above issue, some model-based studies of depression employed CSTMs. These models allow for an evaluation of recurring events over a longer period of time, for example, multiple depressive and recovery episodes. However, the lack of memory (i.e., Markovian assumption) is considered as a major limitation of these models. In the case of depression, the above assumption means that an individual in the 'full remission' state with only one previous depressive episode has the same probability of experiencing 'recurrence' as a patient with a history of multiple depressive episodes. This, however, does not appropriately represent the natural history of depression as the risk of recurrence has been found to increase with the number of previous depressive episodes. One way to overcome this limitation is to create separate states to represent differing numbers of previous depressive episodes, for example, 'remission, one previous episode,' 'remission, two previous episodes,' etc. As implied, this process can soon result in an unwieldy number of health states, and may make model implementation, checking, and analysis difficult.

By modeling individual patient pathways, individual-based state-transition models are able to carry patient histories whilst remaining a manageable size.

Assigning attributes such as the severity of episodes to individuals rather than to health states within a model means that the effect of the Markovian assumption is removed. Individual-based models then facilitate the estimation of probability and timing of experiencing relevant events as a function of patient-recorded attributes (e.g., age, gender, severity, comorbidity, and psychotherapy as attributes). By updating attributes, probabilities can change over time while the model is running.

One practical limitation associated with the use of individual-based state-transition models is the need to define a fixed cycle length by which the model moves forward in time. The cycle length should represent a clinically relevant time span. Modeling studies of depression that use a fixed monthly cycle length may not reflect accurately the length of time spent in certain states as patients can only experience one event within each cycle. It is possible to address this limitation by selecting shorter cycles (i.e., weekly) or linking separate models each with different cycle lengths. However, it may be easier to use a more flexible modeling technique, that is, DES. No model-based studies of depression using DES were located.

DES can accommodate differing cycle lengths more easily and with greater accuracy than state-transition models. In a DES, time does not move forward in cycles, but rather with respect to the sampled timing of events, for example, if a patient relapses after 2 weeks, the model moves forward from time zero (treatment initiation) to time 14 days. If the next event (e.g., remission) occurs 2 months later, then the DES would move forward directly to that time point. Using survival distributions, times (to next possible events) are sampled, and the earliest time represents the next event for a particular

individual. This means that the time spent in a particular state can be estimated exactly.

Considering disease characteristics, the authors argue that DES is the appropriate modeling technique for depression studies to project life-time benefits and resource costs of management options in patients with depression.

Data Sources

A variety of data sources are used to derive clinical parameters.

Clinical trials and observational studies

Using data derived from clinical trials or observational studies, it is widely accepted that 'response' is defined as at least a 50% improvement in baseline scores recorded by the most cited assessment tools, i.e., the Hamilton Depression Rating Scale (HAM-D). HAM-D is considered as the gold standard to measure the severity of depression and is used in the majority of clinical trials of depression. 'Remission' is mostly defined as a score of 7 or less on the 17-item HAM-D. The occurrence of 'depressive episodes' is commonly defined when patients meet the criteria identified by DSM IV.

Retrospective databases

Clinical outcome measures using standard assessment tools are not typically recorded in data sources such as claims databases and medical notes. Thus, proxy measures such as treatment changes should be defined. For example, relapse can be defined as a subsequent antidepressant prescription less than 6 months after the antidepressant stop date. Another form of observational data is claims databases (e.g., US managed care database).

Expert opinion

Expert opinion is another source of data, which was used in a few studies to estimate probabilities of clinical inputs such as dropout rates, reasons for discontinuation, and nondrug-specific events such as relapse rate after discontinuation. An elicitation method is intended to link an expert's underlying opinions to an expression of these in a statistical form, and is an appropriate technique to fill gaps in data where no published information is available. However, it is important to have transparent criteria for the selection of participants, and to recognize the potential for biased estimates that may be in favor of the participant personal experiences (e.g., more frequent patients with the most severe symptoms) and/or preferences.

Conclusions

To date, relatively little attention has been paid to the processes and issues around the specification of appropriate decision analytic model structures, but better specified decision analytic models will contribute to more consistent and better informed decisions for the allocation of limited resources.

This entry has addressed issues around the appropriate choice of model structure for the purposes of economic evaluations of health care technologies, including discussions around the choice of appropriate modeling technique, representation of structural uncertainty, and the potential benefits of the development of disease-specific reference models. The disease area of depression was used to illustrate the issues involved in the process of specifying an appropriate model structure.

State Insurance Mandates in the USA

MA Morrisey, University of Alabama at Birmingham, Birmingham, AL, USA

Introduction

Insurance markets in the US traditionally have been regulated at the state level. This tradition was reinforced by the 1945 McCarran–Ferguson Act, which exempted the business of insurance from federal antitrust oversight as long as the individual states regulated the insurance business. Much of the early health insurance regulation related to reserve requirements and sales practices although the states did impose premium taxes. The number and types of mandates proliferated in the past 40 years.

Insurance mandates are defined as state laws that require a health insurer to include specific categories of individuals, providers, or services within the scope of coverage provided. Less restrictive laws only require that the insurer offer specific coverages to purchasers. Some analysts also have included laws affecting specific types of insurers, particularly managed care plans, as insurance mandates as well. The early mandates of the 1950s tended to expand the cohort of covered persons to include newborns and handicapped children. Thus, if a policy was to be sold in the state it must include coverage for newborns.

Prevalence of State Insurance Mandates

Most mandates apply to employer-sponsored health insurance coverage, although nongroup mandates also exist. There were few statutes until the 1970s when the number of laws began to proliferate. Although they only consider provider and service mandates, Laugesen *et al.* (2006) reported that of nearly 1500 state mandates enacted between 1949 and 2002, 12% were enacted in the 1970s, 25% in the 1980s, 39% in the 1990s, and another 16% in the first 3 years of the 2000s.

The Council for Affordable Health Insurance annually compiles a listing of all state health insurance mandates (Bunce and Wieske, 2010). Their 2010 edition reports the presence of 2156 mandates. The states display considerable heterogeneity in the number of mandates they enact. Idaho and Alabama have the fewest mandates with 16 and 19 provisions, respectively. Four states (Rhode Island, Maryland, Minnesota, and Texas) each have more than 60 provisions. Table 1 reports the most common mandates by category.

Federal Insurance Mandates

It is only relatively recent that the Congress has enacted health insurance mandates. The first was the 1979 Pregnancy Discrimination Act, which required that pregnancy be covered as a medical condition in most employer-sponsored plans. The 1986 Consolidated Omnibus Budget Reconciliation Act provided continuation coverage for 18–36 months for persons separated from employer-sponsored coverage. In 1996, the Health Insurance Portability and Accountability Act, (first) Mental Health Parity Act, and Newborns and Mothers' Health Protection Act were enacted. Other federal laws followed. The enactment of state and federal mandates is not independent of each other. As Laugesen *et al.* (2006) noted, 50 jurisdictions had enacted breast reconstruction legislation by the time the federal legislation was passed in 1998 and 32 states had enacted maternal and newborn minimum stay provisions before or coincident with the 1996 federal legislation. These patterns suggest a common underlying demand for the legislation and may suggest that the federal legislation is merely a reflection of extant state practice.

Rationales for Mandates

There are three rationales for the enactment of a mandate. The first is lack of knowledge. The argument is that individuals and their employer agents underestimate the value of the coverage. By requiring coverage people get the coverage they would have purchased had they been better informed. The second rationale is adverse selection. The argument holds that both low- and high-probability individuals would like to buy the

Table 1 Most prevalent health insurance mandates, by category

Health insurance mandates	*Number of states with the law*
Service mandates (1251 total mandate laws)	
Mammography screening	50
Maternity minimum stay	50
Breast reconstruction	50
Mental health parity	48
Diabetic supplies	47
Alcohol/substance abuse	46
Emergency room service	45
Provider mandates (558 total mandate laws)	
Chiropractor	44
Psychologist	44
Optometrist	41
Dentist	33
Podiatrist	33
Nurse practitioner	29
Nurse midwife	27
Individual mandates (347 total mandate laws)	
Newborn	51
Continuation employee	46
Continuation dependent	45
Adopted children	44
Disabled dependent adult	42
Conversion to nongroup coverage	41
Dependent student/adult	34

coverage, for, say, *in vitro* fertilization. However, when a single insurer offers the coverage those with a high probability of use are disproportionately attracted to the plan, raising plan premiums substantially. The higher premiums lead low probability users to forego coverage. Had the coverage been in all plans, the cost of insurance would have risen only slightly. Thus, mandating coverage allows low risk individuals who value the coverage to actually obtain it at premiums they were willing to pay. The third rationale is one of public choice. The argument is that advocates of a particular mandate will tend to be the providers of the particular service who petition the state legislature for statutes that expand coverage for themselves, the services they provide, and the people who are most likely to use their services. Opponents will be individuals and their employer and/or insurer agents who directly or indirectly face the costs of the law. There has been no empirical work testing the first two rationales. The public choice approach enjoyed some research interest in the 1990s with attention focused on mental health services and laws affecting the composition of managed care provider panels, all with results consistent with the public choice argument (see Jensen and Morrisey, 1999 for review).

One implication of the public choice model is that opposition should be reduced when potential opponents are exempt from the law. The Employee Retirement and Income Security Act (ERISA) of 1974 effectively made larger employers exempt from state insurance regulations. From this perspective it is not coincidental that the growth of state mandate legislation began in the 1970s when key elements of the opposition no longer benefited by expending political capital to oppose the laws.

To try to control the proliferation of mandates, half of the states have enacted mandated benefit review laws, which provide for a review of factors such as the cost and social impacts, medical efficacy, and quality of care before the legislature votes on a prospective mandate. There has been no evaluation of the effectiveness of these laws.

Economics of Employer-Sponsored Health Insurance and State Insurance Mandates

Maximizing behavior on the part of employees and employers implies that workers are paid what they are worth, i.e., their marginal revenue product. Compensation may take many forms: wages, pensions, vacations, health insurance, etc. However, adding an element to the compensation package, other things equal, necessitates taking something else out. When a mandated benefit is added to the bundle the premium will increase. If premiums increase, wages or some other form of compensation must be reduced.

If workers do not sufficiently value the new compensation package they will seek employment in firms that do not offer the new costly benefit or may choose compensation that excludes health insurance entirely. Firms may seek a legal status that exempts them from the mandate. If wages or other forms of compensation can not adjust, perhaps because of minimum wage laws, one would expect reductions in employment. In the following four sections, the empirical evidence associated with these hypotheses will be explored.

Cost of Mandates

The key issue in the chain of economic logic is that a mandate results in higher health insurance premiums. There are three issues bound up in this straightforward proposition. The first question is whether a particular benefit raises the health insurance premium of a firm that now must provide the new coverage. Second is the question of the cost of the mandate, per se. Suppose a chiropractor coverage mandate would raise premiums by US$10 per worker per month, but employees are willing to pay US$6. The benefit cost is US$10, but the cost of the mandate is only US$4 per worker. Finally, if the firm already offers the coverage that is the subject of the mandate, then there is no cost to the mandate for the firm or its workers. The cost of the legislation is the extra burden it imposes, not necessarily the dollar cost of the benefit.

Many of the cost analyses of health insurance mandates are actuarial studies. These works draw on a distribution of the likely claims experience for a health service, such as chiropractic care. The expected claims experience per worker is the additional cost of insurance to a firm that did not offer the benefit previously. Bunce and Wieske (2010) provided ranges of actuarial costs for each of the mandates they report. Mental health parity (e.g., covering mental health illnesses equivalently to physician health illnesses) would increase premiums by 5–10%, *in vitro* fertilization by 3–5%, alcoholism/substance abuse by 1–3%, and most other coverages by less than 1%. Kominski *et al.* (2006) used an actuarial model to estimate the costs of seven proposed mandates in California. The costs of these relatively small-scale mandates were estimated to increase premiums by 0.006–0.2%. The actuarial approach overstates the cost of a mandate for two reasons. First, additional services used under the new benefit may offset, somewhat, utilization of other services that were already covered. Second, workers are likely to have been willing to pay something for the mandated coverage, and indeed, some may already have the coverage.

In principle the first problem is easy to overcome. One could estimate a firm specific hedonic premium regression that includes various benefits along with a set of control variables. The coefficients on the specific benefits reflect the premium cost of adding each benefit, given the coverage already provided by the firm. Thus, any service substitution is accounted for. Unfortunately, this is not an estimate of the cost of a mandate, per se; rather it is the net cost of the benefit to the firm (see Jensen and Morrisey, 1999 for review).

Acs *et al.* (1992) were the first to directly estimate the presence of state insurance mandates on the premiums paid by firms. Using a cross section of more than 2500 firms in 1989, they concluded that each additional mandate increased health insurance premiums for large firms by US$1.50. Although this is a direct estimate of the cost of mandates, it is not without problems. First, the count of the number of mandates in a state forces each mandate to have an equal effect. Almost certainly some mandated benefits are substantially more costly than others. Second, the estimate is likely endogenous. That is, it may be that the legislature enacted particular mandates in their state because they were already commonly offered by large employers in the state or because residents of the state were perceived to benefit from the coverage.

Wage and Benefit Adjustments to Mandates

If mandates are costly, their inclusion in employer-sponsored health insurance plans should lead to reductions in wages or other forms of compensation. This adjustment in the compensation bundle is referred to as 'compensating differentials.' There is one particularly strong analysis relating to state insurance mandates. In the mid-1990s, 23 states enacted legislation requiring that maternity services be included as a covered benefit in employer-sponsored health insurance. Gruber (1994a) examined the effects of the enactment of this law in Illinois, New York, and New Jersey compared to five states that had not enacted the legislation. His approach was to compare: the hourly wages of affected people to those unaffected, in states that enacted the law to those that did not, in the periods before and after the date of enactment. Affected people were employed married women aged 20–40 years, that is, those potentially likely to use the new benefit. Unaffected people were defined as employed single men aged 20–40 years and all employed people aged 40–60 years.

This is the so-called triple-differences model. Gruber's work is increasingly the standard approach to addressing the effects of insurance mandates. Its strength is that it controls for trends occurring over the period before and after the enactment, for differences in the states enacting and not enacting the laws, and for differences that might exist in the average productivity of people affected and not affected by the law. Gruber found that the net effect of the maternity mandate was to reduce the average hourly wages of the affected group, in the enacting states after passage of the law by 5.4% relative to unaffected groups in nonenacting states over the same period. This amount was consistent with the actuarial estimates of the cost of the coverage. This is very strong evidence that the effect of a binding mandated benefit law is to reduce other elements of the compensation bundle. In short, it implies that workers pay for much of the cost of a mandate.

Self-Insured Plans: Avoiding Mandates

The 1974 federal ERISA legislation exempts self-insured firms from state insurance regulation. One way to avoid the costs of unwanted health insurance mandates would be to obtain coverage through a self-insured plan. Virtually all large employers offer plans that are self-insured. Even a small employer could provide self-insured coverage; they would do so by buying stop-loss coverage (sometimes called reinsurance) that limits their liability once claims in total or for individual cases reach a specified threshold. Nearly 60% of insured workers were in self-insured plans in 2009.

The empirical work on the relationship between state mandates and the propensity to self-insure comes from the late 1980s and early 1990s. Jensen *et al.* (1995) examined the effects of costly mandates and other factors on the switch from conventional to self-insured coverage in the 1981–84 and 1984–87 periods. Most mandates had a positive but statistically insignificant effect on the self-insurance decision. They did find that state premium taxes and high risk pool taxes were strongly associated with switching. Subsequent work found no consistent effects of mandates on the self-insurance decision and some suggestion that self-insured status was associated with firms that had multiple locations and who may have been trying to avoid conflicting state regulation.

Mandates and Coverage Decisions

Jensen and Gabel (1992) were among the first to estimate the effect of state insurance mandates on the probability that an employer would offer insurance coverage. Using 1985 data from small employers they concluded that every additional mandate in a state reduced the probability that a firm would offer coverage by 1.5%. Surprisingly, they also found that some arguably high cost mandates such as alcohol and drug abuse treatment and continuation of coverage requirements had no statistically significant effects. Gruber (1994b) examined the effects of five costly mandates: alcoholism treatment, drug abuse treatment, mental illness, chiropractic services, and continuation of coverage using Current Population Survey (CPS) data from 1979, 1983, and 1988. He found no effects of the mandates on the probability of having coverage.

Sloan and Conover (1998) examined data from 1989 to 1994 CPS. They measured regulation as a count of the number of state mandates in effect and concluded that eliminating state mandates would reduce the number of uninsured in the state by 20% and 25%. In a recent working paper Ma (2007) updated these analyses using the 1996–2002 CPS. His focus was on two alternative sets of high cost mandates and unlike the earlier studies in this section he used state and year differences-in-differences to control for contemporaneous trends in coverage and systematic differences across states. He found no statistically significant effects of mandates on coverage decisions.

This set of work highlights two crucial problems that have tended to undermine much of the work that has looked broadly at the effects of state mandates. First, state laws differ markedly with respect to the likely costs they impose on potential purchasers and the nature of the coverage that they actually mandate. The research has been rather cavalier with measuring regulation. Efforts to aggregate state laws via counts of laws, for example, at best can only obtain an average effect of an average mandate. It seems increasingly clear that there is as yet no good empirical way to look at the overall effects of state mandates. One must look at the effects of mandates individually and provide some assurance that the laws under study are homogeneous. Second, state insurance mandates are not enacted randomly. They result from legislative actions that in turn reflect issues such as resident preferences, existing levels of coverage, and the influence of providers. Failure to account for the endogeneity of the laws is almost certainly responsible for much of the inconsistency and uncertainty surrounding a lot of the existing empirical work.

The New Generation of Mandates Research

Several mandate-specific studies have been undertaken in the past decade. They focus on the careful measurement of a particular mandate across the states and they rigorously deal with the endogeneity issue by using differences-in-differences (or sometimes triple differences) or instrumental variables.

These studies have not uniformly concluded that the laws have affected use or outcomes. However, they have given much greater attention to measuring the law and they employ much more sophisticated methods to account for the endogeneity of the legislation. Several examples are noteworthy.

Bitler and Carpenter (2011) examined the effects of mammography screening mandates. They used person-level data from the Behavioral Risk Factor Surveillance System (BRFSS) over the 1987–2000 period and concluded that the mandates account for approximately 7% of the doubling of screening observed over the study period. This conclusion resulted from a triple-difference analysis that compared screening in states that did and did not enact the mandate, before and after enactment, among women at ages that were and were not recommended for screening.

Klick and Stratmann (2007) used the 1996–2000 BRFSS data to examine the effects of mandates that cover diabetes supplies, treatment, and services on obesity among diabetics. They too used the triple-difference model (states that did and did not enact the mandate, before and after enactment, and for those with and without a self-reported diagnosis of diabetes). Their hypothesis was that the presence of the mandate lowered the cost of treatment and, therefore, provided incentives for individuals to let their health deteriorate. They conclude that diabetics in states that enacted the coverage mandates, had greater increases in body mass index (BMI) compared to changes in BMI for nondiabetics in states without mandates over the same period. They also found that the results depended on the use of the triple-difference approach. Less rigorous models suggest that the mandates lowered BMI. In related work also focusing on the moral hazard effects of insurance mandates, Klick and Stratmann (2006) examined the effects of mental health mandates (that included substance abuse treatment) on the per capita consumption of beer in the state. They argue that the mandate lowers the cost of alcohol abuse treatment, should it be needed. They explicitly model the enactment of the law using the enactment of medical malpractice damage caps, diabetes mandates, and the number of nonpsychiatrist physicians per capita as instruments. Their estimates suggest that the mandate enactment was associated with an additional consumption of two cases of beer per capita.

In less controversial work, Liu *et al.* (2004) examined the effect of the so-called drive-by delivery laws. These provisions were enacted to prevent insurers from insisting that women and newborns be discharged from a hospital too quickly after a birth. The researchers used hospital discharge abstract data from 18 states over the period 1995–98. Their differences-in-differences analysis concluded that the laws resulted in 11% longer lengths of stay for vaginally delivered newborns. The effects were larger when the law was a 'mother's decision' rather than specifying a 'physician decision.' The effects were smaller among patients who were likely to be exempt from the law due to ERISA.

Summary

State insurance mandates have proliferated since the mid-1970s. The economics of the laws suggest that they should increase insurance premiums, reduce coverage, and lead to greater self-insured status among employers. More generally, they may affect the use and outcomes of mandated services and may influence the take-up of health insurance. The empirical work has been inconsistent in its findings. This stems from measurement issues in classifying and aggregating the laws and a failure to account for the nonrandom enactment of laws in the states. The new generation of research, largely undertaken in the 2000s and building on Gruber's (1994b) seminal work on maternity mandates, has used much more sophisticated techniques and provided much greater confidence in the evaluations of how the laws have affected behavior.

Statistical Issues in Economic Evaluations

AH Briggs, University of Glasgow, Glasgow, Scotland, UK

Introduction

As health economic evaluation has become increasingly popular, so it has become much more common that individual patient data are collected alongside clinical trials. This has opened up the possibility of using statistical methods to analyze health economic data with the purposes of informing health economic evaluation.

In this entry of the encyclopedia, statistical methods for analyzing health economic data are reviewed. The second section focuses specifically on issues relating to the analysis and testing of cost data, including issues related to nonnormality of the data, censoring of cost-data and other forms of missingness. The third section deals with characterizing uncertainty in cost-effectiveness (CE) analysis, focusing on the commonly employed incremental CE ratio statistic. The fourth section focuses on the net-benefit statistic as an alternative approach to characterizing uncertainty in CE analyses. A final section offers some concluding comments and links to other articles that address similar material, in particular the increasing use of individual data analyses within CE modeling to address issues of heterogeneity in CE.

Analyzing Individual-Level Cost Data

Where health care resource information has been collected alongside randomized controlled trials, so the formal statistical testing of cost differences has become possible. Nevertheless, a number of problems plague cost data in particular. First, that cost data are often highly nonnormal, exhibiting excess zeros, skewness, and kurtosis. Second, that censoring of cost occurs, just as it does for other trial endpoints. Third, that cost data are often missing, due to the nature of the data collection process.

Non Normality

It is well recognized that statistical analysis of healthcare resource use and cost data poses a number of difficulties related to the distribution of these data: they often exhibit substantial positive skewness, can have heavy tails and often have excess zeros representing a proportion of subjects that are not users of health care resources. In medical statistics, the standard approach for handling such nonnormal data has been to use nonparametric methods, such as rank order statistics. However, in health economics it is widely accepted that it is the estimated population mean cost that is the statistic of interest to policy makers – as only the mean cost (when multiplied by the number of subjects) recovers the total cost of care for the patient group.

In a recent review of the literature on methods for the statistical modeling of health care resource and cost data, Mihaylova and colleagues distinguish two broad areas that have developed in relation to the statistical analysis of these data. In the 'randomized evaluation' field, healthcare resource use and cost data are collected alongside randomized controlled trials, in order to study the impact of interventions on average costs and test mean cost differences. These studies are used to evaluate the CE of healthcare interventions and guide treatment decisions. The 'health econometrics' field is characterized by the use of large quantities of observational data to model individual healthcare expenditures, with a view to understanding how individual characteristics influence overall costs. Observational data are vulnerable to biases in estimating effects due to nonrandom selection and confounding that are avoided in randomized experimental data.

The literature on evaluating costs for the purpose of CE analysis and that on health econometrics have developed largely independently. Mihalova and colleagues provide a review of the analytical approaches to estimating mean resource use and costs with a particular focus on mean cost differences for evaluative purposes. Although the fundamental interest relates to the raw cost scale, analysis can be performed on a different scale for the purposes of estimation providing a mechanism exists for returning to the original cost scale.

The objective of their review was to examine the state-of-the-art of statistical analysis of healthcare resource use and cost data, by identifying the methods employed, their ability to address the challenges of the data and their ease for general use. They proposed a framework to guide researchers when analysing resource use and costs in clinical trials and a summary of this framework is reproduced in Table 1.

Their review identified 12 broad categories of methods: (I) methods based on the normal distribution, (II) models based on normality following a transformation of the data, (III) single-distribution generalized linear models (GLMs), (IV) parametric models based on skewed distributions outside the GLM family, (V) models based on mixtures of parametric distributions, (VI) two-part, hurdle and Tobit models, (VII) survival methods, (VIII) nonparametric methods, (IX) methods based on truncation or trimming of data, (X) data components models, (XI) methods based on averaging across a number of models, and (XII) Markov chain methods. Their recommendations were that, firstly, simple methods are preferred in large sample sizes (in the thousands) where the near-normality of sample means is assured. Secondly, in somewhat smaller sample sizes (in the hundreds), relatively simple methods, able to deal with one or two of the data characteristics studied, may be preferable but checking sensitivity of results to assumptions is necessary. More complex approaches for the analysis of mean costs in clinical trials that take into consideration the specific features of the data might lead to gains in precision and to more informative estimates if correctly specified, but run a risk of misspecification leading to biased results. Although some more complex methods hold promise for the future, these are relatively untried in practice and as such are not currently recommended for wider applied work.

XII. Markov chain methods	H	H	P	H	P	P	H	L	L

[a]Small sample refers to tens to a few hundreds of participants.
[b]More complex GLMs require large sample sizes, as does checking parametric modeling assumptions.
[c]Checking parametric modeling assumptions needs large sample size.
[d]The ability to model heavy tails depends on the model used in the second part. If the model used in the second part is from Category II 'Methods based on normality following a transformation of the data' back transformation will be needed. Checking modeling assumptions needs reasonable sample size. The case of implementation depends on the models used in the two parts.
[e]These approaches are not available in standard statistical software.
[f]Depends on data; in small samples opportunities to check parametric model assumption are restricted.
[g]Models beyond those relying on multivariate normality will need large data sets. More details is provided in the review templates in the web appendix at http://www.herc.ox.ac.uk/downloads/support_pub.
Abbreviations: GLM, generalized linear model; H, High applicability; L, Low applicability; P, Possible applicability.
Source: Reproduced from Mihaylova *et al.* (2011).

One of the areas that Mihaylova *et al.* (2011) ruled outside of the scope of their review was the problem of censoring. However, particularly in the field of health economic evaluation conducted alongside clinical trials, the problem of censored cost data is highly prevalent. In the past, many analyses simply ignored this issue and presented analyses that assumed the data were uncensored. Fenn *et al.* (1995) argues that such an approach would lead to biased estimates of the true cost which, when adjusted for censoring, could be substantially higher. They went on to propose that standard survival analyses could be employed using the cost-scale in order to adjust for censoring. However, although this removed some of the problem, other authors demonstrated that the approach remained biased as the cost scale and the censoring event were no longer independent, an assumption required by the standard survival analysis methods.

Two general approaches have been shown to be capable of generating unbiased estimates of censored cost data. The first, known as the Kaplan–Meier Sample Average estimator is based on estimating a mean cost function over fixed time intervals based on the cost of the at risk population, then weighting those mean costs by the proportion surviving (estimated from the Kaplan–Meier survivor function) and summing across intervals to estimate total mean cost for the follow-up period. The other approach, based on Inverse Proportion Weighting (IPW) takes the inverse of the estimated survivor function for the censoring process as a weight to apply to the remaining observed data. Thus, at a given time point, if the censoring is 50% then each remaining data point receives a weight of 2 to reflect that the cost observed must count for both the observed subjects and the additional 50% that are censored at that point. The weighted costs in each time period are then summed and averaged to obtain the mean total cost.

These approaches can be extended into a regression framework in order to handle prognostic patient characteristics. Indeed, parameterizing the cost and survivor functions would also offer a crude approach to extrapolating beyond the data to estimate total lifetime cost. Although rarely acknowledged, the approach taken to estimating unbiased cost-estimates shares a common methodology with the estimation of quality adjusted survival analyses.

Other Forms of Missingness

The problem of missing data is not new and has received much attention in the statistical literature as to the appropriate methods for handling missing data. Although in principle, missing economic data alongside clinical trials is no different to other forms of missing data; the distributional form of cost data (as presented above) may provide challenges for the analyst. Furthermore, because economic evaluation is commonly 'piggy-backed' onto clinical trials, there is a danger that economic variables will be considered less important by researchers responsible for data collection which could result in higher rates of missingness.

Missing data can arise in a number of ways. Univariate missingness occurs when a single variable in a data set is causing a problem through missing values, although the rest of the variables contain complete information. Unit nonresponse describes the situation where for some people (observations) no data are recorded for any of the variables. More common, however, is a situation of general or multivariate missingness where some, but not all of the variables will be missing for some of the subjects. Another common type of missingness is known as monotone missing data, which arises in panel or longitudinal studies, and is characterized by information being available up to a certain time point/wave but not beyond that point.

Little and Rubin (2002) outline three missing data mechanisms:

1. Missing completely at random (MCAR): If data are missing under this mechanism then it is as if random cells from the rectangular data set are not available such that the missing values bear no relation to the value of any of the variables.
2. Missing at random (MAR): Under this mechanism, missing values in the data set may depend on the value of other observed variables in the data set, but that conditional on those values the data are missing at random. The key is that the missing values do not depend on the values of unobserved variables.
3. Not missing at random (NMAR): It describes the case where missing values do depend on unobserved values.

The difference between these mechanisms is quite subtle, particularly for the first two cases of MCAR and MAR. Briggs and colleagues give the following example related to resource/cost data. Consider a questionnaire distributed to patients, in order to ascertain their use of health care resources following a particular treatment intervention, where the response rate is less than 100%. The nonresponse is MCAR if the reason for failure to complete the questionnaire was unrelated to any prognostic variables in the data set. In practice, however, such a situation is unlikely. For example, retired patients may find more time to complete and return a questionnaire than those of working age. Also, being older on average, retired patients may make more use of health care resources. If having conditioned on the age and retirement status of the patients nonresponse is random then the missing data problem is considered MAR. However, it is possible that one of the reasons for nonresponse is that patients have been admitted to hospital. Now the missing data are NMAR because the value of the data that are not observed is driving the reason for nonresponse.

Note that the case of MCAR is quite rare – indeed the impact of administrative censoring is a special case of MCAR and survival analysis techniques employ the assumption that the censoring mechanism is independent of the event of interest when adjusting estimates for censoring. However, the case of NMAR is likely more common but difficult to demonstrate convincingly by the very nature of the problem of the values being related to the missing data problem. By far the majority of missing data methods relate to the attempt to correct statistically for the MAR case – using the observed data to predict the missing information in order to restore the full rectangular dataset for analysis. In general, multiple imputation, using a model-based imputation method is now readily implemented in most statistical packages and is a straightforward way to

appropriately correct for the MAR problem. Alternatively, IPW approaches have been demonstrated to perform well and can obviate the need for creating multiple data sets to inform analyses.

Characterizing Uncertainty for Cost-Effectiveness Ratios

This section focuses specifically on uncertainty in the incremental CE ratio (ICER) statistic, defined as $\text{ICER} = \Delta C/\Delta E$, where ΔE is the per patient mean difference (treatment minus control) in effectiveness and ΔC is the mean per patient difference in cost.

Confidence Intervals/Surfaces for Incremental Cost-Effectiveness Ratios on the Cost-Effectiveness Plane

This subsection considers the presentation of uncertainty on the CE plane and the specific issue of calculating confidence intervals for CE ratios.

The cost-effectiveness plane

The CE plane can be used to show the difference in effectiveness (ΔE) per patient against the difference in cost (ΔC) per patient. By plotting the effectiveness difference on the horizontal axis the slope of the line joining any point on the plane to the origin is equal to the ICER statistic.

One treatment is said to 'dominate' another, being less costly and more effective, if it is located in the northwest (NW) quadrant or the southeast (SE) quadrant of the CE plane. In these two circumstances it is clearly appropriate to implement the dominant treatment and no estimation of CE ratios is required. However, far more common is for one treatment to be more effective but also more costly. In such circumstances, a decision must be made as to whether the additional health benefits of the more effective treatment are worth the additional cost. If the ICER of the more effective therapy ($\Delta C/\Delta E$) – the slope of a straight line from the origin that passes through the (ΔE, ΔC) coordinate – is less than the acceptable 'ceiling ratio' of the decision maker (representing the willingness-to-pay for a unit of health gain) then the treatment should be adopted. This upper limit on CE can be given a value (R_c) and can be represented on the CE plane as a line passing through the origin with slope equal to R_c.

The use of the CE plane has previously been used to illustrate the CE of early endoscopy for dyspeptic patients versus no early endoscopy. In a clinical trial, the early endoscopy arm cost an additional £80 per patient and resulted in an additional 5% of patients free of dyspeptic symptoms at 12 months. This point is plotted on the CE plane in Figure 1 and the slope of the line joining that point to the origin represents the ICER of £1700 per patient free of dyspepsia at 12 months. Also shown on the CE plane are the standard confidence intervals for the difference in effect and difference in effect (the horizontal and vertical I bars respectively that cross at the point estimate). The box that is defined by these I bars (and which is also illustrated in Figure 1) represents an early attempt to approximate sampling uncertainty in the ICER. Nevertheless, subsequent methodological research has demonstrated the utility of two exact methods for confidence interval estimation – nonparametric bootstrapping or the parametric Fieller's approach. These are described and illustrated for the dyspepsia trial below.

Fieller's theorem

Fieller's approach is based on the assumption that the cost and effect differences follow a joint normal distribution, rather than the ratio itself.

The standard CE ratio calculation of $R = \Delta C/\Delta E$ can be expressed as $R\Delta E - \Delta C = 0$ with known variance $R^2\text{var}(\Delta E) + \text{var}(\Delta C) - 2R\,\text{cov}(\Delta E, \Delta C)$. Therefore, a standard normally

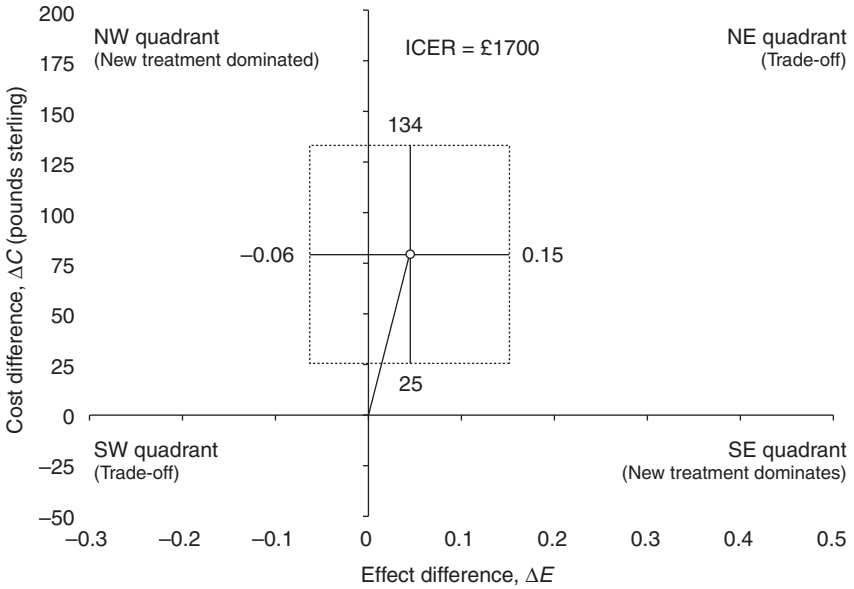

Figure 1 CE plane showing the location of results for the early endoscopy trial. ICER, incremental cost-effectiveness ratio; NE, northeast; NW, northwest; SE, southeast; SW, southwest. Reproduced from Briggs, A. H. (2004). Statistical approaches to handling uncertainty in health economic evaluation. *European Journal of Gastroenterology & Hepatology* **16**(6), 551–561, with permission from Wolters Kluwer Health.

distributed variable can be generated by dividing the expression through by its standard error:

$$\frac{R\Delta E - \Delta C}{\sqrt{R^2\text{var}(\Delta E) + \text{var}(\Delta C) - 2R\text{cov}(\Delta E, \Delta C)}} \sim N(0,1)$$

Setting this expression equal to the critical point from the standard normal distribution, $z_{\alpha/2}$ for a $(1-\alpha)100\%$ confidence interval, yields the following quadratic equation in R:

$$R^2\left[\Delta E^2 - z^2_{\alpha/2}\text{var}(\Delta E)\right] - 2R\left[\Delta E \cdot \Delta C - z^2_{\alpha/2}\text{cov}(\Delta E, \Delta C)\right] + \left[\Delta C^2 - z^2_{\alpha/2}\text{var}(\Delta C)\right] = 0$$

The roots of this equation give the Fieller confidence limits for the ICER.

Figure 2(a) shows the assumption of joint normality on the CE plane for the early endoscopy example: three ellipses of equal density are plotted covering 5%, 50%, and 95% of the integrated joint density. Also plotted are the estimated confidence limits using Fieller's theorem (£300 to −£1100), represented by the slopes of the lines on the plane passing through the origin. Note that the 'wedge' defined by the confidence limits falls inside the 95% ellipse – this is because Fieller's approach automatically adjusts to ensure that 95% of the integrated joint density falls within the wedge.

Bootstrapping

The approach of nonparametric bootstrapping is a re sampling procedure that employs raw computing power to estimate an empirical sampling distribution for the statistic of interest rather than relying on parametric assumptions. A number of authors have demonstrated its potential use for estimating confidence intervals for CE ratios. Bootstrap samples of the same size as the original data are drawn with replacement from the original sample and the statistic of interest is calculated. Repeating this process a large number of times generates a vector of bootstrap replicates of the statistic of interest, which is the empirical estimate of the statistic's sampling distribution.

One thousand bootstrapped effect and cost differences for the early endoscopy example are plotted on the CE plane in Figure 2(b). Confidence limits can be obtained by selecting the 2.5th and 97.5th percentiles of the bootstrapped replications ordered from most favorable to least favorable CE ratio – this effectively ensures that 95% of the estimated joint density falls within the wedge on the CE plane defined by the confidence limits. As is clearly apparent from Figure 3(b), the bootstrap estimate of the joint density and the bootstrap confidence limits (£300 to −£1200) are very similar to those generated by Fieller's theorem.

Estimation or Hypothesis Testing?

In practice, the example in Figure 1 is just one situation that can arise when analyzing the results of an economic analysis conducted alongside a clinical trial with respect to the significance or otherwise of the cost and effect differences. In fact, Briggs and O'Brien (2001) have argued that there are nine possible situations that could arise and these are illustrated on the CE plane in Figure 2 with multiple 'confidence boxes'.

In situations 1 and 2, one intervention has been shown to be significantly more effective and significantly cheaper than the other and is therefore clearly the treatment of choice. In situations 7 and 8 one treatment has been shown to be significantly more costly, but also significantly more effective. It is in these situations that it is clearly appropriate to estimate an ICER and where much research effort has been employed to ascertain the most appropriate method for estimating the ICER confidence interval.

A potential problem arises in the situations where either the cost difference (situations 3 and 5) or the effect difference (situations 4 and 6) is not statistically significant. (The dyspepsia

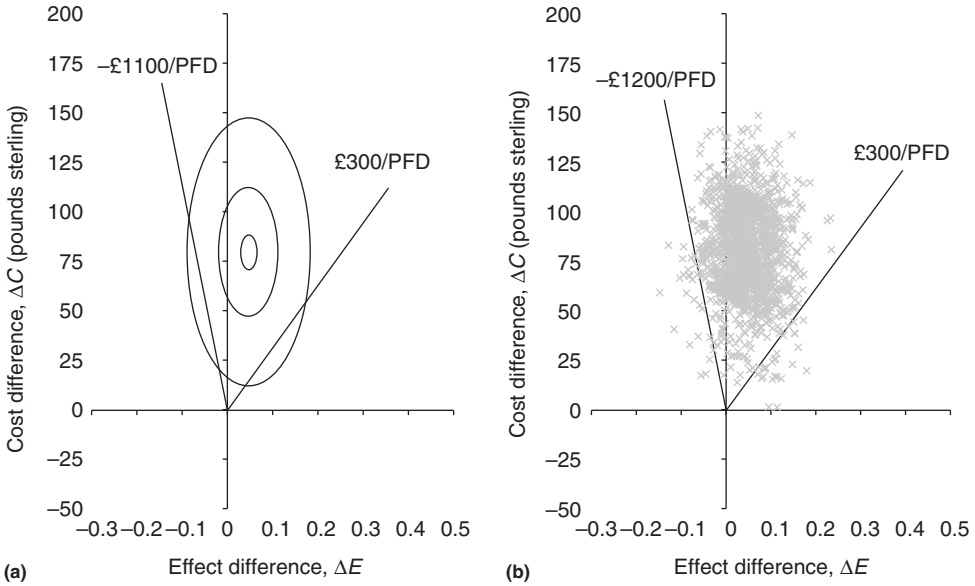

Figure 2 Confidence intervals for CE ratios for the early endoscopy study. (a) Parametric Fieller's theorem and (b) nonparametric bootstrapping. PFD, patients free of dyspepsia. Figure 3 Nine possible situations that can arise concerning the significance (or otherwise) of cost and effect differences illustrated on the CE plane. Boxes indicate the area bounded by the individual confidence limites on cost and effect: statistically significant differences are indicated where the box does not straddle the relevant axis. Reproduced from Briggs and O'Brien (2001).

example falls into situation 4.) It is common to find analysts in these situations adapting the decision rule to focus only on the dimension where a difference has been shown. For example, it might be tempting in situation 4, as in the dyspepsia example, to assume early endoscopy has not better effectiveness than the no early endoscopy option and therefore focus the comparison only in terms of cost. This form of analysis – known as cost-minimization analysis – uses the logic that among outcome-equivalent options one should choose the less costly option.

The problem with this simple approach to decision making in situations where either cost or effect is not statistically significant is that it is based on simple and sequential tests of hypotheses. But the deficiencies of hypothesis testing (in contrast to estimation) are well known, and therefore the goal of economic evaluation should be the estimation of a parameter – incremental CE – with appropriate representation of uncertainty, rather than hypothesis testing.

Acceptability Curves

Although commentators are now largely agreed on the most appropriate methods for ICER confidence interval estimation, such intervals are not appropriate in all the nine situations outlined in Figure 3 above.

An important problem is that ratios of the same sign, but from different quadrants, are not strictly comparable. Negative ICERs in the NW quadrant of the plane (favoring the existing treatment) are qualitatively different from negative ICERs in the SE quadrant (favoring the new treatment) yet will be grouped together in any naïve rank-ordering exercise (note the treatment of negative ratios in the bootstrapping of the early endoscopy example above – because the negative ratios were in the NE quadrant they were ranked above the highest positive ratios to give a negative upper limit to the ratio). Similarly, positive ratios of the same magnitude in the SW and NE quadrants have precisely the opposite interpretation from the point of view of the intervention under evaluation. This is because the decision rule in the SW quadrant is the opposite of that in the NE. For example, an ICER of 500 may be considered as supporting a new treatment in the NE quadrant if society has set a ceiling ratio of 1000. However, in the SW quadrant this value of the ICER would be considered as support of the existing treatment rather than the new treatment. Again, any naïve ranking exercise could easily conflate ICERs with the same magnitude but with different implications for decision making.

Acceptability curves have been proposed as a solution to this problem. If the estimated ICER lies below some ceiling ratio, R_c, then it should be implemented. Therefore, in terms of the bootstrap replications on the CE plane in Figure 2(b), uncertainty could be summarized by considering how many of the bootstrap replications fall below and to the right of a line with slope equal to R_c lending support to the CE of the intervention. Alternatively, using an assumption of joint normality in the distribution of costs and effects, the proportion of the parametric joint density that falls on the cost-effective surface of the CE plane can be calculated. Because the appropriate value of R_c is itself unknown, it can be varied in order to show how the evidence in favor of CE of the intervention varies with the decision rule. The resulting acceptability curve for the early endoscopy example and based on the joint normal assumption shown in Figure 2(a) is presented in Figure 4.

This 'acceptability curve' presents much more information on uncertainty than do confidence intervals. The curve cuts the horizontal axis at the p-value (one-sided) for the cost difference (which is $p<.05$ in the early endoscopy example) because a value of zero for R_c implies that only the cost is important in the CE calculation. The curve is tending toward one minus the p-value for the effect difference (which in the early endoscopy example is $p=.20$), because an infinite value for R_c implies that effect only is important in the CE calculation. The median value ($p=.5$) corresponds to the point estimate of the ICER, £1700 for the early endoscopy example.

As well as summarizing, for every value of R_c, the evidence in favor of the intervention being cost-effective, acceptability

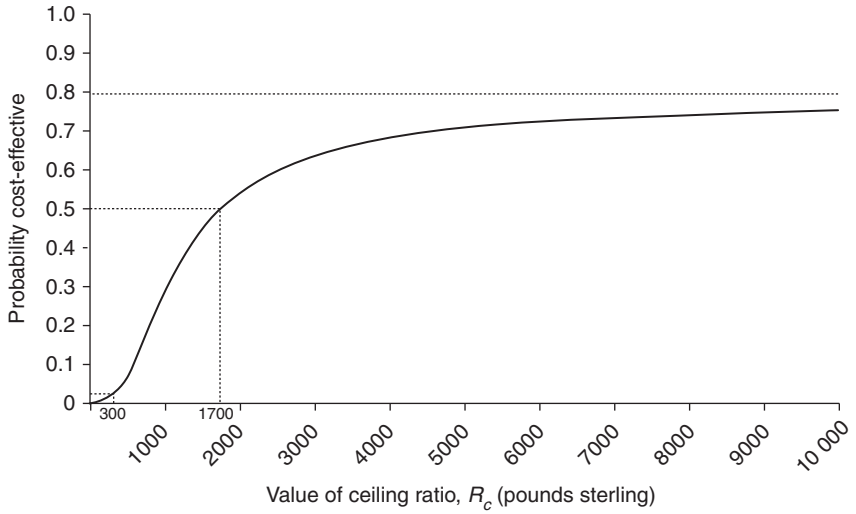

Figure 4 CE acceptability curve for the early endoscopy examples. Reproduced from Briggs, A. H. (2004). Statistical approaches to handling uncertainty in health economic evaluation. *European Journal of Gastroenterology & Hepatology* **16**(6), 551–561, with permission from Wolters Kluwer Health.

curves can also be employed to obtain a confidence interval on CE. The limits are obtained by looking across from the vertical axis to the curve at the appropriate points for the desired confidence level and reading off the associated CE value from the horizontal axis. For the early endoscopy example the 95% upper bound is not defined (because the curve is not defined at 0.975) and the 95% lower bound is equal to £300.

Development of Net-Benefit Solutions

This section describes the reformulation of the standard CE decision rule into one of two possible net-benefit statistics. The use of the net-benefit statistic to estimate acceptability is highlighted, and the section goes on to describe regression approaches that utilize individual-level net-benefits to estimate CE directly.

Net-Benefit Statistics

The algebraic formulation of the decision rule for CE analysis that a new treatment should be implemented only if its ICER lies below the ceiling ratio, $\Delta C/\Delta E < R_c$, can be rearranged in two equivalent ways to give two alternative inequalities on either the monetary scale (NMB) or on the health scale (net health benefit (NHB))

$$NMB: \quad R_c \cdot \Delta E - \Delta C > 0$$

$$NHB: \quad \Delta E - \frac{\Delta C}{R_c} > 0$$

These decision rules are entirely equivalent to the standard rule in terms of the ICER but have the advantage that the variance for the net-benefit statistics is tractable and the sampling distribution of the net-benefits is much better behaved. The variance expressions for net benefits on the cost or effect scales are given by

$$\text{var}(NMB) = R_c^2 \cdot \text{var}(\Delta E) + \text{var}(\Delta C) - 2R_c \cdot \text{cov}(\Delta E, \Delta C)$$

$$\text{var}(NHB) = \text{var}(\Delta E) + \text{var}(\Delta C)/R_c^2 - 2 \cdot \text{cov}(\Delta E, \Delta C)/Rc$$

Because both the net-benefit statistics rely on the decision rule R_c to avoid the problems of ratio statistics, so the net-benefit can be plotted as a function of R_c. Both formulations of net-benefit are illustrated in Figure 5 for the early endoscopy example: the upper pane shows NMB and the lower pane NHB as a function of the ceiling ratio R_c. The net-benefit curves cross the horizontal axis at the point estimate of CE (£1700 per patient free of dyspepsia). Where the confidence limits on net-benefits cross the horizontal axis gives the confidence interval for CE and this is shown between the two panes in Figure 5. The lower 95% confidence limit crosses the axis at £300, whereas the upper 95% limit does not cross the axis indicating that an upper 95% limit on CE is not defined for the early endoscopy example. Note the correspondence with the Fieller limits – this correspondence is explained by the fact that the two methods employ the exact same assumption of joint normality in costs and effects.

Acceptability Solutions

The net-benefit statistic provides a straightforward method to estimate the acceptability curve from Figure 4. The curve can be calculated from the *p*-value on the net-benefits being positive. Note that this gives the acceptability curve a frequentist interpretation, in line with the original paper that introduced the acceptability curve, although that same paper also labeled the vertical axis as 'probability cost-effective.' Strictly, such an interpretation requires a Bayesian view of probability, although it is straightforward to show that the frequentist curve based on the *p*-values for net-benefit and the Bayesian curve based on a normal likelihood and uninformative prior converge.

Regression Possibilities

The Section Net-Benefit Statistics illustrated how the ICER ratio statistic could be reformulated into a linear net-benefit statistic, by using the decision rule. Hoch and colleagues went on to demonstrate how the linearity of the net-benefit

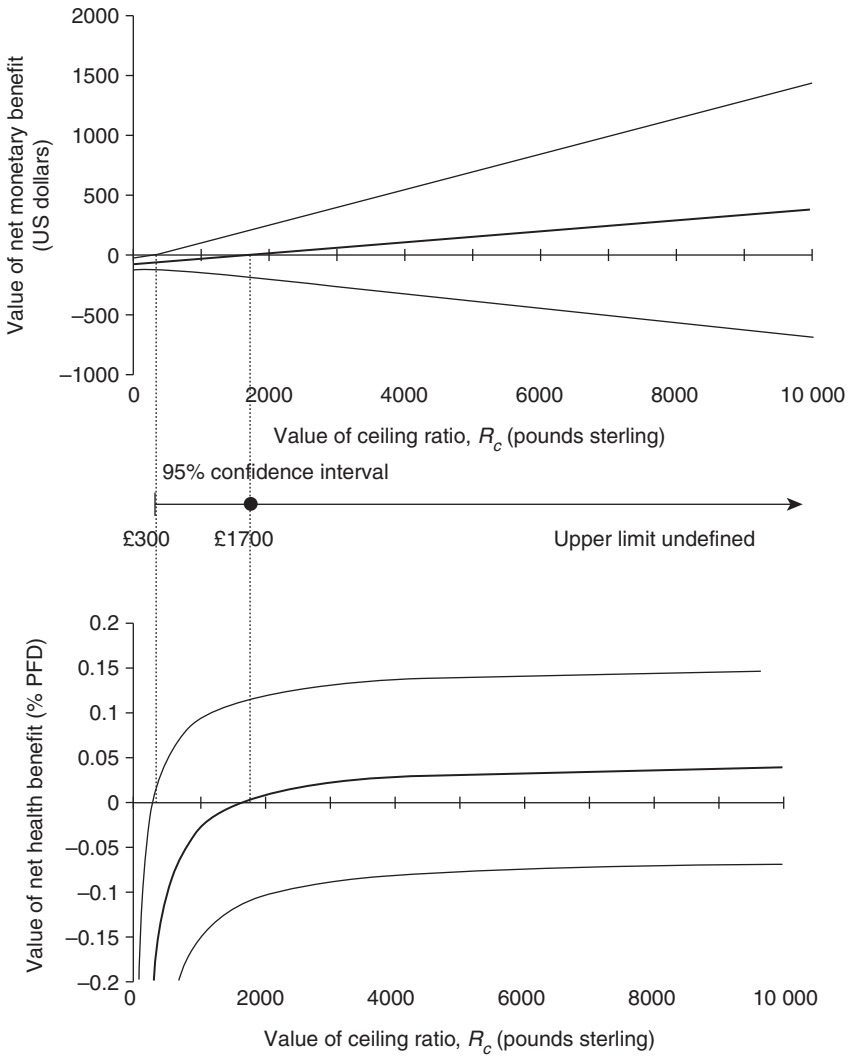

Figure 5 Value of net monetary benefit (upper pane) and net health benefit (lower pane) as a function of the ceiling ratio together with the corresponding confidence interval on cost-effectiveness for the early endoscopy example. Reproduced from Briggs, A. H. (2004). Statistical approaches to handling uncertainty in health economic evaluation. *European Journal of Gastroenterology & Hepatology* **16**(6), 551–561, with permission from Wolters Kluwer Health.

framework can be employed to directly estimate CE within a regression framework. By formulating a net-benefit value for each individual patient i as

$$NMB_i = \lambda \cdot E_i - C_i$$

where E_i and C_i are the observed effects and costs for each patient. At the simplest level, the following linear model

$$NMB_i = \alpha + \Delta t_i + \varepsilon_i \qquad \text{(Model 1)}$$

can be employed where α is an intercept term, t a treatment dummy taking the values zero for the standard treatment and one for the new treatment, and a random error term ε. The coefficient Δ on the treatment dummy gives the estimated incremental net-benefit of treatment and will coincide with the usual estimate of incremental net-benefit obtained by aggregating across the treatment arms in a standard CE analysis. Similarly, the standard error of the coefficient is the same as that calculated from the standard approach. However, the power of the regression approach comes from the ability to covariate adjust (Model 2) and/or look at interactions between covariates and treatments to explore potential subgroup effects (Model 3).

These models are given algebraically below

$$NMB_i = \alpha + \sum_{j=1}^{p} \beta_j x_{ij} + \Delta t_i + \varepsilon_i \qquad \text{(Model 2)}$$

$$NMB_i = \alpha + \sum_{j=1}^{p} \beta_j x_{ij} + \Delta t_i + t_i \sum_{j=1}^{p} \gamma_j x_{ij} + \varepsilon_i \qquad \text{(Model 3)}$$

where there are p prognostic covariates x.

In the context of an experimental design like a randomized controlled trial, the randomization process is expected to ensure a balance of both observed and unobserved confounding factors across the treatment arms. In this case, the use of prognostic covariates will not materially affect the magnitude

of the estimated CE, but may improve the precision of the estimate and lead to a corresponding narrowing of the estimated confidence intervals such that Model 2 should provide a more precise estimate of incremental net-benefit than Model 1.

The final term is the interaction between the treatment dummy and the prognostic covariates. The significance of the coefficients γ_j on the interaction between the covariates of the model and the treatment dummy represent the appropriate test for subgroup effects – although this does not protect against spurious subgroup effects being detected by chance. Where treatment effect modification is detected, the fact that CE varies for different types of patient may have important consequences for decision making.

Despite the potential of using regression for net-benefit, the use of bivariate regression, through techniques such as seemingly unrelated regression, is more powerful, in that the same explanatory variables do not need to be specified for both cost and effect part of the equations.

Conclusions

This article has explored the development of statistical techniques for analyzing cost and CE data where individual data on coat and effect are available, often as a result of collecting patient-level data alongside a clinical trial. The statistical techniques for examining mean cost differences require subtle changes to the often standard approaches recommended in general (medical) statistics texts. This is due to the focus of CE analysis on informing decision making and maximizing potential health gain from available resources. Hence the focus on testing mean differences rather than reliance on rank order statistics, and the development of adaptations to the Kaplan–Meier approach to estimate cost in the presence of censoring. The net-benefit statistic is much better behaved than the ICER statistic when it comes to statistical analysis and representing uncertainty in CE estimates. Although most authors will want to continue to present results to their audience in terms of traditional ICERs, net-benefit statistics remain an important tool for the analyst to generate statistical measures of uncertainty.

Although this article has focused on the analysis of data on costs and effects generated alongside clinical trials, it is of note that CE analysis conducted within a decision modeling framework often employ individual patient data analyses to inform parameter estimates within the models. By using covariate adjusted parameter estimates, these decision models can explore the potential for patient heterogeneity in CE estimates. Statistical techniques can also be used at the patient level or study level for synthesizing multiple sources of evidence through traditional meta-analyses of network meta-analysis techniques.

Supplementary Private Health Insurance in National Health Insurance Systems

M Stabile, University of Toronto, Toronto, ON, Canada, and National Bureau of Economic Research, Cambridge, MA, USA
M Townsend, University of Toronto, Toronto, ON, Canada

This article explores the economic theory and evidence regarding supplementary private health insurance in countries with national health insurance systems. It defines voluntary health insurance for the purpose of the article, and classifies the different roles played by voluntary private health insurance. It will then examine the economic literature on voluntary private health insurance, beginning with the theoretical literature before turning to the empirical evidence.

Defining Supplementary Private Health Insurance

Although private health insurance is available in all countries in the European Union, North America, Australia, and New Zealand, private insurance plays significantly different roles depending on the jurisdiction. Almost all the countries included above provide near universal statutory health insurance coverage for their citizens. The dynamics and scope of this statutory health insurance often influence the nature of private supplemental insurance in these jurisdictions. Thomson and Mossialos (2009) provide a useful classification for the role of private health insurance: supplementary, complementary, or substitutive. Their classification is adopted here.

Supplementary insurance generally provides access to services that are already available within the publicly financed health insurance scheme (presumably affording faster access, greater choice, or other amenities). Example jurisdictions include the UK, Australia, and Sweden. Supplemental private insurance markets tend to have small market shares. For example, the UK market covers approximately 10% of the population.

Complementary insurance generally offers services that are not covered under the statutory scheme such as prescription drugs. Example jurisdictions include Canada and Denmark. Some systems also allow for complementary private insurance to cover costs that are typically left outside the public system (e.g., insurance to cover the cost of user fees). Example jurisdictions include France. Market share for complementary insurance is generally higher given the nature of the insurance. In France, more than 90% of individuals have complementary insurance of some form.

Substitutive insurance generally covers people who are not covered under the statutory scheme. Example jurisdictions include Germany. Market share for substitutive insurance is generally smaller (in Germany the market share for private insurance is approximately 10%).

This article focuses on private insurance that is either supplementary or complementary as defined above. Further, the authors focus on private insurance that is voluntary and not statutory (as in the Netherlands) given that many of the potential market failures that occur do so in voluntary markets. It examines both the theoretical and empirical roles that supplementary private insurance can play and the interaction between public and private insurance within this context.

Theoretical Effects of Supplementary Private Health Insurance in National Health Insurance Systems

This section briefly reviews the theoretical effects of a parallel, privately financed system on the performance of the publicly financed system. It focuses on exploring the existing research on the relationship between supplementary private insurance (either as a substitute or complement as described above) and the national public insurance system. It is reasonable to assume that a privately financed system improves the welfare of those who use it as only those forms of private insurance that are voluntary are being considered. It is therefore possible that even if the effects on the public system are negative the overall welfare effects could be positive. However, because this is not a Pareto improvement, and the empirical evidence cited above suggests that the take up of privately financed care is generally small and concentrated among higher income individuals, the focus here will be on whether supplementary private insurance for health services can exist without harming the public system.

Economic theory regarding the effect of introducing a private alternative for publicly financed services is ambiguous. Models of the interaction between private and public insurance systems approach the problem along various population dimensions. For example, previous theoretical literature reviewed in Zweifel (2011) suggests that Pareto improvements are possible in models of differentiated risk types (high and low). Smith (2007) suggests in a two-income type model (rich and poor) that a first best solution is also feasible with supplementary private insurance but that political economy considerations and tax base erosion generally prevent the implementation of such a model.

Depending on assumptions regarding supply of physicians, demand for services, and the magnitude of the effects of conflicting incentives on providers, the theoretical effects of private insurance suggest several possibilities. It is possible that allowing patients to seek health care outside the public system would release public resources and lead to shorter waiting times both for users of the public and the private sector. Further, it is possible that a parallel private system could serve as a benchmark against which the public system could be compared, allowing health care administrators and political leaders to evaluate the efficiency of the public system meaningfully. However, a parallel private health care system may adversely affect the public system, resulting in, at best, no decline in public waiting lists and, at worst, substantial increases. Under certain assumptions, allowing private health care would induce a shift in health care resources from the public to the private sectors resulting in the crowding out of

 doi:10.1016/B978-0-12-375678-7.00924-X

public provision. Theoretically, physicians may have an incentive to increase waiting lists within the public system in order to encourage patients to switch to the private system, where they can bill more than in the public sector. The existence of a private system with deregulated prices can also reduce the monopsony power enjoyed by the public system and result in upward pressure on the prices in the public system. Cream skimming and dumping of risks by the private system can further increase the perpatient cost of the cases remaining in the public system.

Under other assumptions, an increase in supply afforded by a supplemental private system could be offset by an increase in demand for publicly funded health care, so that waiting lists could be relatively unchanged. In addition, introducing private health care may reduce political support for the public health care system by reducing the size of the coalition that uses the public system.

Models examining the effects of wait lists on the demand for private insurance suggest that longer waiting times for care in the public sector may in some cases increase demand for supplemental private insurance. The methods used to ration care within the public system can also have differing effects on the demand for supplemental private insurance. Private supplemental health insurance markets may be smaller when the public sector rations according to need versus random allocation of public resources. Income gradients caused by the introduction of private supplemental health insurance may also be larger under random rationing of care versus rationing according to need (Cuff *et al.*, 2012).

If private insurance complements the public system by covering costs or services not covered publicly such as user charges on the one hand, or additional health care services on the other, it may result in an inefficient level of utilization. In the case where the user charges are meant to help achieve the efficient level of utilization, it may undo these incentives, and may also result in cross subsidization from the tax payer to the user of private insurance. In the case where private coverage insures health care items not covered under the public system, an increase in utilization of privately financed care may increase the use of publicly financed care.

Empirical Evidence on the Effects of Supplementary Private Health Insurance in National Health Insurance Systems

Empirically evaluating the effects of a supplemental privately financed system is difficult due to the lack of counterfactuals and the multitude of differences in the interaction between publicly and privately financed systems across jurisdictions. Because identification is difficult, some of the evidence presented below is correlational evidence. This supports theoretical predictions. Other papers are able to use a variety of microeconomic strategies to tease out some causal relationships. Overall, what evidence there is suggests that there are some potentially negative consequences of privately financed systems on the public system. Evidence on those theoretical considerations with empirical support are presented below.

Public Sector Waiting Times and Demand for Care

Evidence using pooled cross sectional data from the UK suggests a positive relationship between public waiting lists and private insurance (Besley *et al.*, 1999). The positive correlation could be in response to long wait lists or because there is less attention paid to public lists in areas with higher levels of private insurance. Research from Australia examines the relationship between waiting times for care among patients waiting for elective care and the demand for private insurance using data on individual-specific (vs. average) expected wait times. The findings suggest that on average there is little relationship between expected wait times and the demand for private insurance but that for particular subpopulations, who have high probabilities of long waits, there is an increase in the probability of buying private insurance (Johar *et al.*, 2011).

A significant body of evidence reviewed in Thomson and Mossialos (2009) suggests that, in jurisdictions with both private and publicly financed treatment, patients in the private sector wait less than equivalent patients in the publicly financed sector. In those systems where doctors are able to operate in both public and private sectors (e.g., UK, Ireland, and Austria) evidence suggests that doctors give priority to private sector patients.

Evidence from the UK in the 1990s suggests that physicians who operate in both the public and private systems reduce their hours in the public system significantly and do not heed the requirement that publicly employed physicians only dedicate 10% of their earnings to private practice. Physicians who had dual practices earned on average 70% from the National Health Service (NHS) and 30% from private practice (Morris *et al.*, 2008). These authors also find a positive association between mean private income and waiting lists. They note, as above, that this relationship is not necessarily causal and that the causal relationship between wait times and physician effort in the private sector could run in either direction. Evidence from other jurisdictions is consistent with that of the UK, in that, dual practice physicians often do not work all of the contracted hours in the public sector in order to fulfill private sector demand. Evidence on the overall welfare implications of dual practice in developed health care systems is, however, still incomplete and is an area for further future research.

The evidence relating to how changes in public sector wait times impact on the demand for publicly financed service is inconclusive. For example, McAvinchey and Yannopoulos (1993) found that the long run elasticity of demand for NHS acute care with respect to the cost of waiting (a function of time and forgone income) were quite large. Their results suggest that a 1% decline in waiting times lead to a 4.79% increase in the demand for NHS acute care. This evidence implies that introducing a private system that reduces waiting times in the public sector may result in an increase in demand for care in the public sector. However, Francis and Frost (1979) examined the relationship between the number of hospital beds and the magnitude of waiting lists in the UK and concluded that the elasticity of the number of people on the wait list with respect to beds is 1, suggesting that if the number of hospital beds in the public system remains constant waiting lists do not decline regardless of private sector supply.

Evidence from Germany suggests that individuals with private insurance use more pharmaceuticals than individuals in the statutory social health insurance plans (Krobot *et al.*, 2004). However, Hullegie and Klein (2010) find a negative relationship between private insurance and visits to the doctor in Germany among those patients that have at least one doctor visit. They do not find significant differences in hospital stays. The authors suggest "private health insurance either has a positive effect on investment in prevention, because of the monetary incentives provided to the insured, or that privately insured patients receive more intense or better treatment each time they visit a doctor."

Costs

The theoretical evidence reviewed above suggests that supplemental private insurance may either increase or reduce overall public health care costs depending on the interaction between public and private financing. Evidence from Australia, which has promoted voluntary private health insurance along with the public system through the use of tax subsidies, finds that the combination of tax subsidies and the effects of private systems on the health care input costs (both in the short and long run) limit the potential cost savings for the public sector (Hurley *et al.*, 2002). The authors note that there is no conclusive evidence from Australia that shows a decline in public waiting times following the introduction of a parallel private system, nor that public costs were reduced when the overall cost of the policies are taken into account.

Hopkins and Zweifel (2005) note that an additional effect of subsidizing private insurance is that it encouraged policy holders to use more public hospital services and contributed to the government failing to meet its objective to relieve pressure on the public system. The evidence suggests that subsidized private supplemental insurance is a costly way to relieve public sector pressure.

Cream Skimming

Evidence suggests that private and public providers differ not only in the type of services they provide but also in the types of patients treated. Martin and Smith (1996) examined the determinants in length of stay in the NHS in Britain. They found that patients in the NHS who had more access to NHS hospitals were on average likely to experience shorter lengths of stay. They also found that the level of private health care facilities in the area has a positive impact on local NHS costs, suggesting that private health care tends to take the less severe cases so that those who remain in the NHS tend to have higher average costs. This result is significant in that not only does it suggest that the private sector would not serve as an effective benchmark for the public sector but it also implies that, with the introduction of private health care, costs in the public sector would rise.

Demand for Private Insurance

As noted in the introduction, the demand for supplemental private health insurance in most countries is relatively small, of the order of 10–15%. Evidence on the distribution of the demand suggests that, as would be expected, there is a strong correlation between income and take up of private insurance.

Evidence from Spain suggests a positive correlation between the demand for private supplemental health insurance and both wealth and education. Improved coverage, quality, and timeliness were the main reasons cited in Spain for purchasing additional coverage (Costa and Rovira, 2005). In Australia before 1998, only 20% of people with an annual income of less than US$20 000 had private coverage, compared to percentage of people with an annual income of US$100 000 or more (Tuohy *et al.*, 2004). In New Zealand, approximately 37% of the total population had private coverage. Approximately 60% of people with above-average incomes had private coverage, as compared to only 24% of people with below-average incomes. In the UK, individual private insurance is more prevalent among those with higher income and higher education. In the 1990s, 40% of people in the wealthiest 10% of the population were privately insured, whereas only 5% of people in the bottom 40% held private insurance (Tuohy *et al.*, 2004). Evidence on the relationship between health and risky behaviors and the demand for insurance suggests that both poor self-assessed health and risky behaviors are negatively associated with purchasing private insurance (Doiron *et al.*, 2008).

Evidence on the dynamics of using privately financed care suggests that there is considerable movement in and out of private care. Propper (2000) noted that although there is strong evidence of an association between past and current use of private care in the UK, there is also considerable cross-sectoral flow with past use of the NHS associated with current use of private care.

Complementary Private Health Insurance

Evidence on the relationship between privately and publicly financed services, when private finance is complementary, suggests that private financing may increase costs in the public system. In Canada, private insurance complements the public system by covering items not covered publicly – the largest of these being pharmaceuticals. Stabile (2001) found that individuals with private insurance for pharmaceuticals not only used more drugs but also used more publicly financed services such as doctors visits. Part of this was due to selection into private drug insurance but a large component was also due to the reduction in the cost to the patient of using both private and public services. Costs to the public system are also increased through tax expenditures used to subsidize the purchase of complementary private insurance. For example, Canada exempts employer payments for employee health insurance from the taxable income of the employee. Tax deductions are also available in Canada for the cost of privately purchased complementary care. Research examining the effects of such policies suggests that they increase the quantity of insurance demanded on the extensive margin and result in considerable tax expenditures (Smart and Stabile, 2005).

Evidence from France, which allows for private health insurance to reimburse copayments and charges in the public system, suggests that the private voluntary insurance

increases utilization and therefore publicly financed costs (Buchmueller *et al.*, 2004). Moreover, concern over the inequitable distribution of private insurance in France has led to public subsidies for private insurance for lower income families, further increasing public costs. These measures have not reduced the strong relationship between income and private insurance take up.

Conclusions

In summation, private supplemental insurance plays a large role in supplementing and complementing national health services. The literature on the effects of a supplemental, privately financed alternative for services that are also insured publicly on the overall health care system is ambiguous both theoretically and empirically. That said, the weight of the limited evidence available suggests that introducing a private system may result in a decline in the supply of medical services in the public system partially through physician time shifting, and partially through reduced attention to public lists, further resulting in longer waiting lists for patients who remain in the public system. There also appears to be a fair degree of uncertainty surrounding the impact of private insurance through its affect on waiting times on the total demand for health care and hence public insurance. This is in part a result of the difficulty of modeling both the demand and the supply side responses to changes in waiting times as well as the difficulty of determining the causal relationship between private insurance and wait times in the public system. There is some evidence that introducing a private health care system may result in a more complex case-mix in the public sector, resulting in either higher public costs or longer public waiting lists. The evidence across most jurisdictions suggests wealthier and more educated individuals are more likely to take up private insurance and that this is a stronger predictor than health status. Finally, there is little evidence that supplemental private insurance is able to achieve an often-stated goal of reducing pressure on the public system and reducing public sector costs.

Evidence from jurisdictions that use private supplementary insurance to complement the public system by covering charges or services not covered by the public system also suggests that private insurance increases overall demand – not only for those services that are privately covered but for those that are publicly covered as well. In addition, it serves to increase costs in the public sector through additional utilization and a reduction in the incentives brought about through cost sharing.

Supplementary Private Insurance in National Systems and the USA

AJ Atherly, University of Colorado Anschutz Medical Campus, Aurora, CO, USA

Introduction

Supplemental Insurance

In many countries with public health insurance coverage, individuals have the option to purchase additional coverage from private health insurers to supplement public coverage. This additional coverage can either duplicate public coverage or fill in gaps (supplement) in the public plan, such as covering services outside the public benefit package or filling in cost-sharing gaps in the public coverage. The Organization for Economic Co operation and Development (OECD) defines supplementary coverage as

> Private health insurance that provides cover for additional health services not covered by the public scheme. Depending on the country, it may include services that are uncovered by the public system, such as luxury care ,elective care, long-term care, dental care, pharmaceuticals, rehabilitation, alterative or complementary medicine, etc., or superior hotel and amenity hospital services.

Supplementary policies are commonly held in many OECD countries, including Australia, Canada, Germany, Ireland, Switzerland, the Netherlands, the UK, and the US Medicare population. Although the precise rules vary by country, the key motivation is that many types of public insurance leave policy holders with substantial potential liability for out-of-pocket expenses (Figure 1).

What Does Supplemental Insurance Cover?

Supplemental insurance coverage varies depending on the rules of the particular country as to what it is allowed to pay for and what the public program includes. Typically, coverage may include cost sharing for publicly provided services (e.g., France, USA), coverage for services outside the public benefit package (e.g., Canada, Germany), particularly dental services (e.g., Australia, Japan, UK), and superior amenities, such as private rooms in hospitals (e.g., Italy, UK). In some situations, supplemental coverage may also serve to provide swifter access to some services (e.g., Norway, UK).

What, precisely, supplemental insurance covers varies not only across countries but also for particular countries over time as the rules for what can be covered and the public benefit packages change. For example, supplements for the Medicare program in the USA often provided coverage for prescription drugs before 2006; when prescription drug coverage was added to the benefit package in 2006, supplemental policies often dropped that benefit. Currently, discussions are under way in the USA to limit the amount of cost-sharing supplemental insurers can cover.

Examples of what supplemental insurance policies cover in different countries are as follows:

- *Australia*: medications not covered by the public system; dental services, aid, and appliances; copayments for covered services;
- *Canada*: prescription drugs; dental care; nonhospital institutions (long-term care), vision care, and over-the-counter medications;
- *France*: dental and vision services, and copayments for covered services;
- *Germany*: uncovered services; access to better amenities and some copayments;
- *Italy*: over-the-counter drugs, dental care, access to better hospital amenities, and improved provider choice;
- *Japan*: dental services;
- *Netherlands*: adult dental care;
- *New Zealand*: copayments and cost sharing, elective surgery in private hospitals, private outpatient specialist consultations, and faster access to nonurgent treatment;
- *Norway*: shorter waiting times for publicly covered elective services.

Duplicative Coverage

In some situations, coverage can be purchased that effectively duplicates or replaces the publicly provided coverage. This then provides a private alternative to the public system. OECD defines duplicative coverage as

> Private insurance that offers coverage for health services already included under public health insurance. Duplicate health insurance can be marketed as an option to the public sector because, while it offers access to the same medical services as the public scheme, it also offers access to different providers or levels of service. It does not exempt individuals from contributing to public insurance.

Examples of this approach to supplemental insurance include Australia, Ireland, and the UK. Some countries, such as Canada, explicitly prohibit duplicative coverage.

Duplicative coverage is distinct from supplemental insurance in a number of different ways. Most importantly, duplicative coverage is intended to replace the public coverage – it is essentially an opt-out from the public system. In contrast, supplemental insurance is intended to enhance the public program and improve it by either providing more extensive coverage, reducing financial risk, or providing better access to publicly funded services.

Controversies Regarding Supplemental Insurance

Supplemental insurance has been the subject of some criticism. One of the principal criticisms is that if supplemental insurance provides valuable financial protection, it implicitly suggests that the public system is inadequate because additional coverage is necessary. If additional coverage is necessary, this then implies that there are important gaps in the public coverage. Supplemental insurance, because premiums are not based on income, thus allows higher income individuals better financial protection than lower income individuals, which undermines the goal of public coverage for health care.

Another criticism is that in some cases, the supplementary coverage can have problematic interactions with the public coverage. This can involve risk selection, increases in public costs due to the presence of the supplemental policy, and/or distortions in terms of access, such as wait times, to public care that serves to feed the demand for privately insured care. For example, in both France and the USA, studies have found that the removal of cost sharing by supplemental insurance leads to the increased use of services in the publicly funded program.

Supplemental Insurance in the USA

In the USA, supplemental insurance is most common among beneficiaries of the publicly funded Medicare program, and is sometimes referred to as 'Medigap' plans. Medicare supplemental insurance can either help pay for Medicare cost sharing or provide coverage for services not included in the Medicare benefit package, such as health insurance outside the USA.

The Value of Supplemental Insurance Plans

Medicare is the largest publicly provided health insurance program in the USA, with approximately 49 million enrollees in 2012. Although there are a number of ways to gain Medicare eligibility, the most common is through age eligibility, which occurs at age 65. Although Medicare covers many medical services, it often does not cover the services in full. For example, in 2012, Medicare Part A would pay for the full cost of a hospitalization for days 1–60, with a $1156 deductible (equal to the cost of the first day of the hospitalization). For the typical Medicare beneficiary – with a median income of $22 000 – Medicare cost sharing creates a substantial financial liability. If a Medicare beneficiary used all of the Part A (inpatient) covered services in 2012, the total cost sharing would be approximately $54 910, which includes a $8670 copay for hospital days 61–90, a $34 680 copay for hospital days 91–150, and $11 560 for skilled nursing facility (SNF) for days 21–100. For hospital stays beyond 150 days and SNF stays beyond 100 days, there is generally no coverage.

Medicare gaps are of two different types:

- Cost sharing for covered services
- Benefit limits

For example, for Medicare Part B, there is a $100 annual deductible plus a 20% copayment for covered services. There are also many services outside the benefit package, such as eyeglasses and hearing aids. Supplemental insurance can address either of these program limitations.

Sources of Supplemental Insurance Plans

There are two main sources of private supplemental insurance plans: employers and individual purchase. Individual purchase plans (which are often referred to as the 'Medigap' plans) are designed to be integrated with Medicare; in contrast, employer supplements are often extensions of medical insurance provided for active workers and thus not optimally designed for coordination with Medicare. Employer plans are provided to retired workers, with eligibility rules that often mirror early retirement rules. Typically, eligibility is dependent on the employee's age and length of service with the firm.

For employer plans, Medicare is considered the primary payer with the supplemental/employer plan serving as the secondary payer. Although there are several different methods used to coordinate benefits, with the most common method being carve out, beneficiaries still pay some portion of Medicare deductibles and thus have higher cost sharing than true Medigap plans. However, employer supplementary plans are more likely to include coverage for noncovered Medicare benefits, such as chemical dependency treatment, vision coverage, dental coverage, and 'catastrophic expenses' caps, whereby the total out-of-pocket liability is capped.

The main alternative for Medicare beneficiaries without access to group coverage is individually purchased plans, often called 'Medigap' plans. Medigap plans date back to the beginning of Medicare, in the mid-1960s, and have been extensively regulated since the 1990s. During congressional

hearings before the Congressional Select Committee on Aging in 1978, extensive marketing abuses were described. These abuses by the policy sellers included using high-pressure sales tactics, misrepresentation by the issuer of the policy, misrepresentation of policy contents and competitors' policies and 'rollover' of plans, whereby subscribers were forced to change policies to increase policy commissions.

Subsequent to these hearings, two different regulatory reforms of the individual supplemental insurance market were enacted. The first, in 1980, was the Voluntary Certification of Medicare Supplemental Health Insurance Policies, commonly known as the Baucus Amendment (Public Law 96–265, Sec. 507). The Baucus Amendment addressed the abuses of the market by setting minimum coverage standards, outlawing the knowing sale of multiple policies, and requiring higher loss ratios. The amendment was not considered to have successfully achieved its policy goals. Hearing in the 95th Congress suggested that many of the same issues remained, largely due to the voluntary nature of the Baucus Amendment requirements. Thus, a second reform was enacted in the Omnibus Budget Reconciliation Act of 1990 (OBRA-90), Section 1882 of the Social Security Act. Unlike the Baucus Amendment, the OBRA-90 reforms were mandatory and changed the industry significantly.

OBRA-90 increased minimum loss ratio requirements for the plans, prevented the sale of duplicate plans, established consumer counseling programs, limited agents' commissions, and required a 6-month open-enrollment period. This period allowed beneficiaries to purchase Medigap policies without regard to health status, with guaranteed renewal of the policy. The 'enrollment window' opens when the beneficiary initially enrolls in Part B. After expiration of the 6-month window, some policies (although not all policies) become experience rated or medically underwritten. Finally, OBRA-90 required the creation of model policies, which were the only new Medigap policies allowed to be sold after 30 July 1992.

Standardization of 'Medigap' Plans

The standardization requirement limits the Medigap plans that can be sold to the approved plans. These approved plans have precisely the same benefit structure regardless of seller. Initially, the National Association of Insurance Commissioners was charged with the development of 10 model policies. The initial model policies provided a range of options, although all plans were required to cover a set of 'core benefits,' which include coverage for the Part A hospital daily copayments for days 61 through 150, the 20% Part B coinsurance on physician charges, and the first three pints of blood received each year, as well as coverage for an additional 365 days of hospital care. The model policies (typically labeled policies 'A' through 'J') originally featured various combinations of eight benefits: the Part A deductible, the Part B deductible, coverage for the SNF copayment, foreign travel, prescription drug coverage, preventive medical care, and coverage for at-home recovery. Only 2 of the 10 plans covered the Part B deductible (C and F), but together these two plans included more than half the market in the 1990s and 50.9% in 1994. The most common benefits originally were the Part A deductible (included in 9 of the 10 model policies, B through J) and coverage for the SNF copayment and foreign travel (both included in C through J).

Congress has amended the model benefits a number of times, most recently in the Medicare Modernization Act (MMA) of 2003. After MMA, there are eight different benefits plus the 'core' benefits distributed across 10 plans. The core benefits focus on Medicare Part A copayments for extremely long hospitalizations. All of the plans offer some form of coverage for Medicare Part B cost sharing, the first three pints of blood during a hospitalization (uncovered by Medicare), and the Part A hospice care coinsurance. Plans M and N became available for the first time in June of 2010, at which time plans D and G were modified and Plans E, H, I, and J could no longer be sold, although beneficiaries with those plans could continue coverage (Table 1).

Other benefits include the SNF coinsurance (eight plans), the Part A deductible (nine plans), the Part B deductible (two plans), Part B excess charges (two plans), and coverage for emergencies during foreign travel (six plans).

The two most popular plans in 2010 were Plan F (44% of enrollees) and Plan C (14%) . These are also the most comprehensive plans offered. Both Plans C and F will be revised in 2015 to include some cost sharing for Part B services. Participation in the new plans – Plans K–N – is extremely low. Combined, Plans K and L account for less than 1% of plan purchases.

Table 1 Current standardized Medigap plans

Medigap benefits	*Medigap plans*									
	A	*B*	*C*	*D*	*F*	*G*	*K*	*L*	*M*	*N*
Medicare Part A coinsurance and hospital costs up to an additional 365 days after Medicare benefits are used up	X	X	X	X	X	X	X	X	X	X
Medicare Part B coinsurance/copayment	X	X	X	X	X	X	50%	75%	X	X
Blood (first three pints)	X	X	X	X	X	X	50%	75%	X	X
Part A hospice care coinsurance/copayment	X	X	X	X	X	X	50%	75%	X	X
Skilled nursing facility care coinsurance			X	X	X	X	50%	75%	X	X
Medicare Part A deductible		X	X	X	X	X	50%	75%	50%	X
Medicare Part B deductible			X		X					
Medicare Part B excess charges					X	X				
Foreign travel emergency			X	X	X	X			X	X

Premium Levels and Regulation

Federal regulations establish two different time periods when there is 'guaranteed issue' of Medigap premiums, i.e., time periods when insurers may not decline a beneficiary. The first is during the first 6 months after initial enrollment into Medicare Part B. The second time period covers a series of transitional periods between different types of Medicare coverage, such as between Medicare Advantage (MA) and standard fee-for-service. Medical underwriting is allowed, but is generally limited to age, gender, and smoking status.

Premiums are generally regulated at the state level. Seven states required 'community rating' for Medigap policies in 2010. Community rating requires a single premium for all enrollees in the plan. Four states generally use 'issue age' rating, where the premium depends on the age of initial enrollment. The remainder of states use 'attained-age' rating, whereby the premiums depend on the current age of the policy holder. An ASPE analysis of premiums found wide variation across states, with premiums in the most expensive state (New York) nearly double that of the least expensive state (Michigan). During the decade between 2001 and 2010, average premiums increased 3.8% per year. In six of those years, the increase in Medigap premiums was less than that of total Medicare spending. This trend holds within plan types.

Demand for Supplemental Insurance 'Medigap' Plans

Medigap insurance is generally demanded by individuals who are more affluent. Research has found that those buying Medigap plans tend to have higher family income and other financial assets; to be younger, white, and married; and to have more education and a usual source of care. Evidence regarding age and health has been mixed, with some studies finding higher rates of purchase associated with better health and other studies the opposite. It appears that the relationship between the beneficiary's health and supplemental insurance decision is dependent on knowledge of Medicare. In general, Medicare beneficiaries are badly informed about both Medicare design and insurance. However, chronically ill beneficiaries often have enough exposure to the health-care system to become well informed about Medicare's limitations. Thus, the relatively better informed chronically ill beneficiaries are more likely to buy insurance, whereas those without chronic illnesses are not, regardless of self-rated health.

Other Sources of Coverage

There are also several other sources of coverage available to select groups of Medicare beneficiaries. First, some Medicare beneficiaries are also eligible for Veteran's Administration (VA) benefits. In 2004, 13% of Medicare-only beneficiaries (without supplemental insurance) identified a VA facility as their primary source of care. The services provided at VA and military facilities are generally not charged to either the individual receiving the services or to Medicare.

Second, some Medicare beneficiaries are also eligible for Medicaid. There are a number of different Medicaid programs available, depending on income level, but most at least pay for Medicare's cost sharing and some provide coverage beyond the Medicare benefits package ('wrap-around benefits').

Supplemental Insurance and Medicare Advantage Plans

Medigap enrollment has declined markedly since 2006, when Medicare Part D came into effect. Part D provides prescription drug coverage and allows Medicare beneficiaries to select drug plans. The drug plans can be either 'stand-alone' plans or part of a Medicare managed care product, referred to as 'Medicare Advantage' (MA). MA plans are fully capitated health plans that serve much the same purpose as Medigap plans in that they help reduce Medicare cost sharing and provide additional benefits beyond the standard Medicare benefit package.

MA plans have existed in some form since 1983. The most valuable benefit offered by MA plans was prescription drug coverage, the value of which was diluted by MMA and Part D. However, after 2006, Medicare beneficiaries began switching in large numbers to MA plans from Medigap plans. Total Medigap market share declined from 25% in 2003 to less than 20% in 2010, whereas MA enrollment climbed from 11% to 25% in the same time frame.

Effect of Supplemental Insurance Plans on Medicare Spending

There is an extensive literature on the effect of supplemental insurance on Medicare spending. The theory is that by lowering the out-of-pocket price of medical care, the quantity demanded of care will increase. This basic application of demand theory has extensive empirical evidence supporting it, including findings from the RAND health insurance experiment, a randomized controlled trial of the effect of cost sharing on the use of medical services from the 1970s. Over the past 25 years, there have been more than 15 studies on the effect of supplemental insurance on Medicare spending. The results of these studies vary markedly depending on the empirical methodology, data, and approach to controlling for adverse selection.

Adverse selection is a particular problem for the empirical estimation of the effect of supplemental insurance on Medicare spending. Theoretically, one would expect that higher risk individuals would be more likely to buy supplemental insurance because it holds greater value for individuals at greater risk of medical events. Showing a positive relationship between the purchase of supplemental insurance and Medicare spending thus is consistent with both adverse selection (higher cost individuals buy supplemental insurance) and demand (supplemental insurance leads individuals to become higher cost).

Empirically, studies have found effect sizes varying from zero (no effect) to a 33% increase in Part A spending and a 42% increase in Part B spending. The Congressional Budget Office (CBO) estimates that individuals with Medigap policies use 25% more Medicare services than those with no supplemental insurance and 10% more than those with

employee-sponsored insurance (which has higher cost sharing than Medigap plans). CBO bases its estimates both on an analysis of the supplemental insurance literature and on the results of the RAND health insurance experiment.

Survey Sampling and Weighting

RL Williams, RTI International, Raleigh, NC, USA

Introduction

A sample survey is a method for collecting data from or about the members of a population so that inferences about the entire population can be obtained from a subset, or sample, of the population members. As an example, it may be desired to know the average length of stay in a hospital for surgical versus nonsurgical stays in the US and its territories for the 2012 calendar year. In this situation, a sample of hospital discharges would be obtained along with the duration of stay for each discharge. Then estimates of the average length of stays for surgical and nonsurgical discharges would be calculated and compared. A properly conducted sample survey will support inference from the sample that is scientifically valid about the population. This article focuses on probability sampling and weighting to support such inference.

The discussion is organized around four major steps: (1) survey requirements, (2) sampling design, (3) weighting, and (4) design effect. Although these steps are presented as a linear process progressing in order, in practice much iteration between the steps will occur while planning a sample survey. For example, the initial requirements may prove to be financially infeasible when determining the sample design and compromises will need to be made in the requirements.

Survey Requirements

An important first step is to establish the objectives of the survey that will drive the design. Major areas to consider include:

Target Population

The target population is the finite set of all elements or units about which inferences or conclusions are to be drawn. The definition of the target population should be exact in terms of element, place, and time. For the hospital length of stay example, the target population is all hospital discharges (element) in the US and its territories (place) during calendar year 2012 (time). Various subpopulations are also identified which will be important in the subsequent analysis. For example, it may be important to differentiate between urban versus rural hospitals or public versus private hospitals.

Survey Variables

Associated with each element of the target population are the survey variables to be measured. A survey is conducted to gain information about one or more population characteristics or parameters which are defined in terms of the survey variables. For example, the survey variables might be the length of stay for a hospital visit and if it was surgically related or not. The population parameters of interest might be the average length of stay, the median length of stay, or the total number of hospital inpatient days all by type of discharge (surgical vs. nonsurgical).

Objectives

The objectives of the survey can be either descriptive, analytic, or both. The objectives are stated in terms of the population parameters derived from the survey variables. For the hospital stay example, descriptive objects would include estimating the average length of stay for surgical and nonsurgical stays. Such estimates would be important to planners in determining the number of hospital beds needed in a new hospital or in a service region. The estimates might also be used to determine the anticipated total amount of reimbursement a payer might incur for hospital stays. Alternatively, analytic goals might be to determine factors related to length of hospital stay so that best practices can be established to reduce the average length of stay. For example, average length of stays might be compared between surgical modalities or condition treatment plans.

Precision Requirements

The degree of precision required for the survey objectives are needed to establish the final sample design and the sample sizes. For descriptive objectives, precision is usually stated in terms of the maximum standard error of the estimate or in terms of the maximum length of a confidence interval around an estimate. For example, estimate the average length of stay such that its 95% confidence interval is no longer than plus or minus 0.5 day. Precision for analytic objectives is usually stated in terms of the power, or probability, of rejecting a null hypothesis in favor of an alternative hypothesis for a given value of the population parameters that describe the hypothesis. For example, when testing if average surgical length of stay is the same as the average nonsurgical length of stay, it might be required to have an 80% chance to reject the null hypothesis of equality when the actual, but unknown, population values differed by more than 1 day with a type I error rate of 5%.

Sampling Design

The sampling design consists of the procedures by which elements are selected into the sample from the population. The major attributes of a sampling design are presented next.

Survey Population

The survey population includes any modification to the target population established because of resource limitations or other feasibility factors on the survey. The survey population

usually limits the target population in some way so that the survey is more readily conducted. For example, it might be cost prohibitive to conduct the survey of hospital discharges in the US territories and the survey population would limit the scope of the survey to the 50 states and the District of Columbia of the US.

Sampling Frame

A sampling frame is an important tool in the process of selecting a sample. The sampling frame is the materials or methods which identify and provide access to the elements of the target population. The sampling frame also includes any auxiliary information required to select the sample or to analyze the resulting data. A rule must exist that allows enumeration of all of the elements of the target population. The sampling frame can be a simple listing of all of the members of the target population; for example, a list of all of the hospitals in the US and its territories. More commonly, the sampling frame consists of processes and rules that provide access to the target population. For the hospital length of stay example, a complete listing of all hospital discharges does not exist. However, a multistage approach can be used where lists of hospitals can be used to contact selected hospitals each of which can provide access to a listing of its discharges.

Stratified Sampling

Stratified sampling is one of the major design features used in almost all sample surveys. Stratification is the process of dividing the population into mutually exclusive and exhaustive groups and then selecting a separate independent sample from each stratum. When the observations within each stratum are more homogenous than those between the strata, the variance of the resulting estimate will be reduced. However, stratification is more importantly used to assure that an adequate sample size is obtained for analysis from the various subpopulations included in the survey objectives. For example, it is likely that a nonstratified random sample of hospitals will not contain enough hospitals from rural areas for analysis purposes. In this situation, stratifying the sample of hospitals by urban versus rural areas allows an adequate sample size of rural hospitals to be selected to support the survey's analytic objectives.

Multistage Sampling

Another important and commonly used design feature is multistage sampling. This is a process by which sampling is carried out in two or more stages. At the first, or primary stage, clusters of the sampling elements are formed and a sample of the clusters is selected. At the second stage, a subsample of the elements within each of the selected first-stage clusters is selected. In the hospital length of stay example, the discharges could be clustered by the hospitals where they occurred. A sample of hospitals would then be selected at the first stage followed by a sample of discharges from each of the selected hospitals at the second stage. More than two stages of sampling may be used. For example, a sample of geographic areas, such as US counties, could be selected at the first stage, followed by a second sample of hospitals and then a sample of discharges at the third stage. As noted when discussing sampling frames, multistage sampling is useful when a sampling frame must be constructed in stages. It is also used to control the cost of conducting a survey by concentrating the data collection effort at a limited, and predetermined, number of locations. For example, if a random sample of discharges was selected without clustering, then data collection would occur at a large number of hospitals across the US leading to high data collection costs. However, a two-stage sample of hospitals followed by discharges within selected hospitals would be less expensive as the data collection effort can be concentrated at a smaller number of hospitals.

Probability Sampling

Probability sampling is the mechanism through which inference is extended from the sample to the population. A probability sampling plan associates a nonzero probability of selection with each and every member of the survey population such that the selection probability can be determined for every member of the sample. A random process is used to select the sample so that the desired probabilities of selection are achieved. To demonstrate how probability sampling supports population inference, assume that a probability sample of size n is selected from a survey population of N elements. Then let δ_i be 1 if the i-th element of the survey population is selected into the sample and 0 if it is not selected. The probability that the i-th element is selected into the sample is $\pi_i = \mathrm{E}(\delta_i)$, where the expectation is over the random process used to select the sample. Associated with each survey population element is the value of a survey variable Y_i, with the observed value for each sample member being y_j. The population total is $Y_+ = \sum_{i=1}^{N} Y_i$ with the sample total estimator being $y_+ = \sum_{j=1}^{n} y_j/\pi_j$. It follows that $\mathrm{E}(y_+) = \mathrm{E}[\sum_{j=1}^{n} y_j/\pi_j] = \mathrm{E}[\sum_{i=1}^{N} \delta_i Y_i/\pi_i] = \sum_{i=1}^{N} \mathrm{E}(\delta_i) Y_i/\pi_i = Y_+$ showing that the sample total estimator is an unbiased estimate of its corresponding population total.

Simple random sampling

Simple random sampling is one of the most easily implemented types of probability sampling. The two forms of simple random sampling are with replacement and without replacement. Without replacement sampling assigns the same chance of selection to all $\binom{N}{n}$ possible without replacement samples of size n from a survey population of N elements. With replacement sampling assigns the same chance of selection to all N^n possible with replacement samples. In either case, the selection probability for any member of the sample is n/N. Simple random sampling without replacement is more commonly used and is appropriate when each member of the survey population is of equal interest or importance.

Probability proportional to size sampling

Probability proportional to size (PPS) sampling is commonly used when selecting multistage samples. PPS sampling, as its names implies, results in each sample member having a selection probability proportional to a measure of its size. For

example, the size of a hospital might be measured by its annual number of discharges or its number of beds. Similarly, the size of a geographic unit might be the number of persons living in the unit. The PPS selection probability for a unit is $\pi_i = nS_i/S_+$, where n is the sample size, S_i is the size measure for the i-th unit, and $S_+ = \sum_{i=1}^{N} S_i$ is the total of all size measures for units in the survey population. When a very large sampling unit has a size measure such that $S_i > S_+/n$, then the unit is called a self-representing unit as its PPS selection probability is greater than one. In this situation, all self-representing units are included in the sample with probability one and the remainder of the sample is selected PPS from the survey population excluding the self-representing units.

Equal probability of selection method

Equal probability of selection method (EPSEM) is any sampling design that yields equal selection probabilities for the ultimate sampling elements used in the analysis. Having equal selection probabilities for the analysis units is often a desirable property as it usually reduces the variance of the survey estimates. In multistage sampling, this is achieved by combining PPS and simple random sampling at different stages of sampling. For the hospital length of stay example, assume that a two-stage sample of hospitals followed by discharges within the selected hospitals is planned. A common approach would be to select a PPS sample of n hospitals, where the size measure is the number of discharges from the hospital (S_i). This would then be followed by a sample random sample of m discharges from each selected hospital. The selection probability for the j-th discharge from the i-th hospital is the product of the hospital's selection probability and the conditional selection probability of the discharge from its hospital. This is $\pi_{ij} = \pi_i \times \pi_{j|i} = (nS_i/S_+) \times (m/S_i) = nm/S_+$ and is the same for all discharges regardless from which hospital a discharge is selected. In most situations it is not possible to have a size measure from which exactly equal probabilities of selections are achieved. However, using a measure of size that is proportional to the desired measure of size will yield nearly equal selection probabilities. In the example, the number of hospital beds or the number of discharges from a previous year would usually be good measures of size.

Weighting

As was shown above, probability sampling provides a process for drawing valid inferences from a small sample about the population parameters of a large population. This is done by defining a sampling weight for each sample member that is the inverse of its sample selection probability. Symbolically, the sampling weight for the j-th sample member is $w_j = \pi_j^{-1}$ The sampling weight can be roughly thought of as the number of population members that a sample member represents. The sampling weights are used to expand the sample members up to approximate the population. When all of the selected sample members respond and cooperate with the survey, unbiased estimates of linear population parameters, like population totals, are obtained when the sampling weights are used to expand the sample data. Nonlinear population parameters are consistently estimated through functions of weighted estimates of totals.

To illustrate this process, assume that a probability sample of n hospital discharges, both surgical and nonsurgical stays, from a total population of N hospital discharges has been selected. Two population parameters of interest are the total number of days spent in hospital and average length of stay, both for surgical hospital stays. Let Y_i be the length of stay associated with the i-th discharge in the population and let γ_i be 1 if the discharge is for a surgical stay and 0 otherwise. The population total number of days spent in the hospital for surgical stays is $Y_{S+} = \sum_{i=1}^{N} \gamma_i Y_i$ and the population total number of surgical stays is $N_{S+} = \sum_{i=1}^{N} \gamma_i$. Thus, the population average length of surgical stay is $A_S = Y_{S+}/N_{S+}$. The unbiased estimators of Y_{S+} and N_{S+} are the weighted sample values $y_{S+} = \sum_{j=1}^{n} w_j \gamma_j y_j$ and $n_{S+} = \sum_{j=1}^{n} w_j \gamma_j$, respectively. A consistent estimator of the population average length of surgical stay, A_S, is the ratio of the two weighted sample values $a_s = y_{s+}/n_{s+}$. This example demonstrates the general process of using the sampling weights to expand the survey values associated with the sample members to unbiasedly estimate the population totals. The estimate totals are then combined to consistently estimate other population parameters such as means, percentages, and regression coefficients.

In almost all surveys some selected sample member will not respond and their data will be missing. Simply leaving out the missing data from the sample nonrespondents will bias the resulting estimates. To mitigate the effect of the missing data, adjustments to the sampling weights are used to create analysis weights, which compensate for the nonrespondents in the analyses. Weight adjustment methods are beyond the scope of this chapter.

Design Effect

Complex sample surveys rarely result in a set of independent and identically distributed observations because of sample design features such as stratification, multistage sampling, and unequal weighting. Such features affect the variance of survey estimates and specialized software is needed for the analysis that allows the sample design to be used when estimating the variances. For example, survey data analysis software is available in SUDAAN®, SAS®, and Stata®.

To understand the effect of the design features, the concept of a design effect is used. The design effect is the ratio of the variance under the sample design used to collect the data to the variance of a simple random sample selected with replacement of the same sample size. Symbolically, the design effect of the mean is $DEFF = Var(\bar{y})/(S^2/n)$, where S^2 is the population variance of the variable in question, and $Var(\bar{y})$ and n are the variance of the estimate and the sample size under the sample design used to collect the data.

The sample design feature that usually most affects the variance is multistage sampling. When clusters of observations are selected together, the variance of an estimate is usually increased because the observations within a cluster are most often positively correlated. In a two-stage sample design, where clusters are sampled first followed by individual observations within each cluster, the amount of increase in the

variance of the estimated mean is approximately $DEFF = 1 + (m - 1)\rho_y$ where m is the average number of observations selected per cluster from the analysis domain and ρ_y is the intracluster correlation between two observations in a cluster. In the hospital length of stay example, the clusters are the hospitals and it would be expected that the length of stays for discharges from the sample hospital are positively correlated. For regression coefficients, the inflation, or possible deflation, in variance is approximately $DEFF = 1 + (m - 1)\rho_y\rho_x$, where ρ_y and ρ_x are the intracluster correlation coefficients for the dependent variable and the independent variable, respectively. For certain designs and regression models it is possible for ρ_x to be negative, resulting in a decrease in the variance of the estimated coefficient.

A related concept is the effective sample size which is given by $n_e = n/DEFF$. The effective sample size is the sample size for a simple random sample selected with replacement that yields the same variance of an estimate as that obtained from the sample design used to collect the data. An enlightening example for the mean estimated from a two-stage design illustrates the interpretation of the effective sample size. Consider a two-stage design where 10 $(= m)$ sampling units are selected from each of the 50 sampled clusters for a total sample size of 500. If $\rho_y = 1$, then $DEFF = 10$ and $n_e = 50$, the number of clusters. This is the situation where the observations within a cluster are perfectly related and no further information is gained by selecting more than one observation from each cluster. Thus, the effective sample size is the number of clusters. However, if $\rho_y = 0$, then the observations within each cluster are unrelated, and $DEFF = 1$ and $n_e = 500$. This is the situation of independent observations all of which contribute equal information to the estimate. In most situations, ρ_y is between 0 and 1, and the effective sample in this example is between 50 and 500.

The effective sample size can be used to estimate power or precision when planning a survey. The effective sample size can be approximated using the relationships described above using information from previous studies to approximate $n_e = n/DEFF$ and then used in a power/precision formula or software package to determine the approximate power or precision.

Switching Costs in Competitive Health Insurance Markets

K Lamiraud, ESSEC Business School, Cergy, France

Glossary

Community-rated premiums Premiums are community-rated when, within a given insurance company and for a given type of insurance contract, they are uniform across enrollees with different health statuses.

Risk selection practices in health insurance markets Three main types of risk selection practices exist. 'Dumping' refers to deliberately losing the sickest clients (e.g., based on medical information). 'Cream skimming' refers to attracting healthy individuals, for example, through advertisement campaigns targeted at young people. 'Stinting' occurs when a company initially tries to and then continues to keep high-risk individuals away, for example, by not sending application forms to older patients who ask for them. In Switzerland, risk selection may occur because of community rating: Companies expect to make profits on good risks and losses on bad risks. Dumping is forbidden in Switzerland, but cream skimming and stinting may occur.

Switching costs (barriers) Costs incurred by consumers when switching from one supplier to another. Categories of switching costs include those caused by: Transaction costs of switching suppliers (e.g., monetary costs and time lost due to necessary paperwork when switching to a new provider); uncertainty about the quality of untested brands; psychological costs such as 'brand loyalty'; discount strategies implemented by the current provider; shopping costs when consumers buy several products from the same provider. Switching costs may also be related to search costs.

Introduction

Many European countries have social health insurance where citizens cannot choose between different providers for basic coverage. While Germany and the Netherlands have only recently introduced policies giving citizens the freedom to choose their own health plan, this has been a long-standing feature of the Swiss health care model. The assumption is that competition to obtain consumers puts insurance providers under pressure to increase service quality and/or decrease premiums. As for any market, however, competition in health insurance only works if the threat of consumers 'voting with their feet' is credible. In other words, it only works if enough consumers switch to more competitive insurers.

In this article, the possible presence of switching costs when consumers are offered the opportunity to change their basic health insurance carrier is investigated. It is focused on the specific case of Switzerland as this country, through its pure form of competition and the period of time which has elapsed since this system was implemented, offers one of the best settings to study competition in basic health insurance markets.

The article is organized as follows. Following this introduction, Section 'Switching Costs' provides some insights into the general theory on switching costs. Section 'Managed Competition in Switzerland: The Regulatory Framework' describes the features of managed competition in basic health insurance in Switzerland. Section 'Stylized Facts: The Ineffectiveness of Competition to Date' highlights the persistence of huge premium differences within Swiss cantons, which may be explained by low-switching rates. Section 'Possible Barriers to Switching Behaviors' explores possible switching barriers. Section 'Conclusions' concludes and suggests ways of improving the current system through reducing switching costs.

Switching Costs

In many markets, consumers incur costs when switching from one supplier to another. These costs are called switching costs (barriers).

Categories of switching costs include those caused by: Transaction costs of switching suppliers (e.g., monetary costs and time lost due to necessary paperwork when switching to a new provider); uncertainty about the quality of untested brands; psychological costs such as 'brand loyalty'; discount strategies implemented by the current provider; shopping costs when consumers buy several products from the same provider. Switching costs may also be related to search costs.

In a market with switching costs, the rational consumer will not switch to the supplier offering the lowest price if the switching costs (in terms of monetary cost, effort, time, uncertainty, and other elements) outweigh the price differential between their current supplier and the new one. If this happens, the consumer is said to be locked-in to the current supplier. If a supplier manages to lock-in consumers in this way, it may raise prices to a certain point without fear of losing these customers. However, the incentive to do so must be balanced with the incentive to set a lower price to attract new customers. Despite this second incentive, the first situation is expected to dominate. Switching costs often do raise average prices in competitive markets compared with competitive markets without switching costs. The possible consequence of this is that consumers may be worse-off. Accordingly, policy intervention to reduce switching costs may be appropriate.

Empirical studies highlight the importance of switching costs for a wide range of markets including credit cards, cigarettes, computer software, supermarkets, air travel, phone services, online brokerage services, electricity suppliers, and automobile insurance. In this article, the presence of switching costs in basic health insurance markets is investigated.

Empirical evidence from the Swiss context serves to illustrate several types of switching costs presented above.

Managed Competition in Switzerland: The Regulatory Framework

Switzerland (population 7.8 million in 2009) is divided into 26 cantons, each canton being responsible for the organization of its own health care system. Overall health care is regulated by the Federal Law on Social Health Insurance (LAMal), which has been in force since 1996 after its ratification in a popular referendum in 1994.

The main regulatory features of Swiss health insurance markets are described below.

1. An 'individual mandate' requires all residents to have health insurance coverage. Individuals must take up insurance within their canton of residence. Each family member must contract on an individual basis. Health insurance cannot be provided by an employer as a fringe benefit and so the premium is paid in full by the insurance enrollee, a situation which should make the latter very reactive to differences in premium. Cantons are given the responsibility for ensuring that every resident receives coverage. The threat of lawsuits ultimately enforces the individual mandate in cases of noncompliance.
2. The law defines a standardized benefit package in order to avoid competition on content of coverage. Hence, all insurance companies must reimburse the same basket of goods. Although small variations may exist in the quality of services provided (e.g., different reimbursement time frames), these are minimal in nature and do not call into question the characteristics that the same product has to be offered by various providers. The level of cost sharing is also defined by law and is invariable across insurers (see **Box 1**).
3. The law authorizes full freedom in terms of choosing one's primary physician as well as unlimited access to specialists. Physicians are paid on a fee-for-service basis. However, enrollees can voluntarily opt for contracts with limited choice of physicians and those physicians who provide services within such contracts are paid on a per capita basis (see point 4 below).
4. Premiums charged by companies to consumers are community-rated (see Glossary). This means that although they can differ between health plans, an insurer must offer uniform premiums to people who meet all three of the following criteria: same age group (0–18, 19–25, and >25 years), same geographic area, and same type of coverage. With regard to geographic areas, there are 78 pricing areas, i.e., three per canton. Nevertheless, for a given company, prices turn out to be very similar between the three price areas within the same canton. Hence it can be considered that there are effectively 26 areas of price competition. With regard to the type of coverage, three types of basic health insurance coverage are available: all companies must offer a contract with a low deductible which guarantees access to any physician; they can also offer contracts with higher deductibles (see **Box 1**) and/or contracts with a limited choice of physicians. In 2008, the most frequent choice by enrollees was a 300 CHF deductible health insurance policy (38.7%), followed by plans with higher deductibles (31.2%). Insurance covering a limited choice of providers (Health Maintenance Organizations – HMO contracts) accounted for 30.0% of enrollees. This latter figure reflects HMOs recently increasing market share, given that only 8.2% of enrollees held HMO contracts in 2003.
5. Note that premiums paid by enrollees are neither rosk- nor income-related. Clients on low incomes receive subsidies from their canton of residence. In 2008, the mean yearly subsidy was 1511 CHF per subsidized enrollee.
6. A risk-equalization mechanism is enforced at the cantonal level (see **Box 1**) so that funds with a higher percentage of bad risks are compensated in comparison with those with a higher percentage of good risks and in order to avoid risk selection practices by health insurers (see Glossary).
7. Health insurers must accept every application for basic insurance.
8. Enrollees can switch companies twice a year, in June and December.

Finally, there is clear regulatory separation between basic and supplementary coverage. For health care services not included in the basic benefit package, an individual may subscribe to contracts for supplementary coverage, which cover, for example, dental care, private or semiprivate hospital rooms, cross-border care, and alternative medicine. Supplementary insurance is regulated by the Insurance Contract Law, which allows risk selection by companies and does not impose any constraint on the coverage supplied. Basic and supplementary insurance can be purchased from two different insurers or from the same insurer.

These features suggest that freedom of choice in terms of choosing one's insurer is very much encouraged by the regulatory framework and in particular that changing health insurers for basic coverage involves very low quality-related or transaction-type switching costs. Indeed, basic insurance coverage is virtually identical from one health insurer to the next, and generally, the enrollee can remain with the same physician or hospital regardless of insurer. Furthermore, the switching procedure is simple: the individual must write a letter to their health insurer, the templates for which are freely available on well-known websites. Also, search costs are low. All premiums are published officially every year by the Federal Office for Public Health and distributed to households that request them. Furthermore, the most competitive premiums can be easily found on the Internet and in newspapers.

If one looks at the market structure, it can be seen that enrollees have a great deal of choice. Although the number of health insurers (all nonprofit) offering mandatory health care insurance in Switzerland decreased between 1996 and 2008 (145 and 86 authorized health insurers, respectively), the choice set faced by each consumer has increased since the LAMal was implemented. In 1996, the mean number of health plans per canton was 39. Consumers could choose from more than 40 health plans in only two cantons. The mean number of health plans per canton rose to 57 in 2006, varying between 50 and 69 choices.

Box 1 The Swiss Basic Health Insurance Regulatory Features in detail

Cost-Sharing Arrangements

All contracts include a deductible on yearly expenditures. Enrollees can choose from 6 possible deductible levels (300, 600, 1000, 1500, 2000, 2500 CHF). Once the deductible level has been reached, enrollees pay a 10% coinsurance rate up to a maximum of 700 CHF. Hence, if the enrollee chooses a 300 CHF deductible, then the maximum out-of-pocket amount that they may have to pay is 1000 CHF.

Risk Equalization (or Risk-Adjustment)

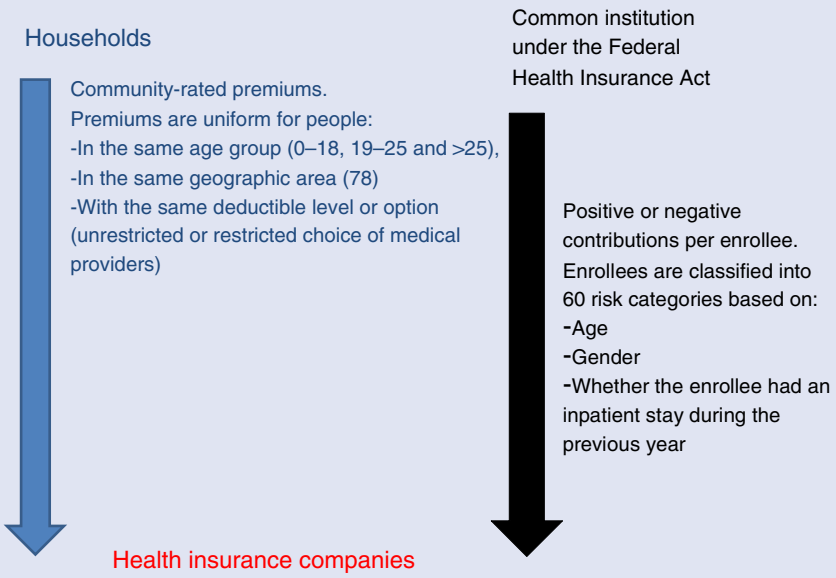
A retrospective risk-equalization mechanism is enforced by the law at the cantonal level. The 'Common Institution under the Federal Health Insurance Act,' a federal office, regulates the system. Risk adjustment consists in adjusting the premium by redistribution.

Until 2011, only age and gender were used as risk-adjusters. Adult policyholders were classified according to 15 age categories (18–25, 26–30, …, >91) and gender. Hence there were a total of 30 risk categories. The average value of costs in a given risk category was computed at the end of the calendar year. The average value of costs within each canton was also determined. The difference between these two averages indicated whether health insurance funds had to pay a contribution (if the value was <0) or receive a contribution (if the value was >0). Sickness insurance funds had to pay (or receive) contributions for each policyholder belonging to the risk category concerned. For example, if the difference between the average of costs for females aged 66–70 and the average of total costs amounted to 1400 CHF over a year in a given canton, then each insurer in this given canton would receive 1400 CHF for each of its female enrollees aged 66–70. Note that the costs used to compute contributions are total health care costs incurred by the patient minus out-of-pocket health expenditures directly borne by the patient. Also note that the value of money transfers obtained/given back for each enrollee does not depend on whether the enrollee has opted for a low or a high deductible level.

A third risk adjuster, based on whether the enrollee had an inpatient stay (of at least three days) during the previous year, was adopted by parliament on the 21 December 2007, hence increasing the number of risk-adjusters to three and the number of risk categories to 60. This change came into effect on 1 January 2012 and will be implemented at the end of 2012.

Hence an enrollee brings their community-rated premium to the insurer plus the risk-adjusted money transfer from the 'Common Institution under the Federal Health Insurance Act.' The chart below illustrates this.

Money flows to health insurance companies:



Sources of Data used in this Article

Data concerning the Swiss health insurance markets come from various sources. Premiums are published officially every year by the Federal Office for Public Health. Information on consumer health plan choices was collected by two surveys. The Federal Social Insurance Office survey was carried out in 2001 and can be obtained from the Swiss Information and Data Archive Service. A follow-up survey was carried out in 2007 by the University of Lausanne under the supervision of Brigitte Dormont, Pierre-Yves Geoffard, and Karine Lamiraud who wrote the questionnaire.

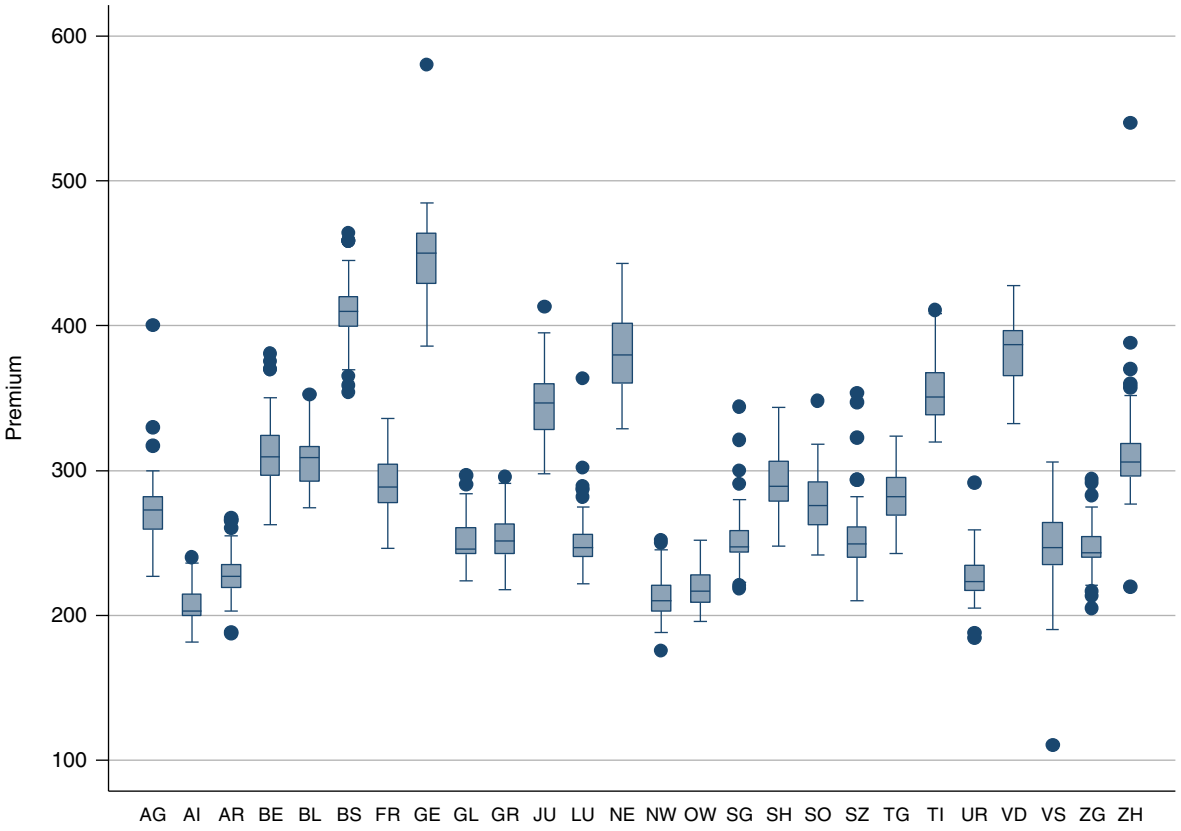


Figure 1 Box plot of adult monthly premium (for a 300 CHF deductible contract).

Stylized Facts: The Ineffectiveness of Competition to Date

In a health insurance market like the Swiss one, with its community-rated premiums for each health plan, homogenous benefits, open enrollment, and a large choice of insurers, one would expect strong price competition within each area of competition, resulting in small premium differences across plans and, in turn, cost-containment or at least a moderation in premium increases.

However, the observed facts are very different. Premiums have continued to rise. In 1997 the price index for an adult basic health insurance contract was 92.3. It increased to 100 in 1999 and 142.1 in 2008. Furthermore, there is a great deal of variability across firms in premiums within a given canton, as suggested by the box plots of monthly premiums displayed in Figure 1. For example, in 2011, in the Geneva canton, the difference between the least and the most expensive yearly premiums equaled 1665 Swiss Francs, a difference of 39%, for an adult contract with the lowest deductible, which is very large, considering it is only for one family member. Moreover, the within-canton variance has remained quite stable over time. Hence, moderation in premium increases has not occurred and premiums have not converged.

Competitive health care plans cannot be held responsible for the increase in premiums. The rise in premiums mostly mirrors the rise in health care costs. Indeed health care costs represent a very high percentage of premiums (administrative costs are quite low and represent approximately 6% of collected premiums) and premiums are highly correlated to health care costs in each canton, with Pearson and Spearman correlation coefficients close to 1. The increase in health care expenditures in Switzerland can be largely accounted for by an increase in wealth and in technological developments. It may also be related to patient behaviors including the moral hazard effect (i.e., overconsumption because of guaranteed coverage) and physician behaviors (e.g., incentives to increase the volume of care in the fee-for-service payment system). However, the moral hazard effect is not specific to private health insurance systems, such as the Swiss one. Public insurance systems can also be affected. Furthermore, as suggested above, competitive health plans in Switzerland do not have the means to control health care expenditures from the supply side. In particular they cannot define modes of payments for physicians or implement selective contracting except in HMO options, which have recently started gaining market share. Hence, competitive health care plans cannot be held responsible for the increase in health care expenditures.

In contrast, the lack of premium convergence may be related to the ineffectiveness of competition, and one important factor for this is low-switching rates. In Switzerland, annual switching percentages are low despite existing price differentials for identical benefit packages. Health plan switching

rates only averaged approximately 3% between 1997 and 2007, ranging from 2% to 5%.

Now the barriers to switching in the Swiss basic health insurance market are investigated.

Possible Barriers to Switching Behaviors

How can low-switching rates be explained?

Given the fact that price information is widely available and that there would seem to be substantial opportunities to take advantage of lower premiums for what appear to be homogeneous health plans, the authors begin by considering how the standard market model addresses consumer choice. The model assumes that, under uncertainty, the expected utility of customers will be maximized. Given a set of N choices, an individual will choose a health plan if its expected utility is greater than that of each of the alternatives. After choosing a plan, a consumer may experience a change in health state or other personal circumstances (e.g., reduced income) or face a new set of premium choices due to new health plans entering the market. The new circumstances may cause the individual to reassess the expected utility of their current health plan in light of alternatives, with the result that they may switch.

Since the implementation of LAMal in Switzerland, the size of the choice set in local markets has grown (see Section 'Switching Costs') and the set of plans offering the cheapest premiums for basic insurance has continued to change. Hence, low-switching rates may be explained by switching costs.

As already mentioned, the most obvious type of switching costs, i.e., transaction-type and quality-related switching costs, can be ruled out in the Swiss context. Consequently others need to be considered. Now the following three main types of switching costs are investigated: psychological switching costs, switching costs related to the multiproduct environment, and switching costs related to regulatory features.

Psychological Switching Costs

Choice overload

Research in economics and psychology consistently brings up the issue of whether greater choice is always in the consumer's interest, the argument being that too much choice may inhibit consumers from making any choice.

Two underlying forces may explain such a phenomenon. First, the information or cognitive overload theory argues that, as the choice set grows, the cost of the individual's information processing increases. This happens if individuals continue to consider all alternatives as the choice set expands. Even if consumers use shortcuts (e.g., eliminating the worst alternative), information processing costs grow with the choice set. This leads to the hypothesis that consumers can be overwhelmed by 'too great a choice.' The result is an inverted U relationship between the size of the choice set and the quality of decision making.

The second psychological force concerns the fear of making an incorrect choice or subsequent regret in situations where decision making is complex, consequential, and uncertain. One response to such decision-making circumstances, observed in both experimental and observational studies, is a tendency toward decision avoidance either by opting for the status quo or by walking away from the decision entirely.

In the Swiss health insurance context, the large number of competing health plans may result in information overload, even though individual health plans can be easily assessed. Frank and Lamiraud (2009) provide some support for this phenomenon. A survey focusing on individuals' health plan choices in Switzerland together with market price data were used to study the factors associated with the probability of switching and, in particular, to investigate the impact of the number of available plans on the probability of an individual switching. The results showed a monotonically decreasing likelihood of switching with increasing choice. Cantons with more choices had significantly lower switching rates *ceteris paribus*. Furthermore, it was demonstrated that consumers consider all health insurance companies, including fringe players (i.e., companies with small market shares) when deciding about insurance cover. These results are consistent with the inertia in decision making associated with choice overload.

Status quo bias

Consumer attachment to the status quo (status quo bias) could also account for low-switching rates. This has been associated with a tendency to exaggerate the disadvantages of leaving one's current situation and to understate the potential gains of switching, in an environment of uncertainty and complex decision making.

Three results highlighted by Frank and Lamiraud (2009) provide further evidence of the existence of a status quo bias in Swiss health insurance markets. First, people with longer periods of attachment to a particular health plan were less likely to express their intention to switch plans. Second, people making new health plan choices (switchers and those new to the market) chose to enroll in a different set of health plans from those who had not switched for some time. Third, survey respondents explicitly reported that their decision not to change their health plan was out of habit or because they were satisfied with their policy.

Switching Costs Generated by the Multiproduct Environment

Another possible barrier to switching behavior is the relationship between basic and supplementary insurance.

Although a clear regulatory separation exists between basic and supplementary insurance in Switzerland, in reality, both types of insurance coverage are strongly linked: Companies are allowed to operate both in basic and supplementary markets and most individuals subscribe to the same provider for both. Of the 88% of enrollees who took out supplementary coverage in 2007, only 9% subscribed to different companies for their basic and supplementary contracts.

To analyze the interaction between basic and supplementary insurance, two characteristics of the Swiss health insurance market have to be considered. First, there are additional costs when a client's basic and supplementary contracts are with different companies (e.g., separately mailed bills). Second, risk selection is authorized for supplementary insurance.

Switching costs generated by the relationship between basic and supplementary insurance have been shown to originate both from the consumer (Supplementary Health insurance as a barrier to switching Basic Health Insurance provider) and the firm (Pricing Strategies).

Supplementary health insurance as a barrier to switching basic health insurance provider

Dormont *et al.* (2009) investigated four possible mechanisms through which holding a supplementary insurance contract may act as a barrier to switching one's basic insurance policy to another insurer.

1. The first mechanism relies on a 'pure switching cost effect.' Given that subscribing to basic and supplementary contracts with two different insurers induces administrative costs, those planning to switch may have to consider moving both their basic and supplementary contracts: This is more burdensome than a single switch.
2. The second mechanism refers to selection practices in the supplementary insurance market, and to consumer beliefs about the existence of such a policy. Take for example a customer who thinks that they are a 'bad risk' and believes that insurers reject applications for supplementary insurance contracts from individuals considered as such. Currently holding a supplementary insurance contract would then act as a barrier to them switching basic insurance. Indeed, the new insurer may reject the application for a supplementary contract or propose an intentionally unacceptable offer (e.g., very high premiums).

   The third and fourth mechanisms ((3) and (4) below) refer to selection practices in basic health insurance markets (see Glossary). In such cases, there is an incentive for insurers to retain enrollees who hold supplementary contracts and drop the others.
3. Mechanism (3) is simply based on the fact that regulation for supplementary insurance is less restrictive. Lack of contract standardization may lead to less competition and profits may be realized from selling supplementary insurance contracts. In this context, profit-maximizing insurers would have an incentive to retain supplementary contract purchasers.
4. Mechanism (4) is based on the assumption that holding a supplementary insurance contract might be correlated with being a 'good risk' vis-à-vis basic insurance, i.e., having a lower probability of consumption in basic insurance for a given illness. This conjecture might be relevant for supplementary insurance covering alternative medicine: Individuals who subscribe to such contracts may be more reluctant to consume 'standard' health care, especially drugs, covered by the basic insurance. This might also be true for other kinds of supplementary contracts, perhaps indicating the subscriber's greater attention to prevention. An insurance company can observe the use of health services by its enrollees, but the econometrician cannot: only self-assessed health is observed. If we suppose that supplementary insurance indicates that the individual is a good risk, then discovering that those with supplementary insurance and/or good health are less likely to switch, would in turn suggest that insurance providers try and succeed in retaining good risks.

Given the prohibition of risk selection in the Swiss market for basic insurance, mechanisms (3) and (4) raise the question of what indirect tools are available to insurers in order to retain certain enrollees. Anecdotal evidence regularly reported in newspapers suggests that some insurance companies rely on such commercial practices as offering discounts on sports items or events.

To disentangle these four possible mechanisms, Dormont *et al.* (2009) assessed to what extent the influence of supplementary contracts on switching rates depends on the enrollee's health status. For (1) and (3) to be true, the effect of supplementary contracts on switching rates would have to be unrelated to the individual's self-assessed health. For (2) to be true, holding supplementary insurance would have to act as a barrier to switching for those in poor health. For (4) to be true, holding supplementary insurance would have to act as a barrier to switching for those in good health.

Controlling for relevant covariates, Dormont *et al.* (2009) show that holding a supplementary contract reduces the probability of switching in basic insurance for those in poor self-assessed health, but has no effect on the switching behavior of enrollees in good/very good health. These empirical findings suggest that the main mechanism at work is (2): If the customers think they are a bad risk and believe that insurers reject applications for supplementary contracts from individuals considered as such, they might refrain from switching basic insurance provider. This effect, identified through survey data covering the period following the implementation of the reform (1997–2000), was confirmed by behaviors observed over 2003–07 (Dormont *et al.*, 2013).

Pricing strategies

Lamiraud and Stadelmann (2011) examine the relationship between basic and supplementary health insurance from a different angle. They analyze firms' pricing strategies (i.e., pricing of basic and supplementary products) as a way of reinforcing consumer inertia. In particular, they investigate whether firms use bundling strategies or supplementary products as low-price products in order to capture consumers. Bundling is the sale of two or more products in a package (i.e., one basic contract and one supplementary contract). The bundle comes at a discount with respect to the total price of the individual goods when sold separately. Another strategy consists in establishing a low price for a product in order to attract customers who are likely to buy other products at regular or high prices.

Lamiraud and Stadelmann (2011) do not show any evidence of bundling in the Swiss setting. They do however show that firms use low-price supplementary products to lock-in consumers. A majority of firms price one of their products at a low price. None offer cheap products overall (i.e., in both basic and supplementary markets). Low-price insurance products differ across companies. When buying a low-price supplementary product, consumers always buy their basic contract from the same firm. Furthermore, those who opt for low-price supplementary products are less likely to declare an intention to switch basic insurance companies in the near future. The latter result is true for each level of risk category.

Hence, pricing strategies seem to generate additional barriers to switching basic insurance provider, thereby reinforcing consumer inertia.

Switching Costs Generated by the Regulatory Features

Another possible barrier to switching behaviors is that some regulatory features may tend to attenuate competition in the basic health insurance market. In this article it is focused on the rules for building reserves and the risk-equalization mechanism.

Health insurers are legally obliged to build reserves in order to protect against unpredictable financial risks associated with unforeseen catastrophic events, such as epidemics. Depending on their size, insurance companies are required to keep between 10% and 20% of collected premiums in reserve. Reserves per enrollee are not transferable to another company. Hence, if a subscriber leaves one insurance provider, their reserves stay with that provider. Consequently that fund becomes richer, whereas the new one is impoverished by the new entrant. The result is that a firm which attracts many new enrollees during a given year (because of low prices) would mechanically have to increase its premium the following year in order to start creating reserves. If a client expects that switching plans will ultimately induce a subsequent rise in premiums (due to the building of reserves as the individual expects that the low-price plan will attract a lot of new consumers), then the expected utility of switching becomes lower and this may induce consumer inertia. Hence the rules obliging reserves creation may result in market failure.

Poor regulation in terms of the previous risk-equalization mechanism (see **Box 1**) may have also induced low-switching rates. When only age and gender were used as risk adjusters, the incentives for companies to practice risk selection were very strong. There was an incentive for insurance firms to try to avoid insuring unhealthy young people, whereas retaining healthy older enrollees. If such risk selection practices existed, they may have represented an additional barrier to switching and consequently may have prevented price competition from working properly.

Conclusion

Switzerland has implemented a relatively pure form of health care competition in which a great degree of free choice has been provided to the consumer. Nevertheless, the persistence of great variations within cantons in terms of insurance premiums, together with low-switching rates, raises the question about the effectiveness of competition in Switzerland in the basic insurance market. Several barriers to switching were identified, namely choice overload, status quo bias, the possession of supplementary contracts for enrollees in bad health, firm's pricing strategies based on providing low-price supplementary products, poor regulation of reserves, and the limitations of the previous risk-equalization system, which left room for profitable risk selection practices.

Do such inefficiencies imply that competition should be replaced by a single health insurance scheme? A referendum was held on such a proposal in 2007. It called for a merger of the existing 87 health insurance companies. Final results showed that 71% of voters opposed the reform. This vote demonstrated that the Swiss preferred the current system.

The analysis provided in Section 'Possible Barriers to Switching Behaviors' suggests some ways of improving the current system. First, evaluating an optimal number of insurance companies in the market may be useful, as the results suggest that having too great a choice effectively inhibits switching between health plans. Furthermore, economic analysis tells us that having a limited number of firms may be enough to achieve effective competition. Nevertheless, one would first need to assess whether, from a supply point of view, having a high number of firms induces each insurance company to achieve better efficiency.

Second, reforming the regulation of supplementary insurance could be an option. Our analysis illustrates that consumer choices for basic and supplementary health plans are not independent from each other. Although both types of insurance markets are regulated by two different laws and supervised by two different institutions, they are closely linked. Managed competition in the basic insurance market may suffer from a lack of adequate regulation in its supplementary counterpart. The two main policy options are either to separate these two markets more effectively (i.e., preventing firms from being active in both markets) or to regulate the supplementary insurance market differently, in particular, by preventing risk selection.

Third, there is probably room for improvement in the current regulation. Reserves could follow the individual when they switch.

In this article the focus is on Switzerland. Large premium variation and consumer inertia rates have also been highlighted in the Netherlands, which implemented a system sharing many features of the Swiss one in 2006. Since 2006, switching rates have been reported to be low in the Netherlands. It has also been found that the possibility for switching for bad-risk individuals in the basic insurance market is substantially reduced by the presence of supplementary insurance.

Synthesizing Clinical Evidence for Economic Evaluation

N Hawkins, Icon PLC, Dublin, Ireland, and University of Glasgow, Glasgow, Scotland

Glossary

Adjusted indirect comparison An analysis in which an indirect estimate of the average treatment effect between two treatments is estimated based on the results of randomized clinical trials that directly compare the two treatments to a common comparator.

Assumption of consistency The constraint applied in network meta-analyses such that $\delta_{AB} = \delta_{AC} - \delta_{BC}$ on the scale of analysis, where δ_{AB} is the indirect estimate of the effect of treatment A compared with treatment B, and δ_{Ac} and δ_{BC} are the direct estimates of the effects of treatments A and B compared with the common comparator treatment C.

Network meta-analysis An extension of pairwise meta-analysis that provides estimates of the relative effectiveness of two or more treatments derived from a statistical analysis of a connected network of clinical trial comparisons.

Introduction

As a vehicle for economic evaluation, model-based cost-effectiveness analysis offers major advantages over trial-based analysis. These include the facility of models to widen the set of options under comparison and to incorporate all relevant evidence. To achieve these, appropriate clinical evidence needs to be indentified and synthesized, particularly that relating to treatment effects on relevant endpoints. Meta-analysis is the field of clinical epidemiology, which focuses on evidence synthesis. Recent method development in this field has focused on the particular needs of economic evaluation to incorporate all the relevant evidence relating to all management options.

Limitations of Pairwise Meta-analysis

Meta-analysis is the process of using statistical techniques to synthesize the results from separate but related studies in order to obtain an overall estimate of treatment effect. Traditionally, randomized clinical trials (RCTs) have been meta-analyzed by combining results or data from a series of trials comparing the same two treatments. This has been referred to as pairwise meta-analysis. This form of analysis has a number of limitations. For example, it may exclude trials that potentially provide indirect information regarding the treatment effect of interest. This may lead to it being impossible to estimate a treatment effect or to a potentially important information being excluded from the analysis. In addition, where there are more than two treatments of interest it can be hard to interpret the results and associated uncertainty of a series of separate pairwise comparisons, particularly where the results of the individual analyses appear to be contradictory.

Network Meta-analysis

Network meta-analysis is an extension of pairwise meta-analysis that provides estimates of the relative effectiveness of two or more treatments derived from a statistical analysis of the data from a set of RCTs, where the trial comparisons form a connected network. The estimates of relative effectiveness, alongside estimates of uncertainty, based on a systematic synthesis of the available RCT evidence, are potentially an important component of medical decision-making.

Adjusted Indirect Comparison

The simplest form of network analysis has been referred to as an adjusted indirect comparison (AIC). In an AIC an indirect estimate of the average treatment effect between two treatments is estimated based on the results of RCTs that directly compare the two treatments of interest to a common comparator. It is adjusted in the sense that it allows for differences between trials in the response to the common comparator. Researchers have suggested the term 'anchored indirect comparison' as an alternative to adjusted indirect comparison to differentiate from those analyses in which covariable adjustment is included.

The indirect estimate is obtained by applying the constraint that $\delta_{AB} = \delta_{AC} - \delta_{BC}$ on the scale of analysis, where δ_{AB} is the indirect estimate of the effect of treatment A compared with treatment B, and δ_{Ac} and δ_{BC} are the direct estimates of the effects of treatments A and B, respectively, compared with the common comparator treatment C.

For example, consider a binary outcome with the constraint that $\delta_{AB} = \delta_{AC} - \delta_{BC}$ on the log-odds scale. An indirect estimate of the log-odds ratio for treatment A compared with B (LOR_{AB}) can be estimated as $LOR_{AB} = LOR_{AC} - LOR_{BC}$, where LOR_{AC} and LOR_{BC} are estimates of the log-odds ratios obtained from single RCTs or from a meta-analysis of multiple RCTs. This is equivalent to $OR_{AB} = OR_{AC}/OR_{BC}$, where OR refers to the odds ratios.

Estimating Uncertainty

The uncertainty in an adjusted indirect estimate can be estimated as the sum of the variances for each of the component direct estimates as these can be treated as independent

 doi:10.1016/B978-0-12-375678-7.01404-8

random variables (coming from separate RCTs). For example, $\text{var}(LOR_{AB}) = \text{var}(LOR_{AC}) + \text{var}(LOR_{BC})$. The standard error and 95% confidence interval can then be derived from the variance estimate. It should be noted that estimates of uncertainty calculated in this way only reflect sampling error and do not take into account the uncertainty as to whether the constraint $LOR_{AB} = LOR_{AC} - LOR_{BC}$ holds for the particular set of trial data. Estimates of uncertainty estimated in this way could be seen as representing the lower bound of uncertainty associated with an indirect comparison.

More Complex Networks

The constraint imposed in an adjusted indirect comparison can be applied to more complex connected networks of trial comparisons in order to obtain consistent estimates of treatment effects. A network is connected if all treatments are connected via direct or indirect comparisons. For example, trials comparing treatments A and B, B and C, and C and D form a connected network whereas trials comparing A and B, and C and D do not.

In a network meta-analysis, estimates of treatment effect are made that comply with the constraint $\delta_{AB} = \delta_{AC} - \delta_{BC}$ on the scale being used for analysis and best fit the observed trial data. These estimates may be obtained using the Bayesian Markov chain Monte Carlo or maximum likelihood methods.

Assumption of Consistency

The constraint that $\delta_{AB} = \delta_{AC} - \delta_{BC}$ has been referred to as an assumption of consistency (direct and indirect estimates are consistent), exchangeability (e.g., if treatments were exchanged between trials the estimated treatment effects would be the same, allowing for random variation), or transitivity (the relationship $\delta_{AB} = \delta_{AC} - \delta_{BC}$ is transitive, e.g., $\delta_{AC} = \delta_{AB} + \delta_{BC}$).

Although it is common to refer to an 'assumption' of consistency in an indirect comparison, it is unlikely that it is believed that the relationship $\delta_{AB} = \delta_{AC} - \delta_{BC}$ holds perfectly across a given set of trial data and that direct estimates comparing treatments A and B, if they became available, would conform perfectly (allowing for random variation) to indirect estimates. Rather, the consistency relationship is an approximation that allows us to make useful predictions based on the available data.

Choice of Scale

The assumption of consistency can be applied on different scales for the measurement of treatment effect. For example, on the log relative risk (LRR) scale ($LRR_{AB} = LRR_{AC} - LRR_{BC}$) or the risk difference (RD) scale ($RD_{AB} = RD_{AC} - RD_{BC}$). These assumptions of consistency are mathematical identities for a single RCT that include treatment A, B, and C (see Figure 1). However, they are not for independent trials comparing A and B, B and C, and A and C. For a set of independent trials, the assumption of consistency may hold on one scale but not another reflect (see Figure 2).

Network Geometry and Testing Consistency

In some networks both direct and indirect estimates of treatment effects may be possible for one or more comparisons. Such a network may be referred to as including loops. The analysis of a network including such loops may be referred to as a mixed treatment comparison (including a mixture of both direct and indirect evidence) and an analysis of a network without such loops as an indirect comparison. The term network meta-analysis is used to refer to any analysis of a connected network of trials evidence including both adjusted indirect comparisons and mixed treatment comparisons.

If the network of trial evidence includes loops it is possible to compare the direct and indirect treatment effect estimates within a network and hence 'test' the reliability of the

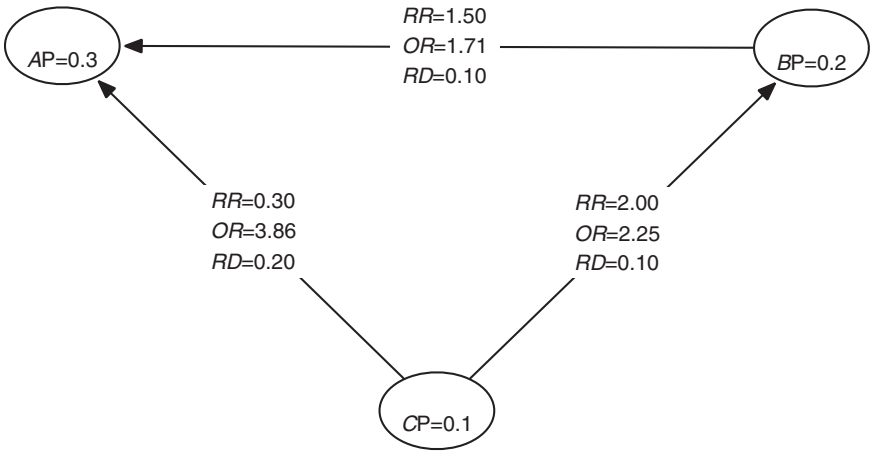

Figure 1 Consistency of a three-arm trial on various scales. Within this three-arm trial, treatment effects are, by definition, consistent on the relative risk: $\left(RR_{AB} = \frac{RR_{AC}}{RR_{BC}}; 1.5 = \frac{3}{2}\right)$, odds ratio $\left(OR_{AB} = \frac{OR_{AC}}{OR_{BC}}; 1.71 = \frac{3.86}{2.25}\right)$, and risk difference $(RD_{AB} = RD_{AC} - RD_{BC}; 0.1 = 0.2 - 0.1)$ scales.

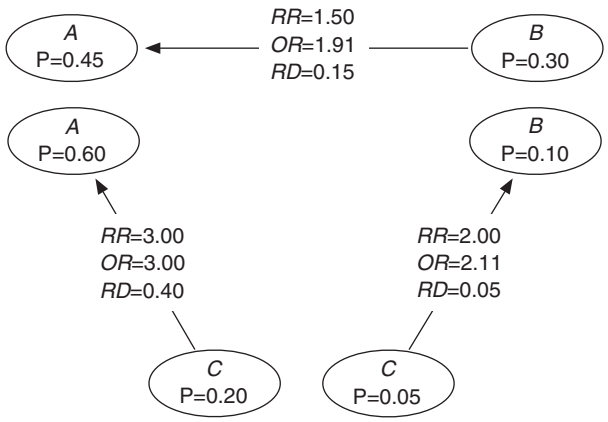

Figure 2 The treatment effect estimates from these three trials are consistent on the relative risk scale $\left(RR_{AB} = \frac{RR_{AC}}{RR_{BC}}; 1.5 = \frac{3}{2}\right)$, but not on the odds ratio $\left(OR_{AB} = \frac{OR_{AC}}{OR_{BC}}; 1.91 \neq \frac{6.00}{2.11}\right)$ and risk difference $(RD_{AB} = RD_{AC} - RD_{BC}; 0.15 \neq 0.3 - 0.05)$ scales.

consistency constraint – at least with respect to those comparisons for which direct and indirect evidence is available. The direct and indirect estimates can be compared in using formal hypothesis tests. It should be noted, however, that even where the direct and indirect estimates for a given comparison are consistent, the component treatment effect estimates may not all be exchangeable; the effect of treatment effect modifiers may cancel out across the network.

Network Meta-analysis in Practice

Any connected network can be analyzed using the techniques of network meta-analysis. The confidence in the utility of analysis will depend on the empirical evidence regarding the likely deviation of true values of treatment effects from the consistency constraint. If there are material differences between trials in terms of study design (including endpoint definition) or subject characteristics this will reduce the confidence in the analysis.

If there is evidence from subgroup or regression analysis within individual trials that those factors that vary between trials modify treatment effects, this will further reduce confidence in an analysis. Conversely, if these factors do not appear to modify treatment effects within trials this will increase confidence in an analysis.

If there is sufficient overlap in the range of subject characteristics between trials, it may be possible to adjust for the effects of treatment effect modifiers based on an analysis of within-trial variation of response. This may take the form of stratified or regression analysis. Propensity score methods have also been used where individual patient level data analysis is available for some trials and aggregate data for others.

If there are sufficient trials meta-regression analysis of the variation in treatment effects between trials and study characteristics or subject characteristics aggregated at the study level can also be used to adjust for heterogeneity between trials.

If empirical adjustment for heterogeneity between trials is possible, this may increase the confidence in the results in an analysis based on indirect comparisons.

Alternatives

Finally, when considering the utility of a network meta-analysis, it is important to consider the alternatives. Decisions could be based solely on analyses of direct evidence. However, the available direct evidence may be contradictory and difficult to interpret in a piecewise manner. In contrast, a network meta-analysis will provide estimates that are consistent with readily interpretable estimates of uncertainty.

In many cases direct evidence may not be available, in this case the decision could be deferred until direct evidence becomes available (although when it does it may be inconsistent with the existing indirect evidence); some assumption of equivalent effectiveness might be made; or the response to treatment in individual trial arms compared. The latter is termed a naive indirect comparison.

Whereas a naïve indirect comparison will be confounded by factors that affect the response to treatment in individual trial arms, an adjusted indirect comparison or network meta-analysis based on treatment effect estimates from RCTS analyzed as randomized will only be confounded by factors that act as treatment effect modifiers. Factors that affect response in individual treatments arms, but do not alter the average treatment effect on the scale used for analysis, will not confound network meta-analyses. This has led several commentators to recommend network meta-analysis or adjusted indirect comparisons over naïve indirect comparisons.

It should also be noted that any use of RCT evidence for decision-making infers some form of exchangeability between the subjects within the trial and those patients who are the object of the decision-making process. If multiple trials are viewed as being relevant to the decision-making process for an individual patient, this infers some degree of exchangeability between these trials. Network meta-analysis could be seen as the formalization of this exchangeability.

Conclusions

Network meta-analysis is increasingly used as a framework for estimating the effects of the full range of relevant options. This article has considered the principles of these methods and, in particular, the underlying assumptions needed for reliable estimates.

Theory of System Level Efficiency in Health Care

I Papanicolas, London School of Economics, London, UK
PC Smith, Imperial College, London, UK

Introduction

In recent years there has been an increased interest in the notion of the health 'system,' the ultimate goal of which is to protect and improve the health of its population. The definition of the health system is contested, but a frequently invoked starting point is the World Health Report in 2000, which "... defines a health system to include all the activities whose primary purpose is to promote, restore or maintain health" (World Health Organization (WHO), 2000, p. 5). Systems level efficiency is concerned with understanding how well a specific system is using the resources at its disposal to improve health and secure related objectives. Identifying inefficiencies in either the system or in its component parts is important as it allows the same objectives to be attained with fewer resources (or alternatively it enables the system to produce more with the same resources). As spending on health care continues to rise remorselessly in all developed countries, this issue has become increasingly relevant for policy makers seeking ways to pursue health objectives at the same time as containing cost pressures.

Although the core idea of efficiency is easy to understand in principle – maximizing valued outputs relative to inputs – it becomes more difficult to make operational when applied to a concrete situation, particularly at the system level. It is, for example, quite conceivable that there are efficiently functioning components operating within an inefficient broader health system. Furthermore, efficiency is not strictly determined by the relationship between the physical quantities of inputs and outputs, but by the value attached to those outputs. Indeed, by analogy with the first law of thermodynamics, which postulates that energy cannot be created or lost, the ratio of all physical outputs to all physical inputs will necessarily remain unchanged. What will differ, according to the structures, processes, and systems in place, is the ratio of valued outputs to inputs.

The general assumption in a great deal of the health economics literature is that the objective of the health system and its component parts is to increase the length and health-related quality of life of the population. This is most famously embodied in the notion of a 'quality-adjusted life-year' (QALY). However, there may be other very important objectives attached to a health system, such as reducing disparities in health, protecting citizens from the financial consequences of illness, and improving the responsiveness of health services to personal preferences.

Valuations attached to different health system outputs can vary because of variations in individual preferences, the decision-making perspective being used, or even because of the level of analysis being applied. As a result, a number of sometimes conflicting definitions for 'efficiency' exist in the economics and policy literature, and even within health economics itself (**Table 1**).

Although each definition attempts to clarify the nature of inputs and outputs, the variety of perspectives illustrates that there is no consistent approach. In particular, there is considerable variation as to what the valued outputs are, including: Volume of care, quality of care, levels of quality, 'performance' and health improvement; and this reflects the lack of clarity as to the concept of 'valued outputs.' Throughout this article the authors generally adopt the assumption that 'health improvement' is the valued health system output. However, on occasions reference to some of the other legitimate objectives that society may attach to the system shall be made.

One terminological issue needs to be addressed: The productivity literature usually refers to the products of a production process as 'outputs.' In health care, it has become conventional to refer to the physical products (such as an episode of hospital care) as an output, but to the health benefits achieved as 'outcomes.' Thus, health outcomes can be thought of as the 'value' attached to an output. Throughout this article the authors use the term 'outputs' and where necessary 'valued outputs' unless it is specifically necessary to refer to the health benefits achieved.

Although there appears to be more consistency regarding system inputs, specifications are often quite vague, referring simply to 'costs' or 'resources.' Only a few of the definitions in **Table 1** identify particular inputs, such as "The relative quantity, mix and cost of clinical resources" (Pacific Business Group on Health, 2006, p. 2). The lack of clarity about the concepts of 'valued outputs' and inputs reflects a wider ambiguity about the organizations and production processes of the health system. In particular, it is often not clear which resources and health outcomes are considered to fall within the responsibility of the health system. This article therefore begins by discussing the health system definition and its relationship to health system efficiency. Key concepts relating to efficiency such as productivity, technical and allocative efficiency, and their relationship to the production frontier are considered. These theoretical concepts are then related back to health policy to indicate the types of questions that might be considered in any analysis of technical or allocative efficiency.

What is the 'Health System'?

To understand and measure efficiency, it is first necessary to define the scope of the entity under scrutiny. Health is the product of numerous determinants, some that can be directly influenced in the short term by factors in the health services (e.g., improving medical care), others that require long-term action of factors not directly associated with health services (e.g., environmental policy), and yet others that depend primarily on the actions of individuals and their families (e.g., diet). If the health system is assumed to be comprised only of

 doi:10.1016/B978-0-12-375678-7.00203-0

Table 1 Alternative definitions of efficiency in a health care context

Key concept	*Definition*
Efficiency of care	A measure of the cost of care associated with a specified level of quality of care (AQA Alliance, 2006)
Efficiency of care	A measure of the relationship of the cost of care associated with a specific level of performance measured with respect to the other five IOM aims of quality (Institute of Medicine (IOM), 2001)
Efficiency of care	A measurement construct of cost of care or resource utilization associated with a specified level of quality of care (National Quality Forum, 2007)
Efficiency	The relative quantity, mix and cost of clinical resources used to achieve a measured level of quality (Pacific Business Group on Health, 2006)
Efficiency	An attribution of performance that is measured by examining the relationship between a specific production of the healthcare system (also called output) and the resources used to create that product (also called inputs) (RAND, 2008)
Efficiency	A measure of the cost at which any given improvement in health is achieved. If two strategies of care are equally efficacious or effective, the less costly one is more efficient (Donabedian, 1990)
Efficiency	Technical efficiency (or production efficiency), getting the maximum output for money, and allocative efficiency, producing the right collection of outputs to achieve goals, or being on the production possibility frontier (Roberts et al., 2008)
Efficient (not wasteful) care	Delivery and insurance administration, delivered at the right time and right setting and where new innovations can be evaluated for both effectiveness and value (Commonwealth Fund, 2006)
Health system efficiency	Production efficiency, the combination of inputs required to produce care and related services at the lowest costs, and allocative efficiency, the combination of inputs that produce the greatest health improvements given the available resources (Aday et al., 2004)
Health system efficiency	Microeconomic efficiency, measured health system productivity as compared to its maximum attainable, Macroeconomic efficiency, what effect a change in the level of resources would have on the desired level of health outcomes and responsiveness compared to other goods and services (Hurst and Jee-Hughes, 2001)
Health system efficiency	Actual (health system) goal attainment achieved related to what could be achieved given the resources available (WHO 2000, 2007)

health services, then actions that may have a greater impact on health are excluded (such as education or employment). Thus under a narrow definition of the health system, confined to health services, an analysis of system level efficiency may not consider the possible efficiency gains that could be secured by allocating resources differently between areas such as health care, education, and housing. However, a broader analysis can rapidly lead to lack of clarity of the boundary of the system, and associated difficulties with measurement and attribution.

For example, **Figure 1** illustrates the potential production process of a health system, with examples of costs and physical inputs put into the system and a selection of outputs and consequent outcomes that are produced. The different shades represent different boundaries of the health system, starting from a consideration of only medical care and extended to consider all factors that influence health. Across these boundaries, many of the outcomes of the system do not change – for example, health improvement and risk protection are outcomes arising from medical care, public health and health promotion, intersectoral action, as well as from economic growth and public sector investment. However, the physical inputs that contribute to the attainment of these outcomes will differ markedly depending on the choice of system boundaries.

In an evaluation of health system efficiency it is important not only to consider the physical inputs that correspond to the health system as defined, but also to ensure that the outcomes being assessed also represent only the contribution attributable to those particular inputs. For example, if the efficiency of medical care were to be assessed it would be crucial to isolate the contribution of medical care to health improvement, and to adjust for any contribution of other activities such as public health, development, and education.

A particular issue that sometimes arises is whether to scrutinize only publicly owned or financed institutions, or to include also the private and not-for-profit sector in an analysis of health system efficiency. The position of the World Health Organization is clear on this – they assign accountability to the government for the entire health sector, however, organized (World Health Organization (WHO), 2000). Under this formulation, the regulation and performance of privately funded healthcare should be included in any analysis. This reflects the WHO emphasis on governments as 'stewards' of population health.

In defining the health system, it is therefore important for analysts to be clear about what allocation of resources needs to be considered, what parties will be affected, and who will be making the decisions regarding allocation. Ideally the definition should be aligned with the factors under the control or influence of a responsible person or organization, such as the health minister. The scope of this accountable entity may therefore vary depending on a country's institutional arrangements. In other words, the definition of the health system should reflect a country's accountability arrangements. Whatever definition is chosen should then determine the scope and perspective of the analysis. It is then crucial that all definitions of inputs, outputs, and exogenous influences on attainment are aligned with that choice. This may lead to methodological

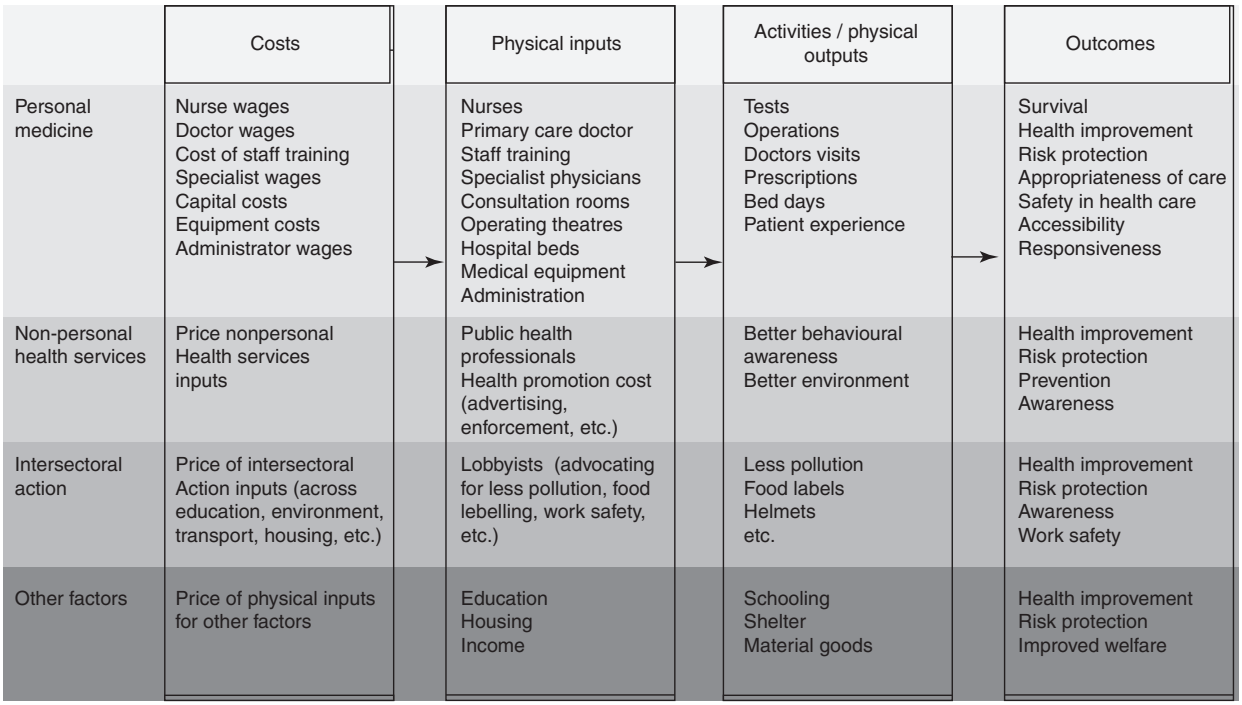

Figure 1 Selected inputs and outputs of the health system at different boundaries.

challenges when attempting to compare one country with another where there exists no universal agreed categorization of diseases, health care procedures, health care organizations, or even health systems (Cylus and Smith, 2013).

Efficiency at Different Levels

Reflecting the wide range of potential perspectives, economists and policy makers have adopted different conceptualizations of efficiency when analyzing different levels of the health system. At the formal organizational level, definitions usually refer to the extent to which health service objectives have been achieved compared to the maximum that could be attained, given the resources available and the external constraints on attainment. The conventional concepts of allocative, technical, and economic efficiency are then used to describe efficiency at this level (see section The Elements of Efficiency).

However, the concept of efficiency may change if the perspective changes. It is possible to take a broader view of sector level resource allocation, for example, by considering the level of resources devoted to the health system relative to other sectors that can also provide a positive contribution to health or indeed to broader welfare. The Organization for Economic Cooperation and Development refers to this broader conceptualization of efficiency as macroeconomic efficiency (Hurst and Jee-Hughes, 2001). In principle, the size of the health sector should be determined by its marginal contribution to welfare, relative to other sectors. Work on macroeconomic efficiency might therefore examine whether healthcare expenditure has reached levels where marginal spending on medical services contributes less to welfare than if it were directed at other sectors, such as education, housing, the environment, or private consumption.

At the other extreme, resource allocation can be considered at the very micro level, for example, by guiding the decisions of individual clinicians on how to distribute healthcare resources across treatment options in order to maximize valued outputs. Study of this type of efficiency often takes the form of a systematic analysis of the effects and costs of alternative methods or programs for achieving the same objective (e.g., improving quality of live, extending year of life lived, or providing services). These methods include cost-effectiveness analysis (CEA), comparative effectiveness analysis, cost-benefit analysis, and cost utility analysis. In principle, these techniques can be crafted to reflect different personal preferences, although in practice they usually produce guidance on the basis of a uniform set of preferences.

Thus, health system efficiency can be characterized in very broad terms at different levels of analysis, as adapted from Chung *et al.* (2008):

- Physician level: How to distribute resources between interventions in order to choose a treatment strategy that maximizes the patient's value or utility given existing resources.
- Organizational level: How to distribute resources within a healthcare organization and across health care processes in order to maximize aggregate health gain and satisfaction.
- Systems level: How to distribute resources within the broad components of the health system (such as prevention, primary care, secondary care) so that production of healthcare maximizes citizen health and welfare.
- Societal level: How to distribute resources between sectors of the economy (education, health, public goods, etc.)

such that health and broader welfare within society are maximized.

These issues are addressed in the section Allocative and Technical Efficiency as Applied to Health Policy.

The Components of the Health System

The different levels of the health system are profoundly interdependent, as actions at one level will often influence behavior and outcomes elsewhere. Bringing together findings from studies at the different levels can provide fundamental tools for understanding how an entire system is managed and sustained. The interconnectedness of the separate areas of study of a health system can be illustrated by the distinct areas of health economics set out in Alan Williams' 'plumbing diagram' reproduced in **Figure 2** (Williams, 1987).

Each box in the diagram represents one of the subdisciplines of health economics. The various fields are connected to one another by 'pipes' with the arrows indicating the direction of the relationship. Each of the boxes, discussed briefly in **Figure 2** involves both positive and normative issues and different societal preferences (Maynard, 2007). In relation to the discussion of efficiency, Boxes A, B, C, and D represent the key factors that determine the initial allocation of resources by society and what inputs and outputs are available and valued within health systems. These factors create the framework for the analysis of efficiency at the patient, organization, and system level represented in Boxes E, F, G, and H.

Box A models the determinants of health, focusing particularly on social and behavioral determinants that lie beyond the immediate control of the health system. These will be important when considering the system boundary issues discussed in the sections What is the 'Health System'? and Efficiency at Different Levels. It is important to understand what is meant by 'health' and how it is valued by individuals and society. Thus, Box B represents the study of perceptions of health as well as the valuations of its different states and life. These are important to the study of efficiency in order to be able to assign value to the outputs being produced at the patient, organization, system, and society levels, and inform decisions on the allocation of resources.

Boxes C and D consider the demand for and supply of health care respectively. In any market, supply and demand will determine how the market allocates resources from producers to consumers. In health services, demand is driven by patients seeking health care to improve their health status and longevity. This can be influenced by information asymmetries between patients and providers, or providers and third-party payers, barriers to care such as cost, distance or culture, and externalities of care. Supply of health care considers a wide

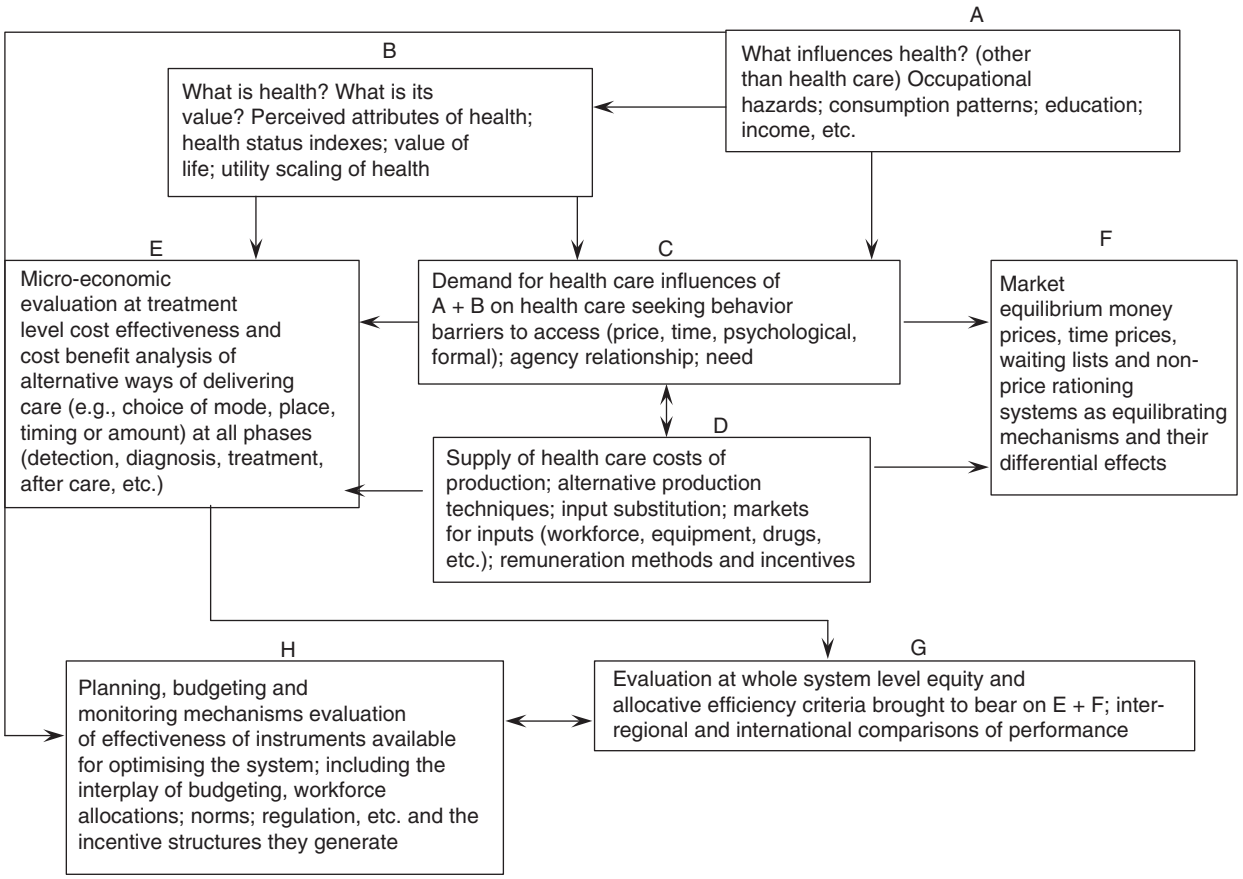

Figure 2 Williams' Health Economics Plumbing Diagram. Reproduced with permission from Williams, A. (1987). Health economics: The cheerful face of a dismal science. In Williams, A. (ed.) *Health and economics*, pp. 1–11. London: Macmillan

range of factors including the use of private and public suppliers, the behavior of institutions and providers, the skill mix and structures available to provide health, the financing structures in place to provide funds, as well as the organization of service delivery. It is important to understand the factors that influence demand and supply in order to be able to interpret how the market allocates resources and how this can be influenced to correct inherent market failures and associated inefficiencies.

Boxes E, F, G, and H represent the application of core economic principles, including the study of efficiency at different levels. Box E is concerned with the microeconomic evaluation at treatment level, and reflects the impact on efficiency of 'physician level' decisions outlined in the section Efficiency at Different Levels. This area of health services research involves conducting microevaluations such as CEA or cost utility analysis to inform rationing and reimbursement choices. They require information on clinical effectiveness of treatments, as well as the measurement of costs and value added.

Box F addresses the issue of market equilibrium, where market demand equals market supply. Private and public markets will in general clear at different levels, depending on factors such as pricing of goods and services, restrictions of benefit packages, rationing, and waiting times. This area of research encompasses issues of organizational level efficiency, where different production processes, input prices, and willingness to pay influence decisions of what and how much of different goods and services should be produced.

Finally, Box G represents the evaluation of the whole system, concerned with understanding how inputs are used to achieve the key objectives of the health system. This includes the area of system level efficiency. Box G will be influenced by planning, budgeting and monitoring mechanisms represented in Box H. All three of boxes F, G, and H can embrace regulatory mechanisms intended to correct market failures and maximize the optimum allocation of resources in order to meet society's health system goals.

Although each box constitutes a separate area of study, the 'pipes' between the eight boxes show some of the linkages between the different areas, indicating their interdependence. For example, the operation of the hospital would be best considered in Box F. Yet the hospital's market equilibrium in Box F would be influenced by the supply and demand for health care (Boxes D and C) as well as the severity of patients being treated (Box A), and the acceptable forms of treatment administered (Box B). Moreover, although the hospital could be perfectly technically efficient at the organizational level, it could be operating in a very inefficient health system, represented by Box G, if the overall health improvements made at the system level are below what could be achieved if current health expenditures were reallocated – say between hospital and preventive services. This may be related to the mechanisms in place for planning and budgeting, represented in Box H, for example, if too much money is being allocated to secondary care as opposed to primary care.

The health system is complex to analyze, because of people's heterogeneous health needs, the enormous scope for market failures, and the interdependencies illustrated in Figure 2. The assessment of efficiency is therefore also challenging. In the next section the authors set out some basic building blocks needed for the successful examination of health system efficiency.

The Elements of Efficiency

The underlying aim of efficiency analysis is to understand how inputs are translated into valued outputs. In this section the authors seek to clarify some of the different general concepts of efficiency as they apply to the health system.

Productivity and efficiency are often used interchangeably, but they refer to slightly different concepts. Productivity refers to the ratio of a (possibly partial) measure of output to a (possibly partial) measure of input. In contrast, efficiency seeks to assess the attained level of output in relation to the maximum that can be produced, given the inputs used, system constraints and available technology. Efficiency will often be calculated taking into account constraints (such as scale) that inhibit improved productivity. Ideally, efficiency will express the outputs being produced in terms of their value to consumers or society. Thus, there is an implication that efficiency is a more comprehensive and normative tool than productivity.

Fundamental to the study of efficiency is the concept of production function, which models the maximum possible level of outputs for given levels of inputs, given current technology. Alternatively, it is sometimes convenient to model production possibilities in the form of a cost function, which models the minimum feasible cost of producing a given set of outputs. In reality, for most production processes, there are both multiple inputs and multiple outputs, and it is more accurate to think in terms of a production possibility frontier, which maps the maximum levels of output attainment for any mix of inputs. Whether a production function or cost function perspective is adopted usually depends on the specific focus of the study. In what follows the focus is mainly on the production function.

Whatever perspective is adopted, efficiency analysis can be considered broadly as the study of two main questions:

1. Are resources being used so that the maximum level of chosen outputs is produced given the available inputs? (or are resources being used so that the minimum level of inputs are used to produce the chosen outputs?) That is, is the entity located on the production frontier, rather than inside it?
2. Is the 'right,' or most valued, mix of outputs being produced, given society's valuation of those outputs. Or conversely, is the 'right,' or minimum cost, mix of inputs being used, given the chosen outputs. That is, is the entity located at the maximum value (or minimum cost) point on the production frontier?

These two questions relate respectively to technical and allocative efficiency, which are now considered in turn.

Technical Efficiency

Technical efficiency indicates the extent to which an entity is producing the maximum level of output for a given level of inputs under the prevailing technological process, therefore

addressing the first question of efficiency analysis posed in the section The Elements of Efficiency. To identify whether the health system is technically efficient, it is thus necessary to determine four key characteristics:

1. What are the inputs of the health system?
2. What are the outputs of the health system?
3. What is the maximum level of health system output that can be produced for different levels of input?
4. What are the external constraints that may limit the ability of the health system to be technically efficient?

The discussion in the section Efficiency at Different Levels illustrated the challenges involved in defining the boundaries of the system under scrutiny and identifying relevant inputs and outputs. In particular, the chosen definition of the health system will determine whether factors such as public health, health promotion, and socio-economic determinants of health are considered in the analysis. The choice of boundaries will be crucial in determining first what resources make up the health system inputs, and second what are considered uncontrollable exogenous constraints on attainment.

With regard to health system outputs, a key challenge relates to the differences in stakeholder perceptions about what the health system should be producing. International and national health system frameworks identify a number of potential health system objectives, some of which are almost universally recognized (such as health improvement) and others where views differ (such as the extent to which a system offers patients choice of provider). Many definitions of efficiency require some measure of quality as well as volume of outputs (**Table 1**), yet notions of what constitutes quality of care are sometimes vague and conflicting (Papanicolas, 2013).

Once inputs and outputs have been identified, it is necessary to identify the maximum level of health system output that can be produced for different levels of inputs, using the concept of the production frontier. Any unit lying on the production frontier will be technically efficient. Inefficient units lie strictly within the frontier. In the context of health systems, therefore, a technically efficient system will be one that produces the maximum achievable level of valued outputs (in the form perhaps of health outcomes) given its inputs (or uses minimum level of inputs, given its outputs). Although this tool serves well in understanding the theory of systems level efficiency, it poses many practical challenges in the empirical estimation of the production function.

A central concern in estimating the production function is the identification of external constraints – the uncontrollable influences on attainment that limit the production of desired outputs. At the health system level such constraints might include: the underlying health of the population, the configuration of provider organizations, and the skills and size of the workforce. In the short term, many of these factors can be considered genuinely exogenous influences on levels of attainment, and so should be included as constraints in the analysis. In the longer term, it might be expected that the health system should be responsible for addressing some of the constraints. So, for example, an inefficient scale of providers might be an acknowledged handicap in the short run, but should not be considered as an 'excuse' for poor attainment in the longer run. However, some constraints, such as the physical terrain of a geographical area, might be considered truly exogenous.

A final key consideration that is rarely modeled satisfactorily is the dynamic nature of the health system. Outputs measured at one point in time will have been influenced by inputs of a previous time period, and similarly inputs in a current time period will to some extent influence outputs in a future time period. Ignoring dynamic aspects of efficiency may incorrectly attribute all current performance to current actions and hold stakeholders accountable for past actions for which they may not have been responsible. In principle, the proper approach to longer term investments in (say) disease prevention is to treat them as a capital investment, the benefits of which accrue over several time periods. They can either be treated in the same way as more conventional investments in physical capital, or by using proxies for the future benefits of current investments (e.g., expected QALYs gained per person immunized). By properly including a time dimension, analysis of efficiency may even provide improved incentives for policies with long-term effects, as future benefits will be recognized even in the short term.

Allocative efficiency

Technical efficiency examines the extent to which the unit is failing to reach the production frontier, as expressed in the cost or production function. In contrast, allocative efficiency examines whether production is allocated across either inputs or outputs so as to maximize the value to society. This principle can be interpreted in a number of ways. However, the common theme is that allocative efficiency refers to the extent to which a socially optimal point on the production frontier has been reached. In a conventional market, market prices can be indicative of the value of goods and services according to the trade-off consumers or society are willing to make between them. In input space this is readily transferred to health systems, where allocative efficiency can be interpreted as the extent to which the minimum cost of inputs is being used, given the market prices of those inputs. For example, to what extent is the right mix of clinical skills, physical inputs and medical products being used to secure system objectives, given prevailing wage rates, property prices, product prices, and so on.

However, in health systems, there are rarely market prices for outputs. It therefore becomes more difficult to define the relative value of outputs, as a guide to identifying the 'right' mix of outputs. As a result, in output space a number of definitions of allocative efficiency have arisen. Roberts *et al.* (2008) are, however, representative in defining allocative efficiency as whether a nation is producing the right mix of outputs to maximize attainment of its overall goals.

Thus, technical efficiency refers to the question of how goods are produced given certain inputs, meaning that a technically efficient point is one that lies anywhere on the production possibility frontier. At such a point a provider can produce more of one output only by reducing production of another. Allocative efficiency, however, refers to the question of what inputs are used or what outputs are produced, and suggests that there is a unique point on the production frontier that maximizes societal values relative to all other

attainable sets. To do this it is (in principle) necessary to specify a 'social welfare function,' which aggregates societal preferences into a single measure of the benefits to society of a social program.

One therefore needs information on the relative value to society of different health system outputs. There are many possible approaches to identifying those values, based on competing theories of justice. Various types of market mechanism, technical analysis, and political process seek to address this challenge. Moreover, even if there is agreement on which approach to adopt, individuals will always hold different values about what are the 'right' outputs to be produced. This diversity in normative perspectives and individual values relating to the allocation of health resources often makes it difficult to agree on a common starting point.

Nevertheless, if policy makers had knowledge of individual utility functions and preferences, they could in principle specify a social welfare function that aggregates the utilities across members of society. One could then examine the problem of efficiency as one of welfare maximization – that is, finding the feasible allocation of resources that maximizes a chosen concept of social welfare. This approach has been labeled 'welfarism.'

However, in practice construction of a social welfare function is extremely challenging, and systematic aggregation of individual preferences is infeasible. Yet – given the importance of health care in society – policy makers must make allocation decisions, and they have therefore used criteria other than traditional welfarism to inform resource allocation, such as potential health gain, need for treatment, demand for treatment, or simply cost. This approach is often referred to as extra-welfarism. This school of thought rejects the notion of using only utility as the outcome of interest, but seeks to consider broader factors such as an individual's capabilities: the goods and services that enable individuals to flourish. The dominant application of extra-welfarism in health economics has been concerned with aggregate health maximization, an approach that allows the aggregation and comparison of individual benefits.

Allocative and Technical Efficiency as Applied to Health Policy

To illustrate the points raised in the section The Elements of Efficiency, Table 2 considers the outputs, inputs, and trade-offs that might be considered in an analysis of technical or allocative efficiency within the health system. The provider (micro) level considers an individual seeking treatment where the inputs being considered are the money spent on treating the patient, and the output is the heath gain. The most efficient point of provision hinges on the choice of treatment. The intention is to treat the patient with the most cost-effective treatment (allocative efficiency), with maximum effectiveness (technical efficiency), within budget constraints. The choice of the allocatively efficient point should in principle consider the patient's preferences for types of treatment (e.g., attitudes toward pain and risk aversion), and offer the treatment that (subject to expenditure constraints) maximizes the expected value of the treatment to the patient. Given the lack of information about potential outcomes for many (if not most) treatments and the practical difficulty of crafting treatment choices specific to each patient, lack of information, and knowledge of medical care and types of treatment, clinical guidelines and payment mechanisms set at a higher organizational level may be very important in ensuring a technically and allocatively efficient distribution of resources.

At the organization (meso) level, assuming the only goal of the health system is to maximize health, the technically efficient point would be where expected health gain is maximized within each organization, by offering an optimal mix of cost-effective treatments to patients with different conditions. To achieve the allocatively efficient point mix of outputs, there needs to be a way to measure health gain across different potential treatments that the organization could provide, perhaps in the form of the QALY. Note that the 'mission' and design of organizations may constrain the range of output options available – for example, a hospital may not be capable of delivering a health promotion program. To overcome organizational boundaries, a correct allocation of resources must be made at the higher (system wide) level.

Macro concerns are represented in Table 2 by the system level and the societal level. The system level considers how resource allocation decisions are made to maximize health within the health system, and the societal level considers how resources are allocated between health and other sectors of the economy. For the system, a technically efficient point might be one that allocates resources across health services so as to maximize health gain. The allocatively efficient point is the one that provides the combination of health services that maximizes aggregate health gain across all

Table 2 Examples of allocative and technical efficiency in health systems

Level of analysis	*Technical efficiency: How are inputs used to produced outputs*	*Allocative efficiency: What mix of outputs is produced*	*Decision mechanisms*
Provider level	Maximizing personal outcomes, subject to cost constraint	Medical or surgical treatment of cancer	Patient consultation
Organizational level	Maximizing health gain in relation to expenditure	Providing hip replacements or cataract surgeries	Priority setting
System level	Minimizing avoidable mortality in relation to health system expenditure	Investing in curative or preventative care	Budgetary processes
Societal level	Maximizing life expectancy in relation to gross domestic product	Investing in health or education	Elections

services. At the societal level, the problem is analogous, but the health gain can be from different sectors of the economy, such as education or housing. Addressing this intersectoral allocation problem in principle requires consideration of the relative value of nonhealth objectives of other sectors, especially if these are produced jointly with health-enhancing programs.

Finally, Table 2 also considers possible decision mechanisms that can be used to determine what mix of outputs will be produced. For example, at the provider level the optimal mix of outputs will be informed by cost constraints within the system and individual preferences for treatment. The decision processes at the organizational level, such as a hospital, will be informed by the priority setting system in place. This priority setting system may differ across health systems, and may be based on factors such as the needs of the population being treated, the costs of inputs, the cost-effectiveness of treatments, or historical trends in purchasing. At the macro level, the resource allocation decision mechanisms in common use attempt to reflect the preferences of society, often through political processes. At the systems level, where the budget must be allocated to resources across the entire health system, the decision mechanism will often be made by bureaucratic processes overseen by elected representatives. At the societal level, decisions arise from a mix of private markets and political decisions about how to spend public finances, typically arising from some sort of election process.

Although Table 2 may help to conceptualize what seem like abstract notions, it takes a highly simplified view. It assumes an extra-welfarist perspective, in the sense that the only valued output of the health system is health gain. In practice, the health system often has broader objectives, and in principle a comprehensive analysis would examine the impact of allocations on broader social welfare. The market for health care makes it inherently prone to inefficiency if left to its own devices. Key market failures include: The lack of competition, especially for the provision of health services; the information asymmetries between patients and physicians, and between physicians and third-party payers; and externalities that are not reflected in prices (such as the spillover benefits offered by vaccinations). These market characteristics may, in the absence of corrective mechanisms, result in highly inefficient allocations of resources. The last column of Table 2 therefore indicates the sort of mechanisms necessary to promote allocative and technical efficiency at the different levels of analysis, given such market failures. This is particularly important for allocative efficiency, where the structure of a particular health system will determine what potential there is at each level of analysis for the provider to decide what mix of outputs should be produced.

Conclusions

There is increasing awareness that the design of the health system has a fundamental impact on the health and broader welfare of the population. Improved system efficiency is an important consideration because it enhances the capacity to produce valued outputs and the consequent sustainability of the system. However, the conceptualization of efficiency in health systems is far from straightforward. The first fundamental challenge is assigning 'value' to outputs (and also possibly inputs). Definitions of efficiency differ across institutions with no consistent reference to valued outputs and inputs. In practice, different definitions in use cover a range of valued outputs such as 'overall' performance, quality of care, health gain, or volume of treatment.

The challenge of identifying a set of valued outputs has implications for the conceptualization of both technical and allocative efficiency. To determine the technically efficient points of production, it is necessary to identify the outputs of the production process. Similarly, in order to determine what bundle of health services to provide, and thus identify the 'allocatively efficient' point of production, it is necessary to understand the preferences of the population being served. This will require consideration of whose preferences to consider, whether they should reflect the utilities associated with consumption of health care or the capabilities created by the consumption of health care, and the aggregation of preferences across society.

The second conceptual challenge refers to the difficulties associated with defining the boundaries of the entities under scrutiny. Determining the boundaries of a health system is one of the key areas of debate in health services research. The central point of discussion arises from the recognition that health outcomes are the result of numerous determinants, many of which might lie outside the direct influence of health policy makers. How narrowly or broadly the boundaries are set will influence judgments about the causal responsibility for improving health, thus influencing assessments of the level of 'efficiency' of the defined health system. A clear definition of relevant boundaries will facilitate the specification of objectives and the valued outputs and inputs for different areas of the health system.

The third challenge in conceptualization of efficiency for health systems relates to the intertemporal nature of the health system. All health systems are dynamic entities; performance in one period will influence performance in later periods. Health outcomes are the result not only of factors in the time period being measured, but also a product of behavior over the lifecycle as well as previous efforts of the health system. The physical resources such as hospitals and medication available in a current period are a result of investments made in previous years, and will in part contribute to future attainment. Any definition and metric of efficiency should in principle attempt to capture the dynamic processes that make up the health system.

In conclusion, the above discussion summarizes a burgeoning literature and policy debate on the theory of health systems efficiency. The challenges at the system level identified amount to an extensive research agenda, the purpose of which should be to create a clearer understanding of the health system and how it can be used to the best effect in line with societal objectives. Although these challenges may appear daunting, considerable progress has been made in addressing many of these issues at the micro level, through the literature of CEA. Research in such analyses has secured major progress both in the theory and use of economic thinking, and has had a fundamental impact on health policy. It is to be hoped that similar progress can now be made at the other levels of analysis.

Time Preference and Discounting

M Paulden, University of Toronto, Toronto, ON, Canada

Introduction

Decision making is a fact of life, both for individuals and for policy makers acting on behalf of society. All decisions result in costs and benefits. The purpose of economic evaluation is to compare these and determine whether the costs of a policy are justified by the benefits.

Economic evaluations comprise two steps. First, a specific intervention is identified (e.g., a vaccination program), along with any relevant alternative uses of the same resources (e.g., other public health activities). The most desirable of these alternatives is referred to as the opportunity cost, since it represents the opportunity forgone by implementing the intervention. Second, the intervention and its opportunity cost are each assigned a value. The intervention is considered desirable only if it has greater value than its opportunity cost.

The opportunity cost of an intervention is usually dependent upon the point in time at which the costs of the intervention are incurred. For example, a rational decision maker would prefer to incur a cost of $100 next year rather than a cost of $100 this year, if this allows the $100 to be invested for an year and yield a positive return.

Meanwhile, the value assigned to the benefits of the intervention and its opportunity cost generally depends upon the point in time at which these benefits will be experienced. For example, the benefits from a vaccination program due to be experienced 10 years from now may be assigned less value by the policy maker than the benefits realized from an alternative health intervention this year, even if these benefits are otherwise identical. This is known as time preference.

To allow for comparability between costs and benefits experienced across different points in time, it is conventional to represent all future costs and benefits in terms of their present value (i.e., their value today), regardless of when they are actually experienced. Typically, the present value of future costs and benefits is less than their value at the time they are experienced. Calculating present values therefore requires discounting of future costs and benefits. Although in everyday language the term 'discounting' is used in a variety of contexts, in economics it is used almost exclusively to describe the steps taken to calculate the present value of future costs and benefits.

Discounting is conducted as follows. First the costs and benefits are disaggregated into time periods (usually years). Then the costs and benefits in each time period are assigned weights, with lower weights assigned to more distant time periods. These weights are usually given by

$$1/(1+d)^{t-1} \quad [1]$$

where t represents the time period and d represents the discount rate. Costs and benefits incurred in the current time period ($t=1$) are not discounted. As a result of compounding, the discount applied to costs and benefits in the distant future can be substantial. For example, since 2003 the UK Treasury has recommended that most future costs and benefits be discounted at an annual rate of 3.5%. This means that a cost of £1000 incurred 30 years from now has a present value of £356 $[1000/(1+0.035)^{29}]$. Before 2003, the UK Treasury recommended a higher discount rate of 6%, which would have resulted in a present value of just £174 $[1000/(1+0.06)^{29}]$. The effect of this compounding is demonstrated in **Table 1**.

In some cases there are further complications to consider. First, costs and benefits might not be discounted at the same rate. For example, the Dutch Health Care Insurance Board recommends discounting costs at 4% per year and benefits at 1.5% per year. This practice is known as differential discounting, and has recently been the subject of considerable debate. Second, the discount rate itself might be conditional upon the point in time at which costs and benefits occur. For example, the UK Treasury recommends that a lower discount rate be applied to costs and benefits more than 30 years in the future, with this rate falling progressively from 3.5% at 30 years to 1.0% beyond 300 years. This is known as non-constant discounting, of which hyperbolic discounting is a common form.

Discounting can tip the balance between an intervention appearing desirable or not. It can also impact upon the relative desirability of interventions. Interventions with upfront costs but long term benefits (including many public health activities) generally appear less desirable following discounting, whereas interventions with long-term costs sometimes appear more desirable.

Given the complexities of discounting and its potential importance, it is the subject of considerable controversy. In the following article, the rationales for discounting are explained in greater detail. Some of the more contentious issues in discounting, such as the merits of differential or non-constant

Table 1 The present value of £1000 incurred at different times using alternative discount rates

Discount rate (per annum)	*Time from the present*						
	1 year	*2 years*	*3 years*	*5 years*	*10 years*	*30 years*	*100 years*
1.5%	£985	£971	£956	£928	£862	£640	£226
3.5%	£966	£934	£902	£842	£709	£356	£32
6%	£943	£890	£840	£747	£558	£174	£3

discounting, are discussed. Recent papers that have attempted to determine the appropriate discount rates for health policy making are then reviewed. The article ends with some suggested further reading.

Conventional Approaches to Discounting

Discounting is founded on considerations of opportunity cost and time preference. A common way of considering the opportunity cost of an intervention is to estimate the 'marginal social opportunity cost of capital,' which represents the amount of private investment foregone by adopting the intervention. Meanwhile, time preference is often considered by estimating the 'social rate of time preference,' which represents society's time preference for consumption.

Opportunity Cost

In cases where the resources used for a publicly funded intervention can otherwise be used in the private sector, the opportunity cost of the intervention is the value of the best possible forgone private investment opportunity. In this case, the intervention should only be funded if its benefits exceed those of the forgone private investment. In technical terms, this requires that the rate of return on the intervention exceeds the marginal pretax rate of return on the forgone private investment, otherwise known as the marginal social opportunity cost of capital.

Many economists have proposed methods for estimating the marginal social opportunity cost of capital. Under strict assumptions, it is equivalent to the marginal pretax rate of return on riskless private investments. This is sometimes approximated by the average real pretax rate of return on top-rated corporate bonds. However, this may be an over-estimate if the average rate of return is higher than the marginal rate of return, or if market distortions affect the rate of return.

Time Preference

It has been widely observed that individuals exhibit time preference: they prefer to receive benefits sooner rather than later. Economists have three standard explanations for individual time preference, each of which may be extended to explain time preference at the level of society.

Individual time preference

The first explanation for individual time preference is that individuals may expect their incomes to increase over time, allowing them to consume more in the future than they do today. However, the extra utility that individuals receive from any additional consumption tends to decline as consumption increases. As a result, individuals may prefer to consume more today, at the expense of future consumption, in order to smooth their lifetime consumption and increase their lifetime utility.

Second, every individual faces some risk of death or some other catastrophe that would prevent them from consuming in the future. Offered the choice between consumption today and identical consumption in 30 years' time, many individuals would prefer to consume today on the grounds that they are not guaranteed to be alive for 30 years' time.

Third, individuals might prefer to consume sooner rather than later regardless of their expectations of future consumption. This is referred to as pure time preference, and reflects the fact that individuals often exhibit myopic or impatient preferences. Individuals might not appreciate that they are forfeiting future consumption by consuming more sooner, or they might regard their future utility as being less important than their utility today.

Societal time preference

Extending the first explanation for individual time preference to the societal level is relatively uncontroversial. As the incomes of individuals increase over time, the aggregate consumption of society also increases. Policy makers, acting on behalf of society, may prefer to enact policies which not only smooth the consumption of individuals over their lifetimes but also smooth the aggregate consumption of society over time, so as to maximize aggregate utility (i.e., social welfare) across generations.

Extending the second explanation to the societal level is more problematic. Although individuals face a non-negligible risk of an event, such as death, which prevents them from consuming in future years, the risk of catastrophe faced by society is much smaller. Although every year some members of society will die (or emigrate), others will be born (or immigrate) and society can be expected to carry on regardless. Only a truly catastrophic event would prevent society from consuming in future years. Consequently, society has much less justification than individuals for preferring consumption sooner rather than later.

The final explanation for individual time preference – that individuals often have myopic or impatient preferences – is particularly controversial in a societal context. Although there is considerable empirical evidence that individuals exhibit these preferences, many economists, philosophers, and other thinkers have argued against considering these pure time preferences in societal decision making. This is discussed further in the next section.

The social rate of time preference represents the rate at which society is willing to postpone current consumption in exchange for future consumption.

Under strict assumptions this may be approximated by the after-tax rate of return on risk-free securities (e.g., government bonds). However, these assumptions require that individuals express all their preferences within the market. In addition, the approximation presupposes that individuals do not change preferences when faced with decisions that affect society rather than just themselves. Where these assumptions do not hold, the social rate of time preference is likely to be lower than that implied by market rates.

An alternative means of estimating the social rate of time preference is to use a formula attributed to British mathematician Frank Ramsey. According to the Ramsey formula, the social rate of time preference is given by

$$\mu g + L + \delta \qquad [2]$$

The formula assigns a separate rate to each of the three standard explanations for time preference given above – the

diminishing marginal utility of consumption (μg), the risk of a catastrophic event (L), and pure time preference (δ) – and sums these to give the social rate of time preference. The rate assigned to the diminishing marginal utility of consumption is calculated by multiplying an estimate of the elasticity of the marginal utility of consumption (μ) by the growth rate of real per capita consumption (g). The UK Treasury used this methodology in 2003 to derive its current 3.5% discount rate: citing various sources, it estimated that $\mu = 1$, $g = 2\%$, $L = 1\%$, and $\delta = 0.5\%$, implying a social rate of time preference of 3.5% per annum.

Deriving a Social Discount Rate

Conventionally, attempts to derive a social discount rate – used to discount future costs and benefits in economic evaluations of public interventions – have focused on reconciling the marginal social opportunity cost of capital with the social rate of time preference. Under very unrealistic assumptions, including complete and undistorted markets, the marginal rate at which present consumption opportunities can be transformed into future consumption opportunities is equal to the marginal rate at which society would choose to substitute present for future consumption. Under such a scenario the marginal social opportunity cost of capital and the social rate of time preference are equivalent. Where these assumptions do not hold, some economists have advocated using one or the other as the social discount rate, whereas others have proposed ways of reconciling the two. These include the 'weighted average' and the 'shadow price of capital' approaches.

The weighted average approach holds that the social discount rate should be a weighted average of the marginal social opportunity cost of capital, the social rate of time preference, and, in the case of an open economy, the cost of borrowing on international markets. These weights should reflect the proportion of funds obtained from each source, implying a different social discount rate for each intervention. A limitation of the weighted average approach is that the benefits of the intervention are assumed to be consumed immediately. If these benefits are instead reinvested in the private sector, the weighted average approach will overestimate the social discount rate.

The shadow price of capital approach addresses a key limitation of the weighted average approach by recognizing that the benefits of an intervention may be reinvested in the private sector. The benefit of an intervention is given by the sum of the consumption resulting from the intervention and any future consumption generated from reinvestment of the benefit. The cost is given by the sum of the consumption directly displaced by the intervention and any future consumption forgone because of the displacement of private investment. Although this approach is theoretically attractive, it is more difficult to implement than the weighted average approach.

Discounting in the Context of Health Policy Making

Conventional approaches to deriving a social discount rate can be problematic in the context of health policy making. Health policy makers are often faced with a constrained budget. In this context, the opportunity cost of adopting a specific health intervention is typically not forgone private investment, but rather displaced health care activities elsewhere within the health care system. Furthermore, health policy makers are often concerned specifically with society's health, rather than society's consumption. Since society's time preferences for health typically differ from those for consumption, health policy makers may therefore need to instead consider the 'social rate of time preference for health.' Finally, health policy makers may have reason to adopt different discount rates for costs and health benefits, rather than a single 'social discount rate' for both (this is returned to in the final section). For clarity, the 'social rate of time preference' will hereafter be referred to as the 'social rate of time preference for consumption,' to differentiate it from the 'social rate of time preference for health.'

The social rate of time preference for health

The standard explanations for society's time preference for consumption also apply to society's time preference for health. As society's health improves over time, it may have a preference for earlier health benefits over later health benefits, because of the diminishing marginal utility of health. Society may also prefer earlier health benefits because of catastrophe risk or pure time preference.

The social rate of time preference for health generally differs from the social rate of time preference for consumption. One reason is that the relative value of health and consumption might change over time. Dave Smith and Hugh Gravelle have suggested that the consumption value of health might grow over time, since it is positively correlated with increasing incomes.

The social rate of time preference for health may be estimated using the Ramsey formula. It may also be implicitly revealed by the allocation of health budgets across time (this is returned to in the final section).

Implications for discounting

Where a health policy maker has a specific concern for society's health, and is faced with a fixed budget constraint, it follows that the appropriate discount rate(s) to adopt for economic evaluations of health interventions cannot be derived from either the marginal social opportunity cost of capital or the social rate of time preference for consumption, but rather by considering the social rate of time preference for health and the specific opportunity cost of adopting the health intervention in question (i.e., the health forgone elsewhere as a result of displaced health care activities). The final section of this article reviews recent work demonstrating how the discount rate(s) should be derived in this context.

Contentious Issues in Discounting

Should Benefits be Discounted at All?

Although there is substantial empirical evidence that individuals prefer earlier benefits to later benefits, there is widespread controversy over whether society should display similar

time preferences. Some authors have expressed frustration that discounting health benefits causes many interventions (particularly public health activities) to appear much less desirable. Others have raised ethical objections on the grounds that discounting benefits discriminates against future generations.

A popular view among contemporary economists is that social welfare should be determined by aggregating the preferences of individuals, specifically those individuals who are members of the currently living generation. It follows that if these individuals prefer earlier benefits to later benefits then society should too. An exception is sometimes made for those aspects of individual time preference resulting from myopia or impatience. Many economists regard economic evaluation as a means of bringing greater rationality into societal decision making, and so oppose the consideration of these aspects of time preference on the basis that they are 'irrational.' This view is not universally shared by economists. For example, the UK Treasury explicitly considered such preferences in the derivation of its 3.5% discount rate.

This focus on the preferences of individuals is a relatively new concept. As Murray Krahn and Amiram Gafni have noted, earlier thinkers, including Jeremy Bentham, David Hume and the early utilitarians, had an objective, interpersonal and intergenerational view of social welfare, in which the subjective preferences of the current generation were given relatively little weight. The time preferences of individuals were viewed as a failing of human reason, as representing intellectual or moral weakness, and potentially harmful to social welfare. According to Arthur Cecil Pigou, the government therefore has a 'duty' to "protect the interests of the future in some degree against the effects of our irrational discounting and of our preference for ourselves over our descendants." More recently, John Rawls argued that the principle of intergenerational justice should guide social decision making, in which the interests of all generations are given equal consideration.

However, there are legitimate reasons for individuals and society to prefer earlier benefits, even if equal regard is given to the welfare of future generations. First, consumption or health may be expected to increase over time. If social welfare is regarded as an aggregation of individual utilities, and if there is diminishing marginal utility to consumption or health, then an equal concern for the welfare of all generations may require that preference be given to improving the consumption or health of earlier generations. Alternatively, if intergenerational justice requires that consumption or health be equalized across generations, then an expectation that consumption or health will increase over time implies that preference should be given to improving the consumption or health of earlier generations. Finally, there is always some risk, however small, of a catastrophe preventing society from enjoying the benefits of consumption or health in the future.

It follows that society's rate of time preference for either consumption or health is most likely positive but lower than that for individuals. For these reasons, future benefits generally should be discounted, regardless of whether society accounts for myopic or impatient preferences in societal decision making.

Should Costs and Health Benefits be Discounted at Different Rates?

Although not a new controversy, this debate was reignited in 2004 by the decision of the UK's National Institute for Health and Clinical Excellence (NICE) to no longer recommend the differential discounting of incremental costs and health benefits (at rates of 6% and 1.5% respectively) but instead recommend that both be discounted at a common rate of 3.5%. In a 2011 paper, Karl Claxton and colleagues brought together the prominent authors from both sides of this debate and clarified the causes of this disagreement.

The authors identified a number of matters of context which must be considered before this question can be answered, including the health policy maker's perspective on social choice, the specific objective adopted by the policy maker, and whether the policy maker faces a fixed budget constraint.

Where the policy maker faces a fixed budget constraint, differential discounting is justified only if the cost–effectiveness threshold is expected to change over time. Alternatively, if the policy maker does not face a budget constraint, and if the policy maker adopts a welfarist or extra-welfarist perspective on social choice, then differential discounting is only justified if the consumption value of health is expected to change over time.

These issues are described in more detail in the next section.

Is Differential Discounting Logically Inconsistent?

A number of arguments have been made that differential discounting is logically inconsistent, and so common discounting is unavoidable. These include Emmett Keeler and Shan Cretin's paradox of indefinite delay, Milton Weinstein and William Stason's chain of logic argument, and William Kip Viscusi's equivalence argument. Karl Claxton and colleagues also criticized the 'illogicality' of differential discounting in a previous paper in the recent debate. In response, Erik Nord has recently argued that all of these 'consistency arguments' are themselves logically inconsistent.

The paradox of indefinite delay

According to Keeler and Cretin's paradox of indefinite delay, if two alternative interventions, X and Y, are identical in every respect, except that X is implemented today and Y is implemented in 10 years' time (Table 2), then discounting benefits at a lower rate than costs will result in Y having a more favorable cost–benefit ratio than X. Unless benefits are discounted at a rate at least as high as costs, this implies that policy makers will always prefer to indefinitely delay every intervention.

A problem with this argument, as noted by Michael Parsonage and Henry Neuburger, is that the policy relevant

Table 2 Keeler and Cretin's paradox of indefinite delay

Intervention	*Current year*	*10 Years' time*
X	$10k, 1 life years	
Y		$10k, 1 life years

question is not where in time to locate an intervention, but rather how to set priorities within a constrained budget in any given year. There is no reason to discount Y to today's present value at all: it can simply be appraised in 10 years' time, when it will have the same cost–benefit ratio as X. Nord argues that a distinction should also be made between start time difference and benefit time difference: policy makers may not wish to indefinitely postpone the start time of an intervention, but they may still have a preference over the timing of benefits in programs with given start times.

The chain of logic argument

Weinstein and Stason's chain of logic argument, cited by the Washington Panel as the 'consistency argument,' runs as follows. Suppose there are two interventions: A costs $10 000 now and saves 1 life year in 40 years' time, while B costs $70 000 in 40 years' time and also saves 1 life year in 40 years' time. Assuming a discount rate on costs of 5%, A and B are equivalent. A third intervention, C, is then considered which costs $70 000 now and saves 1 life year now (Table 3). Assuming a constant value of a life year, C is equivalent to B and hence equivalent to A. Since C costs seven times as much as A, the benefits of C must also be seven times the value of those of A, implying a discount rate on benefits of 5%. Costs and benefits must therefore be discounted at the same rate.

However, Nord argues that this is true only if the value of a life year is constant, which was presupposed in the argument. Indeed, Weinstein and Stason acknowledged that adopting a non-constant value of a life year may justify differential discounting of costs and benefits.

The equivalence argument

Viscusi's equivalence argument considers an intervention that costs $8 million now and saves two lives in 10 years. The value of a life in year 10 is V. Costs are discounted at r and benefits at d. In present value terms, the intervention is worthwhile if $2V/(1+d)^{10} > 8$. Viscusi suggested that one could instead look at 'terminal values,' with the intervention worthwhile if $2V > 8(1+r)^{10}$, which can be rearranged to $2V/(1+r)^{10} > 8$. Since these equations are equivalent only if $d = r$, it follows that costs and benefits should be discounted at the same rate.

However, as Nord notes, Viscusi made only the trivial arithmetic point that if one uses the same discount rate for both costs and benefits then either present values or terminal values may be used. Viscusi presupposed $d = r$ in his argument. The real issue about whether the discount rates should be the same is not addressed.

Further arguments

An earlier paper by Claxton and colleagues made two further arguments against the 'illogicality' of differential discounting: first, that support for differential discounting "must rest on a claim that health, unlike wealth, is not tradable over time"; second, that "the true cost of health gained is health forgone – at whatever date these gains or losses may occur. Put in this fashion, the illogicality of wanting to discount health forgone at a different rate from health gained becomes plain."

The first argument is disputed by Nord, who notes that differential discounting can be justified even if health is tradable over time. The second argument is correct in stating that, faced with a fixed health budget constraint, "the true cost of health gained is health forgone," but does not account for the possibility that the cost–effectiveness threshold might change over time. This possibility was considered in the more recent paper by Claxton and colleagues.

Table 3 Weinstein and Stason's chain of logic argument

Intervention	*Current year*	*40 Years' time*
A	$10k	1 life years
B		$70k, 1 life years
C	$70k, 1 life years	

Is Non-Constant Discounting Appropriate?

Conventional discounting is consistent with Paul Samuelson's discounted utility model, with a key assumption being that the discount rate remains constant over time. For example, if the discount rate is 5% then a benefit today is equivalent to a 5% greater benefit in 1 year, whereas a benefit in 10 years is equivalent to a 5% greater benefit in 11 years. Adopting a constant discount rate results in time consistent decision making. This means that if an intervention with distant costs and benefits appears worthwhile today, then it will also appear worthwhile if reappraised in 10 years' time.

However, empirical studies have demonstrated that individuals rarely have a constant rate of time preference. Individuals often exhibit strong time preferences for benefits in the near future: offered a choice between $10 now or $15 next year, many will prefer $10 now. But this time preference becomes weaker in the distant future: offered a choice between $10 in 20 years' time or $15 in 21 years' time, many of these same individuals will prefer $15 in 21 years. A possible reason is that individuals have difficulty comprehending differences between distant time periods. The result is time inconsistent decision making: although the option of $15 in 21 years appears more attractive today, if asked to reappraise their decision 20 years from now many individuals will regret their decision and, if possible, switch their choice.

The issue of how to deal with time inconsistent decision making remains unresolved. Perhaps as a result, non-constant discounting (including hyperbolic discounting) is rarely adopted in practice. Although constant discounting allows policy makers to avoid this issue, the tradeoff is that society's time preferences cannot be fully reflected. An exception is the UK Treasury, which recommends non-constant discounting for very distant costs and benefits. The discount rate falls progressively from 3.0% (between 30 and 75 years), to 2.5% (76–125 years), to 2.0% (126–200 years), to 1.5% (201–300 years), to 1.0% (beyond 300 years). Even with this declining rate, costs and benefits in 300 years are given just 0.14% of the weight of present costs and benefits (under a constant discount rate of 3.5%, this weight would be 0.003%).

Discounting in the Context of Health Policy Making

Over recent years, health policy makers around the world have made increasing use of cost–effectiveness analysis (CEA) to

guide their decision making around the adoption of new health interventions. Typically a CEA compares the costs and health outcomes associated with a health intervention to each of its comparators, and a judgment made as to whether its adoption would be cost-effective. Policy makers, or the agencies which conduct CEAs on their behalf, generally publish guidance as to the discount rates that should be used. For example, NICE currently specifies that costs and health benefits should both be discounted at 3.5% per year, whereas the Canadian Agency for Drugs and Technology in Health (CADTH) recommends that both be discounted at 5% per year. Such guidance has the advantage of providing consistency and comparability across the variety of CEAs considered by each policy maker. It has also resulted in considerable debate as to the most appropriate discount rates to use, with much of this debate focused on the merits of differential discounting of costs and health benefits.

Recent contributions to this debate have demonstrated that the appropriate discount rates to use depend on the context in which health policy is made. This requires consideration of a number of issues, including the health policy maker's perspective on social choice, the specific objective adopted by the policy maker, and the existence or otherwise of a fixed budget constraint for health.

The Perspective on Social Choice

In defining the policy context, the first consideration is the perspective on social choice adopted by the health policy maker. This is the subject of a vast literature, and there are many possible perspectives that policy makers may reasonably adopt. These can be usefully characterized into two groups: those that regard the primary purpose of policy making to be to improve social welfare, as defined by welfarist or extra-welfarist economics; and those that regard policy making as a means for satisfying specific and explicit objectives, rather than improving social welfare more generally.

A welfarist perspective

Traditional welfarist economics assumes that individuals rationally maximize their utility by ordering the various options available to them and acting according to their preferences. Individuals are regarded as the only judges of what contributes most to their utility. Social welfare is judged to be nothing more than an aggregation of these individual utilities. This notion of social welfare is very restrictive: in particular, it cannot take account of outcomes other than utilities, and it does not permit the use of sources of valuation other than the individuals affected by the policy decision.

An extra-welfarist perspective

Over recent decades, these limitations have resulted in the rise of extra-welfarist economics, in which non-utility information such as the quality of individuals' utilities, equity weights, and individuals' characteristics and capabilities are considered alongside individual utilities. This provides substantially more flexibility in the definition of social welfare. Extra-welfarist economics otherwise retains many of the features of welfarist economics: the purpose of policy making is still to improve social welfare, and individual preferences remain an important consideration.

Problems with the definition of social welfare

To judge whether policy decisions improve social welfare requires the expression of an explicit and complete social welfare function: a ranking over all conceivable social states. However, there are many reasons why the expression of an explicit and complete social welfare function might not be possible or even desirable. The work of Nobel Laureates Kenneth Arrow and Amartya Sen demonstrated that it is impossible to specify an explicit and complete social welfare function that satisfies basic requirements while remaining non-dictatorial and respecting minimal liberty. It is therefore unlikely that any explicit and complete social welfare function could be expressed which would carry social legitimacy. Furthermore, policy makers may express no desire in specifying an explicit social welfare function in any case. This is problematic if improving social welfare is regarded as the primary purpose of policy making.

A social decision-making perspective

In response, many economists have advocated for an alternative approach. The social decision-making perspective identifies a more modest role for policy making: satisfying specific and explicit objectives rather than improving social welfare more generally. Under this perspective, policy making agencies (such as NICE) are seen as agents of a socially legitimate higher authority (in NICE's case the UK's democratically elected parliament). This higher authority does not specify an explicit social welfare function, but nevertheless allocates resources among different sectors (e.g., health, education, etc.) and grants each agent the responsibility to pursue a specific and explicit objective subject to a budget constraint. In NICE's case, this objective may be to improve society's health, subject to the budget for health allocated by the UK parliament. Although the higher authority does not specify an explicit social welfare function, the objectives it delegates to the agents, and its allocation of resources between sectors and within sectors across time, represent a partial expression of some unknown latent social welfare function.

The Objective of the Policy Maker

The second consideration of context is the health policy maker's objective. This is influenced by the perspective on social choice. A recent paper by Karl Claxton and colleagues considers two possible objectives that a health policy maker might reasonably adopt: the first under a social decision-making perspective, the second under a welfarist or extra-welfarist perspective.

A social decision-making perspective

Under a social decision-making perspective, the health policy maker may reasonably seek to improve society's health, subject to the budget constraint set by the higher authority. Society may also have a preference for earlier health benefits, represented by the social rate of time preference for health.

The health policy maker's objective may therefore be to 'maximize the present value of health.'

A welfarist or extra-welfarist perspective

Under a welfarist or extra-welfarist perspective, the health policy maker instead seeks to improve social welfare. Health may be considered in consumption terms by weighting it by the consumption value of health. As Hugh Gravelle and colleagues note, if consumption and health are the only arguments in the social welfare function, or are separable from other arguments, then maximizing the consumption value of health is equivalent to maximizing social welfare. Society's time preferences are represented by the social rate of time preference for consumption. The health policy maker's objective may therefore be to 'maximize the present consumption value of health.'

The Existence or Otherwise of a Budget Constraint

The third consideration of context is the existence or otherwise of a fixed budget constraint for health. This has important implications for the opportunity cost of adopting an intervention.

A constrained budget

Where the health budget is constrained, any additional costs of adopting an intervention fall within this budget. It is inevitable that one or more other health interventions will then be displaced, resulting in forgone health. This represents the opportunity cost of adopting the intervention. A critical part of appraising the cost–effectiveness of the intervention is estimating this opportunity cost. Unfortunately, health policy makers are usually unaware of the specific health interventions displaced, so the extent of forgone health must be estimated in some other way.

One such approach is to estimate the slope of the health production function. This function describes how changes in the health budget affect the aggregate health output of the health system, with health output usually considered to be a positive but diminishing function of the health budget. The reciprocal of the slope of the health production function at the prevailing health budget and health output represents the 'cost–effectiveness threshold,' denoted as k in Figure 1.

The cost–effectiveness threshold reveals how much health output is expected to be forgone following a marginal reduction in the existing health budget. For example, suppose that reducing the health budget by $50 000 reduces aggregate health output by 1 quality-adjusted life-year (QALY). The expected opportunity cost of adopting a new intervention would therefore be 1 QALY for every additional $50 000 spent, implying a cost–effectiveness threshold of $50 000 per QALY.

Since the cost–effectiveness threshold represents a matter of fact – how much health output is forgone, rather than the value of this health output – its estimation is an empirical matter. All else equal, the cost–effectiveness threshold will grow with increases in the health budget and fall with improvements in the marginal productivity of the health system. The possibility of the cost–effectiveness threshold changing over time must therefore be considered by health policy makers.

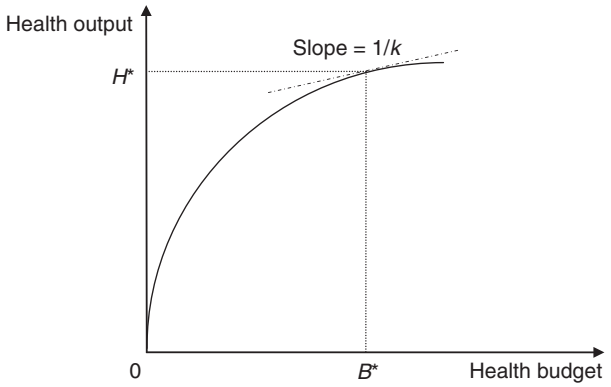

Figure 1 The 'cost–effectiveness threshold' (k) is determined by the reciprocal of the slope of the health production function at the prevailing health budget (B^*) and health output (H^*).

A non-constrained budget

Where the health budget is not constrained, any additional costs associated with adopting an intervention generally fall on other sectors or taxpayers. Under a welfarist or extra-welfarist perspective, the resulting opportunity cost may be regarded in terms of forgone consumption. To determine the cost–effectiveness of the intervention, the health benefits can be weighted by the consumption value of health so that a comparison may be made in consumption terms. Since adopting interventions in this context does not displace health, the cost–effectiveness threshold is redundant.

The Appropriate Discount Rates to Adopt

Recent work by Karl Claxton and colleagues demonstrated how these matters of context determine the appropriate discount rates for the health policy maker to adopt when appraising the cost–effectiveness of health interventions.

In cases where the health policy maker is faced with a constrained health budget, the authors assume that the policy maker determines whether an intervention is cost-effective by comparing its incremental cost–effectiveness ratio (ICER) to the current estimate of the cost–effectiveness threshold. Alternatively, where the health budget is not constrained, it is assumed that this ICER is compared to the current estimate of the consumption value of health.

According to Claxton and colleagues, where the health budget is constrained and the policy maker adopts a social decision-making perspective on social choice:

- Incremental costs should be discounted at approximately the social rate of time preference for health plus the expected growth rate of the cost–effectiveness threshold.
- Incremental health benefits should be discounted at the social rate of time preference for health.

Alternatively, where the health policy maker adopts a welfarist or extra-welfarist perspective:

- If the health budget is constrained, incremental costs should be discounted at approximately the social rate of time preference for consumption minus the expected

growth rate of the consumption value of health plus the expected growth rate of the cost–effectiveness threshold.

- If the health budget is not constrained, incremental costs should be discounted at the social rate of time preference for consumption.
- Regardless of whether or not the health budget is constrained, incremental health benefits should be discounted at approximately the social rate of time preference for consumption minus the expected growth rate of the consumption value of health.

In a subsequent paper, Mike Paulden and Karl Claxton provide an alternative specification for the appropriate discount rates to adopt under a social decision-making perspective. The authors argue that, in societies with a single-payer health system funded by a socially legitimate higher authority (such as a democratically elected parliament), the social rate of time preference for health is implicitly revealed by the allocation of health budgets across time. In this context, the social rate of time preference for health is shown to be approximately equal to the real interest rate faced by the higher authority which finances the health system minus the expected growth rate of the cost–effectiveness threshold.

Combining this result with the findings of Claxton and colleagues, it follows that:

- Incremental costs should be discounted at the real interest rate faced by the higher authority which finances the health system.
- Incremental health benefits should be discounted at approximately the real interest rate faced by the higher authority that finances the health system minus the expected growth rate of the cost–effectiveness threshold.

Intuition and policy implications

Where the budget is constrained, expected growth in the cost–effectiveness threshold must be accounted for, since the opportunity cost of adopting interventions also changes (for higher thresholds, incremental costs result in less health forgone, and vice versa). However, when the ICER of the intervention is compared to the current estimate of the cost–effectiveness threshold, this growth is not accounted for. The only practical way to account for this growth is to adjust the discount rate used for incremental costs. This results in differential discounting.

Under a welfarist or extra-welfarist perspective, if the consumption value of health is expected to change over time, an adjustment must be applied to the discount rate for incremental health benefits. If the health budget is not constrained, this results in differential discounting. However, if the health budget is constrained, the same adjustment must also be made to the discount rate used for incremental costs. This is because incremental costs fall on the health budget and result in forgone health, and any change in the consumption value of health also applies to health forgone. Under a constrained budget, change in the consumption value of health does not therefore justify differential discounting, but rather a lower discount rate for both incremental costs and health benefits. In this case, differential discounting is only appropriate if the cost–effectiveness threshold is expected to change over time.

Estimating the growth rate of the cost–effectiveness threshold requires extensive empirical research. With the exception of recent work in the UK, this research has not yet been undertaken in any jurisdiction. Theoretically, the cost–effectiveness threshold should grow with increases in the health budget but shrink with improvements in marginal productivity. As such, it may not be obvious in many jurisdictions whether the cost–effectiveness threshold is growing or shrinking. As Mike Paulden and Karl Claxton note, it may therefore be reasonable to assume that the growth rate of the cost–effectiveness threshold is zero (implying common discounting of incremental costs and health benefits) until a reliable empirical estimate of the growth rate of the cost–effectiveness threshold is available.

The real interest rate faced by a higher authority may be approximated by the real yield on its long term bonds. As of November 2012, the real yield on long term bonds issued by the UK and Canadian governments was in the region of 0.5–1.5% per annum. It follows that, under a social decision-making perspective, health policy making agencies such as NICE and CADTH should discount incremental costs and health benefits at a lower common rate than currently recommended.

Understanding Medical Tourism

G Gupte, Boston University, Boston, MA, USA
A Panjamapirom, The Advisory Board Company, Washington, DC, USA

Glossary

Competitive advantage An advantage that a firm has over its competitors.
Coronary artery bypass graft (CABG) A type of surgery that improves blood flow to the heart. Surgeons use CABG to treat people who have severe coronary heart disease.
Gestational surrogacy Surrogacy is an arrangement in which a woman carries and delivers a child for another couple or person and is biologically unrelated to the child.
Intracytoplasmic sperm injection One of the *in vitro* fertilization procedures (see the next term) in which a single sperm is injected directly into an egg.
***In vitro* fertilization (IVF)** Commonly referred to as IVF. IVF is the process of fertilization by manually combining an egg and sperm in a laboratory dish.
Medical tourism The travel for healthcare services outside the main local healthcare coverage area.
Organization for Economic Cooperation and Development (OECD) An international economic organization of 34 countries founded in 1961 to stimulate economic progress and world trade.
Synergies Where the whole becomes greater than the sum of the individual parts.

Growth of Medical Tourism

Globalization has inevitably become part of all industries, as we observe the economy stretch worldwide due to cheaper travel, better communication methods, and common solutions to problems. Over the past decade a healthcare practice that has emerged with an unimagined scale of magnitude as a multibillion dollar industry is the global medical tourism industry. Privatization and commercialization of conventional home country or region-based healthcare has been redefined in a global market. Medical tourism (also often referred to as international medical tourism) is generally defined as the travel of patients seeking healthcare services outside the main local healthcare coverage area.

According to sources, the number of medical tourists will rise from approximately 10.5 million in 2011 to 23.2 million by 2017. Some predict global revenue approximately between $40 and $60 billion, with different growth rates estimated over the next 10 years, some at 20% annual growth. Some reports estimate specific area growth, such as worldwide surgical volume at 60 000 patients every year. The most obvious benefit of medical tourism is cost savings for consumers, which typically range from 40% to 90%. For example, heart bypass that may cost approximately $180 000 in the US can be rendered at $10 000 in India or Thailand. Including first class air fare and four-star hotel accommodations for recovery, the savings are routinely more than 60%.

However, one needs to remember that medical tourism is not a new phenomenon, ancient civilizations and historians have recorded the travel of patients across regions and countries searching for appropriate treatment and better care. For example, Greeks traveled to spas known as 'Asklepia' in the Mediterranean for purification and spiritual healing; for over 2000 years foreign patients have traveled to the Aquae Sulis reservoir built by the Romans in what is now the British town of Bath; and Chinese and Indian scholars traveled across countries to seek more knowledge of diseases and conditions bringing patients with them. In the early nineteenth century, sanatoriums attracted tuberculosis patients to pristine mountain air such as Davos, Switzerland.

For the past few decades, outstanding facilities, such as Cleveland Clinic and Mayo Clinic, have attracted medical tourists to developed countries such as US, especially wealthy patrons from the developing world. However, worth noting is the new pattern of reversed care destination where patients from developed countries travel to seek medical services in developing countries such as India, Thailand, Malaysia, Chile, Argentina, Philippines, Jordan, South Africa, and others (Figure 1). These countries offer state-of-the-art technology and facilities, employ US-trained physicians, and concierge healthcare services at a fraction of costs that would have otherwise been incurred in the developed countries (low labor costs and overheads making it affordable). Other factors contributing to the growth of medical tourism include, but are not limited to, financial mobility, free trade, technological advances, cheap transportation, more resources, and rapid communications. Patients unable to gain prompt access to services due to a number of reasons, such as restricted insurance policies, long waiting time, and unavailable treatment options have started traveling beyond their borders to receive the care of preferences. Additionally, 'word of mouth' promotion by recent medical tourists, careful marketing, and interests from health insurance companies are some other drivers of medical tourism.

To attract patients from developed countries, medical tourism packages include procedures (Table 1) with preestablished prices, air fare, accommodation, ground transportation, concierge treatment, food, recuperation therapy, and supplementary trips to popular destinations. Often these packages are well coordinated by medical tourism companies representing care delivery organizations in the host countries.

 doi:10.1016/B978-0-12-375678-7.01007-5

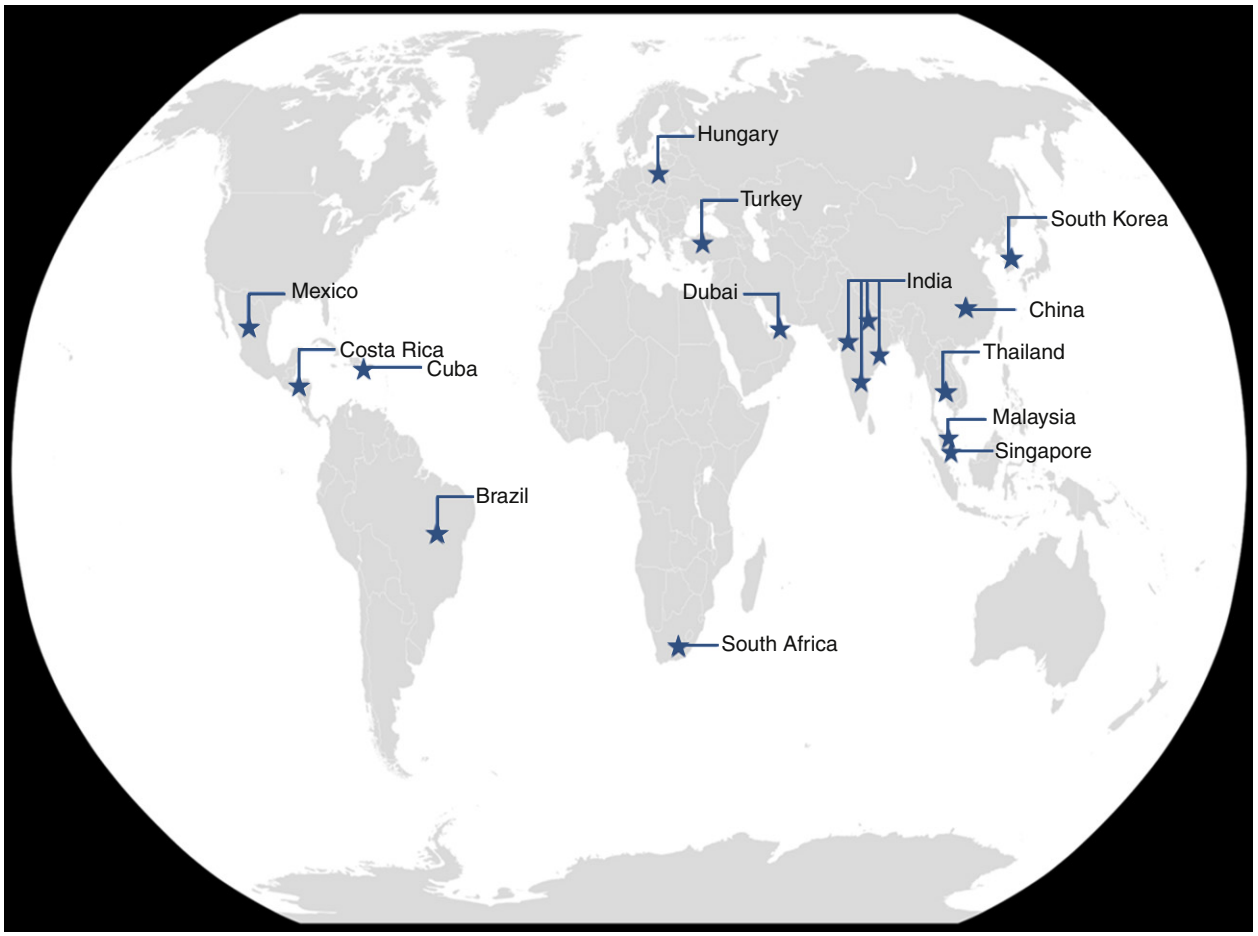

Figure 1 Medical tourism destinations.

Table 1 Commonly conducted procedures/treatments for medical tourism and their countries

Common medical tourism procedures	*Countries*
Dental tourism	Mexico, Bulgaria, Croatia, Argentina, Thailand, Hungary, and Poland
Transplant tourism (kidney, heart, lung, and liver transplant)	Thailand, India, and China
Reproduction tourism (includes *in vitro* fertilization, gestational surrogacy, and intracytoplasmic sperm injection)	India, Barbados, and UK
Cardiac procedures (coronary artery bypass graft and bypass surgery with heart valve replacement)	India, Thailand, Costa Rica, Singapore, Malaysia, and South Korea
Knee surgery	India, Thailand, Singapore, and Malaysia
Hip replacement	India, Thailand, Singapore, Malaysia, and Turkey
Ophthalmic surgery (cataract surgery, cornea alteration procedures, and glaucoma treatments)	Mexico, Bulgaria, Croatia, Argentina, India, Thailand, Singapore, Malaysia, and Turkey

Medical Tourism through a Systems Thinking Perspective

Systems thinking is an approach that reveals the underlying characteristics and relationships of systems. It uses comprehensive suite of tools and approaches to map, measure, and understand a system and its dynamics with the environment. Its utility in understanding and integrating complex, real-world settings makes it the right strategy for explaining the growth in medical tourism industry. To understand the medical tourism industry, it is imperative to understand the complex effects, synergies, and emergent behaviors of various stakeholders affecting this economic explosion. Additionally, researchers have discussed the benefits of using the systems thinking approach in understanding healthcare systems as these systems are self-organizing, constantly changing, tightly linked, governed by feedback, nonlinear, history dependent, counter-intuitive, and resistant to change.

The main stakeholders in the global healthcare marketplace include hospitals (private and public), patients, stand-alone clinics, governments, medical tourism companies, airlines, hotels, health administrators, and healthcare providers (Figure 2). However, first, it is important to understand how the medical tourism industry fits in the healthcare system. World Health Organization (WHO) defines a health system as, 'consists

of all organizations, people and actions whose primary intent is to promote restore or maintain health.' The goal is 'improving health and health equity in ways that are responsive, financially fair, and make the best, or most efficient, use of available resources.' WHO further identifies six systems building blocks that are used as a framework to apply systems thinking to medical tourism. These blocks serve as framework for understanding the medical tourism and effect of stakeholders in the service. The blocks have been identified as: Service delivery, health workforce, health information, medical technologies, health financing, and leadership and governance. These blocks form an integrated relationship that creates interactions in the medical tourism industry. Thus, using this framework and systems thinking approach an attempt is made to understand the world of medical tourism (Figure 3) (Box 1).

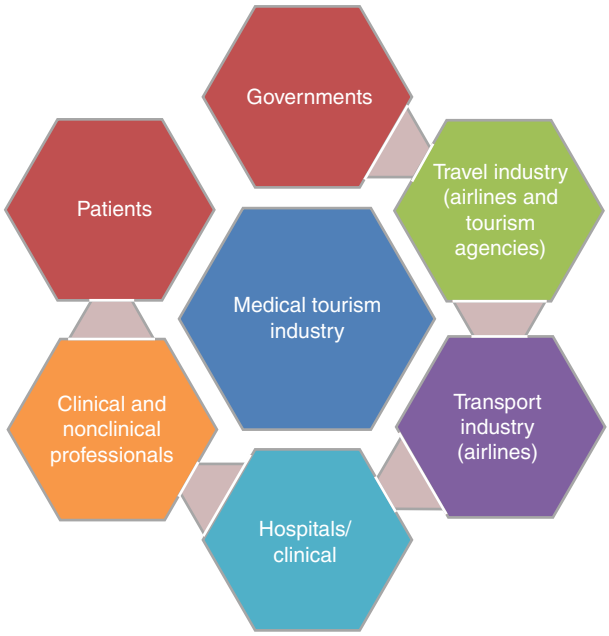

Figure 2 Main stakeholders in the medical tourism industry.

- Service delivery: The most effective medical tourism hospitals are the ones that provide services that are superior quality, reliable, timely, accessible, cost effective, and globally identical to some of the best in the world.
- Health workforce: The workforce is well trained, highly efficient, and reliable. Additionally, the workforce needs to be affordable to maintain the low cost structure. The combination of these attributes is commonly found in healthcare professionals, providing care services in the medical tourism industry.
- Health information: These hospitals ensure that the consumers are provided with current, relevant, and non-asymmetric information. Gaining trust of patients through transparency is what these hospitals aim to achieve at the point of interest initiation. The advancement of information and communications technologies allows consumers to access health information from various electronic sources at their fingertips.
- Medical technologies: To build competitiveness and illustrate advanced medical capabilities, medical tourism providers have invested in medical technologies that are most advanced, cost effective, scientifically sound, and safety and quality focused.
- Health financing: The health financing system is entitled to providing affordable, necessary medical services to patients. Evidently, medical tourism 'provides incentives for providers and users to be efficient' simultaneously.
- Leadership and governance: Strong leadership and effective governance drive strategic thinking to create new care delivery models that meet consumer demands and to generate an accountable care environment via policy and regulation oversight.

Box 1 Perspective

Perspective on Bumrungrad International Hospital

Bumrungrad International Hospital based in Bangkok, Thailand, was founded in 1980 as a 200-bed facility. Since its inception, Bumrungrad has expanded to a 554-beds facility that delivers over 30 specialty services. It is the largest hospital in southeast Asia that meets international standards. Bumrungrad is the first hospital in Asia accredited by the Joint Commission International since 2002 as well as the first hospital in Thailand accredited by the Institute of Hospital Quality Improvement and Accreditation since1990. Bumrungrad opened its outpatient clinic building in 2008. Bumrungrad is a for-profit hospital traded on the Stock Exchanges of Thailand.

Bumrungrad's vision is to offer 'world class medicine' and 'world class service' and its mission is 'to provide world class healthcare with care and compassion.' These vision and mission statements have been the compass directing Bumrungrad in its venture toward being the top international hospital of Asia and probably of the world. As an international hospital, Bumrungrad annually receives an average of 400 000 patients from more than 190 countries, which comprise 40% of all its patients. It is able to do so thanks to various factors such as its workforce, office support, infrastructure, and technologies. The majority of Bumrungrad medical and managerial workforce pursued education and completed training from developed countries such as the UK, Germany, Japan, Australia, or the US. Bumrungrad employs over 1100 physicians and dentists, 200 of whom are US board certified. Bumrungrad employs over 150 interpreters who facilitate the communication between foreign patients and the clinical staff. To better support its foreign patients, Bumrungrad established International Referral Offices comprising 16 international offices based in 16 countries, overseas offices through its liaison between Bumrungrad and patients outside Thailand.

Bumrungrad was designed as a hospital that delivers its services in a magnificent hotel infrastructure. Its main lobby, which contains five shops and a bank, is reminiscent of a luxurious and spacious five-star hotel lobby; its hospital rooms are equipped with bed-side laptop, Wi-Fi, and interactive television with on-demand movies option. Even the hospital rooms are classified according to hotel standards such as single deluxe rooms, premier suites, premier atrium suites, and premier royal suites. Its 51 hospitality suites are self-contained apartments with inside pool and fitness facility. The top floors of the hospital building contain six international restaurants as well as a premium member lounge. These kind of amenities appeal to patients as they feel like they are in a hotel instead of being sick in a hospital.

Furthermore, Bumrungrad's infrastructure is equipped with state-of-the-art medical, pharmaceutical, laboratory, and information technologies. All these technologies were adopted mainly to improve healthcare quality, patient safety, and efficiency. Thus, medical staff and technicians spend less time on routine activities and devote more time on direct patient care. Bumrungrad uses advanced medical technologies such as digital mammography and image-guided radiotherapy. In addition, Bumrungrad owns a pharmacy robot, which is a fully automated drug management system. Bumrungrad' s medical lab automation is a comprehensive system that performs medication packaging, storage, and dispensing.

Bumrungrad has partnered with Microsoft for the implementation of Microsoft Amalga Health Information System, a fully integrated hospital information system that has streamlined its information processing activities. Although the Veteran Health Administration has the most advanced electronic medical record system in the US, its health information technology specialists were sent to Bangkok to study the Bumrungrad information system. In 2008, Bumrungrad received the 'Best Wireless Project South East Asia' award from Motorola's Enterprise Mobility Business.

In addition to the provision of healthcare, Bumrungrad conducts clinical research in the Bumrungrad International Clinical Research Center, which was established in 2001. Its research activities focus on clinical trials on prescription drugs and biomedical and social science research.

Although Bumrungrad caters for the wealthy locals and foreigners and is being propelled to its status as a world-class leader in healthcare, it has not forgotten those who cannot afford to pay for high-cost services. It created a foundation, the Bumrungrad Hospital Foundation to provide charitable services for the underprivileged Thai population. Such services included the provision of 122 pediatric heart surgeries and health education.

Thanks to Bumrungrad' s continuous strive for hospital wide quality and excellence, it has been ranked sixth of the top ten Thai companies, named among the six most admired Thai companies in terms of corporate reputation, quality, and innovation, and considered one of the best destinations for medical tourists.

Author: Zo Ramamonjiarivelo, Ph.D., Assistant Professor, Governor State University, Chicago, US.

Economic Drivers of Medical Tourism

As mentioned in the section Growth of Medical Tourism, globalization of markets and services serve as a strong enabler of healthcare trades between developed countries and developing countries. Specifically, it forces the global healthcare markets to be smaller and interconnected and opens opportunities for the movement of consumers and resources (i.e., healthcare professionals, medical and information technology, pharmaceutical supplies, capital funding, and international laws and regulations) across national borders. As a result, medical tourism has influenced the economic discourse of healthcare services consumption and production. Like other economic goods, the growth of medical tourism inherently rests on the fundamental economic principles of demand, supply, price, and value.

Because a transaction of medical tourism involves a number of relevant stakeholders, such as patients, providers, insurance companies, governments of the patient's countries, and government of the hosting countries (Figure 2), it is complicated to describe the economic drivers by a stakeholder. This article will discuss the economic drivers through the demand and supply lenses in which the multifaceted perspectives of different stakeholders can be well incorporated. Note that the following discussions will focus on the outbound medical tourism from developed countries to developing or hosting countries. Healthcare systems across countries around the world have confronted different unique challenges, which fundamentally result from how the systems are set up.

Multiple US federal mandates and initiatives have been enacted with the aims of sustainably bending the healthcare cost curve and improving access and quality of care. Meanwhile, a number of Americans are struggling with their chronic or acute illnesses every day, requiring necessary medical treatments, many of whom are uninsured or underinsured. Healthcare providers, especially hospitals, are under a lot of pressures caused by reimbursement cuts and new payment models. The result is increasing operating expenses while being required by law to stabilize any patients present at their facilities regardless of their insurance status. Hospitals that keep taking on the burdens caused by unpaid services are in financial distress causing some to discontinue their operations. This results in a negative domino effect on the other

existing hospitals. In addition, underinsured patients are not authorized for certain procedures and cannot afford the difference between the charges and amount their payers reimburse the provider. As a result, price plays a major role for uninsured and underinsured Americans to receive proper treatments, forcing them to search for options overseas where a similar procedure plus travel and accommodation expenses cost much less. Lack of cost transparency for the medical care provided and uncontrolled escalation of medical service and technology costs add more challenges within the healthcare market.

Canada and England are samples of other Organization for Economic Cooperation and Development (OECD) countries confronting their own issues of waiting time. Although the government will take care of sick patients, they are required to wait a number of weeks or months for certain medical procedures causing unbearable pains and discomforts. In addition, some medical services such as fertility and stem-cell treatments have yet to be legalized or approved in many western countries, leaving patients with no choice but to seek the treatments available elsewhere. Given that these medical tourism facilities are well equipped with the state-of-the-art technologies and staffed with western-trained providers, some patients perceive them as providing higher quality of treatments when compared to local providers. The abundance of information technology also allows patients to gather information on medical treatment options from various sources, which assist their decision making process and help protect themselves from information asymmetry and provider-induced demand. As a result, there exist unmet demands of medical services among citizens of these developed countries. Price, unavailable treatment options, long waiting time, and ability to make a decision based on alternative preferences are some of the major drivers on the demand of medical tourism. In summary, price and value in medical tourism can generally be reflected through the notion that world-class quality care is rendered to patients from developed countries at third world prices.

When there is a demand, there will always be an opportunity for a new market, and those who recognize it and have capabilities to supply the needs can take the pie. The supply side of this medical tourism equation is obviously reflected through the hosting or developing countries that provide medical services to the patients from developed countries with unmet needs. Healthcare delivery organizations in developing countries have quickly grasped on the concept of medical tourism and these untapped demands, emphasizing on quality of care and world-class customer services. Some perceive it as a new business development strategy when domestic private patients have turned to publicly funded healthcare systems such as academic health centers where high quality and advanced care is rendered at a lower price. Some countries have seen the great economic potential of medical tourism turned it into the national agenda and supported the provider organizations both financially and policy-wise (e.g., India and Thailand). For example, opening of more health tourist visa approvals, more subsidies on ventures encouraging tourists in the country, and legalization of certain medical procedures such as surrogacy.

The main competitive advantage that these provider organizations have over their counterparts in the developed countries is the cost of labor and supplies. Labor is a major operating cost for healthcare delivery organizations. Because labor costs in these developing countries, even for healthcare professionals, are much lower than those in developed countries, these organizations are operating at a fraction of the cost incurred by their western counterparts, allowing them to develop attractive pricing strategies. In addition, the medical and pharmaceutical supplies in developing countries are at a much lower negotiated price, part of which is due to international trade agreements.

Owing to the dramatic success in the medical tourism industry within a relatively short timeframe, there is an increasing trend in partnership and investment between health systems in the developed countries and medical tourism providers in developing countries, resulting in the flow of capital funding to accelerate the growth of medical tourism. Over the years, medical tourism has expanded its client base from only out-of-pocket individuals to patients with private or employer insurance because both sides share a win-win situation. The potential revenue streams from these groups of patients have led to different types of arrangements between insurance companies in developed countries and providers in developing countries. As a result, low operating costs and increasing capital are two main factors driving the growth of medical tourism on the supply side.

Health Policy Issues in Medical Tourism

Although medical tourism has created tremendous economic gains to the hosting countries and health benefits to the patients receiving care, it at the same time has undergone a number of legal, social, and ethical criticisms and forfeiting challenges. The emerging trade of medical services brings forth a number of regulatory and policy implications at international and country levels affecting both developed and developing countries. Given that medical tourism is relatively in its infancy and merely merits dramatic attention in recent years, there is no existing law or regulation that specifically aims to enforce appropriate actions, penalize misconducts in medical treatments, and prevent future wrongdoing around this new pattern of medical practice.

Certain regulations and policies aim at supporting the medical tourism industry. There exist some international accreditation organizations such as the Joint Commission International (based in the US) and Trent Accreditation Scheme (based in UK–Europe) from which medical tourism organizations seek accreditation to demonstrate their commitment to high-quality care and patient safety. By being recognized by the world-renowned accreditation bodies, these care delivery organizations can not only provide a level of assurance and comfort to patients traveling from developed countries but also leverage the accreditation as a competitive advantage that could also attract local patients.

To support the growth of medical tourism, some developing countries have relaxed their visa process or established a special type of visa for patients seeking medical treatments in the countries. Additionally, with the great attempt to bend the healthcare cost curve, the US Congress

recently held a Senate hearing on the promise of medical tourism titled 'The Globalization of Health Care: Can Medical Tourism Reduce Health Care Costs?' while there is also a push for Medicare and Medicaid to reimburse medical tourism services. Furthermore, insurance companies have caught on the trend and started incorporating medical tourism into their plans, hoping to decrease the cost burdens they would otherwise have borne should the patients were treated in the US.

However, medical tourism has incurred unintended consequences for which no laws and regulations have yet been prepared. Privacy and security of patient information is of great concern. Although the information created or captured on the US soil is protected by the Health Insurance Portability and Accountability Act, healthcare organizations in other countries are not bound by the law, which in turn makes it difficult to handle any violations. Not only patients from developed countries but also the citizens of the hosting countries could be negatively impacted by medical tourism. The economics doctrine was established on the notion of scarcity where limited resources can never fulfill indefinite wants and needs. As a result, when resources are redirected to serve the needs of spillover patients from the developed countries, there will be negative consequences to the unmet needs of basic healthcare services among the consumers in the hosting countries. This poses highly concerned threats to the local patients, especially among the people with financial constraints. Statistics have shown that the ratio of medical providers to patients in developing countries is much lower than that of developed countries. In addition, on top of the existing issue of external brain drain, the heavy recruitment of highly skilled, experienced, western-trained healthcare practitioners into medical tourism facilities has driven a more severe incidence of provider shortage in the public health system of the developing countries (i.e., internal brain drain). Although there is currently no empirical study that shows that the magnitude of medical tourism impacts on provider shortage and healthcare access of consumers in the developing countries, some anecdotal evidence point to the stark increasing disparities.

Without an effective policy set forth by home country governments or international bodies, the issues could have further implications on social gaps and potentially threaten the health-related goals put in place by the countries or international organizations such as WHO and United Nations. To ensure the mitigation of negative effects, home country governments and international regulatory bodies must work independently and cooperatively to prioritize an understanding of these issues and subsequently develop policies that address these arduous obstacles in both short and long term.

The Future of Medical Tourism

Medical tourism has generated global competition in the delivery of healthcare market. In this competition, the more expensive and resourceful countries are increasingly disadvantaged. However, one cannot remain a nonparticipating player in this lucrative opportunity. As a result, a number of frontrunners in the US healthcare have expanded their strategic coverage to compete for market share in medical tourism. For example, Philadelphia International Medicine is building a hospital in Korea; Harvard University has partnered with India's Wockhardt Hospital and the United Arab Emirates to create the Dubai Healthcare City; and The Johns Hopkins University and Tufts University have opened hospitals in India. Such collaboration and partnership have propelled the image of affordable and high-quality care to new heights.

In the long run, medical tourism may also help insurance providers and employers reduce their costs and provide their employees with alternatives for satisfactory coverage. Only a few insurers offer care overseas, but they have already reported remarkable savings. For example, Blue Cross/Blue Shield of South Carolina gives customers a medical tourism option through its Companion Global Healthcare and even offers coordination of foreign care for preexisting and noncovered procedures. Employers large and small are beginning to offer incentives to their employees to have routine care done outside the country, observing considerable savings. For example, Hannaford, a US grocery chain, found that sending its employees to Singapore for knee or hip replacements lowered the price from $43 000 to $9000.

Medical tourism challenges the ability of nation-states and national governments to control affairs within their own jurisdiction. The lack of legal options for patients choosing healthcare overseas, ethical and social justice issues of traveling abroad for organ transplant and reproductive tourism and concerns about large international hospitals providing level of care unaffordable for citizens is a concern raised by opponents. To address these concerns new international steps are taken among a coalition of countries resulting in the Declaration of Istanbul on Organ Trafficking and Transplant Tourism in May, 2008. Nonprofit organizations promoting international medical travel vouching for quality healthcare are also growing; one of such organizations is Medical Tourism Association that currently has 20 000 members and a slick website and magazine. Additionally, organizations such as Joint Commission International – the international division of The Joint Commission, have been working with healthcare organizations, ministries of health, and global organizations in more than 80 countries. Conferences such as the World Medical Tourism and Global Health Conference are being held every year and are attended by representatives from major international medical centers looking for business, Western firms coordinating medical travel and care, and third-party payers and insurance companies seeking ways to contain costs.

On a general note, globalization of healthcare in the form of medical tourism has several advantages:

1. Economies of scale: The production of medical services in an efficient and standardized format encourages value creation in healthcare delivery.
2. Better consumer purchasing power: Apart from quality, the central focus of this industry is cost-efficiency, which gives consumers (patients) more control of their treatment options and destinations.
3. Faster adoption of innovative healthcare treatments and technologies: The presence of innumerable competitors acts as driver for the early adoption of evidence-based

innovative treatment plans and options. It additionally also creates more acceptability of the services that are provided by hospitals.

4. Emergence of global market segments: As the industry grows, more clustering of this industry is being observed. Presently, the Asian region (India, Thailand, Malaysia, and Singapore) seem to be sprouting medical tourism hospitals at an exponential speed.
5. Development of synergies: The global scale of the healthcare industry is also an opportunity for transfer of ideas on healthcare products and treatments from one country to another. Additionally, the global marketing creates more experience in operating in multicultural and diverse environments.

The key to success for medical tourism therefore lies in the strategic global economic growth, focusing on how revenue from worldwide patient travel translates into output, jobs, and income. It will provide an opportunity to both developing and developed countries. Although developing countries will benefit from the travel resulting in revenue generation from the healthcare services provided, developed countries will benefit from the competitiveness of the market as a stop point to reflect on their cost, quality, and accessibility issues in providing their citizens value-driven healthcare. Even though medical tourism is confronting some social and ethical challenges, it without a doubt is an explicit example of international economics in action where the flow of consumers and resources beyond local boundary promotes an affordable, accessible, and quality healthcare environment.

Unfair Health Inequality

M Fleurbaey, Princeton University, Princeton, NJ, USA
E Schokkaert, KU Leuven, Leuven, Belgium

Glossary

Atkinson inequality index An index of inequality that has explicit weights attaching to the measured variable (income, health, etc.) at various levels. This sensitivity parameter ranges from 0 (indifference about the nature of the distribution) to infinity (concern attaches only to the position of the very lowest group).

Capabilities The set of all possible physical and social functioning for a person.

Concentration index A measure of the degree of income-related inequality in health. Where there is no income-related inequality, the concentration index is zero. A negative value indicates a disproportionate concentration of ill-health among the poor.

Direct unfairness Inequalities in health or health care after one has removed the effect of determinants not considered to be or to lead to unfairness.

Fairness gap The gap between an actual and a hypothetical distribution of health in which all legitimate grounds for inequality have been removed.

Gini coefficient A number between 0 and 1, where 0 corresponds to perfect equality (everyone has the same income, health care, etc.) and 1 is perfect inequality (one person has all the income, health care, etc.).

Lorenz curve A graph showing the cumulative percentage of income, health expenditures, etc. held by successive percentiles of the population.

Standardization The adjustment of raw data to avoid making false inferences arising from confounding factors.

Introduction

A fair society should give individuals equal opportunities to realize their own life project. Health is of utmost importance for the flourishing of individuals. It seems, therefore, self-evident that inequality in health should get an important place on the fairness agenda. Yet, this seemingly obvious statement raises difficult issues. First, is all inequality in health necessarily unfair? Some health inequalities can be seen as 'unavoidable,' because they are due to biological factors or simply reflect bad luck. Should we not rather target those inequalities that are caused by the organization of our society, and in particular the health inequalities that are linked to indicators of socioeconomic status such as income, wealth, education, and social class? Socioeconomic inequalities have indeed been the main focus of the research, both in the public health and in the economic literature, and they also figure most prominently in policy statements. Yet, this raises a second, similar, question: Are all socioeconomic inequalities necessarily unfair? What if they are partly caused by individual behavior, such as smoking and drinking, or by choices about where to live and what kind of work to pursue? Should people not be held responsible for their lifestyle choices? And if so, should our measure of unfairness not in one way or another take into account this element of individual responsibility? Third, no matter how important health is for human flourishing, it is not the only important dimension of well-being. Does it make sense to focus on health only? Should we not integrate health inequality in an overall view of unfair inequality in well-being?

These questions are the main focus of this entry and therefore other important issues are left aside. First, an explicit defense of egalitarianism will not be constructed and it will simply be taken for granted that some form of equality is necessary for fairness. The real question is: Equality of what? Second, the possible trade-off between total health and its distribution will not be considered. If spreading information about healthy lifestyles leads to an increase in average life expectancy but at the same time to growing inequality (e.g., because different cognitive capacities lead to differences in the efficiency of processing this information), a complete evaluation of the policy requires trading off these two effects. The focus here is on the specification of the fairness element in this trade-off. Third, unfairness is not exclusively a matter of health outcomes but has also a procedural element: Many will not accept that unfair health inequalities should be tackled by introducing explicit discriminatory practices into the process of accessing health care. Fourth, health can be measured in many different ways. Mortality is one possible indicator, the number of chronic conditions another; and much work is based on subjective self-assessed health, either on a continuous scale or in discrete categories. Different health concepts may yield different fairness results. Moreover, the level at which these variables are measured will determine the kind of inequality measures that can be used. These measurement issues will be left aside and the focus will be on the conceptual question: What is unfair health inequality?

Pure Health Inequality

The most straightforward approach is of course to consider simply all health inequalities as 'unfair.' Provided that health can be measured on a ratio scale, the degree of unfair health inequality can then be gauged by any of the measures that

have been developed in the literature on income inequality (such as the Gini or Atkinson coefficients), and one can also draw the traditional Lorenz curve with the cumulative share of the population on the horizontal axis and health on the vertical axis. The closer this curve is to the diagonal, the smaller is inequality in health. The only difficult issue in this context is the choice of an adequate measure of health. All the rest is standard.

However, the question is, whether such pure health inequality an interesting concept? Suppose the inter-regional differences are to be checked in the performance of a health care system. It is observed that mortality is higher in region A than it is in region B. Yet, it is also observed that the population is on average older in A than it is in B. In that case it could be highly misleading to derive conclusions about the relative performance of the health care system in different regions from the simple differences in mortality. A correction for age seems necessary. In this spirit, the epidemiological literature has derived different methods of standardization of the raw measures by making use of the information from a reference group (e.g., the overall population in the country). Direct standardization estimates the mortality rate that would be obtained in regions A and B in the hypothetical situation in which they had the same age structure as the reference group. Indirect standardization first calculates the hypothetical mortality rate that would have been observed in regions A and B if the mortality rates for the reference population were applied to the age structure of the respective regions. One then computes standardized mortality rates by taking the ratio of the observed mortality rates with these hypothetical rates.

Although the use of standardization seems justified in this application, it has also been advocated for measuring unfairness in health. The authoritative World Health Organization Commission on Social Determinants of Health has emphasized that health inequity only arises where systematic differences in health are judged to be avoidable by reasonable action. Naively applied, this view implies that age and gender differences in health should not be seen as unfair because they can be largely explained by biological factors that are 'unavoidable.' One may deplore these differences, but nature itself cannot be fair or unfair. Although this is a popular opinion, it is controversial. It is hard to deny that social and technological developments interact with this biological background. This is especially obvious for gender: Health inequalities between men and women are definitely not only caused by biological factors but also by the position of men and women in society, including the way they are treated by the health care system and in the labor market. The rapid increase in male but not female mortality in the 1990s in Russia and other former Soviet Union countries, during the transition from a planned to a market economy, is a striking illustration of how socioeconomic factors can impact on gender inequalities in health. The same point can also be made with respect to age: Everybody dies, but health and mortality among the elderly depend on the way society is organized. Even the effects of different genetic endowments cannot really be seen as 'unavoidable:' Not only will the rapid technological developments in the domain of total genome analysis increase the potential of interventions in the near future (e.g., for eradicating diseases caused by genetic defects) but also it has become clear that phenotypical differences are almost always the product of interactions between the genetic endowment and the socioeconomic and natural environment. The latter can be influenced by policy. Biological differences do exist, but they do not completely determine the resulting health situations. The practice of quasi-automatic standardization for age (and even worse, for gender) may, therefore, hide important aspects of unfairness that follow from the differences in the treatment of women and the elderly in different countries or in different time periods.

Socioeconomic Health Inequalities

Whatever the position taken with respect to the effects of biological factors, most people would agree that health inequalities related to socioeconomic status in terms of income, wealth, education, or social class are particularly unfair. Differences in socioeconomic status are on their own already an indicator of injustice – and things get worse if individuals with a better socioeconomic status also are in better health. Both the public health and the economic literature have by now produced overwhelming evidence for the existence of such socioeconomic inequalities in health, with different health measures, for different countries and in different time periods.

Regression-based measures based on gaps or ratios between two extreme groups have been especially popular in the public health literature. These have the advantage of being very simple to interpret. As an example, Figure 1 shows the ratio of the estimated death rate from any cause for males at the lowest level of education over the estimated death rate from any cause for males at the highest level of education. All measures are standardized for age. The results are striking. In countries like Hungary, the Czech Republic, and Poland, mortality differs between the lower and upper ends of the education scale by a factor of more than 4. Similar results are found with other measures of socioeconomic status (such as income and occupation) and indicators of health (such as self-assessed health).

Economists have studied the same phenomenon using the concentration index. The concentration index is a measure of the area between the concentration curve and the diagonal, where the concentration curve is drawn with the cumulative share of socioeconomic status (e.g., income) on the horizontal axis and the cumulative share of health on the vertical axis. Compared with the extreme group measures often used in the public health literature, the concentration index has the advantage of taking into consideration the whole distribution. Here also, standardization for age (and sex) is quite common.

Although their methods differ, the economic and public health literature concur with each other in finding strong socioeconomic inequalities in health. This is definitely a finding with much relevance for evaluating the fairness of the social arrangements. Yet, from a broader perspective, two questions can be raised. Are all socioeconomic inequalities necessarily unfair? And how do socioeconomic inequalities fit in a broader view on fair health inequality?

Are All Socioeconomic Inequalities 'Unfair?'

After having observed and measured socioeconomic inequalities in health, a logical next step is its explanation. Different

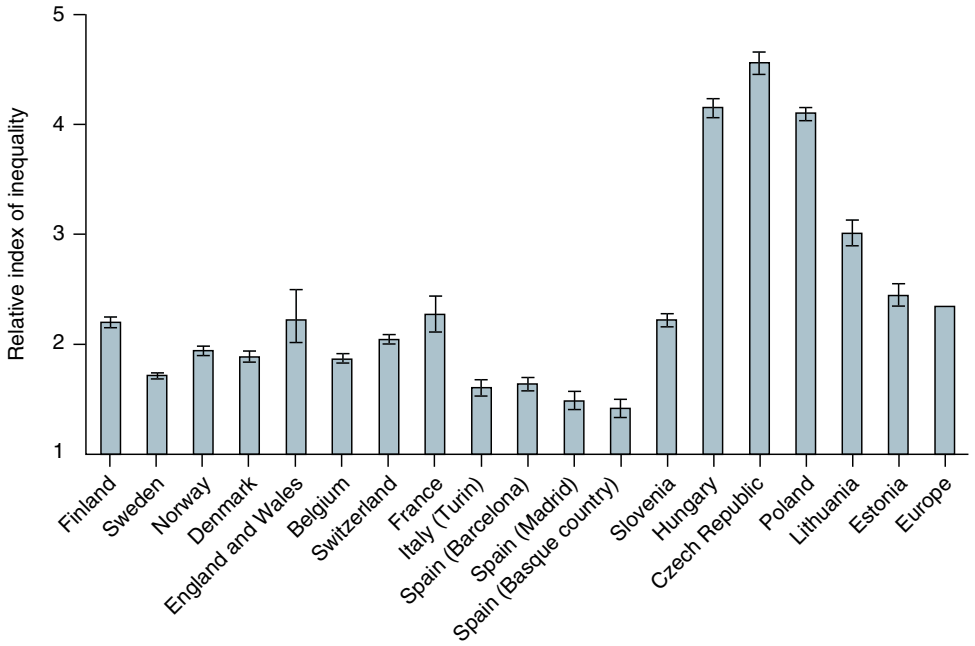

Figure 1 Relative inequality in the rate of death for any cause in different European countries (for men, according to education). Reproduced from Mackenbach, J., Stirbu, I., Roskam, A. J., et al. (2008). Socioeconomic inequalities in health in 22 European countries. *New England Journal of Medicine* **358**(23), 2468–2481.

factors have been documented in the literature. Health and mortality inequalities may be caused by differences in working and housing conditions or by differences in access to good quality health care (apparently, an important factor explaining the poor results for the Eastern European countries in Figure 1). Most people will agree that these are indications of unfairness. However, socioeconomic differences in lifestyles are another important cause of the health differences, for example, smoking has a huge effect on health. This empirical finding has led to a sometimes heated debate about the fairness of the resulting inequalities. Should people be held responsible for differences in lifestyles? A positive answer to this question would mean that at least a fraction of the observed socioeconomic inequalities is not unfair.

The debate on the causes of socioeconomic inequalities in health has recently been considerably enriched and deepened by the rapidly growing empirical literature on the effects of childhood circumstances. Childhood circumstances do not only have a direct effect on adult health but also influence adult socioeconomic status and adult lifestyles. Different channels of influence have been documented. First, there is a direct effect of the prenatal (fetal) environment on adult health and lifestyle. As an example, it has been shown that the cohort of children born from mothers who were pregnant during the influenza pandemic of 1918 had a larger chance of being physically disabled in 1970. Second, illness and socioeconomic status in childhood may have lasting effects on adult health and lifestyle. This may be true even if adult income has hardly any effect on adult health. Third, childhood circumstances may affect the socioeconomic status (including the level of human capital) of young adults and this then may influence adult health and lifestyle. The three channels can work together, but opinions differ about their relative importance. Such different beliefs may lead to different ideas about the (degree of) unfairness of the observed socioeconomic health inequalities if the latter are caused by differences in lifestyles. This issue will be discussed in the next Section Unfairness and the Causes of Inequality: A General Framework.

Other 'Unfair' Inequalities

The literature on socioeconomic inequalities in health can also be seen as too narrow from another perspective. Even when disregarding age–gender differences (a position that, as argued, is not beyond criticism), socioeconomic inequalities are not the only cause of unfair health inequalities. Another (obvious) example is provided by regional inequalities. Regional inequalities in health may be linked to differences in economic infrastructure and amenities and the quality of the overall living environment. They may also be caused by differences in the relative performance of the health care system – a natural indicator of unfairness in an National Health Service context where a central government decides about the regional distribution of the available funds. In the US, the debate on health disparities has mainly focused on the effect of race, which can certainly be seen prima facie as a case of unfair health inequalities.

A priori, one might think that it is possible to distinguish explicitly these different examples of unfair inequalities and to analyze each of them separately. Although such a separated approach indeed may generate useful insights, it begs the question of how these different 'unfair inequalities' should be aggregated in order to obtain an overall measure of unfair health inequality in a given country at a given point in time. Moreover, there may be important interactions between the

various 'unfair' inequalities. Focusing only on race in the US context means that one will tend to neglect the important fact that socioeconomic status mediates (at least partly) the relationship between race and health. However, focusing on socioeconomic status only may lead one to forget the fact that there may be (unfair) health differences between people from different races but with the same socioeconomic status. The choice of perspective may reflect a philosophically different view of the world and may have political consequences. Indeed, focusing either on race or on socioeconomic status alone will inspire different policy measures.

Unfairness and the Causes of Inequality: A General Framework

The different questions and remarks raised in the previous sections converge on the same basic idea: there are many different factors leading to health inequalities. Some of these explanatory factors point to unfairness (e.g., socioeconomic status, race, and access to health care); others may reflect individual responsibility (e.g., lifestyles). Inequalities resulting from the former may be seen as ethically illegitimate, inequalities resulting from the latter may not offer a reason for concern. If this general and abstract picture of the world is accepted, a coherent framework is needed that makes it possible to integrate these different aspects.

Suppose, for simplicity, that the health situation of an individual is determined by two variables only: income and lifestyle. Suppose also that the position is taken that health differences due to income are unfair, whereas due to lifestyle are legitimate. Two caveats are in order here. The method is not limited to two variables (it can be applied to any number of explanatory factors) and the method does not presuppose that individuals are responsible for lifestyle (it can be applied for any partitioning of the set of explanatory variables in 'legitimate' and 'illegitimate' factors). This simplistic example is considered only to illustrate a more general method.

A first approach is to calculate for each individual the health status a person would reach with his/her own income but with a reference value for lifestyle. Because this reference lifestyle is kept the same for all individuals, the inequality in the resulting hypothetical values will only reflect income differences and is, therefore, a measure of unfair health inequality. Call this measure direct unfairness. A second approach calculates for each individual the health status a person would obtain with his/her own lifestyle but with a reference value for income. This can be interpreted as the health situation a person would reach in a 'fair' situation, because the (unfair) effect of income differences is removed. The difference (or the ratio) between an individual's actual health status and this hypothetical fair health status can be seen as an individual fairness gap – and the inequality in these fairness gaps is a measure of overall unfair health inequality. Note the very close analogy between direct unfairness and the fairness gap on the one hand and direct and indirect standardization on the other hand.

In general, the two measures (direct unfairness and the fairness gap) do not coincide. How then to choose between them? It seems natural to impose that an adequate measure of unfair inequality should only be zero if there are no illegitimate inequalities left, i.e., if two individuals with the same lifestyle reach the same health outcome. It can be shown that the fairness gap satisfies this so-called compensation requirement, whereas direct unfairness does not. In this sense, the former is to be preferred. There is a price to be paid, however: the compensation requirement implies that if lifestyle affects health differently in different socioeconomic groups, the resulting health differences are interpreted as unfair. If one prefers a stricter position on responsibility and considers all lifestyle effects as fair, one should rather focus on the measure of direct unfairness.

As emphasized before, the methods sketched are general and can be applied to any partitioning of the set of explanatory variables into 'legitimate' and 'illegitimate' causes of health inequalities. Age–gender standardization boils down to considering 'age' and 'gender' as legitimate sources of differences. Focusing on socioeconomic or racial or regional inequality means that one interprets socioeconomic status or race or region as an illegitimate source of inequality, and (implicitly) all other sources as legitimate. Combinations are also possible, of course. Even pure health inequality can be accommodated in this broader framework: it is the extreme case in which all the causes of inequality are seen as unfair. One of the advantages of the general method described here is that it allows for sensitivity analysis, i.e., measures of unfairness can be calculated and compared for different possible partitionings.

Ultimately, the choice between different interpretations of unfairness should be made on philosophical or ethical grounds. Broadly speaking, it is possible to distinguish two approaches in the philosophical and welfare economic literature on the topic. The first defines responsibility as control. In this view, individuals should be held responsible only for those variables that they in one way or other choose themselves. At first sight, this seems a natural approach and it has also become the most popular. Yet, it raises the difficult question of what is really under the control of individuals in a social science perspective with a deterministic view of the world. If the findings on genetic and prenatal influences and on childhood circumstances are taken seriously, there does not seem to be much room left for genuine choice. A second approach holds people responsible for their preferences, i.e., for their own life project, even if this life project is not fully under their control and is (unavoidably) influenced by their education and social environment. This latter approach looks less like a kind of 'disciplining' device and can also be formulated in emancipatory terms as a way to respect the dignity of all individuals by giving them the freedom to choose their own lifestyle.

From a pragmatic point of view, one has to come down from these broad philosophical perspectives to classify the specific empirical variables. This is not a trivial exercise, and different observers will have different opinions. Is level of education a matter of choice? Does smoking behavior under the influence of social pressure and advertising reveal genuine preferences about a life project? One cannot give a convincing answer to these questions – and therefore one cannot construct an adequate measure of unfair health inequality – if one does not first have a good insight into the different channels

through which these specific variables affect health outcomes. Indeed, there is no a priori reason to treat the various channels similarly in terms of fairness. Consider socioeconomic status. Its influence on health may reflect a direct effect of genetic endowment, the prenatal environment, and/or childhood circumstances; it may capture differences in lifestyles because of different capacities of information processing as a result of differences in human capital that for their part may follow from differences in childhood circumstances or from educational choices much later in life; it may reflect differences in health behavior that reflect different ideas about what is important in life; it may follow from differences in working conditions, themselves partly chosen but from a restricted opportunity set. To measure adequately unfair health inequality, a good explanatory framework is first needed that distinguishes between these different channels as well as possible.

A good explanatory framework is not only necessary to measure unfair inequality but also it is essential from a policy point of view: Health and health inequalities are not only influenced by health care arrangements. Quite the contrary, certainly if the interest is in the health of the most vulnerable social groups, labor market status, working conditions, housing, and education are at least as important. This raises immediately the deeper question about how to fit unfair health inequality into the broader picture of overall unfairness.

Health and Well-Being

Consider a policy that lowers income support for the most vulnerable groups in society but makes a huge investment in their access to health care. The result is a marginal decrease in unfair health inequality, but a considerable increase in income inequality. Should it be considered as a move toward a fairer society? Or what about a policy that improves the labor market opportunities for the unskilled, leading to a sharp improvement of their material well-being but at the same time to a slight increase in health inequality because of the increase in stress? In both cases, information about unfair health inequality is insufficient to evaluate the overall unfairness of these policies: Well-being has more than one dimension, and all relevant dimensions have to be taken into account if a global judgment is to be formulated.

This conclusion seems so obvious that one may wonder why the bulk of research and policy attention goes to the partial issue of socioeconomic health inequality. The answer to this puzzle seems to lie in the kind of results that are described in the Section Socioeconomic Health Inequalities: because overwhelming evidence for socioeconomic inequalities in health is found to be at the expense of the poorer groups in society, there is a cumulative effect and the trade-offs sketched in the previous paragraph may seem to be of second-order importance. Yet, this kind of contingent reasoning is not sufficient to defend a normative position in principle. As a matter of fact, tricky issues arise when one considers only these partial inequality measures. The concentration index will always decrease (suggesting a less unfair situation) if health is transferred from someone who is better off in terms of socioeconomic status to someone who is worse off, independently of their own initial health situation. Moreover, it can be shown that more egalitarian countries will do worse on the most popular measures of socioeconomic health inequalities (including the extreme group measures and the concentration index), if there is a causal link from health to income. This is a mechanical effect of the way in which these measures are constructed and it explains partly why, for example, the Scandinavian countries do not do very well in **Figure 1** (and in similar empirical exercises). All this strengthens the conclusion that it is necessary to go beyond such conditional inequality measures and move to overall inequality in well-being – taking into account, of course, that health is an essential element of well-being.

Multidimensional approaches to well-being have grown in popularity recently, as reflected in the success of Sen's capability approach. Techniques for multidimensional inequality measurement have now been firmly established. However, neither of these two approaches offers an attractive solution to the aggregation problem, i.e., the problem of weighting the importance of the various dimensions so as to obtain one overall measure of individual well-being. The capability approach leaves this question largely open, whereas multidimensional inequality measures implicitly 'solve' the problem by imposing a functional form in a rather ad hoc way. Yet, in a democratic society, it seems natural to require that the weighting of the different dimensions should reflect the preferences of the individuals themselves. Well-being does not necessarily coincide with subjective happiness either: it would be strange to claim that a healthy millionaire who feels depressed because he is not successful in having his poems published is worse off than a sick and poor woman who is reasonably satisfied with her life because she has learnt to adapt to her fate by lowering her aspirations. The real challenge consists in formulating a concept of individual well-being that does respect preferences, although at the same time correcting for aspirations. Recent developments have shown that the traditional welfare economics concepts of money-metric utility and equivalent income offer interesting perspectives in this respect.

Utilities for Health States: Whom to Ask

PT Menzel, Pacific Lutheran University, Tacoma, WA, USA

Overview: Two Main Approaches

For use in cost-utility or cost-effectiveness analysis (CUA or CEA), evaluations of health outcomes in terms of quality-adjusted life-years (QALYs) require judgments of the quality of life in different health states. The quality of life of a state is often referred to as its 'individual utility.' There are two main sources for estimating a state's utility. One is people who have experienced it themselves. For example, people with paraplegia can evaluate the state of being paraplegic. Utility thus measured is called 'experience utility.' 'Ex post utility' and 'patient value' are other names for the same. But a score for quality of life in paraplegia can also be obtained by having members of the general public, who mostly have not experienced paraplegia, consider a description of its manifestations and consequences, and imagine what it would be like for them to be paraplegic. Utility assessed in this way is referred to by a variety of labels: 'ex ante utility,' 'hypothetical utility,' 'public value,' 'hypothetical patient value,' or 'nonpatient value.' A further term is 'decision utility,' which can include both ex ante and ex post utilities (see section 'Decision Utility versus Hedonic Experience').

Standard practice in QALY calculations is to use hypothetical (ex ante) utilities, on the grounds that they are more representative of the values and interests of the population at large than values from patient subgroups. But the practice has been challenged by many, and the issue is of more than mere theoretical interest. It takes on practical importance because of the empirical fact that health state utility ratings are typically higher when elicited from patients, particularly those with chronic illness or disability, than from nonpatients who only hypothetically imagine themselves in such conditions. Debate is further fueled by the fact that a major factor accounting for the discrepancy between patients' and nonpatients' values is patient adaptation to diminished health. Expressing time trade-off (TTO) preferences, for example, people with paraplegia, having experienced and adapted to it, may rate their quality of life as 0.95 (they are willing to trade away only 5% of their time alive to regain full function), whereas members of the general public imagining themselves being paraplegic may evaluate the condition as 0.8 (willing to reduce longevity by 20%). If these are the ratings for paraplegia, using patients' adapted values will reduce the value of preventing or curing paraplegia to a quarter of the value it would have if the general public's values were used ($1.0 - 0.95 = \frac{1}{4}(1.0 - 0.8)$).

Ultimately, the questions here are normative. Whose ratings of health-related quality of life should be used? Is it fair to those who do not yet have paraplegia to assess the cost-effectiveness of efforts to prevent this condition by using the higher utility values registered by someone else – patients who have adapted? Such normative discussion will be pursued explicitly in the later section Normative Considerations in Choosing an Approach of this article. The next three sections focus on descriptive and conceptual issues in experience utility.

The Facts of Variation

The so-called 'standard story' of health state valuation data is that patients, particularly people with chronic illness and disability, rate their quality of life more highly than do hypothetical patients who only imagining themselves with those conditions. For instance, of 39 studies reviewed by de Wit *et al.* (2000), 23 reported patient values higher than public ones, 2 reported higher public values, and 11 found no difference. Arnold *et al.* (2009) in a review of 32 studies, found the mean TTO value for all of the disease states evaluated by current patients to be 0.83, compared to a mean value by hypothetical patients of 0.65. Moreover, the difference in ratings does not seem due to cognitive flaws; a mood assessment study by Riis *et al.* (2005) of hemodialysis patients not only produced higher patient values but also found that patients were less flawed in their prior expectations and later recollections than were nonpatients.

Generalization, however, is dangerous. Damschroder *et al.* (2005) not only found some of the most extreme differences in valuing life with new onset of paraplegia, compared to life with preexisting paraplegia, but also found that when the nonpatients engaged in a simple exercise virtually all of the difference with patient values disappeared. In the exercise, they were merely informed about adaptation and encouraged to consider their own ability to adapt.

For some conditions, patient ratings may actually be lower than nonpatient ratings. Traumatic brain injury (TBI) is an outstanding case. The effects of TBI often involve depression, and adaptation to depression is extremely difficult. Moreover, as shown by Wallace and Bogner (2000), nonpatients may have a very incomplete picture of how low one can sink in depression, and many of the symptoms of TBI – anxiety, hostility, distress, etc. – may worsen, not improve, with time and increased awareness.

Another complicating factor, explored in only a few studies, is that former recovered patients sometimes provide lower ratings of quality of life in a given condition than current patients. In a study by Smith *et al.* (2006) of quality of life with colostomy, for example, not only did public representatives provide lower ratings than patients, but those who had their colostomies successfully reversed also provided lower ratings. The finding is notable. Former patients, presumably, are at least as knowledgeable, if not more, about the comparative quality of normal life and life with colostomy. Current patients may not be good judges, repressing or misremembering how good their previous life without the impairment was.

Still, generally, patient values are higher than public ones.

Reasons for Variation: Knowledge and Adaptation

The difference is due to a number of factors. An obvious one is simply that patients directly know life in a particular health state; nonpatients do not. Insofar as nonpatients fear the

condition because it is different – presumably worse than pre-illness, 'normal' life, and in any case relatively unknown – they rate their prospective quality of life low. Even if actual and hypothetical patients were equally knowledgeable about all the facts about a condition, however, and hypothetical patients were no more fearful, their ratings would still likely differ because patients adapt to their condition. Adaptation has thus attracted considerable attention in accounting for higher health state utility ratings by patients.

It is a very broad phenomenon, undoubtedly comprised of many different elements. Although there is no complete agreement on the elements of adaptation, Menzel *et al.* (2002) described eight components:

1. Skill enhancement: People develop skills they previously did not have or had not developed as much. A person with paraplegia, for example, becomes very accomplished in maneuvering a wheelchair.
2. Adjusted choice of activities: Given limitations that make previous activities difficult, one develops new interests. A person with congestive heart failure, for example, gives up the gardening that was her previously quite physically demanding hobby and devotes time to watercolor painting.
3. Revision of substantive goals: Not just particular activities but fundamental goals in life are revised. Instead of ambitious career success, for example, a person may shift his/her most life-defining goals to esthetic appreciation and personal relationships.
4. Heightened stoicism: A person becomes more patient, taking events in life as less within his/her control.
5. Lowered expectations: Without significantly changing activities or fundamental life goals, and in addition to becoming more patient, one does not expect to operate or perform at the same level.
6. Altered conception of health: A person who previously thought of paraplegia as diminished health now looks on it as a limitation not essentially different than previous and continuing limitations (e.g., not being able to run the high hurdles); he/she retains a vigorous conception of health, but one that now does not include some previous physical capacities.
7. Suppressed recognition of full health: One loses sight of how someone can be as healthy as one was before.
8. Cognitive denial of a lowered health state: One refuses to acknowledge that one's health has diminished, not because one has adopted a revised conception of health but by ignoring the pain or limitation. A variant of cognitive denial is focusing illusions: People focus more readily on new things they can do than on the things that they can no longer do.

Several of these elements – lowered expectations, heightened stoicism, revision of substantive goals, and altered conception of health – were included but categorized differently by Schwartz and Sprangers (1999) in a well-known comprehensive framework for analyzing adaptation known as 'response shift.' In the response shift typical of adaptation, persons living for a considerable length of time in an altered state of health make three changes: in their internal standards of measurement ('recalibration'), in their values ('reprioritization'), and in their definitions of essential constructs such as health ('reconceptualization').

Different contexts for adaptation may lead to wide variations in the proportionate influence of these different elements. There is, in any case, little agreement on their relative influence. Discerning the different elements of adaptation and their relative roles may be important to any normative assessment of the proper place of adapted patients' values in CUA and CEA. If adaptation is dominantly constituted, for example, by skill enhancement, adjusted choice of activities, and revision of substantive goals, it will tend to be accorded greater respect. In contrast, suppression and cognitive denial diminish respect for adaptation. In a later section of this entry, Normative Considerations in Choosing an Approach, the normative issues about adaptation will be pursued.

Conceptual Issues in Choosing an Approach

Numerous issues arise in choosing between public and patient values. The two involve distinctions between different concepts and types of value. Articulating these distinctions clearly lays an important background for more explicitly normative aspects of the discussion.

Individual Utility and Social Value

In approaching the choice of whose values to use in CEA, it is important to understand the role that individual utility plays more generally in the framework for health state evaluation in health economics. If individual utility's role is not dominant but more limited, the question of whose values to employ can be pursued with an awareness that other dimensions of the value of health may be available to resolve certain quandaries.

Individual utilities of any sort, including health state utilities, contrast with social values for priority setting (also referred to as 'societal values'). The former concerns individual well being, whereas the latter relationship between persons or the well being of communities, including considerations of fairness. The difference between individual utility and social value lies not in who expresses or holds the values but in the individual versus interpersonal nature of object to which value is attributed. Both individual utility ratings and social values get expressed by individuals.

Within the influential 'welfarist' utilitarian tradition in health economics, people can easily lose sight of the difference between individual utility and social value. In the welfarist view, only individual utilities are needed to build judgments about social value; the highest social value just is maximum aggregate individual utility. In the case of health care procedures and programs specifically, not only CUA but also conventional CEA are conducted by measuring and aggregating the individual health state utility gains and losses ingredient in the outcomes. In this view, procedures and programs producing the greatest aggregate net health state utility have, *ipso facto*, the greatest social value.

The point here is not to defend or reject such a welfarist utilitarian position in normative economics or social philosophy. The point is to be aware that other options are available once the distinction between individual utility and social value, as categories of value, is recognized. Social values

do not have to follow welfarist utilitarianism. The paraplegia example is again illustrative. Person trade-off (PTO) questions can reveal equal social value in saving the lives of persons with and persons without paraplegia, even when both rate the individual utility of life with paraplegia as less than 1.0. It would appear, then, that a sophisticated model for discerning the value of health will need to account for the distinction between social value and individual utility. PTO questions can be used to elicit social values, but using them does not rule out the use of visual analog scale (VAS), TTO, or standard gamble (SG) questions to elicit ratings of health state utility.

Answers to the question of whose values to use may thus be different for individual utility and social value ratings. One view on the proper overall structure for health valuation, proposed by Nord *et al.* (1999) divides its answer this way: (1) Patients should be asked questions to obtain quality of life ratings, (2) public representatives should be informed thoroughly of those patient ratings, and then (3) public representatives should be asked PTO questions to obtain social values. Such an architecture for eliciting values illustrates the possibility that the question of whose values needs answers on two different levels: whose judgments to use in discerning health state utility and in discerning social value.

Decision Utility versus Hedonic Experience

Heretofore, the authors have been dealing with 'experience utility' as the quality of life in a state rated by people who have experienced that state themselves. A different, second sense of the term used in economics needs to be acknowledged. Experience utility in this other sense refers to the direct, intrinsic hedonic experience of an outcome. The opposite of experience utility in this sense is not utility estimated by people who have not directly experienced the condition being evaluated, but what economists and psychologists call 'decision utility' – utility measured by people's choices about an outcome. Those choices can be manifested in either actual behavior or expressed preference. For health states, decision utility is measured by TTO or SG preferences about that state, whereas experience utility is measured by direct estimates people make about their hedonic level in a given state. Over the centuries, such direct hedonic experience utility has often been referred to as satisfaction/dissatisfaction, pain/pleasure, and happiness/unhappiness.

If direct hedonic experience judgments are used to rate health states, they will presumably be made by patients in those states. Decision utility ratings, though, can be obtained by asking either actual patients or people imagining themselves as patients. Understandably, then, empirical studies of the difference between patient and nonpatient valuations usually focus on decision utility discerned through TTO or SG. Rarely have the direct hedonic experience utility levels of patients and healthy nonpatients been compared.

With direct hedonic experience ratings of health states thus being made by patients in those states, whereas decision utility ratings can be made by either actual or hypothetical patients, the argument between direct hedonic experience utility and decision utility has implications for the debate about whose values should be used in CEA. If direct hedonic experience utility wins and decision utility loses out, patient values need to be used. However, if decision utility wins, whose values to use remains an open question.

For which of these kinds of utility, decision utility or direct hedonic experience, can the stronger case be made? Decision utility suffers from three significant disadvantages: (1) Because it takes choices as basic in discerning and measuring utility, no independently discerned utility is available with which those choices can be assessed. By contrast, "if we equate welfare with [direct hedonic] experience utility…, it should…be possible to assess whether people's choices actually maximize their own (experience) utility." Such assessment is often seen as necessary because, as noted by Loewenstein and Ubel (2008), "behavioral economists have identified myriad ways in which people take actions…patently contrary to their own interests". (2) Beyond deficiencies in serving people's own interests, moreover, there is abundant evidence that choices and preferences routinely manifest various kinds of inconsistency and irrationality. This poses a challenge: Is it morally defensible to be guided in policy decisions by utilities discerned by preferences that are so frequently flawed? (3) In a number of studies where the SG and/or the TTO have been used to get self ratings from patients, a large share of the subjects have been unwilling to sacrifice any life expectancy in order to become well – even when symptoms and dysfunctions have been quite severe. As noted by Nord *et al.* (2009), this is not necessarily because the health problems are without consequences for well being, but because life itself is so highly valued that it takes quite large health gains to justify any sacrifice of length of life. The 'nontrading' subjects automatically receive utility scores of 1.0, which does not seem helpful in evaluations of programs that clearly have value in terms of improving health and health-related quality of life. To obtain usable (policy relevant) values for health states from patients, one may therefore have to have recourse to measures of happiness, etc., rather than decision utility tools like the SG and the TTO.

But the attempt to discern utility independent of choice and preference may not inspire any greater confidence. To be sure, processes are available through which people can rank their state of well being directly, rather than through expressing some preference like TTO or SG, for example, the 'experience sampling method' (ESM) proposed by Stone *et al.* (1999) and the 'day reconstruction method' (DRM) described by Kahneman *et al.* (2004). In ESM, electronic devices are used to ask people at random times during the day how they rate themselves on certain feelings at the time (happiness, frustration, etc.). In DRM, people are asked to divide the previous day into episodes and rate them for affective elements on a specific scale. However, as noted by Dolan and Kahneman (2008), these methods have their own problems: underestimating losses, misremembering, failing to attend accurately to a given moment because of distraction by other episodes during a day, etc. It is not clear that measurement of direct experience utility is any more accurate and reliable than measurement of decision utility through preference elicitation.

Moreover, playing a role in the larger argument is not just the fact that direct hedonic experience utility has its own difficulties as serious as those of decision utility. Decision utility has its own distinctly positive attractions.

First, Decision utility/preference questions are comparatively clear. Direct hedonic utility, well being, happiness, and satisfaction, arguably, have a befuddling breadth, abstractness, and ambiguity. Asked to rate one's life/day/moment directly in terms of them, a person may wonder exactly what they are. "Am I really happy?" "In relation to what desires am I satisfied?" "What is my well being? – there are a lot of candidates!" Almost any preference question for decision utility is clearer. "How much of your lifetime would you be willing to sacrifice to get a cure for your condition?" may be difficult to answer, but its meaning seems clear. Contrast such TTO or SG questions with the ambiguity of a technique like the VAS that asks for a direct ranking of health, analogous to direct hedonic experience utility more generally. "On this bar that extends from 0 (dead) up to 1.0 (full health), rate your health." How is a person supposed to know what a proportion or an amount of health is? Even if the question is more explicitly focused on value, not health *per se* (as in "On this bar from 0 to 1.0, rate your health-related quality of life"), ambiguity persists: what would living with, say, half the quality of life that living in full health contains mean (e.g., as distinct from two-thirds)? By comparison the meaning of any particular amount of decision utility in health-related quality of life seems clear: one will trade-off a certain portion of remaining life but not more to gain a cure, or one is willing to take a certain risk of death but not more.

Second, within the enterprise of CEA in health care, determining quality of life by eliciting preferences has another major advantage. The core function within CEA of a construct like the QALY is to serve as a common unit of value that incorporates both life extension and quality-of-life enhancement. Otherwise one is comparing apples and oranges and would not know what total value an array of diverse lifesaving and quality enhancing outcomes had. TTO and SG questions are appropriate precisely because they transparently involve a relationship between quality enhancement and longevity. The mystery about how the values of life extension and quality enhancement compare is removed by the very nature of the question(s) used to measure health state utility. Measurement methods for direct experience utility – VAS, DRM, and ESM – leave the relationship murky.

If decision utility has thus not lost in its argument with direct hedonic experience utility, the question in health economics of whose values should be used in CEA remains open and vital.

Normative Considerations in Choosing an Approach

As a normative question, whose values for health states to use in CEA may seem naturally weighted toward patient preferences. Patients presumably know more about living in a given health state. Because the ultimate nature of utility is subjective well being, they would seem to hold a privileged position in health state valuation even if they are no better informed of objective facts about their condition. As shall be seen, however, this initial intuitive case for using patient values faces a number of difficulties. One can begin with what is arguably the standard defense of the relatively common practice of using public, not patient values.

The Standard Defense of Hypothetical Patient Utilities

The standard defense has two main points: the societal role of CEA, particularly its role in a democratic society, and practical feasibility.

In CEA, the health state utilities at stake in a medical practice/policy decision are aggregated to generate a picture of the overall value of expected health changes. The perspective of CEA as an enterprise, then, is necessarily societal, not merely individual. CEA is 'for' society (or some subgroup, such as a private or regional insurance plan). Arguably, then, the perspective on the value of health changes needs to be as encompassing as possible: everyone in the society (or the insurance pool). When CEA is located in a democratic society, this line of thought is reinforced further by a higher level societal value that everyone's perspective should be represented in any process like CEA whose wide scope affects potentially everyone. The best way of ensuring that every person potentially affected by a CEA is represented is to elicit health state values from the public, few of whom will be actual patients with the conditions they are evaluating.

Supplementing this argument for public values is a further consideration about fairness. In its 1996 report, after recommending that CEA employ a 'societal perspective' for reasons similar to those just elaborated, the 1996 US Public Health Service panel on cost-effectiveness in health and medicine (Gold *et al.*, 1996) proceeded to discuss fairness. Fair decisions are best made as choices behind a veil of ignorance, where decision-making parties do not know whether they are advantaged or disadvantaged by the matter at hand. For CEA, then, they claimed that "aggregating the utilities of persons who have no vested interest in particular health states seems most appropriate." If we have already agreed that whatever values are used, they should come from perspectives that are informed, rational and unbiased, a challenge is presented for patient values: patients are likely to be biased by having a vested interest in treating the disease they know they have. One skirts this bias by asking people who express themselves only as hypothetical patients.

Practical considerations also play a role in the standard defense of hypothetical patient utilities. If utility ratings are elicited from hypothetical patients, convenience and efficiency is gained by eliciting ratings for many health states from the same people at the same time. This advantage is difficult to dispute factually. Any procedure for eliciting utilities directly from patients will undoubtedly be more cumbersome and expensive, especially if CEA is used to compare measures and programs across a comprehensive range of health states. The case for using patient values will have to be strong enough to justify additional expense.

Adaptation

Adaptation raises the utility ratings patients express about reduced health-related quality of life. In doing so, it lowers the value achieved from restorative, quality of life improving treatments. In this respect adaptation reduces ill persons' leverage in the competition for health care resources. That alone will make a positive role for adaptation controversial. Critical normative argument about adaptation, however, cuts different ways in the debate between patient and public values.

Epistemic Privilege

A strong first line of argument for using adapted patients' values amplifies the initial, intuitive case for patient values in the first place: because patients presumably know more about living in a given health state and the ultimate nature of utility is subjective well being, they hold a privileged epistemic position for discerning health state utility. To see how attractive this claim can be, suppose, for the moment, that we have adopted the opposite practice and are eliciting health state valuations not from patients but from representatives of the general public. People already agree that the states that public representatives are asked to evaluate need to be described in neutral, factually accurate, and sufficiently complete terms. As part of that, they need to understand what life in fact is really like in the condition they are evaluating. How actual patients typically adapt to a condition is part of that understanding. It is an objectively real aspect of the lives that patients in diminished health states actually lead.

Suppose, in turn, that a hypothetical patient challenges this need to absorb the facts of adaptation and insists that he/she in particular would never evaluate life with paraplegia, for example, at so high an adapted level. The insistence would be suspect. To be sure, a given individual could conceivably be correct in claiming he/she would not adapt (or adapt much), but given the empirical evidence, we ought to be skeptical about what will happen to even such insistent persons when they actually become paraplegic. Very likely most of them, too, would end up adapting considerably. But then, when hypothetical patients refuse to accept these prospective facts, they should be regarded as factually mistaken – they do not understand the state they are evaluating. Thus, we ought to enrich the description of a condition provided to hypothetical patients with information about actual patients' adapted values, and we should insist that hypothetical patients truly absorb those facts. But then why not simply use actual patients' health state values?

Such an argument for the epistemic privilege of actual patients is attractive, but it has not been universally accepted. Brock (1995) argues that because the difference in health-related quality of life ratings stems significantly from an adjustment of substantive goals by adapted patients, they have become 'changed persons'. He concludes that the hypothetical patient's earlier evaluation is not 'mistaken.' If we look back now as chronically ill or disabled, we 'view ourselves as having become very different persons,' not as 'having been mistaken in our earlier aims and values.'

Brock's (1995) move may or may not be a plausible gloss on the meaning of 'mistaken' in relation to 'changed person.' In any case, it is debatable whether it provides a defense for hypothetical patients if they have not absorbed the essential facts about actual adaptation. How can they defend the practice of continuing to evaluate the condition at their own nonadapted level, it will be asked. In most of their prospective years in the chronic condition in question, should they ever experience it, after all, they will likely espouse adapted values. Why should they now be trying to imagine themselves as persons who do not adapt to the condition, people they almost certainly will not be? We find ourselves pushed back to the view that the patient, adapted or not, is in a privileged position in the very enterprise that asking hypothetical patients involves, imagining what it would be like to be someone with the condition.

These considerations establish the initial case for using the values of patients with actual experience of a condition regardless of how much their ratings may be elevated by adaptation. That does not, though, end the moral debate. As noted by Menzel *et al.* (2002), other arguments can be made against the use of adapted values. Among them is the problem of entrenched deprivation.

Entrenched Deprivation

Amartya Sen has focused on this reason to discount adaptation in a well-known critique of utilitarian reasoning generally from 1992. At its very basis, he says, utilitarian ethics is guilty of excessively depending "on what people 'manage to desire' … [that neglects] the claims of those who are too subdued or broken to have the courage to desire much…. A thoroughly deprived person, leading a very reduced life, might not appear to be badly off in terms of the mental metric of desire and its fulfillment, if the hardship is accepted…. In situations of long-standing deprivation, the victims do not go on grieving and lamenting all the time…. The extent of a person's deprivation, then, may not at all show up in the metric of desire fulfillment…." Sen concludes that measuring well being by the fulfillment of people's actual desires is ethically wrongheaded.

Utilitarianism, as a general moral philosophy, must respond to Sen's critique. The issue in the context of whose preferences to use in health state evaluation for CEA, however, is narrower: does the deprivation factor that renders a general utilitarian metric of desire fulfillment ethically questionable also render the ratings of health-related quality of life procured from adapted patients morally dubious? Adaptation in contexts of chronic illness and disability often involves achievement and shrewd and successful control over the trajectory of one's inner life. Here, the adapted person is anything but broken. He/she is hardly subdued. If deprivation is handled by people as challenge and achievement, why is not a metric of actual desire fulfillment appropriate? Sen's argument may serve as an appropriate warning about too readily or generally using adapted patients' utilities, but it is highly problematic as a full rejection.

Social Values and Adaptation

Although the argument from entrenched deprivation against using adaptation influenced values may thus be neutralized, other arguments may be more successful. Suppose that after comprehensive assessment we end up thinking that the basic dilemma posed by adaptation remains unresolved. Here, the distinction between individual utilities and social values detailed previously may provide constructive help. This would be the line of reasoning:

The health state utilities of real life with chronic illness and disability are those expressed by patients. Those are the real utilities of health states, and we should use them in CUA. But people also make moral arguments against the use of

adaptation-influenced values – values that are higher than public values and which therefore reduce the value of the health gained by patients from curative/restorative services. They believe, for reasons of justice or whatever, that those services should be accorded higher value than their real utility value for the disabled and chronically ill alone would indicate. In such beliefs, they are expressing social values. At the level of individual utility itself, there is no 'problem of adaptation' at all; the real utility of moving from illness/disability back to full health is just the utility indicated by patient values. The 'problem of adaptation' occurs only when social value intersects with this utility. Maximizing health state utility is hardly the only philosophical choice for social value, and any influence of adaptation on decision making can be altered at the level of social value. Hypothetical patients need to know that real, adapted patients' health state utility values are higher than their own, and they must absorb those facts in imagining prospective illness. Both hypothetical and actual patients, however, may hold social values that blunt adaptation's effect on social decision making.

The Equal Value of Life

The picture portrayed by the discussion so far is incomplete. We have been wrestling, in part, with the fact that as adaptation increases the value of deficient health states, it decreases the utility gain from restorative, quality of life improving measures. That, however, is only half the effect of adaptation in CEA. In increasing health state utility, adaptation also increases the utility gain from life extension. Insofar as these opposite effects on the utility gain in life-extending versus restorative interventions balance each other out, adaptation may leave the total utility gain claimed for health care relatively unaffected. The matter of whose preferences to use would then be of little consequence.

It would not be correct, however, to conclude that counterbalancing effects rendered the debate about adaptation unimportant. The aggregate effects in the two types of programs – restorative and life extending – may not in fact balance each other out, and specific programs being evaluated will often be largely life extending, others largely quality of life restoring. Most importantly, perhaps, adaptation augments a problem for CEA created by any claim of equal value for different lifesavings. Such equal value for saving the life of a person back to full health and saving the life of a person who will continue in chronic illness or disability was cited as a serious problem for traditional CEA by John Harris already in 1987 and later by Nord (1999). It gives rise to what Ubel *et al.* (2000) called the 'QALY trap.' If the value of life extension for the disabled and chronically ill is equal to the value of life extension for the fully healthy, then the value of curing a chronic illness or disability (restoring such patients to full health) is apparently zero. This implication follows given the very structure of CEA, using as it does a common metric like the QALY to put life extension and quality enhancement on the same value scale. However, if restoration and cure retain value, then the respective life extensions cannot be of equal value. Yet, they do seem to be of equal value. Meanwhile, the first option – no value for cures – also seems contradicted empirically. Virtually everyone, including the disabled and chronically ill, accord considerable value to restorative measures. The traditional QALY model for CEA is then trapped between two propositions – that the different life extensions are of equal value, and that restorative cures have positive value – which the model says cannot both be true.

To save CEA against this challenge, one might take one of two approaches: (1) Use the distinction between social value and individual utility to rescue CEA from the QALY trap. Call this the 'value/utility distinction' approach. Or (2) give up the claim that life extensions for the disabled/chronically ill and the nondisabled/fully healthy have completely equal value but maintain that they have 'almost equal value.' Both approaches affect how we view the issue of whose preferences to use in CEA.

In one particular version of the value/utility distinction approach, Nord *et al.* (1999) suggested that all gained life years should count as one as long as they are deemed preferable to death by those concerned. In this and all other versions of the approach, the claim that the value of life extension for the disabled and chronically ill is equal to the value of life extension for those who can be saved to full health is seen as an expression of a societal value and only societal value. It is not a claim that the individual utilities of the two life extensions are equal. If as a matter of individual utility they are not equal, the claim of positive value for quality restoring measures can be retained. Thus, keeping individual utility and societal value distinct frees CEA from the QALY trap (see Ubel *et al.*, 2000).

A second very different approach backs away from the claim that the two respective life extensions have equal value. If one pays careful attention to the values expressed by patients through, for example, TTO preferences, it is clear that quality of life ratings are not much less than 1.0, but are less than 1.0. In 1993, Dennis Fryback and colleagues reported results on the order of 5–8% for arthritis, severe back pain, migraine, angina, cataracts, ulcers, and other serious conditions and 14–17% for depression, asthma, and chronic bronchitis. This suggests that the tension between 'equal value for lifesaving' and 'cure has value' can be reduced by attending to just how close to a maximum value of 1.0 people with disability or chronic illness rate their quality of life. We can then adjust the claim of 'equal value' to 'almost equal value,' and the claim of 'cure has value' to 'cure has very modest value compared to lifesaving.' Again, we are out of the QALY trap, and now in a way that has not changed the structure of traditional, utility-focused CEA.

In this approach, one still needs to face front and center the question of whose values to use. No easy accommodation of 'use both' (though in respectively different senses of value) is possible, as in the value/utility distinction approach. One must determine whether the higher, adaptation-influenced values of patients that raise the value gained from life-extending measures but lower the value gained from restorative measures ought to be used. The advantage in using the value/utility distinction approach is that one can keep both of the key claims that create the dilemma – equal (social) value for the life extensions, yet significant (individual utility) value for restorative/curative measures (for further discussion, see Nord *et al.*, 2003).

Seeing the claim of equal value for the different life extensions as only a claim of societal value is the key move in the value/utility approach. Arguably, however, the equal value claim may also hold at the level of individual utility. To see this, unpack the reasoning behind claims of value in a QALY framework. In responding to SG or TTO questions, patients are saying that a cure for their paraplegia, for example, has a certain proportion of the value of saving their very own life. In saying that, they have not said that their very life itself has less value than the very life of *another* person in full health. Menzel in 1990 noted that, compared to death they very likely believe that their paraplegic life is as valuable to them as anyone else's allegedly 'better' life is to him or her. This belief comes sharply into focus when people attend to the two comparisons involved: the value of their disabled or chronically ill life relative to death, and its value relative to the same sort of death-comparative value of another's life, even a person in full health. Particularly compelling may be a further step: this very realization of equal individual utility value will likely be shared by healthy and nondisabled persons, too, once they think reflectively about the value of their own very lives compared to death. Who among them would want to claim that the value to them of their life is greater than the value of a paraplegic person's own life to him or her?

The conundrum of the QALY trap thus continues. If lifesavings have equal value even as a judgment about individual utility, we face again the trap's full dilemma: the value of curing paraplegia has become nothing. It is doubtful we would ever accept that. The implication of our resistance is that the QALY trap remains a challenge to the very framework of CEA, an enterprise whose current form requires a common unit of benefit like the QALY in which value for life extension and value for quality improvement are integrated on the same scale. Whether and how the field of CEA will meet this challenge remains unclear.

Evaluating Prevention

Is anything different about 'whose values?' when preventive services, not treatments, are evaluated? Actual patients, arguably, hold legitimate evaluative privilege in rating health state utility. They are the only subjects who experience real life with chronic illness or disability, and hypothetical patients who are imagining themselves to be in such conditions must account for the reality of likely adaptation. The situation is arguably different in prevention. The real recipient of a preventive service's benefit is the unchanged person who, if the prevention is effective, will never need to adapt to the illness or disability in question. It may be suggested, therefore, that while actual patients should be accorded evaluative privilege for purposes of prioritizing curative and restorative services, hypothetical patients retain evaluative privilege for the utility ratings that help determine the value of preventive services.

This suggestion immediately encounters an objection. The person whose health will be damaged if preventive measures are not provided is still a person likely to adapt. The real value of prevention is presumably the difference between people's quality of life before disease and their quality of life with disease or disability – that is, after likely adaptation to the conditions, which have not been prevented. The perceived gains from prevention may be higher than the gains from cure, but the real gains are not.

This is only one interpretation of 'real gains,' however. Most persons receiving a preventive service do not contract the condition the service aims at preventing, a fact that is true regardless of how objectively effective the preventive measure actually is. Recipients of prevention continue to experience its benefits from their perspective as healthy persons. Restorative services, by contrast, are received by persons already experiencing both the burdens of illness and disability and the value raising effects of adaptation. Many lifesaving services also apply to persons already experiencing the ravages of illness. One might argue, therefore, that while the utility value of health gain in the case of treatment services should be determined by patient ratings, the value of the avoidance of illness achieved by prevention should be measured from the perspective of hypothetical patients. Although adaptation lowers the value of restorative services, perhaps it should not be allowed a similar effect on the value of prevention.

Careful analysis of such considerations in comparing how the value of health benefits should be measured for treatment as compared to prevention has received little attention in the literature. An exception is a paper by Nord *et al.* (2009), in which the authors side with using the lower public, nonpatient, ex ante values to measure what then becomes a higher benefit from prevention, while at the same time using the higher health state utility values expressed by patients to calculate what then becomes a lower value to benefit from treatment. They claim there is no inconsistency; with different reference points, the negative value of ill health just is not the same for these two different parties with their different perspectives. Another analysis, by Menzel (2012), of the relative value of prevention also emphasizes reference point differences but leans in the opposite direction, a lower value for prevention.

Summary and Conclusion

Utilities for health states can be measured by values elicited either from people who have experienced those states themselves or by hypothetical patients imagining themselves to have such conditions. Ratings by actual patients are generally higher than ratings by hypothetical patients, rendering the question of whom to ask to measure health state utility for CEA of practical importance.

Factors that help to explain patients' higher ratings include their greater knowledge of the conditions and their adaptation, especially to chronic disease and disability. Adaptation is comprised of numerous different elements, the proportionate influence of which remains unclear.

Two conceptual distinctions affect positions taken on whom to ask. By distinguishing rigorously between individual utility and social value, one proposal argues for asking both patients and the general public but differently: elicit utility ratings from patients, inform public representatives of those ratings, and then elicit social values from the public representatives. Also affecting the debate is a distinction between two different senses of utility, direct hedonic experience and

decision utility expressed through preference or choice. The latter, measured in health utility analysis by choices between preserving life and improving quality of life, has the advantage of yielding a common metric for measuring the value of all changes in health. With decision utility, unlike direct hedonic experience, the debate about whom to ask is kept open; either patient or hypothetical patient values can be sought.

Normatively, the initial intuitive case for patient values sees patients as having epistemic privilege in understanding what real life with disease or disability is actually like. On the opposite side, the standard case for public values cites both the societal perspective that is seemingly natural to CEA – and especially important in a democracy – and practical considerations of convenience and efficiency. The phenomenon of patient adaptation gives rise to numerous and conflicting moral arguments. One attempt to resolve the normative debate would elicit utility ratings from adapted patients but allow societal values elicited from others to discount adaptation's influence on decision making.

The generally higher utility ratings of patients who have adapted to a diminished health state reduce the value gained from curative/restorative services, but those higher ratings have an opposite effect as well: raising the value of life extension for the chronically ill and disabled. Strong arguments are available to defend equal value for different lifesavings – life extension for the disabled/chronically ill and life extension for people returning to full health. Equal value for these lifesavings, while it can be celebrated as a removal of discrimination against the disabled and chronically ill, poses a difficult challenge for the very structure of CEA. A 'QALY trap' emerges: with lifesavings held to be of equal value, restorative care loses its value. It is unclear whether carefully distinguishing between social value and individual utility enables CEA to handle this challenge; if the individual utility, not only social value, of such lifesavings is also equal, the challenge remains unsolved.

Even if the utility values expressed by patients affected by adaptation are the appropriate ones to use for evaluating treatment programs, objections have been made to using them to evaluate preventive programs. Attempts to resolve whether the treatment/prevention difference should affect whose values to use have recently been made; their success is far from clear.

Most of the moral questions about whose values for health utility should be used in CEA are well clarified. Some, perhaps, are even answered, but many are not. Vigorous debate is likely to continue.

Vaccine Economics

S McElligott, University of Pennsylvania, Philadelphia, PA, USA
ER Berndt, Massachusetts Institute of Technology, Cambridge, MA, USA

Introduction

Vaccines have been historically hailed as one of the great global public health success stories. Major infectious diseases with significant morbidity and mortality are largely under control in many parts of the world, or have been completely eradicated, for example, smallpox. The World Health Organization (WHO), the United Nations Children's Fund (UNICEF), and the World Bank estimate that 3 million lives are saved worldwide each year through childhood immunization. In the US, routine immunization has been estimated to prevent 10.5 million cases of infection and 33 000 deaths each year. It has been projected that in the US, diphtheria-tetanus-pertussis (DTP); diphtheria toxoids (Td); *Haemophilus influenzae* type b (Hib); inactivated polio (IPV); measles, mumps, and rubella (MMR); and hepatitis B (HepB) vaccines were responsible for saving US$42.5 billion dollars per year from a societal perspective in 2001.

Despite these successes there have been historic signs of market failure. An estimated 20% of the global birth cohort, 24 million children, remains unvaccinated because they live in poor countries that lack the resources to invest in vaccines and infrastructure. More than 2 million vaccine-preventable deaths still occur annually. Even in highly developed countries, there continue to be outbreaks of diseases due to declining immunization rates. For example, cases of whooping cough or pertussis are rising in the US and the UK because of low DTP immunization rates. The vaccine market also experiences episodic supply shortages in both high-income and low-income countries. For example, in the US, many vaccines have only one or two suppliers, and manufacturing disruptions or regulatory actions can lead to insufficient supply. UNICEF has historically experienced periods of potential supply shortages. Several manufacturers have exited the pediatric vaccine market in both developed and developing countries, and concerns have been raised that vaccines may be undervalued by payers, which may lead to underinvestment in vaccine research and development (R&D).

This article examines vaccines from an economic perspective, highlighting the distinct features of the vaccine market that affect the demand, supply, and market outcomes for vaccines. The article is organized as follows. The first section provides an institutional background on vaccines and the vaccine market. The second section discusses the demand for vaccines. The third section examines supply and market outcomes. The fourth section summarizes key points and provides concluding remarks. The analysis and discussion here focuses on preventative vaccines. The emerging area of therapeutic vaccines, although interesting, is outside the scope of this discussion.

Background

The vaccine market can be roughly broken down by consumer age: pediatric, adolescent, adult, and elderly. Pediatric vaccines have historically represented the largest segment. However, new vaccines are spurring growth in both adult and adolescent markets. Globally the recommended vaccines vary by country and are set based on vaccine availability, available funding for immunization programs, and differing perceptions of risk/reward trade-offs. For example, most developed countries use an IPV because of its lower risk profile. However, in low-income countries it is more common to use the oral polio vaccine because it is less expensive and easier to administer, even though there is a risk of vaccine-associated paralytic poliomyelitis.

In the US, the Advisory Committee on Immunization Practices (ACIP) currently recommends that children be vaccinated against approximately 15 different diseases. For adolescents, the ACIP recommends that young adults be vaccinated against five diseases, including yearly influenza. The adult and elderly markets primarily revolve around annual influenza vaccination, booster shots against tetanus, diphtheria, and pertussis (Tdap), and herpes zoster vaccines for the elderly. The WHO recommends vaccinating children for 11 different diseases, and approximately three vaccines for adolescents and adults if they are in a high-risk group or previously not immunized.

Consumers rarely pay directly for vaccines, with the exception of influenza vaccines. In developed countries, physicians and pharmacists are the primary private purchasers of vaccines, thereby assuring proper handling of heat labile vaccines. Physicians, pharmacist, or other healthcare workers typically administer vaccines and then are reimbursed for the cost of the vaccine and its administration by private or public third-party payers. Physicians can theoretically profit from both the vaccine and its administration. In the US, estimates vary on the degree to which physicians profit or take a loss from vaccinations. A significant amount of public purchasing occurs for vaccines in all countries, including the US, where 55% of the volume is purchased by federal or state governments. For less developed countries, UNICEF, the single largest purchaser of vaccines on a volume basis, purchases 40% of all vaccines produced globally. The financing for these vaccines is through the United Nations and the GAVI Alliance (formerly the Global Alliance for Vaccines and Immunization). Required copayments or user fees for vaccines are generally discouraged by the WHO.

In the US there are approximately 43 different types of vaccines protecting against 19 diseases, supplied mainly by six large multinational pharmaceutical companies. These manufacturers are responsible for the supply of a significant amount of global demand to high-income countries. For the low-income markets, there are a total of 30 manufacturers that are WHO prequalified, meaning that they can supply vaccines to UNICEF or any other country that accepts WHO prequalification. However, at the antigen level there are very few to one supplier in most markets (**Table 1**). For example in

Table 1 Number of suppliers by pediatric vaccine in 2012 for UNICEF and the US

Vaccines	*UN*	*USA*

2012 in the US, most vaccines were supplied by only one or two suppliers. Additionally, UNICEF relies on anywhere from one to five suppliers for any given type of product. There has been some recent entry of new products into the vaccine market, due to the introduction of newer higher priced vaccines such as the human papilloma vaccines (HPV) that protect against cervical cancer, smaller firms focusing on the biodefense market, and entry into low-income markets.

Product Characteristics

The vaccine market differs from the traditional pharmaceutical market for a number of reasons. These differences in product characteristics have consequences for demand, manufacturing, research, and the role of the government.

Vaccines are largely preventative in their aim and are typically consumed only occasionally in a person's lifetime. For example, most vaccines are given in childhood and many confer lifelong immunity or require a booster dose every 10 years. The preventative nature of vaccines means that the consumption decision is based on preventing a future adverse health outcome, whereas many pharmaceuticals and biologics are targeted on treatment, so the consumption decision occurs only when the consumer is ill. Because vaccines are consumed only a few times in a person's lifetime, their demand is concentrated and largely limited by the size of the birth cohort. This contrasts in particular with pharmaceuticals for chronic conditions that may need to be used regularly on a daily basis for a patient's entire remaining lifetime.

Another important distinction is that vaccination may provide benefits to those that are not vaccinated, a positive externality. If a person chooses to be vaccinated, that lowers the probability that an unprotected person will become ill. At a certain point, but below 100% immunization rate, it does not make sense to continue vaccinating because the population has reached the so-called herd immunity rate. The proportion of persons that are immune to the disease from vaccination is high enough that the probability of a disease outbreak is effectively zero. For example, the herd immunity for polio is achieved at an immunization rate of approximately 80%: the remaining 20% of the unvaccinated population is still protected. This herd immunity is important for the protection of those who cannot be immunized, such as the very young or those with a compromised immune system; however, the positive externality from one person's vaccination decision and herd immunity can also lead to a free-rider problem. The existence of the free-rider problem is commonly cited as a justification for government intervention in the vaccine market through mandates and subsidies.

On the supply side, the research, development, and production characteristics of vaccines are distinct from small molecule chemical pharmaceuticals. These differences influence a firm's decision to enter or exit the vaccine market. For example, vaccine clinical trials are typically larger than pharmaceutical trials (Table 2). However, there is some evidence to indicate that vaccine development costs are about the same as that of chemical pharmaceuticals and vaccines have historically had a slightly higher probability of success once they have entered Phase I trials. Additionally, vaccines, as biologics, entail a production process and product characteristics that are intimately linked, necessitating that the final phase of clinical development, Phase III trials, is for both the product and the manufacturing process. This means that investments in full-scale manufacturing need to be made before product approval. Thereafter, the biologic nature and the inability to fully characterize vaccines necessitate greater regulation after product approval. For example, changes in the vaccine production process may require repeating clinical trials to demonstrate that the production changes did not affect product quality. However, changes in chemical pharmaceuticals production process can be demonstrated to not have affected product quality through bioequivalence testing. Finally, defining the regulatory pathway to entry following patent expiry becomes more complex. In the US, for example, generic pharmaceutical companies need to demonstrate 80–125% bioequivalence to receive marketing approval for their drug. Although vaccines are biologics, they may be too complex to currently demonstrate biosimilarity and therefore follow-on entry will likely be more difficult. For example, in their guidance on biosimilars, the European Medicines Agency has stated: "Vaccines are complex biological medicinal products. Consequently, vaccines have to be considered on a case-by-case basis."

Demand

Consumer demand for vaccines is influenced by price and a number of other nonprice factors; these have been studied

Table 2 Clinical trial enrollment by phase for vaccines and nonvaccines (1999–2011)

	Nonvaccines			*Vaccines*		
	N	*Mean*	*Standard deviation*	*N*	*Mean*	*Standard deviation*
Phase I	6 740	62.7	456.7	343	59.4	74.2

Source: Data from http://ClinicalTrials.gov. To investigate concerns that nonvaccines trials may have disproportionately smaller trials due to orphan drug or specialty drug trials, the mean enrollments for vaccine and nonvaccine trials were also examined for trials with enrollment >100 people and >200 people. Vaccine trials were still larger in these additional analyses.

extensively in the epidemiological and economic literature. Examples of nonprice demand factors are herd immunity thresholds, population heterogeneity around the benefits and risk of vaccines, how members in a population come in contact with one another, the influence of incentives, and the availability of other disease avoidance behaviors or treatments. Finally, policy makers actively try to influence demand for vaccines by heavily subsidizing them or making vaccination mandatory.

In general, demand for vaccines has been modeled in the economic literature using expected utility theory with consumers comparing trade-offs and choosing to remain unvaccinated or becoming vaccinated. Inherent in this stylized model are a number of important factors. First, in the unvaccinated state, the consumer is healthy and has a certain level of utility. The person is susceptible to disease and will become ill and enter a lower utility state with a given probability. The risk of getting the disease increases with the number of people in the population with the disease (prevalence), the ease at which the disease can infect a disease-free person (transmission and infectivity), and the number of exposures a disease-free person has to the disease (mixing). The utility loss between the healthy and sick states increases with increasing disease virulence, with the greatest loss coming from diseases that have high mortality rates or a significant morbidity burden. For example, before eradication, smallpox killed an estimated 400 000 people annually with an estimated mortality rate of 30%, and of those that survived, 30% would suffer blindness.

In this literature the consumer is depicted as comparing the expected utility from remaining unvaccinated with the expected utility derived from vaccination. Choosing to vaccinate will reduce the probability of getting sick and therefore decreases the expected utility loss from the disease, but there are costs to vaccinating. The direct costs are in the form of payments made by the individual for the vaccine and the administration of the vaccine. In actuality, these are typically small in that governments typically subsidize vaccines or require private insurance programs to provide first-dollar coverage for vaccines. In the US, for example, the Vaccines for Children Program provides free vaccinations to all children below a certain income. Internationally, the degree of coverage varies depending on the health system, but typically the direct cost to vaccinate is subsidized to some degree, especially for pediatric vaccines. But the cost of vaccination also includes the actual and perceived side effects of vaccinating. As with any medication, vaccines carry some risk of side effects such as fever and arm soreness, but in the vast majority of cases, these side effects are relatively minor. However, the perceived risks of vaccination are nontrivial in certain groups of consumers who have expressed a strong dislike toward vaccines and may overemphasize the risks associated with vaccination. Understanding consumer reticence for vaccination is important as this will ultimately be useful for designing policy interventions to achieve socially optimal vaccination rates.

Differences in attitudes toward vaccine and vaccine risk suggest that if a subset of the population views vaccines as more risky than the majority of the population, vaccination rates and attitudes toward vaccination can have a wide variance, and demand may oscillate. Vaccination rates will also be below the socially optimal level if the perception of the risk of disease is lower than the actual risk. For instance, consumers have expressed reticence toward getting the varicella vaccine to protect against chickenpox because of the perception that the impact of the disease is minor.

Another potentially important factor influencing vaccine demand is the prevalence elasticity of demand. Put simply, as the prevalence of a disease decreases in a population, the demand for the vaccine will decrease because the probability of becoming ill falls. This has important implications because a stable equilibrium may not be possible, and instead there can be dynamic oscillations in the disease prevalence and vaccination rates. Therefore, static policies that aim at increasing vaccination rates may not have the intended effects. Additionally, during disease outbreaks and product shortages, the prevalence of the disease will rise quickly and may cause people to vaccinate in self-interest. This may not be optimal because there may be some in the population who would derive greater benefits from the limited vaccines. For example during influenza outbreaks, immunization of the elderly and children are typically prioritized because the elderly can have the most severe complications from infection and children are the primary transmission vectors. However, a healthy adult may not account for the higher-than-average marginal benefit of vaccinating these groups and may choose to try to vaccinate based on maximizing their own expected utility. Evidence suggests that during periods of vaccine shortages, providers and consumers do not allocate scarce vaccines optimally.

Free-riding and herd immunity are other demand influencers. A person may decide not to vaccinate if many other

people have chosen to vaccinate because of the benefit from having a lower probability of becoming ill. Additionally, population-level protection can be achieved at the herd immunity level, which varies based on disease characteristics but is approximately 90% for most diseases. Therefore, the marginal net private and social benefit to vaccinating above the herd immunity point are strictly less than zero if there is any cost associated with vaccination.

The demand for vaccine is also influenced by a number of other factors such as how people share information about vaccination and a disease, a person's experience after a health shock, and the social influence of peers. Models of these factors predict that vaccination rates will oscillate over time.

Some authors suggest that moral hazard from vaccination may actually also increase infections. Vaccination provides a type of insurance against getting a disease and therefore a person that is vaccinated may engage in other high-risk behaviors that could increase their chance of getting a disease especially if the vaccine is not perfectly effective. For example, the introduction of a vaccine for Human immunodeficiency virus (HIV) may actually increase the incidence of HIV or other sexually transmitted diseases if the vaccine induces other high-risk behaviors.

Policy Demand Modifiers

Policy makers have a number of tools that have traditionally been utilized to try to influence vaccination rates. These vary by country, but in the developed world the use of mandates and subsidies is common. Mandates raise the cost of not vaccinating, whereas subsidies decrease the cost of vaccination. In the US, each state determines its vaccination policies with regard to mandates and subsidies. The states also vary in the allowable reasons that a person can express to obtain an exemption to the mandatory vaccine policy. Exemptions can be granted for medical, religious, or simply philosophical reasons. In contrast, the UK does not mandate vaccination but provides vaccines at no cost.

Mandates

There is a broad base of evidence examining the impact of mandates on disease incidence and vaccination rates in the US. School-entry mandates are a requirement that a parent must document that their child is fully immunized in order to attend school. A number of studies have found that school mandates significantly reduced the incidence of disease in the US. The estimated impact of mandates on vaccination coverage varies widely with a median increase of 15% (range: 5–54%). Implementation of a mandate also appears to reduce racial differences in immunization rates. Many of these studies were conducted in the US and most did not control for exemptions. It should also be noted that these studies typically do not control for the potential endogeneity of mandate strength and underlying population characteristics despite preliminary evidence that they may be related.

Mandates also appear to have a spillover effect and may be associated with increased immunization rates for nonmandated vaccines. For example, one study found that the implementation of a mandate for the tetanus, diphtheria, pertussis (Tdap) vaccine increased not only the Tdap immunization rate from 29% to 83% but also the tetravalent meningococcal vaccination rate from 10% to 60%.

Exemptions

A study of exemption rates showed that US states that had an easy exemption process, or that allowed exemptions from mandates based on personal beliefs, had an increase in the number of exemptions between 0.99–2.54% and 1.26–2.51%, respectively, from 1991 to 2004. Additionally states with easy exemptions or personal belief exemptions had an increased incidence of pertussis (incidence rate ratio of 1.53 (ease of exemption); incidence rate ratio 1.48 (personal belief exemptions)). Interestingly a survey of parents of children who received a nonmedical exemption reports receiving at least some vaccinations (75.5%), with the varicella vaccine being the most common one not being received (53.1%).

Subsidies

There is limited evidence on the effects of direct subsidies on immunization rates in high-income markets. Providing free influenza vaccine to elderly patients increased the vaccination rate by a modest 0.6% from a base of 40.6% in the US. Additionally, another study estimated that providing free vaccines increased the overall immunization rate for DTP, polio, and MMR vaccines by 7% from 76% to 83% ($p=.03$) based on the implementation of a new insurance program that provided free vaccines to poorer children. In low-income markets, vaccines are highly subsidized and there has been a marked increase in the vaccination rate for older vaccines, through UNICEF, and newer vaccines, through the GAVI Alliance.

Many countries provide free vaccination to all children. In the US there is a mix where some states provide all vaccines to all children, whereas other states provide them for only low-income publicly insured or uninsured populations. All other children receive their vaccine in the private sector. The evidence on the role of US state level insurance policies is mixed. For example, US states that provide Medicaid coverage to a larger proportion of their poor residents are more likely to have residents that are up-to-date with vaccination, but only to a certain point. States that provide Medicaid coverage to more than approximately 50% of their poor residents are actually less likely to have poor and nonpoor residents being up-to-date with vaccination. Also, children residing in states that provided a higher percentage of immunizations through the public sector were less likely to be up-to-date (Mayer *et al.* 1999). Children residing in states that provide all vaccines for their entire pediatric population do not appear to be more up-to-date than those residing in states that provide it only for their low-income populations (Olshen *et al.*, 2007; Mayer *et al.*, 1999; Davis *et al.*, 2003). However, in contrast a different study found that publicly insured children were more likely to be up-to-date on vaccine requirements compared to their privately insured counterparts (Blewett *et al.*, 2008).

Finally, in the US, children who are black, reside in an urban area, are poor, and are the children of young single mothers who do not have college degrees are more likely to be completely unvaccinated. In contrast, white children who live in families with incomes more than US$75 000 and are the

children of married mothers who have college degrees tend to have some vaccination but are not fully up-to-date or undervaccinated. These findings indicate that policies such as subsidies and mandates may need to be more nuanced with regard to groups that are completely unvaccinated and those that are undervaccinated.

Supply

The vaccine industry in the developed world is primarily comprised of large multinational pharmaceutical companies that produce vaccines as part of their overall product offerings. These multinationals typically supply product to most parts of the world. However, developing world manufacturers now supply much of the demand in low- and middle-income countries. In prior decades, governments and universities were major suppliers of vaccines but few still exist globally with most of the vaccines being manufactured in the private sector.

The relatively small number of manufacturers and recurrent shortages has led much of the economic literature on vaccine supply to focus on two interrelated areas, causes of shortages and the impact of sole source suppliers. Shortages are a recurrent feature in the vaccine market as historically there have been only a few suppliers for each vaccine in each market, and because vaccine production typically takes many months. It is difficult for other suppliers to quickly increase production to meet unanticipated demand. The causes of the shortages vary. For example, an increase in demand due to an early and more severe flu season caused shortages of influenza vaccine during the winter of 2004–05. Additionally, regulatory actions have caused shortages of a number of vaccines over time as manufacturers have either decided to cease production or needed time to meet compliance requirements. Finally, the natural uncertainty in biologic manufacturing has also been associated with vaccine shortages. Supply-side research tends to examine why there is such limited capacity and few suppliers at the product level. Causes such as demand and supply shocks, excess regulation, undervaluation of vaccines, greater profitability of pharmaceuticals relative to vaccines, and fixed cost competition along with winner-take-all procurement policies have all been posited as causes for the current market structure. Analysis of the vaccine supply-side features is important to understanding these market outcomes.

Firm perspective

From the firm's perspective a number of considerations are required to determine whether to enter or exit the vaccine market. A 2004 survey of vaccine manufacturers by the Centers for Disease Control and Prevention (CDC) found that manufacturers highlighted the regulatory burden, the high cost of delay between initial investment and sales, and the higher cost of new technologies for new vaccines as barriers to entering the vaccine market. However, the manufactures also noted that they have increased investment in R&D because new technologies have allowed for the development of vaccines previously not thought possible. During the late 1990s and into the early 2000s there was significant exit from the vaccine market. For example, in the US during the 1980s there were 18 vaccine manufacturers and by 2007 there were six. Exit was not limited to the US market; UNICEF received bids from 10 different manufactures to supply their demand for measles vaccine in 1996, and only three in 2001. However, more recently firms have entered the vaccine market. The causes for potential increased entry are multifactorial. For example, more recent vaccines, like the HPV vaccines, have been priced higher than traditional vaccines, leading to greater expected revenues. Additionally, improved technology, such as cell-based influenza vaccines, has also led to new firms entering the market. Internationally, the GAVI Alliance has substantially increased the donor base for funding low-income markets, increasing the overall market size for many vaccines. Finally, manufacturers in emerging markets, including India, China, and South Korea have entered as major suppliers to emerging and middle-income markets.

Vaccine projects must compete for both internal and external capital that could be dedicated to other innovations. Within the pharmaceutical firm these are typically other pharmaceutical or biologic products that may be more profitable. Firms also consider the increased regulatory requirements and the need to make significant investments early in the product life cycle for vaccine projects. Because vaccines are given to healthy recipients and are complex biologics, there is a higher level of regulatory proof required to show product safety, product efficacy, and the reliability of the manufacturing process. Clinical trials for vaccines typically enroll larger number of subjects than pharmaceutical trials because of the need to prove prevention of a disease rather than showing treatment effects (Table 2). The clinical trials must also demonstrate both the safety and the efficacy of the product and the manufacturing process. This is due to the biologic nature of the product, requiring that investment and decisions on full-scale manufacturing be made before product approval. This increases the opportunity costs of vaccines relative to pharmaceuticals. Finally, because of the linkage between the product and the manufacturing process, changes in manufacturing may necessitate new clinical trials. Therefore, firms face high sunk costs when entering the vaccine market relatively early in the clinical trial process and need to wait longer to recoup their investment. A rational firm will invest in a higher fixed cost endeavor only if there is a high enough willingness to pay for the eventual vaccine.

Vaccines also typically tend to have a longer life cycle than pharmaceuticals because of the uncertain regulatory pathway to entry for biosimilar vaccines. Firms wishing to enter an existing vaccine's market will most likely have to do their own full-scale clinical trials for both their product and their manufacturing process. This regulatory barrier to entry means that firms currently in the market will face less competition and have longer product life cycles than a typical pharmaceutical for which entry is typically very rapid after patent expiry. It should be noted that although there has been increased entry into the overall vaccine market, competition at the product level is still limited.

Market outcomes

A distinctive feature of the vaccine market is that for each type of vaccine there is a limited number of suppliers selling in most countries (Table 1). Single (or few) suppliers is not necessarily a bad outcome if the last remaining supplier is the

lowest cost reliable producer and monopsony purchasing can balance monopoly market power. Moreover, this may be the long-run equilibrium for vaccines. However, having few suppliers can cause episodic shortages if there is a regulatory action, a manufacturing problem, or some other unexpected supply shock, especially if storability is limited or costly. For instance, updated regulations may cause firms to exit due to increasing regulatory costs and if firms do not have a reasonable expectation of being able to recoup their investment.

Multiple factors may contribute to exit of individual suppliers and/or temporary shortages of vaccines in the vaccine market. Vaccines have a high fixed cost component. If there are multiple entrants and competition drives prices to marginal cost, none of the competitors can recoup their fixed costs and all but the low-cost supplier will exit the market. Additionally, demand is relatively concentrated because it is limited to the birth cohort for many vaccines, in which case economic theory predicts there will be fewer suppliers. Regulatory actions have also caused firms to exit the market as well as have led directly to shortages. Historically, liability risk for adverse events associated with vaccination was a significant concern as vaccine recipients are healthy infants; these risks were the impetus for the Vaccine Injury Compensation Act in the US. In the US, most vaccine sales have an excise tax, which is used to fund a Vaccine Injury Compensation Fund. Persons harmed by vaccination must go to a special court to seek compensation from the fund. Finally, some have posited that vaccine prices are too low due to undervaluation by payers and the large amount of government purchasing. However, these studies were done before the introduction of newer and higher priced vaccines. Additionally, a US study did not find evidence that government purchasing led to fewer suppliers and therefore may not be a contributing factor to shortages.

A number of solutions to combat shortages have been suggested. In the US, the CDC has established 6-month stockpiles for all pediatric vaccines. This may be the optimal solution if fixed-cost competition along with winner-take-all procurement provisions leads to sole-source supply from the least-cost manufacturer, as has been hypothesized.

Conclusion

The economics of vaccines are complicated and have a number of interesting features that can shed light on various economic phenomena. Vaccines are preventative against contagious diseases, and therefore marginal demand may decline as immunization rates increase because the risk of infection decreases. A rational consumer may prefer not to vaccinate given that the probability of infection becomes very small at high immunization rates. This creates incentives to free ride. For related reasons, immunization rates in private markets may be suboptimal if consumers ignore the positive externalities from immunization. On the supply side, vaccines are distinct from chemical pharmaceuticals due to their biologic complexity. This complexity leads to greater regulatory oversight and more complicated manufacturing processes for both vaccines and biologics compared to traditional chemical pharmaceuticals. Suppliers deciding to enter the vaccine and biologics market need to demonstrate the safety and efficacy of both their product and their manufacturing process because they are intimately linked. This also means that changes in regulations or manufacturing processes may necessitate new clinical trials. Therefore, significant investments must be made early in a vaccine's life cycle and decisions on capacity may be difficult to modify later. However, once in the vaccine market most vaccines have traditionally enjoyed a longer economic life than chemical pharmaceuticals, due to the absence of a regulatory pathway for generic vaccines. Whether this will change in the future remains to be seen.

Finally, the overall vaccine market has historically experienced shortages and few manufacturers per product. The possible causes of the shortages and few suppliers range from prices being below the full social value, changes in regulation causing manufacturer to exit, fixed cost competition, and high levels of centralized purchasing, either by national governments or by groups like UNICEF. Solutions to these problems range from increasing prices to reflect the full social value of vaccines, stockpiling vaccines, and reducing regulatory barriers to increase global competition.

Value of Drugs in Practice

A Towse, Office of Health Economics, London, UK

Introduction

To understand the role of establishing value in practice, one needs to briefly recap on the role that value can in theory play in pharmaceutical pricing and use by health systems.

Most industrialized countries have universal coverage with modest patient copayments. By lowering out-of-pocket prices to patients, insurance counteracts the impact on patients of companies using patent protection to charge high prices, protecting consumers from financial risk and, through cross-subsidies, making health services more affordable to low-income consumers. However, because such insurance makes patient demand highly price-inelastic, insurance creates the potential and incentives for manufacturer prices that exceed the level that would result from patents alone. Public and private insurers use various forms of price regulatory strategies to constrain this producer moral hazard. These price regulatory strategies are generally an ad hoc mix of historical policies. It is, however, possible to identify five broad types of measure, often used in combination:

1. Cost-effectiveness requirements: Drugs are assessed for use or for a reimbursement price by looking at incremental health-related effects (often measured and valued using the quality-adjusted life-year (QALY) and incremental costs relative to existing treatments using cost-effectiveness analysis (CEA). Economists regard the use of CEA for drugs (which has the effect of regulating drug prices indirectly through a review of cost-effectiveness) as in theory more consistent with principles of efficient resource allocation than other regulatory methods for drug prices. It means that more effective/safer drugs (delivering more QALYs) can charge higher prices and still be cost-effective relative to less effective/less safe drugs. This provides efficient incentives for research and development (R&D). In addition, by using the CEA approach, the indications in which the use of the drug would be efficient can also be identified and potentially controlled, thereby encouraging a more cost-effective use of the drug in the health care system.
2. Therapeutic added value requirements: These typically involve comparison with other, established drugs in the same class, or with other treatments used in the standard of care (SoC) with higher prices allowed or negotiated for improved health or health-related effects in the form of efficacy, better side effect profile, or convenience (a form of internal reference pricing). If internal reference pricing ignores potential differences between drugs in a therapeutic group and prices them all at the same price, then it is not rewarding innovation efficiently. However, if companies are able to charge higher prices if they can demonstrate superior effect over other products in a therapy class or over the SoC then prices are taking account of the value generated for payers and their patients. This can be done by using an assessment of relative effectiveness (RE) (the term used in Europe) or comparative effectiveness (CE), the term used in the USA.
3. Comparison with the price of the identical product in other countries ('external reference pricing'): This involves setting prices by reference to the prices of the same product in a basket of other countries. It limits the manufacturer's ability to price discriminate across countries. Predicted effects include convergence in the manufacturer's target launch prices across linked markets, with launch delays and nonlaunch becoming an optimal strategy in low-price countries, particularly those with small markets. Parallel trade, which is legal in the EU, has similar effects to external referencing, except that it generally only affects a fraction of a product's sales. The welfare effects of regulatory pressures for price convergence across countries are theoretically ambiguous but likely to be negative. Price discrimination increases static efficiency if volume increases relative to uniform pricing. That differential pricing increases drug use seems plausible, given evidence of new drug launch delays in low price countries when there is external referencing or parallel trade.
4. Cost-based approaches where manufacturers supply production and research cost information: Most countries have now moved away from direct price control based on costs and profit margins. The difficulties of allocating joint costs across global markets and taking account of R&D failures rendered this a particularly inefficient way of regulating pharmaceutical prices. The United Kingdom (UK) uniquely among industrialized countries regulates the rate of return on capital on the whole drug portfolio, leaving manufacturers free to set the initial launch prices of individual drugs (but not to increase them thereafter except in very prescribed circumstances). Indirect price control is, however, operated via the National Institute for Health and Clinical Excellence (NICE) using a cost-per-QALY threshold in making recommendations for the use of drugs in the UK National Health Service (NHS). Following a 2007 review of the Pharmaceutical Price Regulation Scheme (PPRS), the UK Office of Fair Trade recommended that the UK move to a system of 'value-based pricing' regulation, in place of profit regulation. As a result, the renegotiation of the 2009 PPRS may lead to a move away from profit regulation to a more uniform reliance on the use of NICE's cost-effectiveness requirements to constrain pharmaceutical prices.
5. Limits on total spending with various clawback mechanisms to penalize companies when revenues exceed the target set. Controlling expenditure through drug budget caps is a form of 'silo budgeting,' which may create perverse incentives for cost shifting to less efficient inputs or to curb sales of products that are delivering a lot of health gain.

The first two approaches (the use of CEA and a 'therapeutic added value' approach involving a comparison with other

 doi:10.1016/B978-0-12-375678-7.01205-0

drugs or the SoC) link price to value. There has been a substantial increase in the number of third party payers using formal CEA, or pharmacoeconomic approaches for assessing the value of drugs, vaccines, and other heath technologies to inform decisions about pricing, reimbursement, and use within their health care systems. In addition a number of countries use 'therapeutic added value' approaches, in some cases involving the use of CEA.

The main rationale for using CEA is to limit reimbursement to drugs and technologies that meet specified standards of value for money or cost-effectiveness. CEA also has the effect of regulating drug prices indirectly through a review of cost-effectiveness. This is in theory more consistent with the principles of efficient resource allocation than other regulatory methods for drug prices. It means that more effective/safer drugs (delivering more QALYs) can charge higher prices and still be cost-effective relative to less effective/less safe drugs.

Australia was the first jurisdiction to adopt such a policy in 1993 and was quickly followed by New Zealand and several Canadian provinces. The UK established the NICE in 1999 to review the effectiveness and cost of technologies expected to have major health or budgetary impact, using cost per QALY, and to formulate guidance on the use of these technologies in the NHS in England and Wales. In Sweden, the Dental and Pharmaceutical Benefits Board (tandvårds- och läkemedelsförmånsverket (TLV)) undertakes CEA to inform decisions on the reimbursement of drugs. Other European countries requesting economic submissions for some, or all, new medicines, include Belgium, Finland, Ireland, Norway, The Netherlands, Portugal, and Germany. Similar policies have also been recently adopted by some countries in Eastern Europe (e.g., Hungary), Asia (e.g., South Korea), and Latin America (e.g., Brazil).

It would be more appropriate to include the new German pricing system in the second 'therapeutic added value' category, along with the French system. Both place a strong emphasis on the need to demonstrate benefit against an appropriate comparator in order to demonstrate added value, before a higher price can be considered. In Germany, if there is no agreement on the price to be paid for the added value, then a CEA can be required to help resolve the issue. In France a CEA is not required at launch, but is required at the point at which a postlaunch review is conducted.

Both the use of CEA and the therapeutic added value approach therefore link price to value. Price (P) can therefore be thought of as a function of the decision maker's perception of value (V). This can be characterized as

$$P = f(V) \quad [1]$$

For the decision-maker value (V) is additional benefit (B) minus additional cost (C). These costs can be thought of as comprising additional costs associated with using the technology (excluding acquisition cost or 'price') minus cost offsets (including the costs saved by the displacement of other technologies). In addition decision-makers looking at value are also concerned about the opportunity cost of resources (k). In the case of payers using CEA this is explicit (although they may not say what opportunity cost threshold they are using). In the case of payers rewarding price premiums for value it is implicit in their willingness to accept higher prices for additional value. Finally, decision-makers are concerned about the uncertainty (U) associated with their estimation of value. Substantial uncertainty is likely to lead to a lower price, delay in use of the drug pending resolution of the uncertainty with more evidence, or some form of use linked to the collection of evidence designed to resolve the elements of uncertainty (often called coverage with evidence development (CED) or managed entry). The decision-maker value determination can be characterized as being a function of these four elements:

$$V = g(B, C, k, U) \quad [2]$$

To understand how value is determined in practice requires consideration of a number of issues, which are explored in the remainder of this article:

- the elements of benefit and cost payers are willing to have included in their assessment of value and how the most important component, health effect, is assessed;
- the use of opportunity cost in determining price or value;
- how pricing and access decisions are made, given the assessment of value;
- the use of CED to handle uncertainty in decision-making about value;
- the challenges of getting value decisions implemented in practice. Do health systems use recommended drugs;
- can poor value be identified using the same approach, leading to disinvestment from drugs and other treatments that are not good value; and
- trends in regional collaboration in the assessment of and decision-making about value.

The Elements of Value to Be Included

What is theoretically included should, in principle, depend on the perspective of the decision-maker. However, some omissions may be unintended and lead to unintended measurement error. For most decision-makers:

- The health effect is usually the single most important benefit and hence element of any assessment of value.
- Cost-offsets within the healthcare system are a second key benefit.

Other elements of value that are sometimes used by decision-makers fall into three distinct types:

- The 'value' of the health gain to society may be higher or lower depending on who gets it. The severity of the disease is a particular factor. The UK NICE applies a specific value weight when appraising end-of-life medicines. Several health systems treat drugs for orphan diseases differently (where a requirement for designation is that the degree of disease severity is high), allowing higher prices and/or lower evidence standards for evidence of RE or therapeutic added value. In the German arzneimittelmarktneuordnungsgesetz (AMNOG) process, orphan drugs are automatically assumed to be innovative without a consideration of the strength of the evidence, although this is now subject to review. In the UK, orphan drugs were exempt from the NICE review process, but this has now changed.

However, NICE will use a different process to review these drugs as compared with its conventional CEA approach.

- There may be elements of benefit to the patient that are not necessarily captured in the measure of health gain, including:
  - Health-related-quality of life aspects not well captured by a generic measure of health gain such as the QALY and
  - Health-care-process-related aspects such as being treated with dignity, at a convenient time and location, and after only a short wait.
- Information for the patient which, for example, enables life style choices to be made, independent of any health effects.
- Other costs and benefits beyond those to patients and the health care system. Outside of health care a societal perspective is conventionally used by economists, including all costs and consequences related to the initial interventions in a cost–benefit analysis. Applying such an approach would involve expanding the CEA to include unrelated medical costs, costs incurred outside the health care sector, and benefits accruing to all stakeholders in society including those for the patient not captured in the QALY. Several countries, including Norway, Sweden, and the Netherlands, already require that economic evaluations are conducted using a societal perspective.
- Innovative attributes of a technology may be deemed to have value independently of the health gain generated. Japan and Italy use a categorical rating to assess the degree of innovativeness. France uses a categorical rating to estimate the degree of therapeutic added value.

Table 1 is a summary of the ways that value is linked to medicine prices in a range of eight countries whose third party payers use either CEA or a variant of 'therapeutic added value' to assess price. The authors look at:

- Australia, Canada, England, and Sweden which use CEA to determine whether at the price sought by the manufacturer the medicine is deemed cost-effective or not;
- France, Germany, Italy, and Japan – whose approaches include allocation of new medicines into a number of pricing categories defined by assessment of the therapeutic added value of the medicine.

Table 1 sets out the key points to note. For example:

- The Australian approach to medicines pricing is focused around health gain per dollar, i.e., 'clinical effectiveness' and 'cost effectiveness.' Official guidance there notes that cost per QALY is commonly used but does not require it, meaning that a number of approaches may be acceptable. The overall assessment of the value of a new medicine, in the sense of how different aspects of value are weighed up against price, is opaque. For example, there is no specific monetary 'threshold' value applied to QALYs where some of the medicine's benefits are expressed in QALY terms. A national committee representing the payer engages in a deliberative process: there is no formulaic derivation of the price ceiling. Repeat manufacturer submissions are normal as both sides 'negotiate' toward an acceptable price.
- None of the countries has gone so far as to define an explicit method for aggregating qualitatively different nonfinancial elements of a medicine's value, although three of them group medicines into a small number of categories before price determination: five categories in France, three in Italy, and six in Japan.

There is an important division between those markets and payers who use QALYs and those who do not. Typically payers using CEA require or prefer the use of QALYs and those using therapeutic added value do not require it. In the US, the 2010 US Patient Protection and Affordable Care Act (ACA) specifically forbids the use of "a dollars per quality-adjusted life-year (or similar measure that discounts the value of a life year because of an individual's disability) as a threshold to establish what type of health care is cost-effective or recommended…" in public funding decisions (ACA 2010). The wording of the ACA means that the emphasis in the public sector in the US is likely to be around assessments of therapeutic added value (termed CE) that use clinical or disease-specific patient reported outcome measures. Many private health plans and pharmacy benefit managers (PBMs) require elements of a CEA submission for drugs to be provided to them in a standard format agreed by the Academy of Managed Care Pharmacists (AMCP). This format allows for, but does not mandate, use of the QALY.

Estimating the Opportunity Cost of Adopting a Technology

Decision-makers need to know what they are giving up if they adopt a drug. In the case of a health care system with a 'hard' fixed global budget for a specified time period, such as the UK, the opportunity cost in the short terms is usually displacing another health care related activity. This is often referred to as an 'extrawelfarist' approach. In the case of (1) a 'soft' public budget system, (2) as spending budgets are varied over time in 'hard' global budget countries, or (3) in a private sector system, adoption may lead to increases in taxes or premiums and so reductions in private consumption elsewhere. In this context, the relevant opportunity cost is the expected willingness to pay (WTP) for health-related value of the covered population. This is often referred to as the 'welfarist' approach. Which one is relevant depends on the context. In the case of countries using therapeutic added value approaches, a rule of thumb is usually used to estimate WTP for additional value (e.g., by reference to prices sought elsewhere) or a price is negotiated. The approach to the threshold is implicit in these cases and may not reflect either WTP or an estimate of displaced value.

Setting an appropriate opportunity cost threshold for use in decision-making by estimating what is 'displaced' is difficult because (1) it is hard to estimate and (2) it is hard to apply in decision-making as the covered population has usually not accepted explicit rationing of health care on this basis.

The UK has the most explicit policy in respect of using a cost-effectiveness threshold for assessing price in relation to value based on the 'displacement' of other health-providing activities by the NHS within a fixed global budget. In its early days, NICE denied that it was applying a specific threshold. However, as the information on the decisions made by

Table 1 Assessing 'value' and linking to price: current practice in selected countries

Country	*Elements included in 'value'*	*How measured*	*How valued, whose values*	*How aggregated*	*How converted into price*
Australia	• Clinical effectiveness • Cost-effectiveness	Quality-adjusted life-year (QALY) and incremental cost per QALY are commonly used but not obligatory	Not specified	Deliberation – opaque	Negotiation – approximately 30% margin on costs for the most innovative products; effectively therapeutic reference pricing for others
Canada – Federal level	• Cost-effectiveness • Safety • Effectiveness	• Incremental cost per QALY, where possible • ? • QALY where possible	Preferences of general public preferred; patients' preferences may be acceptable	Not specified	Price not linked to value: max price of 'breakthrough drugs' = median of prices in 7 other countries; effectively therapeutic reference pricing for others
France	• Relative Efficacy • Safety • Availability of therapeutic alternatives • Disease severity	• Not specified • Not specified • Not specified • Not specified	Not specified	Categorization by expert clinical committee into one of five categories of incremental health benefit (ASMR)	Negotiation (on price and volume, i.e., total revenue). For drugs with major therapeutic improvements, reference is made to European prices (in Germany, Italy, Spain, and UK)
Germany	• Relative efficacy • Very small or orphan market	• One of three categories for strength of proof • Yes/no	Not specified	Deliberation – opaque	Negotiation for products with additional therapeutic value. If negotiations fail use of a cost-effectiveness analysis and/or pan-European reference pricing. Therapeutic reference pricing for others
Italy	• Clinical effectiveness • Availability of therapeutic alternatives • Disease severity	• Unspecified clinical end-points leading to one of the three categories • One of the three categories • One of the three categories	Not specified	Categorization by expert clinical committee into one of three overall categories	Negotiation
Japan	• Efficacy • Safety • New mode of action • Indicated for children • Small or orphan market	• Not specified • Not specified • Yes/no • Yes/no • Yes/no	Not specified	Categorization by Ministry of Health and Welfare into one of the six usefulness and market size categories	Negotiation
Sweden	• Clinical effectiveness • Cost effectiveness • Cost savings in any sector: health care, nonhealth, public, private, patients, carers, and relatives • Production loss	• QALYs • QALYs • Money • Money (human capital method)	Preference for 'QALY weightings based on appraisals of persons in the health condition in question'	Not specified	Manufacturer selects price and faces coverage decision by TLV

(*Continued*)

Table 1 Continued

Country	*Elements included in 'value'*	*How measured*	*How valued, whose values*	*How aggregated*	*How converted into price*
England	• Health gain • Health service cost savings • Severity/end of life (cancer only)	• QALY • Money • Within 2 years of expected death: yes/no	• General population perspective de facto • Market prices • Appraiser deliberation	As QALYs (weighted if 'end of life')	Manufacturer selects price and faces coverage decision by National Institute for Health and Clinical Excellence

NICE accumulated, it was possible to estimate a revealed threshold. NICE then stated that it applied a threshold range: interventions with an incremental cost per QALY ratio below £20 000 have a high probability of funding; and those with a ratio exceeding £30 000 have a low probability of funding although the upper bound of £30 000 can be exceeded, for example, on grounds of equity. This range is set out in the NICE Methods Guide. Research in the UK is beginning to tackle the issue of the value of what might be displaced in the NHS. One study using case studies found it difficult to identify what in practice was displaced at the local level. Another series of studies have attempted to estimate the threshold level implied by a longitudinal and cross-sectional analysis of the current pattern of expenditure by disease area by geographic area within the NHS combined with data on mortality and estimates of morbidity. Their conclusion is that NICE's threshold range may be a little too high (i.e., closer to £18 000 than £20 000–£30 000). Yet other evidence analyzing the revealed preference of NICE decisions suggest the actual threshold used by NICE may be closer to £46 000 per QALY when other factors are taken into account by the NICE Appraisal Committees. NICE has commissioned WTP-based opportunity cost estimates of the social value of a QALY. One study suggested a distinction in WTP between life-saving (£70 000), life-extending (£35 000), and quality-of-life-enhancing (£10 000) considerations. A second study suggested a range of £20 000–£40 000 per QALY. The UK Department of Health currently uses a WTP for a QALY estimate of £60 000 for its own impact assessments, adapted from WTP estimates used elsewhere in the government.

Evidence from other countries suggest the following:

- In Canada, a revealed preference estimate of the ICERs of drugs approved and refused by the CDR between 2003 and 2007 suggesting overlapping ICERs indicating other factors were important (Belgian Health Care Knowledge Center, 2008).
- In Australia, revealed preference estimate of AUS$37 000–69 000 per QALY was derived for decisions in the 1990s (Belgian Health Care Knowledge Center, 2008).
- WTP estimates for the US range between $100 000 and $300 000 per QALY (Eichler *et al.*, 2004).
- The Swedish TLV uses WTP-based estimates ranging from €40 000 to €90 000 per QALY (Persson, 2012).

The main arguments for an explicit threshold are that it may encourage more consistency in decision-making and lead to a more equitable outcome as a result of public debate. Manufacturers will know what payers want to reward and invest in R&D accordingly. There are issues as to whether such a cost-effectiveness threshold encourages the 'right' amount of innovation. Some have argued that the amount of the social benefit going to innovators will be too low; others that allow innovators to price up to the threshold means they can appropriate all of the benefit. The patent system is intended to provide temporary monopoly rights that can enable innovators to exercise some market power. Arguably, the most dynamically efficient outcome is for as much as possible of the social surplus to accrue to the innovator in that period. Payer use of cost-effectiveness thresholds will be (second best) efficient if thresholds reflect societal WTP. For a discussion of this issue, see Danzon *et al.* (2011).

Making Decisions about Value

Use of CEA and/or 'therapeutic added value' requires decision-makers to assess the evidence of value, use judgement, and make a decision. A key part of the process of review is the submission by drug companies of a dossier of evidence to support their claim for a price based on their estimate of value. By way of illustration one can look at the process used by the UK NICE, which is regarded by many as an exemplary process. It involves the appraisal of a single technology:

- The opportunity for early scientific advice (before Phase 3 trials) as to the health and cost outcomes likely to be of importance to NICE. This is nonbinding on both parties and can involve the drug licensing body should the company wish this.
- A scoping exercise before the preparation of the company dossier at which both parties (and other relevant stakeholders) seek to agree the exact scope of the evidence required.
- The submission of the dossier, which should follow the Methods Guidance. Other stakeholders (e.g., patient groups) can also submit evidence.
- Review of the dossier(s) by an independent Evidence Review Group contracted by NICE and preparation of an assessment report by them.
- Appraisal by the NICE Appraisal Committee of the dossier and the Assessment Report and a recommendation by the Committee about the NHS use based on the price offered by the company.
- Opportunity for comment by the company and all other stakeholders before reconsideration by the Committee.
- An Appeal option for the company.

- The option for the company to apply for a Patient Access Scheme should its proposed price proves to be too high. This could involve some sort of price discount or collection of improved evidence to support the proposed price.
- The option of a rereview at a later specified time (usually 2 years).

Note that in practice two types of decision are made by health systems depending on whether (1) the health-technology-assessment (HTA)/pricing and reimbursement body, given an assumption about access, is determining the price or (2) given price, the committee is determining if value is positive for some/ all groups of patients, in order to list or otherwise make the product available for the relevant patient groups. There is inevitably some blurring:

- A company may refuse to accept the price offered and supply more evidence on value.
- If access is denied, the company can resubmit claiming higher value or offering a lower price.

Most payer/HTA bodies have a committee similar to the NICE Appraisal Committee to assess the evidence and make a decision. The mechanism by which the members of a committee combine the various forms of evidence with local context and judgements about interpretation and uncertainty to reach a decision is a deliberative process. This may be particularly valuable in circumstances where there is either uncertainty about technical information (scientific uncertainty), or where issues relating to fairness and social values (value judgements) need to be taken into account. Culyer (2009) defines these as follows:

- Scientific judgment is usually about an effect (positive or negative), its size, the ways in which it can be achieved, for whom, for how long, and how much uncertainty there is about the outcomes;
- Value judgments tend to be in a different territory but they might be about, for example, how worthwhile a technology is, how defensible the tough bits of the decision are, how tolerant of uncertainty the committee ought to be, how important interpersonal comparisons are (who benefits), and whether the outcome measure is a good tracker of the relative health benefits of the interventions that were compared.

Although NICE appears to be more transparent than other HTA bodies, some researchers are critical of its failure to formally codify the impact of decision criteria other than cost-effectiveness, claiming that its statements on these matters have been vague and uninformative. The importance of social value judgements and other factors beyond cost-effectiveness is regularly emphasized, and examples of interventions with high questionable cost-effectiveness being recommended on the basis of such factors are given. These are, however, unusual cases. It is difficult in most cases to understand the extent to which they have contributed to the final recommendation decisions and it is not possible from a review of decisions to find any factors other than the threshold that explain NICE decisions except when they are in the areas of cancer. Thus, though in principle NICE's decision-making fits the description of a sound deliberative process, the lack of explicit reporting of this process means that clarity is not always achieved.

This raises the question as to whether decision support tools can improve the transparency and effectiveness of a deliberative process used by a payer HTA body. Multicriteria decision analysis (MCDA) methods have been advocated for use in health care priority setting. MCDA is a methodology for appraising options on multiple (often conflicting) criteria with the goal of providing a combined appraisal that includes an overall ordering of those options. It provides a framework for explicitly trading off various objectives against each other. It is particularly useful when these objectives do not share a common unit of valuation – for example, health care programs typically involve a mixture of health, monetary, distributional, and political objectives.

Use of MCDA would be attractive if it led to processes becoming more transparent and systematic, so improving both the signals sent to patients and drug developers, and the quality of decision-making. However, it could require a greater time commitment on the part of decision-makers. The burden on decision-makers in using this approach would need to be proportional. To date no HTA body is using formal MCDA techniques.

Using Coverage with Evidence Development Evidence to Handle Uncertainty in Decision-Making

Decisions by payers about the adoption of health technologies are almost always made under uncertainty and on the basis of limited information. Yet it is not at all clear how decision-makers handle uncertainty. Most request evidence on the sensitivity of the evidence to different assumptions or statistical error. NICE asks for probabilistic sensitivity analysis and the presentation of results in a Cost-Effectiveness Acceptability Curve, which estimates the likelihood of a decision to adopt representing good value at different cost-effectiveness thresholds. However, there is no guidance in the Methods Review or in published guidelines as to how judgements about value take uncertainty into account.

Health care payers have three options in respect of uncertainty. One is to adopt the technology and live with the uncertainty. A second is to refuse to adopt the health technology in question until the uncertainty is reduced – either through better evidence or a lower price. The third is to adopt the health technology, but make this decision conditional on the collection of further additional evidence. This is usually termed 'CED or a Managed Entry Agreement (MEA). Adopting a drug may make some forms of additional research more difficult, for example, by reducing the likelihood of enrolling patients in a clinical trial (although data could be collected in another jurisdiction if it is likely to be transferable), and there may be costs of reversing decisions if subsequent evidence suggests that a drug in use is not cost-effective. Yet payers are increasingly using MEAs, many of which are forms of CED. In some cases MEAs are designed to address uncertainty as to how well the drug will perform or as to the overall budget impact. Agreements in France, Australia, and New Zealand are

designed to cap expenditure. In other cases, they are intended to provide an effective price discount, at least for the period of the agreement. The dose-capping agreement that NICE entered into over ranibizumab (Lucentis®) for macular degeneration could be seen as an effective price discount. Cost-effectiveness to NICE was only acceptable if the NHS paid for up to 14 injections per eye of eligible patients. Novartis had to bear the costs of treatment beyond this.

There has been a surge of interest in the use of one particular form of CED – 'performance-based risk sharing' (PBRSA) – that involves an agreement between a payer and a pharmaceutical, device, or diagnostic manufacturer, where the price level and/or revenue received is related to the future performance of the product in either a research or real-world environment. In particular, there is an agreement about a program of data collection to reduce uncertainty about the expected cost-effectiveness of the drug (or device or diagnostic), and the price and/or revenue is linked to the outcome of this program of data collection (Towse and Garrison, 2010). This may be prospective or retrospective. These may be as follows:

- Tackling outcomes uncertainty: The UK multiple sclerosis (MS) drugs scheme addresses outcome uncertainty with a prospective observational study of patient health status with price linked to a cost-per-QALY threshold. In Australia, the agreement for bosentan (Tracleer®) linked price to patient survival using a prospective observational study.
- Tackling subgroup uncertainty, conditional on expected outcomes: The UK bortezomib (Velcade®) example tackles subgroup uncertainty, ensuring identification of responders. There is retrospective payer reimbursement for nonresponders. Responders receive further doses of the product. The Italian Medicines Agency (AIFA) has established several responder-related pay for performance agreements with discounts for trial periods, and rebates for nonresponders. For responding patients, the treatments are reimbursed at full price.
- Tackling subgroup uncertainty via utilization management. In Australia, expenditure caps can also be viewed as risk-sharing agreements that have implicitly tied revenue to outcomes, under the assumption that high volumes mean cost-ineffective care at the prevailing price.

Evidence to date has been mixed. In the UK, for example, the MS risk sharing scheme has attracted much criticism. However, schemes appear to be much more successful in Australia and in Italy, and the UK NICE does operate a form of MEA called Patient Access Schemes, which combine options of effective price discounts and forms of CED including PBRSAs.

Implementation of Technologies Regarded as Good Value

To help facilitate the implementation of decisions and the adoption of cost-effective treatments, national and local health authorities employ a variety of strategies, ranging from provision of financial planning tools; additional funding to cover the adoption of new technologies; and information dissemination. Sweden uses a network of experts to assist decision-makers in understanding guidance and adopting recommended technologies into clinical practice. NICE in the UK takes a similar approach via the use of an in-house Implementation Directorate to ensure that dissemination activities are targeted to the local NHS. It assesses and reports on the level of compliance with guidance across the NHS using a variety of data sources on prescribing and practice patterns, examining utilization trends in relation to the expected level consistent with NICE guidance. Reaching local practitioners may be especially important given their role in the diffusion of technologies – a survey of HTA initiatives in Europe concluded that clinicians frequently fail to change their practice in line with HTA-based recommendations.

Research indicates a range of issues that influence whether recommended treatments are indeed used in health care systems. Such factors include insufficient or misaligned policy aims (i.e., differences in objectives between the HTA process and the needs of decision-makers – the more decentralized a given health system, the more this may be an issue); a lack of a holistic approach to implementation, where not all relevant stakeholders are informed of decisions or there is poor dissemination of guidance; limited use of formal mechanisms to enforce implementation; and rapidly changing political situations. In addition, local authorities often deal with different resource capacities, patient populations, health needs, and available budgets, which can impact their ability to implement national decisions or guidance to make treatments accessible to their populations. In the case of high-cost drugs a problem often arises if local budget holders are reluctant to make monies available to fund the prescribing of a drug approved by the HTA/P&R body.

In the UK, for example, an analysis of public comments on NICE suggests that there is a significant concern regarding the patchy and slow implementation of adoption recommendations, with many stakeholders deeming this a key issue in terms of the Institute's effectiveness, efficiency, and public credibility. A study of NICE guidance implementation found that poor financial planning by local health authorities, in terms of adequately estimating the costs and resource requirements of implementation, was one of the factors contributing to poor implementation. The UK government has published an 'Innovation Health and Wealth Report,' which has reinforced the requirement for local purchasers (commissioners) to provide funds to enable clinicians to prescribe NICE-approved drugs.

Although negative guidance will always be implemented, positive guidance often may not due to the resource consequences and difficulty making disinvestment decisions elsewhere. It may also reflect a local view that the threshold is too high. In Sweden, the local authorities who fund health care are unhappy with recommendations made by the national drug HTA body (the TLV) because they regard the items they will have to displace from their budgets are more valuable than the drugs approved by the TLV.

Although budget holders may have an incentive to resist adoption, financial incentives can be created to reward the use of cost-effective treatments. Several jurisdictions, namely, Denmark, Germany, and England, have introduced regulatory levers to make decisions or guidance legally binding, with the latter also using financial incentives through 'pay for

performance' schemes linked to the uptake of NICE guidance and standards via NHS Quality and Outcomes Frameworks (which make additional payments to GPs for achieving health outcome targets), and a Commissioning for Quality and Innovation payment framework, which holds back a proportion of tariff payments from hospitals who fail to achieve pre-set quality targets and gives the money to those that do achieve them.

Reassessment after a technology has been used in practice is also an important mechanism to facilitate effective implementation and appropriate use of technology. It helps ensure that assessments of value are up-to-date with changes in a technology and the availability of evidence. Several countries, such as France and the UK, have a structured process, conduct re-evaluation at fixed or variable intervals (e.g., every 3–5 years), whereas other jurisdictions initiate subsequent reviews if new characteristics of the product emerge or if new or better clinical and/or economic evidence becomes available.

Disinvestment from Treatments that are not Good Value

HTA processes often focus on new technologies, giving insufficient attention to existing treatments that may be potentially inefficient or used inappropriately. However, given increasingly limited resources and growing emphasis on value for money, several review bodies, such as NICE and the TLV, are implementing 'disinvestment' programs or strategies.

Disinvestment is an explicit process of taking resources from one service in order to use them for other purposes of better value. Rather than a sole focus on allocating new resources, it focuses on eliminating existing 'waste' in the system. These technologies may be effective and hence valued by patients and clinicians. They may, however, be poor value for money.

The notion of disinvestment makes obvious conceptual sense to ensure efficient resource allocation. In practice, however, removing or limiting currently available services, even if cost-ineffective, raises challenges. There is likely to be opposition from clinicians, interest groups, and patients if existing technologies, services, or facilities are no longer made available. Local citizens may give a higher value to services at risk, than to technologies they do not yet have, even if the latter deliver more health care than the former.

A recent HTAi Policy Forum discussion of the issue (Henshall *et al.*, 2012) concluded that the term 'disinvestment' was unhelpful. It was more helpful to think of a process of reassessment, followed by decisions of optimal use, followed by implementation of optimal use decisions. Implementation should be through Managed Exit strategies in the same way as Managed Entry strategies were considered for the introduction of new technologies.

Regional Collaboration in the Assessment of and Decision-Making about Value

As a growing number of jurisdictions request economic data in support of their decision-making procedures for the pricing and/or reimbursement of health technologies, demands on study sponsors and researchers increase, especially as the various national guidelines may insist on the presentation of local data, or the use of specific methods that are not required elsewhere.

There are several reasons (related to benefits, costs, uncertainty, and opportunity cost), why the value of health technologies might vary from place to place. The most important of these are (1) differences in population mix, including the incidence and severity (baseline risk) of the disease in question; (2) clinical practice patterns that may influence relative or CE by impacting on one or more of (a) the relevant comparator or existing SoC, (b) the effectiveness with which the patient is managed with the drug, and (c) the resources associated with current SoC or use of the new technology; (3) relative prices, and (4) the willingness of the health system to pay for the new drug.

However, the requirement that economic evaluations should use local data, or that particular methods should be used, means that analyses increasingly need to be customized for each setting. Transferability is a key issue and there is guidance on good research practices for dealing with aspects of transferability, including analytic strategies and guidance for considering the appropriateness of evidence from other countries.

As discussed above, methods to assess value can vary. There are, for example, differences as to (1) how health effects should be presented, notably in attitudes to the acceptability of the QALY and (2) the acceptability of evidence using indirect comparisons or observational studies. Together with the scientific issues and different WTP these put bounds on the potential for regional collaboration.

The most important attempt to date at increasing regional collaboration is the EUnetHTA project (www.eunethta.net) promoted and funded by the EU designed to produce a 'core' HTA template for an assessment that could potentially be used by decision-makers in several jurisdictions. Progress will depend on the extent to which there is agreement on common methods and requirements and on the extent to which evidence in one jurisdiction is relevant to another. In other words, real benefits from regional collaboration may come not only from methods of convergence but also if some data is transferable with little or no adaption required. This is an empirical issue for which there is currently little evidence. We might expect, however, the potential for common HTA assessments (using agreed methods and data generalizability) to be greater in the systematic reviews of the clinical efficacy data than in the economic evaluation component of assessing benefits and costs. EUnetHTA is exploring the potential for single RE assessments to be shared by EU Member State HTA bodies. The expectation is that (1) the translation of this evidence into an estimate of benefit, (2) prices and resource use (and therefore cost), and (3) the threshold WTP would vary by member state. Thus value decisions would remain local.

The final step in regional collaboration could be to make a common decision, as is currently the case for drug licensing within the EU. Some have argued for a new body making decisions on behalf of all EU Member States. There are scientific, practical, and political issues here. As noted, clinical practice may vary, with implications for the choice of relevant comparator and resource use. RE will depend on patient mix,

baseline risk, and the comparator. Cost-effectiveness is likely to vary between countries. Even where it does not, decision-makers in one country, faced with the same assessment of evidence, may still come to a different decision than those in another jurisdiction about use of the same technology. This is because countries have different levels of resource to devote to health care and different priorities. It would be efficient for prices to differ to increase availability across countries, although the use of reference pricing and parallel trade within the EU make this difficult. EU countries retain different health care systems, with the intent that access decisions will differ. It makes sense, however, to take advantage of economies of scale in information generation, whilst recognizing this does not require that the information is used the same way by different countries.

Regional bodies exist in other parts of the world – notably Asia (HTAsiaLink) and The Americas (HTA Network of the Americas (RedETSA)). However, they are at relatively early stages of collaboration, and there is even greater heterogeneity between the health systems of countries participating in the networks than between the member states of the EU. As in the case of the EU, however, it makes sense to take advantage of economies of scale in information generation, and to share institutional learning, whilst recognizing this does not require that the information is used the same way by different countries.

Value of Information Methods to Prioritize Research

R Conti and D Meltzer, University of Chicago, Chicago, IL, USA

Introduction

Value of Information (VOI) is an outgrowth of advances in Bayesian decision theory and welfare economics that seeks to quantify prospectively the benefits and costs of research and development (R&D) activities under uncertainty. VOI allows for the identification of sources of treatment uncertainty and provides a method to calculate the incremental value of pursuing research to inform clinical practice. This article provides details of the principles behind its estimation, and the different decisions it can inform. Some practical applications of VOI in research prioritization are considered.

Before exploring current applications of the method in detail, it is important for readers to appreciate why the development of economic methods to prospectively assess the value of medical R&D is important. Economists have long noted that economic growth in advanced economies is driven by the creation of innovative ways of producing goods and services, a process that triggers productive investments and allows its benefits to spill over from one country to others. Typically, these economies rely on the profit motives of private enterprises and capital markets to fund innovative efforts. Yet in some economic sectors, such as biomedicine, there is substantial public investment in R&D. According to economic theory, public R&D efforts should act only to complement private investments, where the expected social value is large, but expected profit is small. Economic work since Smith has suggested relief from premature morbidity and mortality offers significant individual and social value. Recent empirical work suggests that the spillovers from public investment in medical R&D to the private sectors' production of novel medical therapies and diagnostics are significant. Schumpeter (1942), Nelson (1959), and Arrow (1962), among others, are the first to articulate the view that R&D and innovative activities are difficult to finance in a freely competitive marketplace. The general argument goes as follows: the primary output of resources devoted to invention is the knowledge of how to make new goods and services, and this knowledge is nonrival so that use by one firm does not preclude its use by another. Moreover, if that knowledge cannot be kept secret, the returns to investment in knowledge cannot be captured by a firm undertaking the research investment, so that firms will be reluctant to invest, leading to under provision of R&D in the economy.

As a consequence, public policies that promote and underwrite innovation are centerpieces of national economic strategy. In the US, National Institute of Health (NIH) funding leads both the public and private sector as the single largest source of support for medical R&D. Within the NIH's purview are direct investments in intramural research, including basic science, preclinical and clinical medical studies, and extramural grants supporting university research efforts. Other advanced economies support medical R&D efforts along similar mechanisms.

And yet, over the past several decades, the unprecedented increase in healthcare expenditures throughout the world, and especially in the US, has prompted increasing concerns that current levels of healthcare expenditures are excessive. It has been suggested that medical care has been provided not only beyond where its marginal benefit exceeds its costs, but often into ranges where there is little or no benefit. The importance of determining when specific medical technologies are worthwhile has intensified with the growing recognition that increases in medical spending have been largely driven by the development and diffusion of new medical technologies. As a consequence, controlling healthcare costs will ultimately require controlling the development and diffusion of medical technology. In accomplishing this goal, reimbursement systems that provide both developers and users of new technology with the appropriate incentives to control costs and produce quality healthcare are essential. Similarly, it is critical to have tools and policies to prioritize investment in public medical R&D efforts.

Retrospective analysis of previous investments may provide useful information to inform assessments of future research endeavors. Recent empirical economic research suggests that improvements in health have been a major component in the overall gain in economic welfare during the plast century for the US, developed, and developing countries. Murphy and Topel (2006) have used cost-benefit analysis to estimate the overall value of medical research and the value of R&D for specific medical conditions. They have found that gains in US longevity due to advances in medical research since 1970 have had an aggregate value of $3.2T, a figure roughly equal to half of gross domestic product. Furthermore, programs aimed to expand public support for specific types of medical innovation, such as the 1970 declared 'War on Cancer' appear to have produced substantial gains in morbidity and mortality. For example, pediatric cancer patients in the US and abroad, and adult patients suffering from breast and prostate cancer, some forms of leukemias, have experienced substantial gains in life expectancy over the past 15–20 years and many believe that such efforts have a great potential to produce more success. Philipson and Jena (2005) have used cost-benefit analysis to estimate the net value of antiretroviral therapies for the treatment of human immunodeficiency virus infection/acquired immunodeficiency syndrome. They have found that patients gained substantial benefits (measured in survival) from the introduction of antiretroviral therapy. In addition, US patients diagnosed with cancer between 1983 and 1999 experienced greater survival gains than their European counterparts; even after considering higher US costs. These findings do not appear to have been driven solely by the earlier application of diagnostic methods.

Whether research funds underwriting these efforts are being allocated to the 'correct' opportunities, and whether the fruits of these investments are valuable at the margin, applied to specific patients, are important and complementary questions. For example, novel approaches to cancer have been a significant focus of public and private sector investment in the past 30 years. These investments are bearing much fruit – in 2012 alone, the Food and Drug Administration has approved 19 anticancer drugs and over 900 anticancer drugs are in various phases of preapproval testing, more than the number for heart disease, stroke, and mental illness combined. Yet, anticancer drugs also rank first in terms of total drug spending by therapeutic area: $23 billion in 2011, up from $18 billion in 2007. Global spending on anticancer therapies is projected to amount to $75–80 billion by 2015, more than any other therapeutic class of pharmaceutical products. Conti *et al.* (2013) have found that commonly used, novel chemotherapies are more often used onlabel than offlabel in contemporary practice. Total national spending on these chemotherapies has amounted to $12 billion (B; $7.3B onlabel, $2B offlabel and supported by additional clinical evidence and expert judgment, and $2.5B offlabel and unsupported by clinical evidence and expert judgment).

Both Congress and the National Institutes of Health have faced increasing pressures from disease specific interest groups in recent years to justify their decisions regarding medical resource allocation, and questions such as these have been sufficient concern to Congress that they have played a role in recent discussions regarding increased funding for research, and have led Congress to request the advice of the Institute of Medicine (IOM) on whether priorities for the allocation of funds at the NIH have been appropriate. Indeed, although the resulting IOM report did not conclude that medical expenditures to date have been allocated inappropriately, it did conclude that NIH should pay greater attention to the burden of illness in assessing research priorities. Building on this, others have suggested that the NIH could better identify the most promising projects if it capitalizes on the formal approaches to assess the burden of illness and opportunities for research to lessen this burden.

VOI is the most well-developed method based in economic theory and may have potential as a practical tool to assist decisionmakers in the process of identifying the value of specific medical technologies and the most promising avenue for future research. In the remaining sections, it is argued that VOI may have the potential to provide important insights into the value of medical research if applied in the right settings with methodological rigor and a thoughtful understanding of its underlying assumptions, strengths, and limitations.

A Review of Value of Information Analyses Applied to Clinical and Policy Questions

VOI has been increasingly used by researchers to inform stakeholders whether additional research would be worthwhile, and to demonstrate the benefits and feasibility of using such analytic methods to inform policy decisions within the timelines demanded by existing procedures. Illustrations of the potential value of the methods include applications to issues of resource allocation in neurology, oncology, and ophthalmology, clinical areas with high burden of disease and/or cost of care. For example, in neurology, VOI decision analytic methods have been utilized to determine the feasibility of magnetic resonance imaging (MRI) as a cost-effective approach to treating multiple sclerosis. The analysis was twofold. It was first determined that the cost of immediate MRI exceeded the cost of the expected value of perfect information. Next, advanced MRI technology had to be shown preferable to the fallback strategy of waiting, given a reasonable estimate of accuracy in MRI. A similar study was completed in orthopedics, utilizing VOI analysis to assess technological advancements in MRI technology to estimate the decision uncertainty that remained after a randomized control trial was completed.

VOI has also been proposed to identify and prioritize medical R&D in a number of clinical areas, where public investment in the later stages of novel therapeutic development has been significant. This interest requires VOI analyses to be calculated for some investment decisions from the public's perspective and with available data and a timely manner consistent with NIH's decision-making process. The idea is to incorporate economic decision analytic tools into trial consideration alongside scientific and trial design criteria to help ensure that public resources are spent efficiently and equitably. For example, in oncology, VOI methods have been analyzed to determine phase III clinical trial research prioritization, feasibility, and areas for greater investment into personalized therapies. Basu and Meltzer's (2007) analysis suggests that identifying cost-effective treatments at the individual level could be greater than 100 times the annual value of identifying the cost-effectiveness treatment on average for the population. In ophthalmology, a VOI analysis was completed to inform governmental health spending and technological priorities. The results of the analysis suggests that the expected value of perfect information (EVPI) could be implemented in a timely fashion to inform the type of research prioritization decisions faced by any healthcare system.

The current reporting standards in the VOI literature is for mean estimates of all stochastic and deterministic model parameters to be described. The uncertainty of the intervention should also be assessed based on the distribution of the incremental costs and incremental quality-adjusted life-years (QALYs) in the cost-effectiveness plane. Additionally, the assumptions underlying the approach should be enumerated. Similar to traditional cost-effectiveness analysis (CEA), typically, main analyses are undertaken with standard assumptions: the discount rate for benefits and costs accrued in the future is 3.5%, and the research findings have a 10 year life span. Sensitivity analysis should be performed to test these assumptions over a range of possible values drawn from the literature. For example, CEAs performed for private insurers tend to use an alternative discount rate that allows for both the timing of costs and revenues and the risk associated with the trial. One commonly used metric is to estimate the adjusted discounted rate based on the capital asset pricing model. The inclusion and exclusion of benefit and costs outcomes and the sources of this information in all analyses should be reported.

A critical practical challenge in the application of VOI methods is that the method has most often been performed by

constructing decision analytic models, which is very time consuming and, therefore, costly. More recently, VOI methods have been developed that use data from existing but often underpowered clinical trials to develop estimates of the value of more definitive trials, or an understanding of the conceptual basis of VOI to bound VOI estimates with even more limited information. Application of practical methods for VOI such as these will continue to be important in developing and validating VOI as a tool to provide timely guidance for decision-making with regard to medical R&D investments.

The promising areas of concern for future methodological advancement in VOI include the following:

1. Individualized care: VOI methods need to be expanded to understand how costs may be better internalized as to capitalize on the value of individualized care, utilizing an expected value of individualized care (EVIC) measure. EVIC is the expected cost of ignorance of patient-level preference heterogeneity and represents the potential value of research that helps to elicit individualized information on heterogeneous parameters, which can be used to make individualized decisions. The heterogeneity parameters of interest are random; hence, rather than larger samples, individualized elicitation will reveal the true values of these parameters. This measure is rather different than the EVPI, in which the parameters of interest have a fixed value in the population. Individualized care offers enormous cost savings, as the value of such may far exceed the value of improved decision-making at the group level; however, such benefits will vary immensely with insurance. EVIC can provide a guide as to when the high value of individualized care may make population-level decision-making especially at risk of providing poor guidance for coverage decisions.
2. Product lifecycle concerns: Despite advancements, uncertainty remains sufficiently high in some potential clinical application areas, hampering VOI calculations, and yet decision-making and research prioritization are required. Analytic methods must evolve further to address significant uncertainty in the potential costs and benefits of novel therapies over the lifecycle of the product. It is believed that questions regarding how risk and uncertainty should be assessed in policy decisions deserves more analytic consideration, because preferences concerning these dimensions are critical to decision-making. Meltzer et al. suggest that it may also be useful to distinguish between uncertainty in insured and uninsured costs in assessing the implications of uncertainty in costs in cost-effectiveness analyses and further characterizations of optimal decision-making when insurance is not complete. Further questions of uncertainty include assessments of the changing value of research due in part to technological or demographic changes.
3. Technological change: Standard CEA and VOI calculations assume a general and uniform rate of technological diffusion across technologies and diseases in clinical practice. However, recent work by Conti, Bernstein and Meltzer (2012) suggests that diffusion patterns of novel molecular-based therapeutics may not follow standard diffusion paths implicit in the standard assumptions of CEA, and may differ substantially from that of new therapies in other clinical areas. Progress on understanding the rate of technological advance across different clinical settings, as well as the product-level, provider-level, and patient-level determinants of this rate, are important inputs for next generation CEA analysis and VOI calculations. *A priori*, replacing standard assumptions with an empirical based model of technological diffusion alters the numerator and denominator of such estimates. How sensitive CEA and VOI calculations are to actual rates of practice that change across a variety of acute, emergent, and chronic disease settings are important subjects for future work.
4. Public versus private investments in research: Finally, future applications of VOI should explore the validity and applicability of the method to help guide decision-making in clinical areas where the public is the main funder of R&D, and also the major source of funding treatment purchases. In the US and other countries, funding for medical R&D, insurance coverage, access to new diagnostic methods and treatment modalities are not shared under the public government budget; rather, the presence of private insurance and private funding for medical R&D challenges the adoption of the social perspective in the widespread use of VOI to guide investment decision-making. VOI can be explored as a tool to guide decision-making in the US, where public monies are a main source of medical R&D, and the main source of insurance coverage and access, once new treatments are developed. The developing world are typically funded by government sources, sometimes in collaboration with experts in public health at the World Health Organization and the Gates Foundation. High profile and sustained gifts from the Gates Foundation in recent years have played an important role in vaccine development successes and in seeding the pipeline for more development in the near future. Recent economic work identifying financing barriers for underwriting R&D in this area have produced novel insights and new approaches to public policy incentives to either 'pull' R&D efforts from the private sector through the credible reward of research activities or to 'push' R&D through direct and indirect underwriting of the perceived costs of R&D and the delivery of vaccines to relevant populations. In this context, the use of VOI methods could be seen as an alternative push mechanism, one that public agencies and public-private partnerships use as a tool to invest funds wisely in the development of new vaccines.

Key Empirical Challenges

A number of empirical challenges are encountered in the practical implementation of VOI, for which practitioners should be aware of, when implementing these methods. First, the most fundamental ambiguity is how to best measure the benefits of a medical intervention. Although disease specific measures such as the number of cancer cases detected or cured may be useful in certain circumstances their effects on mortality (as measured by life years saved) have the advantage of comparability across diseases, they do not capture the important effects of medical care on quality of life. In some

empirical applications, analysts assume for analytical simplicity that quality of life is not a concern so that outcomes may be measured in life-years. This assumption likely provides a lower bound on the total benefits of treatment for some diseases. Yet, there are many clinical examples where including quality of life measurements into a fuller assessment of mortality and morbidity gains could decrease overall benefits of an alternative therapy; for example, if the side effect profile of a treatment that provides mortality gains is quite severe. Recognition of this has led to the development of the concept of QALYs. Using this approach, each year of life is weighted by a factor between 0 and 1, intended to reflect the quality of life in that year, where 0 is equivalent to death and 1 to perfect health. These quality of life weights are most commonly derived by psychometric techniques based on responses to hypothetical choices. Two common approaches to assessment can be fairly readily connected to neoclassical economics; these describe either choices between life with a given illness and a gamble involving life in perfect health and death, with some probability or choices between longer life with illness and a shorter life in full health.

There are also clinical situations where the benefits of alternative therapies that potentially affect morbidity and/or quality of life are not available. For example, quality of life may not be as outcomes in a phase II or phase III trial of novel therapeutic modalities for the treatment of some cancers. In these cases, an extensive literature review of other trials may produce some supportive data. Judgment is required regarding the likely effect of excluding these outcomes on the magnitude and direction of bias introduced into the VOI calculation. Additionally, even when more complete information regarding the impact of treatment on morbidity or quality of life outcomes are available, index QALY weights for these effects may not be available in the published literature for all illnesses and treatment modalities. This hampers the analyst's ability to capture the full range of potential effects of alternative treatments, and also limits the ability of the analyst to compare the full potential benefits of research into one area for research prioritization across alternative uses of supporting funds. When such values are available, it is important to perform a sensitivity analysis over a range of plausible values.

Challenges may also be encountered in the analysis due to the availability of data on the full health costs of alternative treatments. In many settings, treatment costs for standard of care and alternative therapies may not be available from clinical trial data collection efforts, prior studies or estimated using observational data. In addition, innovative therapies that alter the bundle of treatments provided to patients, including the use of diagnostic tests, the length and use of inpatient admissions and physician input, may substantially alter the costs of standard treatment protocols for some illnesses. Validation exercises may need to be performed using actual per person resource use collected on observation data. When the availability of short-term and long-term costs of treatment are lacking, the analyst may choose to ignore costs or perform sensitivity analyses over a range of plausible values. It is important to keep in mind that the dropping of costs from the VOI calculation altogether may be required for analytic convenience, but it limits the comparability of the analysis for research prioritization efforts.

Conclusions

This article provides a review of the rationales behind and the recent practical applications of economic methods to assess priorities in medical research and development. VOI is the most well developed set of tools based in economic theory and advanced cost-effectiveness analysis that could be used by analysts to construct measures of the potential gains from investing in further research. Although these methods have been recently applied to a number of challenging scenarios, the work required to move from what is theoretically possible to the practical application of these principles, to produce valid and reliable estimates of the value of research, involves a series of methodological and empirical challenges. Methodological challenges include the measurement of benefits and costs. Additional issues specific to VOI include developing meaningful priors concerning the parameters of decision models. This may often require extensive review of existing data, primary data collection or even, sometimes, analyses based on a variety of arbitrary priors. It may be difficult to determine priors for the likelihood that the research project will find a meaningful result. Whether it is possible to adequately address these challenges will be resolved through efforts to address these ideas empirically in a number of promising areas.

To apply these approaches to prospectively inform medical research and development decision-making, there are a number of additional and important analytic considerations. These include whether and when typical assumptions of uniform medical technology diffusion rates and discount rates for benefits and costs accrued in the future are justified. Future work in this area needs to empirically grapple with the possibility that the research may be less valuable over time, as other technological or demographic changes can arise that alter the management frequency or natural history of disease and the unpredictability of how the results of research might be useful in areas outside the initial areas of inquiry. These issues imply that the sort of formal analysis suggested here may be more likely used for evaluating clinical research rather than basic preclinical work. Such difficulties suggest that the practical development of VOI for identifying and prioritizing future research is important as one additional tool in the current and evolving armentarium of public research and development decision-making alongside scientific and biostatistical criteria.

Despite these concerns, the importance of making more informed decisions regarding the allocation of resources to medical interventions and medical R&D suggests that work in this area should be an important priority in health economics. It is important to keep in mind – even with evidence that some treatments may have little value at the margin, and with limited evidence of the connection between research and gains in health – health is a domain that people value very highly and at which great strides have been made in recent decades. There is ample reason to believe that such gains may continue in the future. Progress on methods, such as VOI, and the applications for work on the value of medical research and development as a complement to existing methodologies for prospectively evaluating the potential benefits of future investments, have a critical role in ensuring the sustainability of

medical spending and gains in mortality and morbidity that has been conferred by medical science over time.

Value-Based Insurance Design

ME Chernew, Harvard Medical School, Boston, MA, USA
AM Fendrick, Harvard Medical School, Boston, MA, USA, and University of Michigan, Ann Arbor, MI, USA
B Kachniarz, Harvard Medical School, Boston, MA, USA

Introduction

The US healthcare system has widely acknowledged problems with cost, quality, and access. Medical spending is higher than that in any other country, at 17.6% of GDP in 2009, and rising at a rapid rate; such a cost trajectory is unsustainable. Meanwhile, quality is often lacking, and lags behind that of many other nations (Table 1).

Among the most widely used strategies in recent years to address spending has been an increase in patient cost sharing. In addition to shifting the economic burden associated with healthcare from purchasers to patients, economic theory suggests that shifting more financial responsibility onto the patient should reduce wasteful overuse and decrease spending. Unfortunately, patients have been shown to make poor clinical decisions when faced with higher cost sharing by reducing the use of both unnecessary and essential services. Information asymmetry, time-inconsistent preferences, and the impact of marketing and cultural values, all contribute to inefficiencies created by shifting more decision-making power onto the patient. Although such programs inevitably lead to lower spending in the short run, they have been associated with poor adherence and outcomes, increased disparities across socioeconomic groups, and possibly higher long-term spending for some patients.

Value-based insurance design (VBID) was proposed in 2001 as a means to mitigate the negative impact of increased cost sharing and improve the efficiency of our healthcare system. VBID refers to insurance packages that align copays with value, charging patients less for high-value services and more for low value services. By focusing on value, rather than cost alone, VBID aims to improve quality, lower barriers to essential care, and perhaps, if copays are increased for low value services, to save money. VBID programs recognize that different services offer differing amounts of benefit for the money spent. More sophisticated versions can also recognize that value reflects patient traits and can recognize patient heterogeneity.

Most commonly, VBID lowers copayments for high-value services, like diabetes and asthma medications. Cost sharing for low-value services may be increased to help offset program costs and discourage use of low-value services, but this is less common.

Although the concept of VBID is relatively recent, emerging data point to its feasibility and effectiveness. VBID approaches have been successfully adopted by numerous employers with mostly positive clinical results. Both observational data and more systematic controlled analyses support the idea that VBID improves medication adherence and clinical outcomes, and may even lower overall spending. Because its greatest impact is on low-income individuals, it may also help reduce the widespread health disparities seen in the chronically ill.

Rather than a cure-all for our system's problems, VBID is a tool that should be integrated into other innovative approaches, including pay-for-performance (P4P), patient-centered medical homes (PCMH), consumer-driven health plans (CDHPs), and disease management (DM) programs. The ultimate objective of VBID is not to save money, but rather to maximize the health benefit achieved for the money invested; its goal of maximizing value-based limited resources is inherently aligned with that of our entire healthcare system. VBID is growing in popularity among employers, patients, and policymakers. It was included in the Patient Protection and Affordable Care Act (PPACA) and state legislation healthcare reform laws, and has been the subject of plans for new pilot programs within Medicare.

Theory

Consumers seek insurance in order to transfer the unpredictable risk of illness to others and gain access to otherwise unaffordable care. Health insurance helps individuals pool the financial risk of illness. As consumers are risk-averse, they would rather pay a certain fixed premium than risk the possibility of a very high expenditure. In addition, health insurance offers access to treatments that would otherwise not be obtainable. Regular premiums are generally more affordable than the large costs associated with major illness. Thus the benefits of insurance extend beyond risk avoidance to accessibility of care in case of a catastrophic event.

At the same time, insurance introduces moral hazard, which can reduce social welfare. Because the patient's cost of medical treatment is greatly reduced under insurance coverage, patients will utilize more services than they otherwise would. The amount of insurance-induced consumption depends on the price elasticity in demand. The welfare consequences of the extra consumption depend only on the portion of insurance induced over consumption due to the distortion of relative prices. Any extra consumption due to an implicit transfer of income associated with insurance is not a concern. Nevertheless, because insurance distorts prices, it induces greater use of services, necessitates higher premiums, renders health insurance less appealing, and reduces the value of the healthcare system.

Cost sharing has traditionally been used to transfer some risk onto the individual consumer and reduce moral hazard. A price above zero but below the market level allows some risk pooling, while reducing insurance-induced overconsumption. Theory suggests that because of their greater insurance-induced overuse, more elastic services should attract greater cost sharing, whereas inelastic services should be fully reimbursed. Under standard economic theory, because patients utilize services for which their perceived benefit outweighs the

Table 1

Setting	*Methods*	*Intervention*	*Conditions*	*Clinical effect*	*Financial effect*
Large firm independently offering DM and VBID options (Gibson *et al.*, 2011a, b)	VBID examined among DM participants and among those who opted out; comparison group consisted of enrollees not offered VBID	Lowered coinsurance from 10–35% tiered structure to 10%	Diabetes	Largest effect seen by combining DM with VBID; drug adherence increased 6.5% over 3 years	Combination of VBID with DM was cost-neutral, with higher drug costs, but lower medical spending
Large employer offering VBID within DM setting (Chernew *et al.*, 2010 Chernew *et al.*, 2008)	Difference-in-differences approach, using a large employer with same DM program as control	Copayments for generic drugs waived, and those for brand-name drugs reduced by 50%	ACEIs, ARBs, beta-blockers, diabetes, statins, and steroids	7–14% reduction in nonadherence for all drug classes except steroids	Possible savings from societal perspective, but less likely for employer. Medical spending would need to drop 9–17% to break even overall, and 29–48% to break even for employer
Pitney Bowes, a large US employer (Choudhry *et al.*, 2010)	Interrupted time series with concurrent control group; commercially insured enrollees with same pharmacy benefit manager were used as controls	Mean copayment for statins decreased by 97%, and that for clopidogrel decreased by 25%	Statins, clopidogrel	Adherence increased by 2.8% for statins; adherence to clopidogrel decreased by 4% in control group, but remained stable in VBID group	
Large pharmaceutical firm (Gibson *et al.*, 2011a, b)	Retrospective, observational with matched comparison group from peer firms	Retail prescription coinsurance lowered from 20% to 10%; Mail-order prescription coinsurance lowered from 10% to 7.5%	Asthma, hypertension, diabetes	Medication adherence rose 5% across all enrollees, and 9.4% for hypertension drugs after 3 years	Entire program was cost-neutral; hypertension patients realized savings of $3700 per enrollee in third year
Over 20 000 enrollees from three CVS Caremark clients who implemented VBID plans (Chang *et al.*, 2010)	Retrospective prepost controlled study	Eliminated insulin and generic drug copayments, and reduced preferred brand copayments from US$30 to US$10–15	Diabetes	Compared to the control group, VBID increased treatment initiation rates by 44% and lowered discontinuation rates by 13–34%. Mean medication possession ratio increased by 4.9% in VBID group, but dropped by 2.3% in control group	
Pitney Bowes, a large US employer (Mahoney 2005, 2008)	Observational with no control	Lowered coinsurance from 25–50% tiered structure to 10%	Asthma, diabetes, and hypertension	Use of medication increased by 35–144%, and ED visits dropped by 22–26%	Pharmacy costs decreased by 7% and overall costs decreased by 6% for diabetes patients; pharmacy and total costs decreased by 19% and 15% respectively for asthma patients

(*Continued*)

Table 1 Continued

Setting	*Methods*	*Intervention*	*Conditions*	*Clinical effect*	*Financial effect*
All adults on cholesterol-lowering therapy (Goldman *et al.*, 2006)	Simulation based on results from retrospective analysis of claims data	Eliminated cost sharing for high- and medium-risk patients, but raised copays from $10 to $22 for low-risk patients	Cholesterol-lowering therapy	Adherence rose by 9–10% in patients with full coverage, but dropped by 8% in low-risk group	No change in total pharmacy spending, with a potential $1 billion in savings from reduced hospitalizations and ED visits nationwide
All Medicare patients (Rosen *et al.*, 2005)	Markov model using literature and Medicare claims data	Full coverage of medications	ACEIs	Assumed adherence increase from 40% to 60%	Program would break even with a 7.2% increase in adherence
Widespread application of VBID to pharmacy benefits and other services (Braithwaite *et al.*, 2010)	Computer simulation	Eliminated cost sharing for high-value and increasing cost sharing for low-value services	All services	VBID would increase benefit of healthcare from 4.7 life-years to 4.73 life-years if applied to drug benefits, and 4.95 life-years if applied to all other services as well	Assumed to be cost-neutral
Medicare beneficiaries (Choudhry *et al.*, 2008)	Markov cost-effectiveness model	Provided full coverage drug therapy to postmyocardial infarction patients	Aspirin, beta-blocker, ACEI or ARB, and statin	Survival after initial event increased from 8.21 QALYs to 8.56 QALYs	Reduced overall spending by $2500 per patient, with cost-savings even if assuming only a 1% increase in adherence. Program was cost effective, but not cost-saving from Medicare perspective.

Abbreviations: ACEI, angiotensin-converting-enzyme inhibitor; ARB, angiotensin receptor blocker; DM, disease management; ED, emergency department; VBID, value-based insurance design.

cost, higher price will reduce consumption disproportionately for low-value services, which will preserve value in the healthcare system.

Across-the-board copayment increases typically do not take into account differences in benefit of different treatments. The expected benefit of a therapy should be inversely proportional to the elasticity of demand, and thus copayment requirements prevail. An essential medical service should have an inelastic demand, and be covered fully by insurance. Most traditional benefit plans only take into account the cost, not benefit, of a service when determining the degree of cost sharing. Such plans also fail to appreciate patient heterogeneity; a single service might have a different benefit and elasticity for different patients depending on the clinical diagnosis. For example, beta-blocker therapy may play a vital role in the management of heart failure patients, or be used more electively in the treatment of anxiety. Differences in risk and outcome preferences among patients further contribute to patient heterogeneity, rendering indiscriminate changes in copayments suboptimal because too much risk is being transferred for inelastic services.

Yet, if patients do not make optimal decisions, placing more risk and decision-making power in their hands may have detrimental effects. As patients are risk-averse, such increased cost sharing reduces the value of the insurance plan. In addition, patients often misjudge the costs and benefits of medical therapies, and make poor clinical decisions. Inherent information asymmetry between patient and provider may lead to underuse of essential services and suboptimal resource allocation. The physician has limited information regarding patient preferences, values, and history. Likewise, patients often fail to fully understand medical information, or are otherwise influenced by external biases like marketing. They lack the clinical training to completely comprehend underlying principles and make objective decisions. Physicians typically have years of experience and better ability to predict disease progression. Similarly, patients' time-inconsistent preferences may bias their clinical decision-making. Individuals tend to undervalue future benefits and prospective cost savings. These phenomena contribute to underutilization of valuable services, increased overall medical spending, and poor outcomes, particularly in chronic disease patients like diabetics or asthmatics.

Higher copayments further tend to have a greater impact on low-income patients, contributing to healthcare disparities. These populations already face significant barriers to essential care, which are only exacerbated by increased cost sharing. Patients with higher education and better understanding of their care are also more likely to make better clinical decisions. The increased responsibility and financial risk associated with increasing copayments places an unnecessary burden on less affluent populations, and tends to preferentially worsen their health outcomes

VBID addresses these problems using a 'clinically sensitive' approach to align financial incentives with value in the healthcare system. It recognizes that if decision-making is flawed, the amount of cost sharing should depend not only on the cost, but also on the evidence-based benefit of a therapy.

Defining value in the context of VBID programs is complex. Conceptually, value relates to the cost effectiveness of a given service for a given patient (health gained per dollar spent). The growing emphasis on cost effectiveness and comparative effectiveness research can support efforts to assess value and implement VBID. But it is unlikely that evidence will be detailed enough to be tailored to specific patients so most VBID programs will be applied on average for groups of patient remain. The crucial assumption is that fully informed consumers, given the economically efficient income transfer associated with insurance, would purchase these services even if they faced the true prices. In cases of high-value (e.g., highly cost effective) services, increased consumption does not represent moral hazard, and thus should not be financially discouraged. This principle is also in line with standard economic theory. Essential high-value care should have price inelastic demand (once implicit income transfers associated with insurance are taken into account), and thus little or no required cost sharing.

VBID ultimately employs evidence-based medicine to reinforce the financial incentives of using high-value care. It addresses the inherent information gap between patient and provider, and may even offer benefits beyond those of patient education for underused services. Lower cost sharing would increase consumption, improve health outcomes, and possibly even reduce long-term healthcare costs. Through lower copays, a value-based benefits design not only encourages optimal utilization of cost-effective services, but also offers a greater degree of risk protection to the consumer.

The overall financial profile of VBID initiatives can be favorable, particularly if cost sharing is increased for low-value services, and depends largely on the disease state being targeted. Services that have elastic demand and reliably prevent expensive complications that are highly likely to develop otherwise, tend to be best candidates for copay reductions. Increased cost sharing for such services might reduce short-term spending the form of lower utilization, but will likely accrue higher long-term costs through increased complications. Conversely, VBID may save money and improve outcomes in such cases.

Although VBID may reduce aggregate healthcare spending by avoiding expensive exacerbations and complications, the financial impact on the employer is less obvious. Employers face increased initial spending due to more generous coverage of high-value services, and greater demand for those services due to improved adherence. Employers take on increased medication costs, and might not be able to reap the savings if they have high employee turn-over rates. As an example, promoting the use of statins will likely increase short-term spending for the employer. A significant part of the savings in the form of avoided complications might go to Medicare once the patient retires. As long as health insurance is largely employer-based, there will be an inherent divide between employer healthcare spending and aggregate spending on a population level.

Nonetheless, some of these employer costs may be offset by savings on other medical spending, such as hospital or emergency department visits. Increased productivity, employee satisfaction, and decreased disability also contribute significant value to the employer. The return on investment will largely depend on the degree and accuracy of patient targeting. Programs that offer copayment reductions for very specific

patient populations and specific medications will tend to have more attractive financial profiles. Although not a major part of VBID, increased cost sharing for other, preferably low-value services, may further help reduce implementation costs. Above all, it is vital for employers to appreciate the often overlooked value of improved productivity and lower disability. VBID will offer greatest financial benefits where the patient population is responsive to changes in cost sharing and expensive complications may be reliably prevented using cheap medications. This is true of many chronic diseases, such as diabetes or asthma, which have been the first targets of VBID programs. VBID principles may be extended to other high-value therapies as well. Nonetheless, it is important to recognize that increasing the use of cost-effective services will not in itself be cost-saving. The chief benefit will be improved efficiency and value of the healthcare system, with reductions in spending possibly requiring increased cost sharing for low-value services.

By lowering copayments for high-value services, VBID may support a number of other health system reforms, including pay-for-performance, patient-centered medical homes, and CDHPs. Both P4P and PCMHs are supply-side interventions that encourage evidence-based medicine and improve access to high-value care. These programs allow clinicians to claim a portion of savings from reduced medical spending and offer financial rewards for improving outcomes. Similarly, VBID offers patients a financial incentive to pursue lower-cost higher-value therapies in the form of reduced cost sharing. VBID naturally complements P4P and PCMHs by aligning patient and provider incentives. DM programs would likewise benefit from value-based benefit designs. DM utilizes a variety of strategies, including patient education and coaching, to encourage high-value care. Patients are often given easier access to doctor visits and relevant medications. Reducing copayments for these drugs naturally complements DM initiatives by reducing the financial barriers to care. Like VBID, CDHPs emphasize consumer incentives to improve value and curtail costs. However, CDHPs significantly increase patient cost sharing for all services below the deductible with likely reductions in the use of both low-value and essential care. Implemented together, these programs would promote cost-conscious decision-making while encouraging use of high-value care. For example, the use of 'VBID waivers' for certain services would mitigate the negative impact of higher cost sharing in CDHPs. Applying VBID principles to subsidize high-value services would increase their use and improve efficiency within the healthcare system.

Although drug benefits are a very natural application of VBID, the concept may be extended to other health services. As an example, it has been proposed that the field of oncology would be a natural candidate for VBID implementation for several reasons. Different therapies will offer varying degrees of benefit for patients; whereas some treatments add years of life, some might only extend survival by a few weeks. The benefit of one drug may also depend on the diagnosis. Although the same chemotherapy or radiation might be used for many different cancer types, some will be more responsive to the therapy than others. Finally, the expected value of a treatment often depends on the particular patient. Biomarkers may be used, as in the case of breast cancer, to identify patients likely to respond to certain therapies. Oncology would naturally benefit from evidence-based targeting to encourage use of high-value services. In parallel, gastroenterology has also been proposed as a possible target for VBID. For example, a colonoscopy will rather have different value for a high-risk or elder patient, than for a young patient seeking the same procedure. The basic principles of targeting and adjusting copayments according to value of a service may be applied in a variety of clinical situations, ranging from drug benefit design to oncology and gastroenterology.

Practitioners

Over the past decade, VBID has grown steadily in popularity, and by one estimate is currently utilized in some form by 20–30% of large employers. It has garnered significant support for its adaptability, depending on employer goals and the patient population. The basic principles of VBID may be applied for any balance between improved employee health and reduced spending. In practice, it is impossible to achieve perfect targeting and evaluate the value of each service for every patient. A balance must be struck between program effectiveness and feasibility, often limited by availability of evidence-based data, accurate assessment of patient's clinical condition, and health information technology. To address these issues, several approaches for implementing VBID have been used that target patients based on service, condition, condition severity, participation in other health programs, or a combination of them.

One approach is to simply reduce cost sharing for certain drugs and services that are deemed to be of high value. All employees would face the same copayments, irrespective of clinical diagnosis or use of the therapy. Pitney Bowes and Marriot have adopted such a solution for diabetes, hypertension, and asthma medications. Pitney Bowes was among the most widely celebrated employers of VBID; although there was no external control, it reported $1 million in savings after introduction of the program in 2002. Most importantly, the program has received widespread attention and has demonstrated that VBID is feasible and may be effective.

Another possibility is to target a specific patient population and offer reduced copayments for high-value evidence-based treatment. Patients with a specific condition would be eligible to participate and receive free or subsidized care. Such programs typically target chronic diseases with known evidence-based therapies, including cancer, cardiovascular disease, obesity, respiratory conditions, and diabetes. The University of Michigan, MI, USA, is among the first to utilize this approach. All employees with diabetes are eligible to enroll and receive subsidized insulin, beta-blockers, diuretics, and other high-value medications. Started in 2009, the University of Michigan Focus on Diabetes Program is the first prospective controlled trial of VBID, and will likely shed light on its effects on outcomes and spending. The city of Asheville in North Carolina and United HealthCare have used a similar approach to target diabetes.

Less commonly used approaches include targeting high-risk patients either eligible for, or actively enrolled in, a DM program. These patients would likewise receive reduced or waived copays for certain medication classes. This design is

offered by WellPoint, although it has not been widely adopted by its clients; Gulfstream offers subsidies for utilizing providers that meet certain evidence-based care criteria. Other major providers using VBID include Caterpillar, Service Employees International Union, Mid-America Coalition on Health Care, and Health Alliance Medical Plans (HAMP). Each company targets different combinations of chronic diseases, depending on the employee population and claims data. Employers may fine-tune their VBID implementation to reach a desired level of medical costs and employee health. Many providers had incorporated VBID into more comprehensive novel healthcare delivery systems. Hannaford Brothers, for instance, combined VBID targeting certain diseases and minimally invasive surgical procedures, with promoting healthy lifestyle habits and better information technology. All available results point to improved drug adherence and outcomes, especially for diabetes and hyperlipidemia.

Finally, there are increasing calls on the government to promote the adoption of VBID, and include it in any healthcare reform laws. The American Academy of Actuaries recognized the importance of VBID and recommended that any new legislation do not discourage its implementation. The government should also continue investing in comparative effectiveness research (CER) and health information technology (HIT) as means to improve value and clinical outcomes in the healthcare system. Unlike many other interventions, VBID has garnered bipartisan support, with 73% of healthcare leaders generally in favor of its adoption. VBID has the benefit of offering important financial incentives without limiting patient choice. By targeting primarily high-value services, patients are encouraged to pursue valuable care, but are given the freedom to access other services as well. In addition, it avoids placing physicians into the role of healthcare gatekeepers, and maintains low administrative barriers to care. VBID has gained support from patients, providers, and payers, by aligning their incentives.

Accordingly, VBID has gained much attention among policymakers. The PPACA includes language permitting the use of VBID for high-value preventive services, such as immunizations and screenings (2010). As required by the new law, the Department of Health and Human Services has devised a National Strategy for Quality Improvement in Health Care, which promotes the use of VBID models at the federal level (2011). Similarly, there has been interest in using value-based principles to improve the financial profile of Medicare. There have been proposals to introduce a VBID pilot program for Medicare to evaluate its effectiveness. More recently, the Medicare Payment Advisory Commission (MedPAC) report to Congress has underscored the importance of using VBID to steer patients toward higher-value services. President Obama has likewise included VBID in his Deficit Reduction Plan, and has called for vesting the Independent Payment Advisory Board with power to promote value-based benefit designs (2011).

Empirical

Patient cost sharing has been steadily on the rise over recent years, in an attempt to curtail growing healthcare spending. Between 2000 and 2009, the average generic, preferred, and nonpreferred prescription drug cost sharing increased by 25%, 80%, and 59%, respectively. Paradoxically, copayments have also risen both within DM programs and for services used as quality indicators. As DM programs implement innovative approaches to encourage use of essential services and improve adherence, rising copays discourage the consumption of those same therapies. Likewise, services accepted as high-value and used as quality measures for hospitals often lack demand-side financial incentives. Indicators contained within the Health Plan Effectiveness Data and Information Set (HEDIS) have suffered increases in copayments similar to that of other services. HEDIS is widely used to evaluate health plan performance and includes measures such as receipt of beta-blockers after a heart attack and treatment of asthma. Higher cost sharing for HEDIS services may lower health plan performance.

Further, there are significant data demonstrating the effects of greater cost sharing on adherence and outcomes. Many studies have shown that patients tend to indiscriminately cut use of both essential and low-value services when faced with greater copayments. Even vital medications, like those used for hyperlipidemia, rheumatoid arthritis, diabetes, and asthma, suffer the effects of increased cost sharing. Doubling of copayments for diabetes and hypertension drugs has decreased medication use by 23% and 10%, respectively. This is particularly alarming, considering that many crucial services are widely underutilized by patients. The resulting decreased adherence often leads to poorer outcomes and higher rates of complications. This has been particularly evident in the case of asthma, diabetes, and cardiovascular disease. Under some circumstances, increased cost sharing may actually raise long-term costs by increasing the incidence of expensive and preventable complications. Importantly, the effects of increased cost sharing have the greatest impact on low-income patients. These patients are more likely to delay treatment due to cost concerns; for example, higher out-of-pocket expenses are also associated with more frequent asthma exacerbations in children of low-income families. The higher incidence of chronic illnesses like diabetes and asthma, combined with the effects of increased copayments, contributes to worse outcomes in these populations with resulting greater health disparities.

There is less evidence regarding the effects of lowering copayments, which is the principle instrument of VBID. The impact of lower cost sharing might be different than that of higher cost sharing because of psychological phenomena, but in practice, it is generally similar in magnitude. Some indirect data had come from the introduction of Medicare Part D, which lowered out-of-pocket drug spending for seniors. There was a 3–13% increase in medication use, with the opposite effect seen in the coverage gap. This corresponded to improved outcomes and a 4.1% reduction in hospitalizations relating to diabetes and several cardiovascular and pulmonary conditions. The effects of Medicare Part D were largest for patients with previously high copays or no coverage. In this subgroup, savings on medical expenditures generally offset increases in drug costs. In other settings, it has been observed that lower cost sharing for diabetes patients is associated with better adherence and better glycemic control, as measured by the degree of hemoglobin glycation. Fixed-effects modeling further suggests that lower medication copayments may lead to

higher pharmacy benefit costs, but significant overall savings in congestive heart failure, hypertension, diabetes, and dyslipidemia patients.

Direct evidence on the impact of VBID programs is relatively recent; the concept of VBID is fairly new, and it takes years to see long-term outcome and spending effects. The data are also more heterogeneous because the programs' impact largely depends on the particular implementation. Results that are not peer-reviewed and lack a control group suggest that the experience has been generally positive. Pitney Bowes had boasted of one of the first widely celebrated programs. Caterpillar, Hannaford Brothers Company, United Healthcare, and others, reported similarly improved outcomes with no change in, or reduced, spending. Controlled studies and more systematic analyses are fewer, but offer important, often less positive insights into the consequences of VBID programs.

Earliest data on the effects of VBID come from several mathematical models. A very broad implementation targeting various high-value services throughout the healthcare system would confer an additional 5–9% health benefit, as measured in life-years, without increasing overall or out-of-pocket spending. Better targeting of high-value therapies, such as angiotensin-converting enzyme (ACE) inhibitors or cholesterol-lowering drugs, offers even more advantages. Simulation analysis suggests that eliminating cost sharing for ACE inhibitors for Medicare patients with diabetes would both improve outcomes and lower costs by up to US$1600 per patient. Adjusting copayments for cholesterol-lowering therapy based on the patient's risk level would offer similar benefits. Thousands of hospitalizations and emergency department visits would be avoided, with over US$1 billion in annual aggregate savings. These simulations are particularly sensitive to estimates of the impact of lower cost sharing on adherence. Nonetheless, even with conservative assumptions, VBID is expected to confer clinical benefit with little change in spending.

More recently, there have been emerging data from employers implementing VBID principles. Analyses of two large firms with VBID options had demonstrated improved adherence and outcomes, with potentially neutral effects on aggregate spending. The financial impact on the employers was somewhat less favorable, but some of the cost could be offset by improved employee satisfaction and productivity. Both the State of Maine and the City of Springfield in Oregon had initiated pilot programs that targeted diabetes patients. In addition to waiving copayments for drugs and physician visits, the latter program also provided free individualized pharmacist consultations. Compared to randomly chosen controls, patients in the intervention group in each case had improved medication adherence and had better glycemic control. Sick leave had declined and productivity had improved for both programs. Although Maine reported significant savings, Springfield's healthcare costs had actually increased. Nonetheless, it is possible that savings in the form of employee productivity and reduced disability have helped offset any program costs, and long-term savings are likely to accrue beyond the timeframe of the initial study. Both pilot programs were considered a success, with VBID options becoming more widely available soon thereafter. Overall, these data demonstrate the varied consequences of VBID implementation. The financial profile will largely depend on the level of targeting, patient population, and other employer-specific parameters. Nonetheless, there is consistent evidence that VBID improves clinical outcomes and value of the healthcare system; by promoting the use of high-value services, it offers improved employee health and productivity. These indirect benefits are often overlooked in cost-effectiveness analyses.

VBID has also been applied in the context of DM programs and patient-centered medical homes, with very positive results. Although both DM programs and VBID improve medication adherence, a combination of the two strategies offers further benefits. Within a single DM program, VBID had increased medication adherence by 7–14% for statins, ACE inhibitors, beta-blockers, and diabetes medications. In a separate study, a combination of DM and VBID to target diabetes patients had proved to be cost-saving and improved drug use by almost 7%; these effects were significantly better than controls in either program alone. Similarly, several employers have combined VBID with PCMHs. Among others, the City of Battle Creek in Michigan and the State of Minnesota have reported positive results using this approach. Various performance measures have greatly increased by at least 20–35% following introduction of the programs. Patients have received more preventive care, and have avoided both expensive hospitalizations and emergency department visits. Blood pressure, glycemic control, and cholesterol levels have improved by 5.7–22%. Other examples further reinforce the benefits of integrating VBID into innovative payment reform approaches. Although effective on its own, VBID may be easily and effectively combined with other strategies.

Conclusion

As the persistently growing healthcare spending is addressed, it is important to maintain a focus on value and not cost alone. The purpose of healthcare is not to save money, but to provide the greatest health benefit given limited resources. Limiting access to essential care might save money, at least in the short term, but is not socially desirable. Further, focusing on shortsighted interventions like indiscriminate increases in copays may actually have opposite effects on spending in the long term. Curtailing spending should not be at the expense of reducing essential high-value care. VBID is an important approach that aims to improve the value of the healthcare system, as well as reduce barriers to essential care and health disparities.

Nonetheless, there are some challenges that lay ahead of a more widespread acceptance of VBID. Patients might have concerns of privacy and fairness. Different patients might be charged different fees for the same service. Some of the patients' clinical data are also used for benefit design. Nonetheless, most of these issues may be addressed through patient education and careful program design. Another major challenge to VBID implementation is a lack of CER and HIT infrastructure. VBID relies on CER to identify high-value services; there are currently few studies that compare the effectiveness of competing therapies. Likewise, HIT is necessary to incorporate the data from CER into benefit design. Nonetheless, there are known high-value therapies for the treatment

of many chronic diseases, and HIT is adequate for basic targeting. In these areas, VBID could be implemented successfully. As there iscontinuous expansion in targeting capabilities, opportunities for VBID will expand.

Employers have also been cautious in adopting VBID because of its somewhat uncertain financial impact. The return on investment profile of VBID largely depends on the particular implementation. Employers can improve the financial profile of their program by finer targeting. Reducing copays for a smaller group of high-risk patients is more likely to reduce program costs. Employers may also choose to raise copays for all other services, or preferentially target low-value services, though it may be difficult to identify low-value services based on easily identifiable patient characteristics. Few treatments are low-value for entire patient groups, requiring more sophisticated targeting and incorporation of clinical judgment. Another concern of VBID is that such plans might preferentially attract sickest patients who would receive lower copays for high-value services targeted at chronic disease.

The success of VBID will require a new mindset of simply embracing value over costs. After allocating the most efficient amount of resources to healthcare, the health benefit to patients will need to be maximized. This will also call for more comprehensive ways of assessing costs, benefits, and value than the often shortsighted methods being used today. Such a new approach to insurance design will require an integration of clinical medicine, economics, and actuarial analysis. The feasibility of VBID will grow with continued investment in CER and HIT. As new data become available on the relative value of services, it will be crucial to align financial incentives with the highest-value options. The recent growth of HIT will also make better benefit design feasible. As communication between patients, providers, and insurance benefit managers improves, better plans that align incentives between the parties will become a reality.

Although not a sole remedy for the healthcare system's issues of cost, quality, and access, VBID is a powerful tool that aligns financial incentives for patients with evidence-based medicine. By adjusting cost sharing based on the value of a service in the context of a particular clinical situation, VBID can facilitate more efficient resource allocation and better health outcomes. Integrated with other approaches, including DM, CDHPs, and patient-centered medical homes, VBID may prove to be a powerful tool for tackling major health care reform in the coming years.

Introduction

Cost-effectiveness analyses of health interventions and policies are often conducted using quality-adjusted life-years (QALYs) as the metric for quantifying health outcomes. A related metric called disability-adjusted life years (DALYs) has been used to assess the burden of disease attributable to different causes as well as in cost-effectiveness analyses, especially those in low- and middle-income settings. Both QALYs and DALYs provide summary measures of health outcomes that (1) combine information on survivorship and the health experience among the living; and (2) accommodate comparisons across diverse types of health problems by expressing outcomes in a common 'currency'. A critical feature of DALYs and QALYs is that they attach weights to time spent in different states of health to reflect the relative severity of these outcomes. These weights have been called, among other names, 'health state valuations,' 'health-related quality of life weights,' and 'health utilities,' with some associated variation in the interpretation of the meaning of the weights; in this article, these will be referred to as 'health state valuations.' Health state valuations are given on a scale that ranges from 0 to 1.0. For QALYs, 1.0 implies a state of optimal health and 0 implies a state equivalent to being dead, whereas for DALYs, the scale is reversed: 0 implies no health loss, whereas 1.0 implies severity equivalent to being dead. For use in QALY and DALY calculations, health state valuations must have interval scale properties, that is, differences between two values on the scale must be meaningful, with a given distance between two scale values having the same significance, no matter where the points are located on the scale. For instance, the difference between 0.4 and 0.6 must be understood as equal to the difference between 0.7 and 0.9.

Various methodological and empirical issues relating to health state valuations have inspired a rich and growing literature. The focus of this article is on techniques for eliciting valuations. Where other relevant topics are mentioned, cross-references are provided to those articles in which these topics are treated in greater detail.

Overview of Techniques

There are six types of techniques that have been used prominently in eliciting health state valuations.

Standard Gamble

The standard gamble is a method that has its theoretical basis in the von Neumann–Morgenstern axioms of expected utility theory. It aims at measuring the 'disutility' of a health state by observing the willingness to accept a certain risk of death in order to avoid the state. In a typical framing of the standard gamble, a respondent is asked to consider a choice between two alternatives. In alternative A, the person would live with a particular health problem (the one for which the valuation is needed) with certainty, for the remainder of his or her life. Alternative B is usually characterized as a risky treatment, with two possible outcomes: life in a state of optimal health, with probability p, or immediate death, with probability $(1-p)$. The measurement objective for the standard gamble is to identify the probability of optimal health, p, at which the respondent is 'indifferent' between alternatives A and B, in other words, the point at which the two alternatives seem equally attractive. Once this indifference point is identified, a health state valuation for the particular health problem of interest is equal to p. The logic of this inference derives from setting the utility of optimal health to 1.0 and that of death to 0 and assuming that at the point of indifference, the respondent considers the expected utility of alternatives A and B to be the same. In mathematical terms, the equality is stated as $p \times \mathrm{U(optimal)} + (1-p) \times \mathrm{U(death)} = \mathrm{U(health\ \ outcome)}$, or $p \times 1.0 + (1-p) \times 0 = \mathrm{U(health\ outcome)}$, which simplifies finally to $\mathrm{U(health\ outcome)} = p$.

Time Trade-Off

The time trade-off is another of the most widely used methods for eliciting health state valuations. Like the standard gamble, it invokes the notion of willingness to sacrifice something that is valued in order to avoid an inferior health state. In the standard gamble, what is sacrificed is the certainty of survival, whereas in the time trade-off, what is sacrificed is the length of life. The time trade-off asks respondents to consider a choice between two alternatives. The first is to survive for a specified amount of time, t_1, with a particular health problem, followed by death. Different time trade-off studies have taken different approaches to defining t_1, including using an arbitrary duration such as 10 years or using the respondent's estimated life expectancy (or some rough approximation to this). The second alternative in the time trade-off is to survive a (presumably) shorter amount of time, t_2, but in optimal health. The measurement approach in the time trade-off is usually to hold t_1 constant and vary the amount of time t_2 until the indifference point is identified. A health state valuation may then be computed as the ratio t_2/t_1. The logic of this inference, similarly to the standard gamble, is to equate the overall value between the two alternatives at the respondent's indifference point. In case of the time trade-off, the value of an alternative is taken to be the product of its health valuation and its duration. Thus, the indifference point implies the equality $\mathrm{U(health\ outcome)} \times t_1 = \mathrm{U(optimal\ health)} \times t_2$. Again taking the valuation of optimal health to be 1.0, this simplifies to $\mathrm{U(health\ outcome)} = t_2/t_1$.

 doi:10.1016/B978-0-12-375678-7.00502-2

Rating Scale

The rating scale approach comes from psychometrics. In contrast to both the standard gamble and time trade-off, it consists in eliciting a numerical valuation for a health outcome directly, without invoking the notion of sacrifice. A series of health outcomes are often simultaneously located on a numerical scale such that a respondent evaluating outcomes A, B, and C must consider whether A is preferable to B, B preferable to C, and A preferable to C, and also to decide the strength of these preferences, in other words the distances between them on the numerical scale. A number of different ways of operationalizing a rating scale are possible but most feature a straight line with marked intervals (like a meter stick), with the endpoints marked with numbers (e.g., 1.0 and 0 or 100 and 0) and labels referring to the best outcome (e.g., as 'perfect health' or 'best imaginable health state') and the worst outcome (e.g., as 'worst imaginable health state' or 'dead'). Sometimes the marked intervals are accompanied by numerical labels. Rating scales can also be constructed without marked intervals, in which case they are called 'visual analogue scales.' In practice, the latter term is sometimes used in a generic way that includes both marked and unmarked scales. There has also been variation in practice concerning the range of the scale. If researchers want to accommodate states that are regarded as worse than being dead, then the scale spans from the best to the worst imaginable outcomes, and respondents are asked to locate 'dead' on the scale amidst one or more nonfatal outcomes. Issues around states regarded as worse than being dead are mentioned in the Section on Key Conceptual and Methodological Issues. Typically, health state valuations are derived from rating scales by taking the ratio of the distance between a particular state and the point on the scale assigned to 'dead', divided by the distance between the upper endpoint of the scale (the best outcome) and the point assigned to 'dead.'

Magnitude Estimation

Another technique that arose, like the rating scale, from the direct measurement tradition of psychometrics is magnitude estimation (sometimes called 'ratio scaling'). In this approach, a respondent is given one health state as a reference benchmark, and then asked to indicate how many times better or worse some other states are compared with the reference state. Sometimes, the reference state has been defined as an endpoint of the scale (e.g., the most desirable outcome), although other studies have chosen an intermediate state as the reference. For example, a seminal magnitude estimation study by Patrick *et al.* (1973) anchored comparisons to a reference item describing 'a day in the life of a person who was as healthy as possible on that day,' which was assigned an arbitrary score of 1000. Other days were to be scored in relation to this reference, for instance, the instructions noted that a day that was regarded as 'half as desirable as the standard' should be scored at 500. Based on this scheme, results may be rescaled to the unit interval simply by dividing the scores by 1000. In fact, by translating the ratios into scores in this way, the operationalization of the task comes to bear a strong resemblance to the rating scale. Another influential magnitude estimation study by Rosser and Kind (1978), anchored the comparison task with the second best outcome (no disability and mild distress) as the reference, and asked respondents to indicate how many times worse other states were compared with this reference. In this case, rescaling of the results depended on normalizing the scale, so that the best state had a value of 1.0 and death a value of 0. Thus, if death were regarded as 200 times worse than the reference state, this would result in the reference state having a value of $(1-(1/200))=0.995$; a state that was considered 10 times as bad as the reference state would then have a value of $(1-10\times(1-0.995))=0.95$.

Person Trade-Off

The person trade-off is a technique that has been used less commonly than many of the other techniques mentioned so far. Unlike these other techniques, the person trade-off asks respondents to answer from the perspective of a social decision maker considering alternative policy choices rather than as an individual making choices for himself or herself. The person trade-off has been framed in various ways, but a typical presentation asks respondents to consider two options, one that will result in longer survivorship for a group of people and the other that will result in prevention of a nonfatal, usually chronic, condition. For example, a respondent might be asked to weigh an option that would prevent $x_1=1000$ deaths in a healthy population versus an alternative that would prevent $x_2=5000$ cases of some particular chronic disease outcome. The measurement approach in the person trade-off would usually be to hold constant the number of averted deaths (x_1) and vary the number of nonfatal outcomes averted (x_2) to find the indifference point between the alternatives. A health state valuation for the nonfatal outcome being considered would then be computed as $(1-(x_1/x_2))$. For instance, $x_2=10\,000$ would yield a value of 0.9.

Ordinal Response Methods

Finally, there has been renewed interest recently in ordinal response methods. Over much of the history of measuring health state valuations, ordinal methods such as ranking have been deployed primarily as a 'warm-up' exercise, for example, as a preliminary step to eliciting rating scale values for a range of health states. However, there have been a number of examples of analyzing ordinal response data in order to infer latent cardinal values that are consistent with these responses, and these examples have grown numerous over the past several years. Methods for collecting ordinal responses fall into two main categories: (1) rank ordering of health states and (2) paired comparisons of health states, residing within the broader methodological tradition of discrete choice analysis. Analysis of ordinal response information has been based largely on a random utility framework operationalized using regression models for discrete outcomes. These models are based on the presumption that ordinal responses may be related to differences between values on an unobserved cardinal scale. Specifically, regression-based approaches formalize the intuitive notion that two states that are distant from each other on some underlying measurement scale are more likely

to produce agreement in the pairwise ordering of the outcomes than will two states that are very near to each other. If distributions of values on the latent scale are assumed to be normal, then the ordinal responses can be modeled using probit regression; analogously, the assumption that the values follow an extreme value distribution leads to logit regression.

Historical Development of Health State Valuation Techniques

The development and adaptation of techniques for measuring health state valuations have occurred mostly since the early 1970s, but historical antecedents for this work may be found decades earlier. The history of the standard gamble is perhaps easiest to trace, as the technique debuted alongside the introduction of the expected utility theorem of von Neumann and Morgenstern (1944). Following this introduction, various approaches were proposed to assess von Neumann–Morgenstern utilities through specific types of standard gamble comparisons. The type of comparison that has been commonly adopted for use in health state valuations, in which the respondent chooses between a certain prospect of an intermediate outcome on the one hand and a gamble with the best and worst extreme outcomes on the other, was featured originally by von Neumann and Morgenstern and used subsequently in formulations for general utility assessment (i.e., not specific to health) by Frederick Mosteller, Duncan Luce, Howard Raiffa, and others. In 1968, Arnold Packer explicitly noted the applicability of the standard gamble to evaluation of health programs. Torrance *et al.* (1972) presented what may be the earliest published example of a comprehensive approach to measuring effectiveness of health programs with a utility assessment strategy based on the standard gamble. George Torrance had previously (in an unpublished dissertation, in 1971) undertaken a pilot test of the standard gamble technique, among others, in the context of a health care program evaluation.

The time trade-off approach, as currently implemented in valuing health states, appears to have been devised and named in the same study comprising Torrance's dissertation work, although the basic approach was discussed around the same time by Fanshel and James (1970), who referred to the notion as 'weighting through equivalence in time.' Torrance himself described the time trade-off as evolving from the so-called 'direct measurement technique' attributed to the psychologist Stanley Smith Stevens (1959), although the final format of the time trade-off bears little resemblance to this earlier proposal to directly elicit ratio assessments for two quantities. The time trade-off was originally developed to assess values for states considered better than being dead; another important milestone in development of the time trade-off was the elaboration by Torrance in 1982 of the method to accommodate states regarded as worse than dead.

Rating scales in health state valuation draw on a long history of related scaling approaches used in psychology and attitude measurement, including work by Louis Leon Thurstone in the 1920s. Patrick *et al.* (1973) applied a 'category scaling' approach to health measurement based on the method of equal-appearing intervals attributed to work published by Warren Torgerson in 1958. Patrick *et al.* operationalized this approach by having respondents place cards labeled with various health outcomes into equally spaced slots in a desk file sorter, numbered between 0 and 16. In another study published in the same year, the same authors used a linear rating scale, which has become the conventional rating scale approach in health state valuation. Subsequently, George Torrance adapted the approach with a 'desirability line' representing 101 equal interval categories spanning the range between 'Death, Least Desirable' and 'Healthy, Most Desirable.' Following these early precedents, numerous applications of rating scales in health state valuation have introduced a number of variations on this basic theme.

Magnitude estimation was proposed by Stevens (1951), in part as a response to the chief limitation he saw in the use of rating scales, which is that responses on rating scales appear to be nonlinearly related to the actual underlying scale that is being measured. Patrick *et al.* (1973), citing earlier work from the field of criminology, presented what appears to be the first application of magnitude estimation in valuation of health states. Another prominent use of the technique was in the Rosser and Kind index in 1978.

The person trade-off approach was named by Erik Nord in 1992, but the technique itself was applied already by Patrick *et al.* (1973) under the name of the 'equivalence' method. A proposal for 'weighting by equivalence in population' had appeared in the work of Fanshel and Bush (1970), but that earlier study presented the concept without applying it in empirical study. The person trade-off gained prominence through the publication of a review and empirical study by Nord (1995), which summarized prior applied work using the person trade-off and related techniques and presented the first comprehensive assessment of the reliability and possible biases in the technique. The profile of the method was also raised by its adaptation in the measurement of disability weights for DALYs in the Global Burden of Disease Study, as described by Murray (1996). The DALY study used two variants of the person trade-off in a deliberative group exercise. One of these variants – which compared life extension among disabled and nondisabled groups and thus differed from the typical person trade-off format described above – inspired criticism from Trude Arnesen and Erik Nord in 1999 for its potential ethical implications.

One of the most recent trends in measuring health state valuations actually relates to one of the oldest methodological traditions, which concerns estimation of cardinal measures based on ordinal responses. In the 1920s, Louis Leon Thurstone developed the 'law of comparative judgment' that provides the conceptual foundation for most approaches to deriving cardinal values from ordinal assessments. Following Thurstone, Ralph Bradley and Milton Terry, Duncan Luce, and Daniel McFadden further developed the axiomatic basis for choice models and refined analytic approaches based on a random utility model. Kind (1982) presented the first application of the Bradley–Terry–Luce approach to health state valuation, and there has been a recent revival of interest in these methods due to the relative simplicity of eliciting ordinal responses and a widening range of analytic tools to accommodate these responses.

Key Conceptual and Methodological Issues

There have been various conceptual interpretations of health state valuations that have produced some amount of ambiguity in defining the basis for measuring and understanding these valuations. When valuations are measured with the standard gamble, some people refer to these valuations as 'health utilities.' In fact, some have suggested that the standard gamble is the only method that produces 'utilities,' according to the von Neumann–Morgenstern framework. Others are less restrictive in the use of this term. Richardson (1994) and others have questioned the primacy of the standard gamble and challenged the prevailing argument that the standard gamble is preferred because its inclusion of risk aligns the technique with the inherently uncertain nature of medical decision making.

There has also been variation in the use of terms like 'quality of life' or 'health-related quality of life' in reference to health state valuations. The term 'quality of life' has been used widely in various social science contexts to refer to the overall subjective appraisals of happiness or satisfaction experienced by individuals. In health, the term 'quality of life' has sometimes been used in a more particular way to refer to a multidimensional construct relating to symptoms, impairments, emotional states, and domains of functioning. Because this use of 'quality of life' diverges from more general uses of the term, health researchers often refer to the distinct construct of 'health-related quality of life'. To the extent that an individual's health-related quality of life is understood in terms of a vector of levels on 'health-related' dimensions of life, it is similar to the conceptual notion underlying health state valuation, which can be used to attach an overall scalar value to such a multidimensional profile. Where health-related quality of life is viewed in terms of the contribution of an individual's health to his/her overall well-being, conceptual problems emerge from the fact that well-being is not clearly separable into independent health and nonhealth components (as, for instance, philosopher John Broome has argued).

In considering empirical differences between the different techniques for eliciting health state valuations, it is useful to recognize how the different constructs embodied in the techniques, for example, the 'utility' notion reflected in the standard gamble, may combine judgments about health with other values such as risk aversion. There has been a general consistency in the ordering of values (for the same state) produced by responses to the different valuation techniques, with rating scale values tending to be lowest (on a scale in which higher numbers imply better outcomes); standard gamble and person trade-off values highest; and time trade-off values tending to fall between these extremes. One interpretation of this typical finding is that the systematic variation across valuation techniques relates to the specific types of other values that are invoked by the particular framing of each technique. For example, a highly risk averse person will answer standard gamble questions in a way that produces values near 1.0, as the person will be unwilling to entertain even small probabilities of mortality. Several commentators have suggested that person trade-off responses are susceptible to an analogous set of values at the population level, which may be understood in terms of the 'rule of rescue,' by which respondents tend to choose a program that averts a relatively small number of deaths over a program that averts a very large number of nonfatal outcomes. Time trade-off responses may be influenced by a range of factors, such as discounting of future events, but the net effect of these factors may be relatively modest compared with the impact of risk aversion. Finally, various possible biases in rating scale responses have been considered, including a propensity to avoid values near the extreme ends of the scale, which is consistent with an overall downward shift in rating scale values.

Some health states are considered to be worse than being dead. Assignment of values to these has presented some challenges, especially in the use of the time trade-off. A typical approach to the time trade-off is first to ask whether a state is regarded as better than dead or worse than dead, as in the protocol developed by the Measurement and Valuation of Health (MVH) Group in 1994. For a worse-than-dead state, respondents in the MVH study were asked how many years spent in the health state (t) followed by a period of perfect health, summing to 10 years, would be equivalent to immediate death. By assigning values of 0 and 1.0 to dead and optimal health, respectively, valuations for a worse-than-dead outcome may be derived from the following equality: $\mathrm{U}(\text{health outcome}) \times t + \mathrm{U}(\text{optimal health}) \times (10 - t) = 0$, which simplifies to $\mathrm{U}(\text{health outcome}) = 1 - (10/t)$. In principle, this implies that the weight for a worse-than-dead state falls in the interval $(-\infty, 0)$. In practice, the lowest possible valuation using the MVH protocol is -39 (due to reporting of responses in quarter-year increments). Several studies have observed that treating worse-than-dead responses as originally intended – although faithful to the conceptual development of the time trade-off question – can lead to a large number of health states having negative average valuations, challenging face validity. In response, George Torrance, Paul Dolan, Leida Lamers, and others have considered various transformations of the worse-than-dead responses, which have prompted some controversy and a range of alternative proposals.

Conclusions

A large and growing literature on health state valuation has been directed toward a range of key issues including: the choice of technique for eliciting valuations; whose values to elicit; related issues around changing valuations over time (e.g., due to adaptation to decreased function); how to describe states for valuation; and the relevance of other values that may influence responses to health state valuation questions. This article has introduced six prominent techniques for eliciting valuations, discussed certain milestones in the historical development and evolution of these techniques, and mentioned some of the most salient conceptual and methodological issues relating to measurement of health state valuations.

Valuing Informal Care for Economic Evaluation

H Weatherly, R Faria, and B Van den Berg, University of York, York, UK

Glossary

Genomics The science of the function and structure of genomes, i.e., the DNA within a single cell of an organism.
Longitudinal study Any study using time series data.
Meta-analysis Using statistical techniques to synthesis the results from separate but related studies in order to obtain an overall estimate of treatment effect.
Multi-criteria decision analysis (MCDA) A framework for decision makers who need to consider multiple and sometimes conflicting factors when assessing the advantages and disadvantages of comparator interventions. MCDA has been applied broadly to inform health-care decisions. It has been used for shared decision making across different health-care stakeholders in the analysis and selection of interventions and for setting health-care priorities.
Regression discontinuity A cutoff or threshold above or below which a discrete intervention is performed or not performed.
Selection bias A distortion created when using data from a sample that differs systematically in its characteristics from the general population due to a feature of the selection process.
Shadow price The marginal cost or marginal value of a service as revealed in experiments or estimated by adjusting market prices.

Introduction

Informal care is the mainstay of support for many people living in the community, particularly those with long-term care needs. It refers to the care provided to individuals who would have difficulties managing without this help, by family or friends who are unpaid, although they may receive some nominal payment or state benefits. Some definitions also add that informal carers spend a significant proportion of their life providing care and support, however, if the amount of time spent caring is an important consideration, this requires specification. Informal care tasks include providing a range of care and assistance with activities of daily living, such as support with mobility, social support, personal care, and domestic assistance. In low-income settings, carers might even provide support with a broader range of medical-related tasks which could involve health-related care, particularly where state funding of health care is highly limited.

The size of the informal care economy, while substantial, is challenging to quantify and value. On an average one in nine people aged 50 years or more reported providing care for a dependent relative across all Organization for Economic Co-operation and Development (OECD) countries in 2007 (see http://www.oecd.org/health/health-systems/long-termcare.htm). The World Health Organization predicts that during the next 40 years the dependency ratio in China and India, in particular, will increase greatly. There is also a concern that young carers do not get adequate support. Substantial differences in informal care can be seen across OECD countries and, in part, this reflects the input of informal care versus formal, paid long-term care. For example, the level of informal care is twofold larger in Italy and Spain as compared to Sweden where care provision is more formalized. In economic terms, informal care can be described as a quasi-market commodity as there is no explicit market where informal care is bought and sold, and it does not have a directly observable value, such as a price, to reflect either the resources required to provide care-related tasks, or the benefits of doing so.

Informal care does not have an explicit value; however, this does not imply that it is a free resource. From an economic perspective, there are two key considerations relating to the carer when considering the value of informal care: (1) people offering informal care face an opportunity cost in that time spent on caring replaces other activities, such as education, employment, and leisure, and (2) there is an opportunity cost of using informal care as, while generating some potential benefits, such as the utility gained from caring for a loved one, being an informal carer is also associated with burden and disutility, such as reduced quality of life and negative health impacts. It is worth noting too that carer and care recipient's values are interdependent but this article focuses solely on the value of informal care in relation to the carer.

Informal care is rarely valued for inclusion in economic evaluation studies. Economic evaluation is increasingly used to inform national policy decisions about the efficient allocation of public funds across the economy. It offers a transparent framework to assess the relative costs and benefits of comparator interventions and has been applied in a range of sectors including the environment, health, and care. Many countries have developed detailed methods guidance for the economic evaluation of health-care interventions and now more attention is being given to the development of methods for the economic evaluation of care interventions. For example, from 1 Apr 2013 the remit for the National Institute for Health and Clinical Excellence in the UK is extending beyond health care to provide evidence-based guidance on social care interventions. Such guidance requires a systematic approach to measuring and valuing costs and benefits, consistent with the perspective chosen and considerably more research is required to identify the best approach to dealing with informal care in economic evaluations.

Valuing informal care for economic evaluation might be important in the following three respects: (1) for evaluating the cost-effectiveness of interventions or technologies to directly support informal carers (and care recipients), such as carers breaks or use of technologies such as robotic devices

for house cleaning, (2) to assess interventions in which there is an indirect impact on informal carers, such as health-related packages of care in which informal carers contribute, for example, use of medication for Alzheimer's disease, in which a carer is involved in administering the medication, or (3) for use in testing and redesigning services to evaluate the cost-effectiveness of different levels of access to more formal input, for example, from universal access to means-tested access. Once informal carer input is valued, their contribution is accounted for in an economic evaluation for use in informing the decision maker. In a scenario in which a new health-care intervention reduces health-care costs and increases use of informal care, relative to the comparator intervention, an analysis omitting this might result in a potentially undesirable shift of resource use from the health-care sector to the informal economy.

A broad range of methods have been developed to value informal care for economic evaluation but to date no formal guidance is available. This article reviews the methods for valuing informal care, including the methods used to measure time spent on informal care and the monetary valuation of this time, as well as nonmonetary methods and offers a brief review of the advantages and issues associated with applying currently available methods. The entry concludes by considering the implications of valuing informal care for economic evaluation. The same approach is used to review monetary and nonmonetary methods (see Figure 1). Four key steps comprise: (1) conceptualization of informal care, (2) identification of the caring activities or description of the effects of informal care, (3) measurement of the time spent on informal care (monetary) or the effects of informal care (nonmonetary), and (4) valuation of the time spent caring or the effects of informal care. This article focuses on the measurement and valuation, steps (3) and (4).

Monetary Valuation of Informal Care

Informal care can be incorporated within an economic evaluation on the cost side of the analysis. Figure 2 summarizes the methods involved in monetarily valuing informal care based on the four above-mentioned steps. Obtaining a clear and consistent definition of what constitutes informal care is far from straightforward. The majority of informal care is provided by one or more individuals known to the care recipient, such as their family, however informal care might be offered by individuals who are friends or who befriend them. As van den Berg *et al.* (2004) have discussed, this raises issues about the nature of the interaction between the care recipient and the carer. Activities such as cooking and cleaning ordinarily might be provided by a spouse when neither partner requires care. Typically, only those activities that take place because the care recipient requires care, owing to, for example, deteriorating health, should be included as informal care. These can be less than straightforward to identify, particularly when caring has taken place over a long time horizon and, additionally, life styles vary across different healthy couples. There may be shared benefits or some joint production involved in the carer undertaking tasks which complicates the ability to distinguish the component that is categorized as informal care. For example, the carer may provide informal care while participating in a leisure pursuit with the care recipient. Another consideration is the multiple tasks that carers might undertake. Some activities might be health related, such as supporting the care recipient with mobility and may substitute the need for health-care assistant input, whereas other aspects of care such as personal care and support with administrative tasks or keeping the care recipient company are more likely to impact beyond narrowly defined health. The impact of the caring task on the informal carer might be affected by the intensity and duration of the care provided. All these issues need to be specified upfront so that assumptions underlying the analysis are transparent. To aid comparability across economic evaluations and across settings, a systematic approach is required to conceptualizing, identifying, measuring, and valuing informal care.

Measuring Informal Care

Once tasks are identified as informal care, a method is required to measure time spent on informal care and four methods are reviewed next.

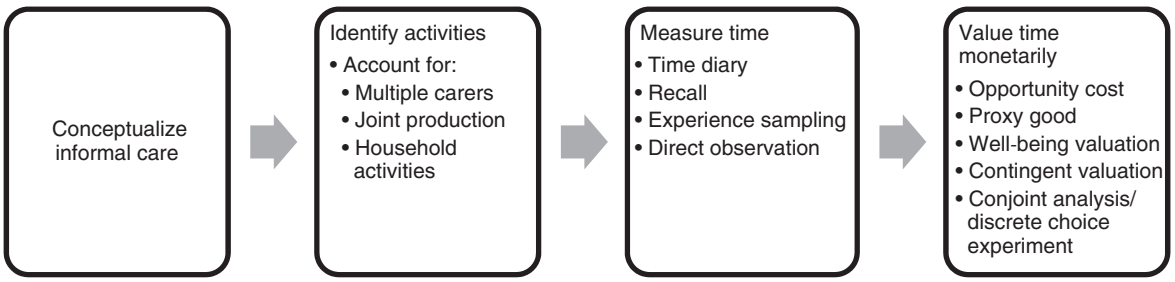

Figure 2 Monetary valuation of informal care.

Time diary method

Respondents are asked to report the sequence of activities undertaken as defined by the analyst and the amount of time spent on each activity over a set period of time, such as every quarter of an hour. An example of use of the diary method developed to measure informal care time is found in van den Berg and Spauwen (2006). Advantages include systematic collection of data within a brief space of time of the activities occurring, thus minimizing the recall period. In addition, respondents can indicate whether they are undertaking more than one care-related activity at the same time and, in principle, this allows the analyst to correct for joint production. There is, however, no generally agreed method to do this and in practice there is often no correction for joint production. Disadvantages of the method include that it can be very time-consuming to complete the diary and this can put carers off participating in such studies and completing the diary can impact on the time spent caring. In principle, this method might be thought to be the most accurate, but it has problems with compliance.

Recall method (also known as the stylized or questionnaire method)

This is probably the most commonly used method of time measurement. It involves asking respondents to report the amount of time spent on a particular activity and the frequency of the activity over a set period of time in the past. Examples of its use include the Carer Activity Survey by Davis *et al.* (1997), and the recall questionnaire used by van den Berg and Spauwen (2006). On other occasions, the recall method only asks about the amount of time spent on providing informal care even without referring to any care task. Compared to the time diary method, the recall method is less time-consuming to complete. Disadvantages, however, include that it is more sensitive to recall bias including systematic error because of differences in the accuracy of reporting past events by respondents. Although this method might be less accurate than the diary method, this consideration needs to be weighed against potentially greater compliance as carers seem able and more willing to use this method.

Experience sampling method (also known as beeper or buzzer method)

This has been used in time use and in wellbeing research, but to date, to the best of knowledge available, this approach has not been applied to measure informal care time. The method prompts respondents to register their activity at random instants over a prespecified time using a signal emitted from an electronic device. As the device beeps, respondents record the activities they are undertaking at that point in time. Gershuny (2011) found that on average this method provides highly accurate weighted sample estimates of time use across the sample. Experience sampling is less prone to recall bias than the time diary method because of immediate recording of the activity. If the respondent records their own responses rather than being given a closed-ended questionnaire, this method is likely to record all activity taking place. Disadvantages include respondent burden. A beeper system can intrude in daily life and might result in failure to respond. The method does not record the duration of the activities, nor are activities recorded sequentially, so there is a lack of context to the activity.

Direct observation method (also known as the continuous observation or outsider method)

This method involves observers recording activities and as such might be considered objective, rather than relying on self-report, and therefore it is considered to be highly accurate. However, it is very time- and resource-consuming and can also be very intrusive.

Valuing Informal Care in Monetary Terms

Once the time spent on informal care is measured, a method is required to attach a monetary value to informal care time. Examples of studies valuing informal care in monetary terms are provided in **Table 1** and this shows that the monetary values derived vary considerably by method and by caring task. There are two broad economic approaches for valuing time of using revealed preferences or stated preferences, as described next.

Revealed preference

These preferences are obtained by analyzing individuals' behavior or indirectly via preferences revealed in other markets such as from datasets recording individuals' decisions about services which are close substitutes for activities undertaken by informal carers. Typically, revealed preference methods use wages or income data to derive monetary values. Note that both the opportunity cost and proxy good methods do not incorporate the full impact of informal care on carers. However, whether the full impact should be included in the analysis will depend on the decision problem and the perspective taken.

Opportunity cost method

This method values informal care as the income forgone by the carer when spending time on informal care. There are many examples of how the opportunity cost method has been used to value informal care time, for example, in van den Berg *et al.* (2006). Income forgone is the carer's current wage rate (if employed) or can be estimated based on the previous wage rate if the carer worked in the past. The average (or median) net wage of people employed in the labor market who have the same sociodemographics might be used for those who have never worked. Use of this method is less straightforward for children and younger people as time spent on informal care may reduce the time available for education, which can have consequences later in life. Therefore, this method can result in different values for informal care, for example, a person with the potential of higher wages (e.g., a skilled professional) will have higher income forgone and the value attached to an hour of informal care will be higher for this person than for a person with the potential to earn a lower wage. Another issue is how to account for informal care activities that replace leisure time or unpaid work. Applying the wage rate of paid work to leisure time assumes that the wage rate reflects the marginal value of the time across the different uses of time. Another issue relates to the implications

Table 1 Examples of studies valuing informal care in monetary terms[a]

Method	*Reference*	*Application*	*Unit cost per hour (price year if stated/country)*	*Cost converted to GB sterling 2013*[a]
Opportunity cost	Smith and Frick (2008)	Average hourly income for all employed county residents	$17.34 (2004/US)	£12.56
	Wilson *et al.* (2009)	Average gross hourly wage rate for both genders	£13.11 (2004/UK)	£17.44
Proxy good	Dewey *et al.* (2002)	Hourly rate per type of activity	Community and domestic services, A$11.20	£8.53
			Personal care, A$13.45	£10.13
			All care by secondary carers, A$11.20 (1997/Australia)	£8.44
	Gaugler *et al.* (2003)	Hourly rate for home care services	$2.93 (1993/US)	£3.38
Wellbeing	van Den Berg and Ferrer-i-Carbonell (2007)	Extra compensation to maintain same level of wellbeing after providing additional hour of care	€8–9 (2001/the Netherlands)	£7.13–8.02
Contingent valuation	Gustavsson *et al.* (2010)	Carers' monthly willingness to pay for 1 h per day of reduction in informal care	UK, £105, Spain, £121, Sweden, £59, US, £144 (date not stated)	As stated
	van den Berg *et al.* (2005)	Care recipients' WTP for an additional hour of informal care per week and their and willingness to accept (WTA) for a reduction in 1 h of the informal care received	Rheumatoid arthritis:	
			Care recipients: WTP €7.84	£6.99
			WTA €8.22	£7.33
			Carers: WTP €7.80	£6.96
			WTA €9.52	£8.49
		Carers' WTA to provide an additional hour and WTP to provide one less hour of care	Heterogeneous sample:	
			Care recipients:	
			WTP €6.72	£5.99
			WTA €8.62	£7.68
			Carers: WTP €8.61	£7.68
			WTA €10.52	£9.39
			(2001/the Netherlands)	
Conjoint Analysis/ Discrete Choice Experiment	van den Berg *et al.* (2008)	Extra compensation per hour required to provide 21 h instead of 7 h of informal care per week	€12.36 (2001/the Netherlands)	£11.02
	Mentzakis *et al.* (2010)	Carers' willingness to accept to provide an additional hour of care of a number of tasks	Personal care: £0.12–2.29, Supervision: £0.07–0.81, Household tasks: £0.25–1.04 (date not stated/UK)	As stated

[a]The two websites used to convert the monetary values to GB sterling for the financial year 2012–13 are given in the section Relevant Websites.

of using net or gross wage rates. The wage rate net of tax reflects the opportunity cost to the carer, whereas the gross rate reflects the opportunity cost to society. The choice of wage rate needs to be consistent with the perspective chosen for the analysis.

Proxy good method

Also known as replacement cost method, proxy good method values informal care time use at the price of a close substitute. The relevant substitute depends on the activities undertaken, for example, a health-care assistant wage could be used to value informal care time spent on help with feeding and the wage of a housekeeper for help with cleaning the house or doing the laundry. To use this approach the analyst requires data on caring activities undertaken, time spent on these activities and proxy values for each activity. This method assumes exact substitutability between formal and informal care, including assuming that the informal carer and care recipient are indifferent or have the same preferences for informal care as compared to formal care. The method implicitly assumes that any prices used are appropriate reflections of value.

Wellbeing valuation method

This method estimates the monetary value of providing informal care. It does so by estimating the carer's wellbeing as a function of income and time spent caring, among other things. This allows the analyst to estimate the income required to compensate the carer for the loss in wellbeing because of providing informal care. The wellbeing valuation method uses data directly obtained from carers. The first application of this approach to valuing informal care time was undertaken by van Den Berg and Ferrer-i-Carbonell (2007). An assumption underlying the wellbeing valuation method is that wellbeing can be measured empirically and some analysts even assume that this measurable wellbeing is a proxy for utility, more specifically for experienced utility. An empirical finding is that providing informal care is associated with wellbeing losses as

well as a positive association between income and wellbeing. In cases in which informal care would not be negatively correlated with wellbeing, it would not be possible to calculate the related monetary compensation and in case of a positive empirical association between informal care and wellbeing one could argue that the informal carer would be willing to pay to provide the care themselves: In other words, they may have a strong preference to provide the care and may benefit from caring. Although the authors are not aware of any published study that has found this positive association, the information obtained using this method might still be included in an economic evaluation.

Stated preference

Stated preferences are obtained directly from respondents by asking them to consider hypothetical situations, typically using survey methods. The method relies on statements of preference, and not on actual choices and, hence, may not reflect the respondent's actual behavior and are, therefore, criticized by mainstream economists.

Contingent valuation

Contingent valuation values informal care either in terms of the maximum monetary amount informal carers would be willing to pay for reducing caring activities, or the minimum monetary amount that they would be willing to accept for supplying extra informal care. Contingent valuation has been used to estimate the value of informal care in a few studies, for example, Gustavsson *et al.* (2010) estimated the willingness to pay for reductions in informal care need in Alzheimer's disease. Although contingent valuation questions might be relatively simple to ask, they might not be straightforward to answer as carers might not be used to thinking about monetary valuation of informal care time and, therefore, some respondents may be unwilling to value carer time in monetary terms. This might be especially true if the question is framed as if the care recipient might pay the carer. In an attempt to solving this problem van den Berg *et al.* (2005) suggested framing the question as if the government was going to compensate the carers, as sometimes happens via carer allowances for example. There is a substantial literature on biases involved in applying this method especially as willingness to accept values tend to be larger than willingness to pay ones and this difference cannot be explained based on economic theory. When van den Berg *et al.* (2005) explored this issue in relation to informal care in the Netherlands, the differences were quite small suggesting this bias is less persistent when applying the method to value informal care. It might be necessary to explore this further and to consider whether responses might be influenced by culture and the health and care system of the respondents participating in the study.

Discrete choice experiment (although strictly speaking based on different theories also known as conjoint measurement or conjoint analysis)

Discrete choice experiment uses survey methods to obtain respondents' estimation of the relative value of different attributes of a service which might include health, nonhealth, and process attributes. In addition, if a cost or a price is included as an attribute, a monetary value of the other attributes can be derived. Mentzakis *et al.* (2011), for example, included an attribute of the amount of money (£0, £4, £10, and £17) a respondent would receive as compensation per hour for the informal care they provided and in answering this, respondents were asked to consider the effect of the caring role on their own health and wellbeing. The methodology assumes that a service can be described by its constituent characteristics and that the total utility, satisfaction, or preference that a respondent derives from a service is determined by the utility they gain from each of the constituent parts. Examples using this method applied to informal care, have, to date, mainly included care tasks and care time and although this method in theory can also take into account the full impact or value of undertaking informal care on the carer themselves, including for instance involved health losses, this has not been contested in empirical applications so far.

Nonmonetary Valuation of Informal Care

Informal care can also be incorporated in the effect side of an economic evaluation, rather than on the cost side. As for monetary valuation of informal care, there are four key steps (see **Figure 3**): (1) conceptualize informal care, in a similar way as described in Section Monetary Valuation of Informal Care, (2) describe the effect on the informal carer, (3) measure the effect on informal care, and (4) attach a nonmonetary valuation to the effect. This section focuses solely on the impact on carers, however, as noted earlier, there is likely to be considerable interdependence between the outcomes for the carer and the care recipient.

Methods to incorporate informal care as an effect comprise three key measures: Burden, health, and health-related quality of life and informal care-related quality of life and some examples of these are provided in **Table 2**. In practice there may be some overlap between these measures.

Table 3 compares the dimensions included in three measures of care-related quality of life, the Carer Quality of Life Instrument (CQLI), the care-related quality of life (CarerQoL), and the Carer Experience Scale. As can be seen from the table, not all measures include the same dimensions, for example, CQLI and CarerQoL include physical health and energy, whereas the Carer Experience Scale does not.

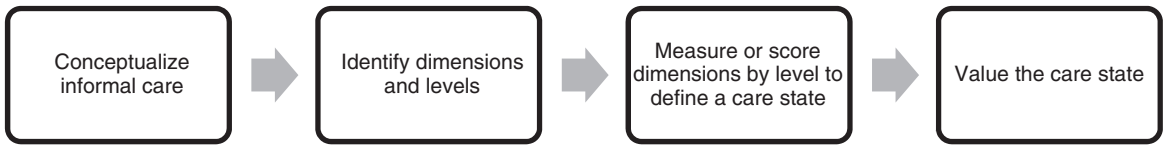

Figure 3 Nonmonetary valuation of informal care.

Table 2 Examples of nonmonetary methods for measuring informal care

Constructs of informal care	*Measures*	*Examples of nonmonetary instruments*
Burden of care	• Objective burden of informal care in terms of caring activities undertaken • Subjective burden in terms of impact of informal caring on carer wellbeing	Objective burden: • Carer Activities Time Survey (Clipp *et al.*, 1996) • Carer Activity Survey (Davis *et al.*, 1997) Subjective burden: • Caregiver Reaction Assessment (Given *et al.*, 1992) • Carer Strain Index (Robinson, 1983) Objective and subjective burden: • Carer Subjective and Objective Burden Scales (Montgomery *et al.*, 1985) • Cost of Care Index (Kosberg and Cairl, 1986)
Health and health-related quality of life	• Health • Health-related quality of life	Health: • SF-36 (Hughes *et al.*, 1999) Health-related quality of life: • EQ-5D (Dixon *et al.*, 2006)
Informal-care related quality of life	• Carer quality of life • Carer wellbeing	• Carer Quality of Life Instrument (CQLI) (Mohide *et al.*, 1988) • The care-related quality of life (CarerQoL) instrument (Brouwer *et al.*, 2006) • The Carer Experience Scale (Al-Janabi *et al.*, 2008)

Table 3 Comparison of the dimensions included in three measures of care-related quality of life

Dimensions	*CQLI*	*CarerQoL*	*Carer experience scale*
Physical health and energy	☑	☑	
Emotional and mental health	☑	☑	
Social relationships and other activities	☑	☑	☑
Sleep	☑		
Relationship carer/care recipient	☑	☑	☑
Fulfillment with carer situation		☑	
Financial consequences of carer		☑	
Support (formal and/or informal)		☑	☑
Carer's control over care-giving activities			☑
Carer's perception of fulfilling a duty			☑

As different dimensions are incorporated across the three instruments, this limits their direct comparability and this complicates synthesis of effects across the instruments. An additional consideration is to what extent each measure incorporates the full effect on informal carers.

Measuring the Effects of Informal Care

Burden of informal care

Carer burden is one of the most commonly used indicators of informal care. It is an attempt to quantify the physical, psychological, social, and financial impacts of caring. Sometimes a distinction is made between objective and subjective burden with objective burden referring to observable aspects of informal care, such as the events and activities, with subjective burden referring to the perception of the caring experience by the carer, including feelings, attitudes, and emotions. Both concepts of burden are complementary as the time spent on caring and the activities involved (objective burden) also involve the perception of the burden of care by carers (subjective burden). Several instruments are available to measure burden as, for example, reviewed by Deeken *et al.* (2003). This heterogeneity adds to the complexity of cross-study comparisons and makes synthesis of results across studies difficult. Although the concept of burden traditionally focuses on the negative aspects of caring and places less obvious emphasis on the benefits or utility obtained by the care from caring, there have been attempts within the burden literature to incorporate benefits and the Caregiver Reaction Assessment is an example of such a measure.

Informal carer's health-related quality of life

Measures of health-related quality of life have been used to account for the consequences of informal care on carers.

Caring may impact positively and negatively on carers' health-related quality of life. Instruments for use in measuring health-related quality of life include the SF-36 and the EQ-5D. Using health-related quality of life instruments to incorporate the impact of informal care on carers has been criticized because it may not capture the full effects on quality of life and well-being. However, the use of generic health-related quality of life instruments is helpful for comparing results across economic evaluations, including across disease areas.

Informal caregiver quality of life

As discussed by Stull *et al.* (1994), this concept is broader than health extending to incorporate all the factors that may impact on the carer's life. Three examples of such instruments are reviewed briefly here including the caregiver quality of life instrument, the care-related quality of life instrument and the Carer Experience Scale.

The caregiver quality of life instrument

This was the first carer-specific instrument developed to value carers' wellbeing states. Mohide *et al.* (1988) report the CQLI as comprising five dimensions which were identified from a review of the literature and clinical opinion. The dimensions comprise two social (amount of time to socialize with family and friends and quality of the interpersonal friendship between the carer and the care recipient), two physical (adequacy of amount of sleep and degree of physical wellness and energy), and one emotional (degree of happiness and freedom from anxiety and frustration). Each dimension is described using one of four levels, comprising almost always, most of the time, half of the time, rarely, or almost never. Four standardized hypothetical health states are included, that is, the ideal caregiver quality of life reference state where the caregiver was almost always well on each of the dimensions, mild, moderate, and severe caregiver wellbeing states. Twenty-nine family caregivers and ten relatives of well older people describe their state of wellbeing, relative to the standardized states, over the preceding fortnight.

The care-related quality of life instrument

CarerQoL was developed to incorporate the impact of informal care on carer's quality of life for use in an economic evaluation. Brouwer *et al.* (2006) presented the conceptualization and first test of the CarerQoL instrument. The CarerQoL-7D questionnaire measures how satisfied the carer is with their care-giving situation. The CarerQoL-7D contains seven dimensions comprising fulfillment, relational, mental, social, financial, support, and physical and each dimension is judged on one of three levels; some, a lot of. The dimensions were identified by selecting those most frequently assessed in several carer burden scales. To the authors' knowledge, the CarerQoL instrument has not been applied in an economic evaluation in practice.

The carer experience scale

This scale also values the carer experience for possible use in an economic evaluation. Developed by Al-Janabi *et al.* (2008), it has six dimensions comprising the carer-recipient relationship, institutional support, informal support, activities outside caring, control, and duty. Each dimension is described on one of three levels, that is most, some, or sometimes, few, little, or rarely. The dimensions were identified through a metaethnography of qualitative research in informal care together with interviews with carers.

Valuing the Effects of Informal Care

Informal carer's health-related quality of life

Published algorithms are available to convert health state descriptors from generic health-related quality of life instruments, such as the SF-12, SF-36, and the EQ-5D to HRQoL weights. Valuation tools include the visual analog scale (VAS), which strictly speaking does not generate a utility value, and the time trade-off (TTO) and standard gamble techniques which both incorporate choice, and standard gamble also includes uncertainty and for this reason tends to be the most favored valuation tool. However, VAS and TTO are considered easier to use and less cognitively burdensome.

It is worth noting that in undertaking informal care, caring may negatively impact on health-related quality of life but carers may also have health problems themselves: The causality of undertaking care and having poor health-related quality of life is unclear and this presents a challenge to analysts who aim to separate these issues. If providing care causes health-related quality of life loss and if carers are happy to take the loss, that is, the utility function of the carer might be interdependent with that of the care recipient's: A key challenge is how to value this preferred health loss. Further consideration is required on the role of interdependent utility functions in economic evaluations, particularly if the local context has an influence.

Informal caregiver quality of life

The carer quality of life instrument

CQLI uses the TTO to value states by indicating the number of years of future life in the 'burdened' test state they would exchange for a year in the 'ideal' reference state. The 'ideal' reference state refers to the best wellbeing state, in which carers almost always feel physically well and energetic, almost always feel happy and free from worry or frustration, almost always have sufficient to socialize with family and friends, almost every night get an adequate amount of undisturbed sleep, and almost always gets along well with the person being cared for. Drummond *et al.* (1991) used the CQLI in an economic evaluation comparing a support program for carers of elderly people with dementia with usual care. Quality-adjusted life-years (QALYs) with and without the support program were calculated using the CQLI values to inform the wellbeing experienced by the carers.

It should be noted that this is not the same as standard QALYs which are solely health-related.

The care-related quality of life

CarerQoL includes a VAS to quantify how happy the carer feels currently on a scale of 0 (completely unhappy) to 10 (completely happy).

The carer experience scale

This scale was valued using best-worst scaling in an orthogonal main effects design. In best-worst scaling, respondents compare statements within a profile and select the most and

the least desirable statement. The best state, i.e., that with the lowest burden, has the value of 0 (zero), whereas the worst state, i.e., that with the worst burden and which every dimension has the worst level, was set to 100. Each dimension has different values and together these descriptors define the health state. For example, the health state with dimensions at the middle level has the value of 64.58. This provides a cardinal scale, however, there is no means of combining it with length of life to generate QALYs.

Discussion

This section offers an overview of methods to value informal care in monetary or nonmonetary terms. The choice of method depends on the research question, the data available, and the type of research being undertaken. This section has focused on the application of these methods describing their use in practice and has not discussed the normative foundations underpinning different approaches. However, in undertaking an economic evaluation, assuming a decision is taken to value informal care, a key issue is how to combine the method chosen with other methods used in economic evaluation and to ensure no double-counting. If monetary valuation is chosen, as a consequence of which the values are included on the cost side of an economic evaluation, then it could be combined with the cost of other inputs. A challenge for monetary valuation methods is that the values obtained are dependent on the individual's income, as greater ability to pay will drive up their willingness to pay for a service and possibly willingness to accept to provide informal care. Valuing informal care in terms of the effects of health-related quality of life raises the question on how to aggregate the values with care recipient's health-related quality of life, and it is not clear how to incorporate this formally into economic evaluation. It has been suggested that multicriteria decision analysis could be used to get around this issue, although this approach is not without its detractors.

Stronger guidance for analysts on whether and how to value informal care would result in greater uniformity in valuing informal care within studies and this would enhance the transferability and comparability of economic evaluations. Before this, more conceptual work needs to be undertaken to examine how to identify, measure, and value informal care. Informal carers provide a vital service within the community and this review illustrates that there are many methods available to quantify the economic value of this essential service.

Waiting Times

L Siciliani, University of York, York, UK

Glossary

Inpatient waiting time Time between the addition to the list, following specialist assessment, and the date of admission for treatment.

Maximum waiting-time guarantee Establishes that no patient should wait more than a predetermined maximum.

Outpatient waiting time Time between family doctor visit and specialist visit.

Introduction

Publicly funded systems are often characterized by limited budgets and free-of-charge (or highly subsidized) access to healthcare. These two features often translate into an excess demand which generates a waiting list. Patients may have to wait for a significant time before accessing health care. Waiting times generate dissatisfaction for patients as they postpone benefits from treatment, may induce a deterioration of the health status of the patient, prolong suffering, and generate uncertainty. How to deal with or reduce waiting times is often the subject of debate in political campaigns: it is not surprising that waiting times have become a key health policy concern in many Organization for Economic Cooperation and Development (OECD) countries.

This article is devoted to presenting some key ideas on the role of waiting times in the market of health services. It draws selectively on the existing health economics literature. The article discusses: (1) different types of waiting-time measures; (2) how waiting times can be thought of as a rationing mechanism which brings together the demand for and the supply of health services; (3) the potential role of patients' choice and competition among public healthcare providers to reduce waiting times; (4) the role of waiting times in allocating patients between the public and the private sector; (5) the scope for policies based on the maximum waiting-time guarantees; (6) the equity implications of using waiting times in the health sector. The Section 'Technical Appendix' provides formal frameworks on waiting-time measurements, waiting-time dynamics and hospital competition, which are covered more intuitively, respectively, in the first three sections. The final section provides references for further reading.

Waiting-Time Measures

Patients in need of health care can experience different types of waiting. In many countries, the first contact point of the patient is the family doctor (also known as general practitioner). The family doctor will then refer the patient to a hospital specialist. Between the visit of the family doctor and of the specialist the patient will have to wait. This is often referred to as the outpatient waiting time. Once the specialist visits the patient and thinks that the patient needs (a medical or surgical) treatment, then the patient is typically added to the waiting list. The time between the addition to the list and the date of admission for treatment is often referred to as the inpatient waiting time.

For many nonemergency (also known as 'elective') treatments, like hip and knee replacement, and cataract surgery, inpatient waiting times can be substantially long with an average of 3–6 months. Waiting times are typically shorter for more severe conditions (e.g. patients in need of cancer treatment). This article does not focus on emergency treatment, where waiting times are short (and a matter of minutes or hours).

Waiting times for non-emergency treatments are routinely collected in many OECD countries (e.g., Australia, Canada, Norway, Portugal, and the UK) through administrative databases. Each country collects several measures. Definitions, however, tend to vary across countries. They can refer to specific procedures (like hip replacement, cataract surgery) or broader categories (like specialties or all nonemergency patients). Waiting times are often reported according to basic descriptive statistics: the mean or the median waiting, the number or proportion of patients waiting more than a given time (say 6, 9, or 12 months) or the waiting times at the 80th or 90th percentile of distribution. Given that the waiting-time distribution is skewed and characterized by a small number of patients with long wait, the mean is typically longer than the median (up to 20–30% difference). Measures based on the number (or proportion) of patients with a long wait capture only the upper tail of the distribution. For example if 5% of patients wait more than 12 months, it could be that the remaining 95% wait for 10 months or 5 months. The reason for reporting such figures is that the number of 'long waiters' are seen as the most problematic ones.

Regardless of which specific figure is employed to report waiting times, waiting-time information can serve different purposes. For example, waiting-time information can be used to set targets for health care providers, with hospitals reporting a longer wait being subjected to penalties or a closer monitoring. Waiting-time information can be used to enhance patients' ability to choose providers: in such cases the information is provided either to the family doctors or is publicly available on the internet. Waiting-time information may also be necessary to establish and enforce maximum waiting-time guarantees, under which governments state that no patient should wait more than a predetermined waiting time.

For a given procedure, condition or specialty, two common measures of waiting times can be recorded: (1) the waiting

 doi:10.1016/B978-0-12-375678-7.01304-3

time of the patients on the list at a point in time (or a census date) and (2) the waiting time of patients who have received a treatment (during a predetermined period). The first measure refers to an 'incomplete' measure of waiting time as the patient is still on the list (all patients are still waiting): there will be some patients who have just entered the list and some patients who have been on the list for a long time. The second measure refers to the full duration of the waiting-time experience from the time the patient is added to the list to the time the patient is admitted to the hospital for treatment: the measure is computed retrospectively once the wait is terminated.

Figure 1 provides an example which illustrates the difference between the waiting times of the two distributions. In each period two patients enter the waiting list, the first waiting for 1 month and the second waiting for 5 months. In period t only two patients have their wait completed. One has waited for 1 month and one has waited for 5 months. The average wait of patients treated (which is the correct expected wait for the patient) in period t is therefore three periods. At time t there are 6 patients waiting on the list: two patients have waited for one period, one for two periods, one for three periods, one for four periods, and one for five periods. The average wait is therefore 2.7 periods. The key difference between the two distributions is that the distribution of patients on the list tends to ''oversample'' long-wait patients. Indeed, in the example five out of six are long-wait patients at the time of observation while in fact there is an equal proportion of long and short-wait patients. The reason why in the example the average wait of patients on the list is shorter than the average wait of patients treated is that most of the patients in the list at the time of observation have not completed their wait yet. Hence the data on patients on the list suffers from ''interruption'' bias. In the present example the interruption bias dominates the long-wait oversampling bias. In Section 'Waiting Time of Patients on the List Versus Waiting Time of Patients Treated: An Example' differences between the two distributions are illustrated more formally. An example where the average wait of the patients on the list is higher is also provided.

Waiting Times as a Mechanism to Bring the Healthcare Market to an Equilibrium

A Simple Theoretical Framework

Publicly funded healthcare sectors in many countries are often characterized by zero or little copayments and simultaneously by capacity constraints. If capacity is less than potential demand, this generates an excess demand. If patients in 'excess' are added to a waiting list, then patients will have to wait a certain time before receiving treatment.

Economists have argued that waiting times can then be thought of as a price (a non-monetary one), which patients have to pay to access healthcare. In other sectors of the economy, monetary prices bring demand and supply in equilibrium; higher prices reduce demand by discouraging some consumers to buy a certain good and increase supply by encouraging the provider to expand production. Equilibrium prices are determined where the demand curve crosses the supply one. The standard economic demand–supply framework can readily be adapted to the health sector. Like monetary prices are determined such that demand is equal to supply, in the health sector waiting times (the non-monetary price) are determined to bring demand and supply in equilibrium. Note that if demand would systematically be larger than supply, and both demand and supply do not respond to waiting-time variations then the waiting list and the waiting time would keep growing over time.

There are different mechanisms through which waiting times affect the demand for and supply of healthcare (as measured, e.g., by the number of discharged patients). On the demand side, patients may opt for care in the private sector if they are not willing to wait and if they can afford to pay the (monetary) price charged by the private sector. Some patients may also simply give up the (public or private) treatment or opt for a pharmaceutical one. On the supply side, higher waiting times may induce providers to increase activity either because waiting times are used as key performance target (associated with penalties or monitoring) or because providers (doctors) feel bad about patients waiting for a long time.

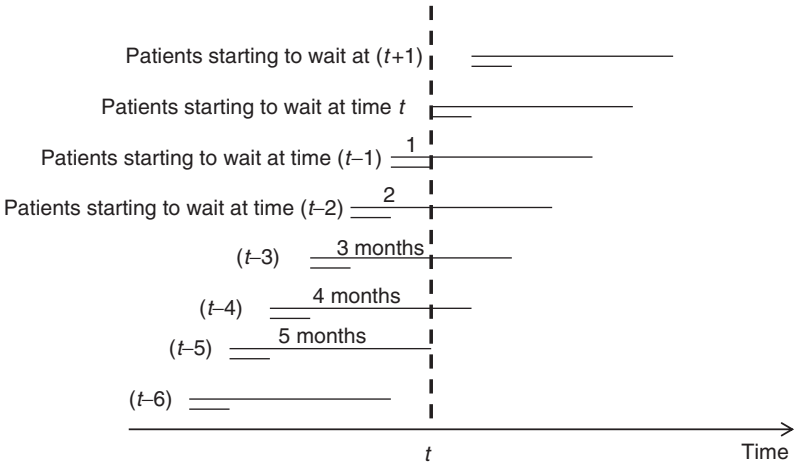

Figure 1 Distribution of waiting time of patients treated and on the list.

Perhaps, most importantly when waiting times are higher, policymakers may be willing to allocate more resources to increase the supply of healthcare (although this may also generate perverse incentives if providers artificially inflate the list to attract more resources).

A simple formal model is provided. Define $D(w)$ as the demand for healthcare which depends on the waiting time w. If assumed that higher waiting times reduce demand, then $D'(w)<0$. Similarly, the supply curve is defined by $S(w)$ with $S'(w)>0$. In such a market the equilibrium waiting time is determined such that $D(w^*)=S(w^*)$. The equilibrium waiting time is described in Figure 2 as point A.

Using this framework, the effect of exogenous shifts on the demand and the supply curve can also be explored. If, for any given waiting time, demand increases (an upward shift in the demand curve) then its equilibrium waiting time and activity will also increase. A higher demand implies that more patients are added to the waiting list, which ultimately leads to an increase in waiting time. Providers will respond to such an increase in waiting time by making more effort to increase activity (point B in Figure 2).

Similarly, if, for any given waiting time, supply increases (a shift to the right of the supply curve) then in equilibrium waiting time will reduce and activity will increase (point C in Figure 2). This shift may be due to an increase in capacity, as measured by an expansion in the number of hospital beds and doctors. A higher supply implies that more patients are taken out from the waiting list, which reduces waiting times; such a reduction is offset to some extent by an increase in demand.

Figure 2 also shows that the responsiveness of demand and supply to waiting times play a crucial role. If demand is very inelastic (nearly vertical, as drawn in Figure 3) an increase in supply will lead to a large reduction in waiting times. In contrast if the demand is elastic (nearly horizontal, as drawn in Figure 4), an increase in supply will lead only to a small reduction in waiting times.

Figures 3 and 4 illustrate a point which is critical in policy discussions on how to reduce waiting times. Some policymakers argue that increasing supply to the health sector will not reduce waiting times because the increase in supply will be offset by an equal increase in demand. As clearly depicted in Figure 4, this type of reasoning implicitly assumes that the demand is elastic. Others argue that a higher supply will bring down waiting times. As depicted in Figure 3, it implies that the demand is inelastic. Empirical estimates of how demand responds to waiting times are therefore paramount to decide whether increasing supply can or not significantly reduce patient waiting times.

Most of the existing empirical estimates of the demand curve from England put the elasticity of demand to waiting time at -0.1 (a 10% increase in waiting times leads to a reduction in demand by 1%). This suggests an inelastic demand curve: higher supply will lead to significant reductions in waiting times (as in Figure 3). It is worth emphasizing however that the existing empirical studies on demand elasticity have been derived mainly for the English healthcare system and should therefore not necessarily be transposed to other countries. One study from Australia, for example, has observed that demand was elastic to waiting times (with elasticity greater than one). Estimates of the supply elasticity even for England vary depending on the study (see discussion below).

Figures 2–4 also show the critical role of demand and supply shifts over time in determining the evolution of waiting times. In the health sector demand tends to increase over time. This is both due to the aging of the population that increases the healthcare needs and also due to technologIcal development, which makes new treatments available (some patients can be treated now who could not be treated in the past). This generates increasing pressures on waiting times. Supply may also increase over time due to the technological advancement that allows treating patients safely with less invasive treatments and a shorter length of stay. Whether waiting times

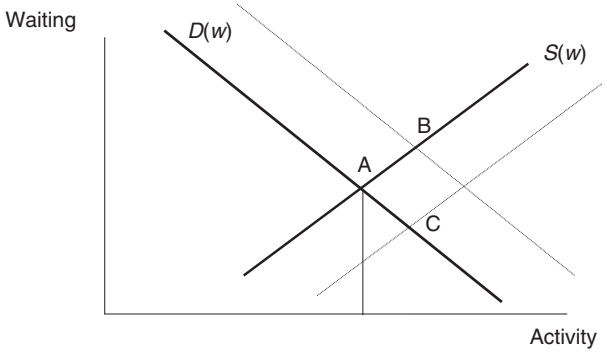

Figure 2 Demand and supply. A positive shock on demand implies a higher waiting time. A positive shock on supply implies a lower waiting time.

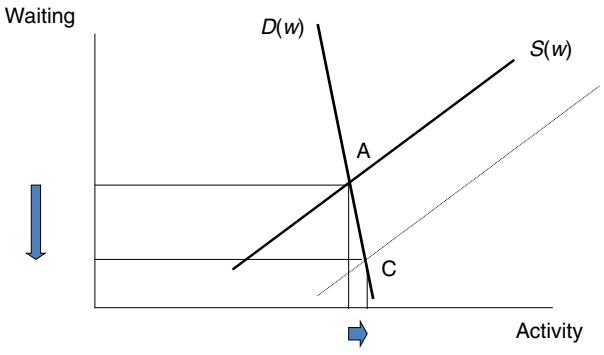

Figure 3 Inelastic demand.

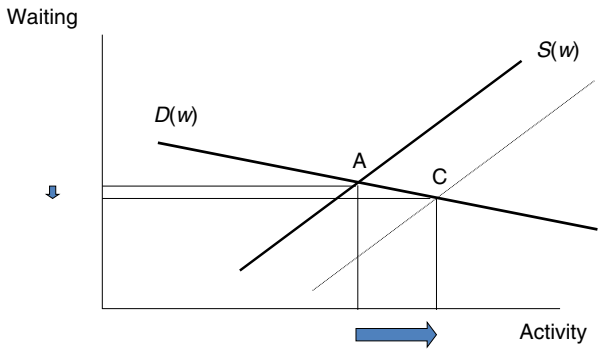

Figure 4 Elastic demand.

increase or reduce over time depends on the difference between the increase in demand and increase in supply. The gap between demand and supply may also depend on the type of system, with National Health Services being generally associated with tighter capacity constraints, and longer waiting times, than public (or private) insurance systems.

Policymakers have also tools available to influence the demand and supply of healthcare. For example, on the demand side countries with a gatekeeping system (where the patient has to see a family doctor before seeing a specialist) may have lower levels of demand. Moreover, eligibility to public treatment may be made conditional on certain criteria (like severity thresholds, benefits, appropriateness, and cost-effectiveness). More stringent criteria will lead to lower demand. Policymakers may also control the type of technology that is available to hospitals (and e.g. decide not to provide a certain treatment).

On the supply side, policymakers can influence supply by deciding the level of capacity in the public sector (the number of hospitals, doctors, nurses). The payment system for doctors and hospitals will also influence supply with fee-for-service rules and activity-based funding possibly being associated with a higher supply compared with a salary system and fixed budget rules.

Empirical Evidence

Estimates on demand and supply responsiveness to waiting times have been the subject of several empirical studies, mainly with data from England. They have used either a cross-sectional (i.e., a sample of hospitals or small areas at a point in time) or a panel-data (a repeated cross section over time) approach. The cross-sectional approach aims at identifying whether regions with higher waiting times have lower demand, for a given supply, or have higher supply, for a given demand. The analysis can be carried out either at a hospital level (variations across hospitals) or at a small-area level.

One problem with the estimation of demand and supply responsiveness is that separate measurements of demand for healthcare and supply are generally not available. What the researcher can typically observe, say at the hospital level, is different combinations of waiting times and activity levels. The researcher cannot tell whether the different activity levels reflect demand or supply variations.

To disentangle the differential effect of waiting times on the demand and supply of healthcare more sophisticated approaches than Ordinary Least Squares (OLS) need to be implemented. Estimating the responsiveness of the demand function to waiting times by regressing activity on waiting times and demand shifters (e.g., health needs or population) will lead to biased (distorted) results. Similarly, estimating the responsiveness of the supply function regressing activity on waiting times and supply shifters (e.g., the number of doctors and the number of beds) will lead to biased results. The endogeneity of waiting times in determining both demand and supply is typically addressed through the use of one or more 'instrumental' variables (a variable that is correlated with waiting times but not the dependent variable). In the demand equation this entails finding a variable that affects waiting times but does not affect the demand: a natural choice is a supply-shifter; for example, more doctors reduce waiting time but have no effect on demand. Similarly, in the supply equation the researcher needs to find a variable that affects waiting times but not the supply. In this case a suitable instrument is one or more demand shifters; for example, a higher proportion of elderly population will be correlated with waiting times but not with the supply.

Using a cross-sectional approach, Martin and Smith (2003) suggest that the elasticity of demand in the English NHS is between 0 and -0.2 depending on the year (-0.2 in year 1991–92, 0 in years 1993–94 and 1996–97, and between -0.12 and -0.15 in the remaining 4 years). The demand function is therefore inelastic: a 1% increase in waiting time reduces demand by at most 0.2%. In contrast, the supply function is rather elastic: between 2.1 and 5.9 depending of the year considered.

An alternative approach to cross-sectional analysis is the panel-data analysis, which involves data collection on activity and waiting times over several years (say approximately 3–7 years). In this case, the analysis tries to exploit how variations over time for a specific provider affect the demand and supply of healthcare. The results are very much in line with the cross-sectional one with an overall demand elasticity of -0.09 and a supply elasticity of 5.3. The elasticities also vary for different specialties; for example, the demand elasticity is higher (in absolute terms) for general surgery and oral surgery (equal to -0.24 and -0.21, respectively) and smaller for orthopaedics (-0.07).

Waiting Times versus Waiting List

The above discussion refers mainly to the duration of waiting times and not to the size of the waiting lists. This is for two reasons. First, from the patients' perspective what matters is how long they wait, and not necessarily how many patients are on the waiting list; if each patient waits for 2 weeks the disutility from waiting is the same regardless of whether there are 100 patients or 1000 patients on the list.

Second, waiting times and waiting lists do not necessarily move in the same direction. To illustrate this point, recall that the number of patients treated in equilibrium is $\gamma^* = D(w^*) = S(w^*)$. Define L as the waiting list. Note that at steady state (when the waiting time and the waiting list do not vary over time), $w^* = L^*/\gamma^*$. This expression is intuitive; it simply says that the waiting time for a typical patient is equal to the number of periods necessary to treat all the patients on the list. Therefore, if the waiting list has 200 patients and only 10 patients per week are treated, then the waiting time is 20 weeks.

Perhaps less intuitively, the waiting list can be rewritten as the product of activity and waiting time: $L^* = \gamma^* w^*$. Figure 2 can then again be used to investigate the effect of shocks on the demand and supply side on the waiting list. Figure 2 shows that an exogenous increase in demand increases both equilibrium waiting time and equilibrium activity (compare point A with point B). As the waiting list is the product of the two, then the waiting list will also increase. An exogenous increase in supply instead reduces waiting times and increases activity.

The waiting list which in the long run is given by the product of activity and waiting time can then either increase or reduce in response to an exogenous increase in supply (e.g., due to an increase in the number of doctors and beds).

Historically, waiting lists have been initially collected by policymakers as they were more easily available but in recent years a shift in focus on waiting times has been observed.

This section has used a static framework. The Section 'Waiting Times Dynamics over Long Periods of Time' expands such framework and allows demand and supply to increase over time driven, for example, by the technological development.

Competition and Choice

Many OECD countries have introduced in the last 20 years hospital payment systems of the Diagnosis Related Groups (DRGs) type where a public insurer (or the government) pays each hospital a tariff for every patient treated with a given diagnosis. This type of system is also known as activity-based financing. Patients typically receive treatment free of charge or are subject to small copayments.

As tariffs are the same across providers (they are regulated), hospitals have to compete on quality and waiting times to attract patients. Policymakers often argue that such competition among hospitals can also be beneficial to reduce waiting times. The intuitive idea is that under a competitive system, the provider will have an incentive to reduce waiting times to attract more patients and ultimately increase hospital revenues.

A prerequisite for implementing such competition policies is patients' choice; it is only if patients (or family doctors on their behalf) actively compare waiting times and quality across providers that providers will have an incentive to reduce waiting times to attract patients.

The higher the tariff paid to the hospital, the stronger will be the incentive to attract patients. DRG prices are normally based on average-cost rules. However, in some countries, like Norway, the price can be significantly less than the average cost (between 40% and 50%) in which case the incentive is reduced. Moreover, in some cases even countries that make use of DRG pricing have caps on the number of patients treated; the price can be significantly reduced once a certain volume of patients has been reached. In such cases the incentive to compete on waiting times can be significantly reduced.

Whether the hospital has a financial incentive to attract more patients by reducing waiting times depends on the difference between the tariff and the marginal cost. It is only if the profit margin is positive that the financial incentive is present. However, even if the profit margin is positive the provider may still lack the incentive to compete on waiting times. If the number of doctors is fixed and if the demand for treatment is high and there are strict targets on waiting times, doctors may be working at a point where the marginal utility from treating an extra patient is negative. In such cases, the introduction of competition may have an adverse effect on waiting times; intuitively by increasing waiting times, the provider can shift the cost of an unprofitable patient to another provider, which may generate a spiral towards high waiting times. Such results can be derived more formally through the stylized model provided in the Section 'A stylized Model of Hospital Competition'.

Empirical Evidence

There are two main empirical approaches to test the model outlined above. First, one prerequisite for competition to 'work' is that patients are willing to move when waiting times are higher. Empirical studies that model patients' choice suggest that at least in two countries (England and Norway) patients do react to variations in waiting time but the elasticity with respect to waiting time is low. The results are derived by regressing the hospital's choice of the patient (measured through a dummy variable equal to one for choosing a given hospital) as a function of waiting times in all hospitals in the catchment area of the patient (e.g., where the patient resides).

A second approach is to focus directly on the relationship between waiting time and competition, regressing waiting time of a given hospital on the number of hospital within the catchment area of the hospital. Using a cross-sectional framework one empirical study finds that in England an increase in competition by one hospital (from five to six hospitals) has a modest effect on waiting times reducing them by half week, from 17 to 16.5 weeks. A different study also tested the effect of competition on waiting times using a natural experiment framework in England: the control group includes providers who are 'local monopolists' and have no potential competitors within their catchment area. During 1997–99 competition (the policy of interest) was highly encouraged whereas during 1992–96 market boundaries were assigned geographically. The study shows that the introduction of competition leads to a reduction in waiting times by 0.8 months (see final section for detailed references).

Waiting Times and the Private Sector

Waiting times play a key role in the interaction between the public and the private sectors. Patients who are not willing to wait for a free public treatment may opt for the private sector paying a fee. Higher waiting times will lead to more patients being treated in the private sector. Anticipating that they will want care in the private sector, higher waiting times may also induce more individuals to buy private health insurance to cover the price charged by the private sector.

The incentive to set waiting times in the public sector may differ when a private sector is present or banned. Without a private sector, a public sector incentive to increase waiting times is such that the probability of idle capacity is optimally minimized. With a private sector a marginal increase in waiting times has the additional benefit (from the public provider perspective) of shifting patients to the private sector, which reduces costs in the public sector. Waiting times may therefore be higher in the presence of a private sector.

The incentive of the public sector to increase waiting times may be reinforced in the presence of 'dual practice', that is, when doctors are allowed to work in both the public and the private sectors. An increase in waiting times increases revenues in the private sector and generates a conflict of interest for doctors working in the public sector.

When the public and the private sectors interact, and patients differ in their severity, doctors may have an incentive to cream-skim the patients in the private sector to gain higher profits. Which patients are cream-skimmed depends on the rationing rule used by the public provider and the threshold severity level over which patients are entitled to public treatment. Intuitively, it would be expected that patients with the lowest severity to be cream-skimmed in the private sector. This may not always be the case. Patients with lower severity may not be willing to pay the price charged by the private sector and may also not be eligible for public treatment. Incentives to cream-skim will be highest for patients with middle severity when the severity threshold required for public treatment is high; for those patients severity is high enough to be willing to pay the price in the private sector but not high enough to be eligible for public treatment.

Maximum Waiting-Time Guarantees

In a number of countries, in response to rising waiting times, policymakers have introduced maximum waiting-time guarantees. In its simplest form, a maximum waiting time guarantee says that no patient should wait for more than a predetermined number of months or weeks. This has been the case, for example, in England. Such guarantees are 'unconditional;' they hold for every patient regardless of the treatment.

One problem with such unconditional guarantees is that they may conflict with clinical prioritization. As they refer to a maximum, the patients who benefit from this guarantee are likely to be those with a lower priority, who indeed wait the longest. There is therefore a risk that patients with lower severity may be given priority over patients with higher severity, who tend to wait less. Empirical evidence from England suggests that this is indeed the case; the probability of being admitted for treatment increases as it approaches the target but it decreases after the target.

To address this issue, unconditional guarantees have been replaced in some countries (like Sweden in the 1990s) with 'conditional' ones where the guarantee is given only conditional on having a certain severity. The maximum waiting time can differ between different severity groups (normally three or four). The most sophisticated form of conditional guarantee is one that specifies a 'personalized' waiting time (like in Norway), which depends on several criteria including urgency, benefit and cost-effectiveness from treatment. In contrast to unconditional ones, conditional guarantees conflict less with prioritization (and can actually be seen themselves as prioritization rules). They however suffer from their own limitations: as the provider has discretion over assigning a guarantee to a certain group and a provider can use such discretion to make sure it complies with the guarantee. One possibility to reduce the scope of such discretion is to develop explicit guidelines (though developing a guideline is quite a costly procedure as it involves extensive consultations).

One common problem to maximum waiting-time guarantees is how to enforce them. Although it is quite simple to state that no one or a subset of patients should not wait for more than a predetermined amount of time, it is not clear why the provider should have the incentive to respect such guarantees. The empirical evidence suggests that maximum waiting times work only when they are in the form of targets and clear penalties are attached to them. In England, one study made use of a 'natural experiment' to test whether or not a waiting-time target policy combined with sanctions for hospital managers resulted in a reduction of hospital waiting times. Scotland was used as the control group. The study finds that 'targets and terror' policy significantly reduced the number of patients waiting more than 6 and 12 months by 20% and 60%, respectively.

Equity Issues

This article has argued in the Section 'Waiting Times as a Mechanism to Bring the Healthcare Market to an Equilibrium' that waiting times act as a rationing device that brings about an equilibrium to demand and supply. It can also be argued that, despite waiting times generating disutility to patients, one advantage of rationing by waiting is that such form of rationing is equitable because the ability of affording such nonmonetary price does not depend on the ability to pay. This is in contrast to price rationing, for example, in the form of a copayment, which can be more easily afforded by richer individuals.

A recent empirical literature suggests, however, that waiting times may not be as equitable as they appear because individuals with higher socioeconomic status (usually measured by income or educational attainment) tend to wait less, and therefore pay a lower nonmonetary price, in publicly funded hospitals, than patients with lower socioeconomic status. Such gradient is found in separate studies in Australia, England, Norway, and Sweden and may be interpreted as evidence of inequity, which favors the rich and more educated patients over poorer and less educated ones.

One advantage of copayments over waiting times to contain demand, as opposed to waiting times, is that the cost to patients generated by long waiting times is not necessarily recovered by anyone else (except from the reduction in idle capacity that are exhausted quite rapidly). In contrast, copayments raise resources for the provider, which can be recovered by the government. Moreover, copayments could be income-tested to address equity concerns though there may be administrative costs associated with it.

A final argument in favor of waiting times is in terms of redistribution. Waiting times induce some better-off patients to opt for the private sector. Patients who opt for the private sector pay twice; they pay the price to receive the treatment in the private sector and also pay taxes, which contribute to the funding of public health systems. If governments have limitations to the extent to which they can redistribute between different income groups, the presence of waiting times may then help to redistribute resources form the rich to the poor (although indirectly).

Conclusions

Waiting times are a pervasive feature of many public-funded healthcare systems and increase with the gap between demand

and supply. In future, demand is likely to grow driven by the aging population and by the technological advancements. In contrast, given the current economic climate, there are limits to the extent to which governments can allocate additional resources to increase supply or identify significant efficiency gains. Waiting times may therefore be on the rise. As waiting times generate a significant dissatisfaction among patients and the general public, optimal demand management and patients' prioritization will play a key role in future policy developments.

Technical Appendix

Waiting Time of Patients on the List versus Waiting Time of Patients Treated: An Example

To illustrate the difference in the distribution of waiting times for the patients on the list versus the distribution in waiting times of patients treated, a simple illustrative example (based on Dixon and Siciliani, 2009) is provided. For expositional clarity, one period is referred to as 1 'month.'

Suppose that in each period there is a fixed number of patients who enter the waiting list, which is normalized to one, and an equal number who are treated (therefore a steady state is assumed). Suppose also that the proportion of patients entering the waiting list at any point in time and waiting more than 1 month is p_1, so that $(1-p_1)$ get treated in the first month. In the second month, conditional of having waited for 1 month, a proportion equal to $(1-p_2)$ get treated and p_2 keep waiting. By the third month, everyone is treated so that $p_3=0$ or $(1-p_3)=1$: no patient waits for more than three periods.

The distribution of the patients treated at any point in time (say in any given month) is the following. There are $(1-p_1)$ patients waiting for 1 month, $p_1(1-p_2)$ waiting for 2 months, and the remaining (p_1p_2) patients waiting for 3 months. The average waiting time of the patients treated (AWT), measured in months, is therefore

$$\text{AWT} = 1 \times (1-p_1) + 2^{*}p_1(1-p_2) + 3^{*}p_1p_2 = 1 + p_1 + p_1p_2$$

The length of the waiting list at any point in time, denoted by L, is equal to $L=1+p_1+p_1p_2$. At any point in time there is a whole cohort of patients (equal to one) who waits for 1 month (i.e. the minimum wait), plus those who started to wait the previous period (equal to p_1 as $1-p_1$ were treated in the previous period) and those who started to wait 2 months before (equal to p_1p_2). The average waiting time of the patients on the list (AWL) is therefore equal to

$$\text{AWL} = (1 + 2^{*}p_1 + 3^{*}p_1p_2)/L$$

It is straightforward to show that the AWT>AWL if $(p_1(1+p_2)^2 - p_2)p_1 > 0$. The comparison is, in general, indeterminate and depends on p_1 and p_2.

As a numerical example suppose that $p_1=0.2$ and $p_2=0.8$, which implies that only 20% of the patients keep waiting to the second month, and conditional on having waiting for 1 month, 80% keep waiting for 3 months. Then, AWT=1.32 months and AWL=1.38 months, and the average waiting time of the patients on the list is higher than that of patients treated. The opposite holds if $p_1=0.4$ and $p_2=0.8$.

As the first measure refers to an 'incomplete' measure it would intuitively be expected to be shorter than the second measure. This is however not necessarily the case. When looking empirically at the distribution of waiting time it may well be the case that the proportion of patients waiting more than 6 months or the average waiting time for the patients 'on the list' is actually larger than those treated. This arises because 'long waiters' are overrepresented (or oversampled) under the first measure, which causes the waiting time to go up.

Waiting Times Dynamics over Long Periods of Time

This section provides a simple stylized model of waiting-time dynamics, which illustrates the long-run determinants of waiting times. The analysis provided above (and in Figures 2–4) is static as demand and supply depend on waiting times and not directly on time. Changes over time have been analyzed only through exogenous shocks on demand and supply. As argued above, both demand and supply can vary over time possibly at different rates due to the technological development and a range of other factors. A simple way to model time-varying demand and supply function is to assume that they are linear and, respectively, equal to $D(w,t)=a+bt-cw$ and $S(w,t)=d+et+fw$, where t is the time and a, b, c, d, e, and f are positive parameters. Other parameters a and d can be interpreted, respectively, as demand and supply at time zero when the waiting times are zero; c and f as the responsiveness of demand and supply to waiting times; b and e as the degree at which demand and supply increase over time due, for example, to technology developments. The waiting time dynamics can be formally represented by the following differential equation:

$$\frac{\partial w}{\partial t} = D(w,t) - S(w,t) = (a-d) + (b-e)t - (c+f)w$$

which suggests that waiting times increase over time when demand is higher than the supply and reduce when waiting times are lower than supply. The closed-form solution of the above equation (assuming $a=d$ to keep the exposition simple) is as follows:

$$w(t) = \left[w_0 + \frac{b-e}{(c+f)^2} e^{-t} - \frac{b-e}{(c+f)^2} \right] + \frac{b-e}{(c+f)^2} t$$

The first term in the square bracket goes to zero as time passes. The long-run dynamics of waiting times is then driven by the difference between b and e, that is, the difference in the speed at which demand and supply grow over time. Intuitively, if demand grows faster than the supply, then waiting times will increase over time. *Vice versa*, if supply grows faster than the demand, then waiting times will reduce and eventually disappear. The smaller the growth in waiting times, the higher is the response of demand and supply to waiting times.

Given the current economic climate, public budgets allocated to healthcare may reduce or stagnate, and therefore slow down the growth in the supply of healthcare. As a result, waiting times may be on the rise. Policymakers will have to

either seek efficiency gains on the supply side or intervene on the demand side to prevent rapid growth of waiting times.

A Stylized Model of Hospital Competition

Some of the arguments provided in Section 'Competition and Choice' can be illustrated through a simple stylized model (adapted from Brekke *et al.*, 2008). Suppose that there are two hospitals i and j. It is assumed that the total demand is inelastic and equal to 1 (which can be thought of as 100% of the patients being treated) and every patient receives treatment in one of the two hospitals. A Hotelling set up is used, which assumes that the two hospitals are located at the extremes of a unit line is used. The demand function of hospital i is given by $D_i(w_i,w_j) = \frac{1}{2} - (w_i - w_j)/2t$, where w_i and w_j are, respectively, the waiting times in hospital i and j. If waiting times are identical, then each hospital has half of the market. If waiting times are higher in hospital i, then the demand in hospital i is less than half of the market. The parameter t is a transportation (or other) cost parameter, which can broadly be interpreted as the extent to which patients are willing to switch from one provider to the other. Lower transportation costs imply that patients are more willing to switch from one provider to the other when waiting times are lower. This parameter can be influenced by policymakers: making, for example, waiting-time information easily available to patients is equivalent to a reduction in transportation costs.

Assume that the payoff function of the hospital, defined by U, is given by the difference between revenues and the sum of monetary and non-monetary costs, which is given by the following expression:

$$U_i(w_i,w_j) = T + pD_i(w_i,w_j) - C(D_i(w_i,w_j),w_i) - \frac{k}{2}w_i^2$$

where p is the price for each patient treated, T is a fixed-budget component, $C(\cdot)$ is the cost function of treating patients (discussed in more detail below), k is a parameter that is proportional to the penalties from having long waiting times (e.g., deviations from waiting-time targets): higher waiting times imply a higher disutility in the form of more monitoring and a higher threat of dismissal for senior managers. To keep the presentation simple assume that the cost function $C(\cdot)$ is quadratic:

$$C(D_i(w_i,w_j),w_i) = F + \frac{c}{2}D_i(\cdot)^2 - zw_i + \frac{d}{2}w_i^2$$

where F is a fixed cost, and c, d, and z are positive parameters. Assume also that a higher activity increases costs at an increasing rate $(C_{D_i}(\cdot) = cD_i)$. This cost function captures both monetary and non-monetary costs. As in public hospitals the number of doctors is fixed, it is plausible that the marginal disutility (i.e. the nonmonetary marginal cost) from treating an extra patient is increasing. This specification also allows for the possibility that higher waiting times reduce costs by lowering the probability of idle capacity $(C_{w_i}(\cdot) = -z + dw_i)$. When waiting times are zero, a marginal increase in waiting reduces costs. However, this happens at a decreasing rate and there may be a point where higher waiting times increases costs due to the higher costs of managing the waiting list.

Differentiating the utility function, the following condition for optimal waiting times is obtained:

$$(p - cD_i(w_i,w_j))\left(-\frac{1}{2}\right) - kw_i + (z - dw_i) = 0$$

A marginal reduction in waiting times generates benefits and costs. On one hand, it increases activity which generates higher revenues and also makes waiting-times target figures look better. On the other hand, it increases monetary and nonmonetary costs either directly through higher activity or indirectly through higher idle capacity. In the symmetric equilibrium,

$$w^* = \frac{z + (p - (c/2))(-1/2t)}{k + d} > 0$$

which is always positive whenever the price p is not too high (or the cost c not too low). As expected, stricter targets (higher k) or higher prices p reduce waiting times, and higher costs (c) increase waiting times.

Critically, in equilibrium the price-cost margin $(p - (c/2))$ can be positive or negative. This depends on the price and the steepness of the marginal cost. Figure 5 illustrates the two possible cases with one price p and two marginal cost curves being characterized by $c_1 > c_2$. When the marginal cost is higher (lower), the profit margin is negative (positive).

How does more competition affect waiting times? Policies that encourage competition can be thought of as policies which reduce the transportation costs or the cost of switching between providers. Differentiating the equilibrium waiting time with respect to transportation cost parameter yields the following:

$$\frac{\partial w^*}{\partial t} = \frac{(p - (c/2))}{k + d}\left(\frac{1}{2t}\right)^2$$

Whether more competition increases or reduces waiting times depends on the price-cost margin $(p - (c/2))$. More competition (lower transportation costs) reduces waiting times only if the margin is positive (i.e., the price is sufficiently high). In contrast, more competition increases waiting time if the margin is negative (i.e., the price is sufficiently low). The intuition for the latter result is that if providers are working at a negative margin, then under more competition a marginal increase in waiting times becomes more effective in shifting

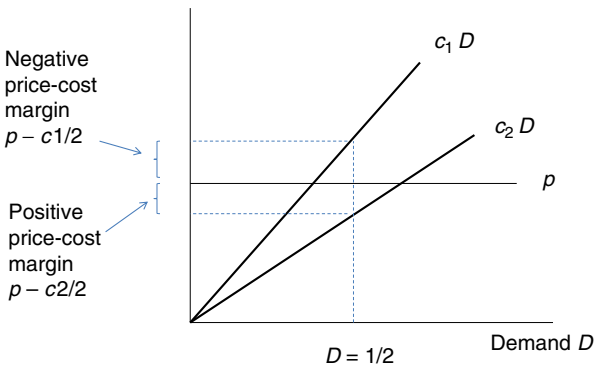

Figure 5 Price-cost margins.

unprofitable patients to the other provider. In contrast, if it is positive a reduction in waiting times attracts profitable patients.

The above analysis assumes that providers are altruistic, which is a realistic and plausible assumption for healthcare providers. Introducing altruism generates two additional effects. On one hand, altruism makes the providers even more willing to work at a negative profit margin, which in turn tends to reinforce the result that competition increases waiting times. On the other hand, altruism induces providers to compete for patients because they can do more 'good.' This effect goes in the opposite direction.

Water Supply and Sanitation

J Koola, Harvard University Kennedy School of Government
AP Zwane, Bill & Melinda Gates Foundation

Glossary

Chlorine Is sodium chloride, used as a disinfectant to clean contaminated water.
Point of use Is the location or time in which the water is actually used or consumed.
Sanitation Is the practice of eliminating contact between humans and urine and feces.
Wells Are an excavation or structure built to provide access to groundwater at the surface.

Introduction

Water supply and sanitation are at their core a public health issue. Every year, 2.2 million people die from diarrheal diseases, a leading cause of which is unhygienic water and sanitation. Improving health and mitigating diarrheal morbidity and mortality is the underlying rationale for water and sanitation Millennium Development Goals, which call for reducing by one half those who lack access to safe and sustainable water and sanitation. In the US, David Cutler and Grant Miller have shown that piped water, centralized water treatment, and waterborne sanitation interventions were jointly responsible for most of the rapid decline in the child mortality rate in the early twentieth century. Tara Watson has demonstrated more recently the link between water and sanitation coverage and substantial health improvements on Native American Indian reservations.

The outstanding question is not whether water and sanitation prevent diarrheal diseases in a biomedical sense, but what interventions are appropriate and effective in settings in which piped water and sanitation are unavailable because of their expense. In much of Africa, rural residents typically live on their farms rather than being concentrated in villages. In such circumstances, policy often focuses on providing improved drinking water sources outside the home, such as communal taps, wells, and protected springs. In developing countries in rural Asia and Africa, feasible sanitation interventions are generally latrines of some sort. The health impacts and cost-effectiveness of these interventions and the urban equivalents of shared standpipes and septic tanks or shared toilet blocks are less well understood compared to our understanding of the epidemiological transition in developed countries. The challenge in identifying appropriate institutional mechanisms for service provision is also great.

This article critically reviews the evidence on the health and nonhealth benefits of water and sanitation investments that are common in developing countries. Evidence on valuation for these interventions has been explored, and the implications of the evidence on valuation for government policy to support improvements in this sector have been discussed. Some implications for a future research agenda have also been briefly highlighted.

Water Supply

Water Quantity

This article considers separately how quantity and quality of water affect health because different water supply interventions affect water quality and quantity asymmetrically. For example, adding chlorine to water affects quality but not quantity. In contrast, providing household connections to municipal water supplies to households that currently use standpipes is likely to have a bigger effect on the convenience of obtaining water, and thus on the quantity of water consumed, than on water quality. Much of the most convincing nonexperimental evidence on the health impact of water and sanitation makes it difficult to separate the impact of quantity and quality because the interventions studied both reduced the cost of collection and improved quality, making it unclear which route of disease transmission matters the most in practice.

In the 1980s and 1990s, nonrandomized studies were frequently cited as evidence that water quantity was more important for health impacts than was water quality. Some researchers argued that these results could be explained because increased availability and convenience of water facilitate frequent washing of hands, dishes, bodies, and clothes, thereby reducing disease transmission. There is indeed strong evidence that hand washing is important for health. However, it is difficult to assess the causal impact of water quantity on hand washing in the absence of randomized evaluations or other convincing identification. In the Section Water Supply, numerous randomized evaluations that have shown impacts of improved water quality on health is discussed.

Although impacts may be heterogeneous across settings, and caution is warranted in drawing general conclusions, the one available randomized evaluation finds that increasing the quantity of water while maintaining unchanged quality did not lead to significant health improvements. Researchers, Florence Devoto, Pascaline Dupas, Esther Duflo, and William Pariente examine provision of piped connections to homes in urban Morocco previously served by public taps. This increased the quantity of water used by the household, but did not improve water quality, because the alternative, chlorinated

water from communal taps was of similar quality to the water received at home.

As part of a planned piped water service extension in Tangiers, Morocco, these researchers randomly selected half the households eligible for a first connection to receive (1) information about and an offer of credit toward a new connection and (2) administrative assistance in applying for credit. Take up was 69% (compared with 10% in the control group).

These researchers compared outcomes of those who received this treatment with outcomes for households in the control group. They found that piped water provision in this urban Moroccan context had few health benefits. There was no evidence for an impact of treatment on a subjective ranking of health of the family or on diarrhea in children under 6 years of age (although baseline rates were relatively low, with the average child in the control group experiencing 0.27 days of diarrhea in the past week). Households in the treatment group reported increasing their frequency of baths and showers: The number of times that respondents in the treatment group washed themselves (through baths or showers) during the past 7 days was 25% higher than in the control group. However, hygiene practices that required less water, such as hand washing, were not affected, according to self-reports.

It is not to be concluded that increased water quantity never yields health benefits. The benefits of increased water quantity may be context specific and require further research for a complete understanding. In particular, understanding when and how increased access to water leads to more hand washing is a research priority.

In the study mentioned above, having a piped water connection had substantial private benefits, despite the lack of impact on self-reported diarrhea, consistent with the evidence that most households that received information and an offer of credit toward a new connection were willing to pay for it. In particular, piped water connection saved time, which was spent for leisure and social activities. Measures of social integration and overall welfare improved. One year into the program and it was noted that, not only did the encouragement design result in high rates of take up in the treatment group, but also for these households, their average monthly water bill more than doubled, from 73 to 192 Moroccan dirhams, or US$9–24 a month (the previous cost came from households that took water from their neighbors). Other authors also note evidence of substantial willingness to pay for water quantity in observational studies.

Water Quality

Several randomized evaluations find that improvements in water quality reduce reported diarrhea. One study by Jessica Leino, Michael Kremer, Edward Miguel, and Alix Zwane examines source water quality improvements. The researchers estimate that protecting springs reduced fecal contamination, as measured by the presence of *Escherichia coli* bacteria, by two-thirds for water at the source but by only 25% for water stored at home. This is likely due in large part to recontamination in transport and storage within the household. Despite the incomplete pass-through of the water quality improvement, mothers reported approximately 25% less child diarrhea in the treatment group. The importance of recontamination suggests either to treat water at the point of use, close to the time of use, or to treat water in a way that provides residual protection, for example, with chlorine at a sufficiently high dose to remain at levels that provide disinfection for at least 24 h.

Household water treatment at the point of use, for example, with filtration or chlorine treatment, also reduces child diarrhea. The bulk of the evidence suggests that, with take up rates on the order of 70% (achieved via frequent visits and reminders to subjects), household water treatment reduces child diarrhea by 20–40%. There are multiple comprehensive reviews of this literature. Some question the validity of this literature because the outcome measure in these studies is typically mothers' reports of child diarrhea. Studies with objective outcomes, infrequently measured, would be preferable. However, the extent of reporting bias in treatment groups would have to be very large to explain the reported reductions in diarrhea associated with cleaner water. To the extent that reporting bias lowers estimates of diarrhea in treatment and comparison groups, such bias may make it harder to statistically detect reductions in diarrhea. If the reductions in diarrhea were even a fraction as large as those estimated, water treatment would still be very cost-effective.

Because water treatment can be extremely cheap, even a 20–40% reduction in diarrhea makes water treatment extremely cost-effective. For a sense of how cheap it is to treat water, a 1.42-Ga generic bottle of bleach with approximately 6% sodium hypochlorite concentration sold at Walmart for $2.54 as of December 2009 has enough chlorine to treat 163 400 l of water. This corresponds to a price of $0.00002 per liter of water treated. Actual costs of treatment with chlorine are higher because chlorine used for treatment is normally at lower concentrations and the concentration quality has to be made more consistent. Nonetheless, under the assumptions that chlorination reduces diarrhea by 20–40% and that mortality reductions are proportional to reported morbidity reductions, the cost per disability-adjusted life year (DALY) of chlorine provision using the traditional social marketing approach is less than $40, considerably less than the benchmark of $100–150 per DALY saved that is typically used in health planning in low-income countries.

Sanitation

Health Impacts – Diarrhea

The methodology used to evaluate sanitation programs is diverse but generally weaker than that which has been used to identify the impacts of water on health. Many studies are cross-sectional, some are longitudinal, others compare differences between two 'matched' groups, but very few rely on a randomized design. Studies of sanitation often try to address omitted variable bias by controlling for variables suspected of being confounding or by 'matching' subsamples. This method can only attempt to control for observable characteristics, such as maternal education or income, but will not control for unobservable characteristics, such as health attitudes.

Moreover, controlling for all possible confounding variables which could plausibly influence an outcome of interest is an impracticable undertaking.

Two more shortcomings of impact studies in the sanitation sector is that they neither have adequate sample size nor do they account for the fact that the interventions are provided at the community, rather than the household level. A large sample size is necessary to control for many factors in a multivariate regression. When interventions are targeted at the community level, individual households cannot be considered discrete observations because households within a community are likely to resemble each other, termed intercluster correlation. This 'clustering' means that a statistical test has less power to determine the existence and size of a treatment effect. Researchers point out that many early evaluations of sanitation compare an intervention village to a 'control' village, but this is tantamount to a sample size of two individuals because households within a village are not independent units of observation. Early reviews of health impact studies of water and sanitation interventions pointed out these methodological flaws and others.

Although there is broad consensus that improving sanitation will have a positive health impact, very few studies have established this causal effect in practice. In two survey papers, several authors critically examined the evidence for the health impacts of water, sanitation, and hygiene interventions alone or in combination. Despite the limited number of studies on sanitation interventions, these reviews suggest that sanitation is effective in reducing diarrheal illness, with a pooled relative risk estimate of 0.678 (with a 95 confidence interval of 0.529–0.868). Yet, the research on which these reviews are based has significant shortcomings. Of the four studies identified as sanitation specific, three were classified by the authors as poor quality. For example, two of these did not have an adequate control group and there was not clear or convincing measurement of confounding variables in two others. The only intervention studies were not randomized and used heterogeneous interventions and methodologies that prevented pooling of results. Moreover, nearly all combined sanitation with water or hygiene interventions, making it impossible to determine the contribution of sanitation alone.

In the ensuing years since these reviews, research quality has not improved dramatically. In a recent systematic review, researchers stressed the lack of rigorous evidence on the contribution of sanitation interventions to prevent diarrhea in young children. Others come to the same conclusion after conducting a Cochrane review of excreta disposal interventions to prevent diarrhea. A cohort study on the effectiveness of a city-wide sanitation intervention in Salvador in Northeast Brazil suffers from several of the methodological flaws reviewed above. For example, there is no external control group; the children, aged 0–36 months, are recruited from households where the intervention took place. The researchers simply compare the prevalence of diarrhea among two different cohorts of similarly aged children before and after the intervention and conclude that the intervention reduced diarrheal rates in children by 21%. Another shortcoming of the study's design is that the main outcome of interest is self-reported diarrhea, which is problematic because of respondents' recall bias and the bias introduced by frequent interactions with researchers. The single exception, to our knowledge, is a randomized-controlled trial of a community-lead total sanitation campaign (TSC) in 40 villages in Orissa, India. This study finds that the campaign increased child mid-upper arm circumference (MUAC) z-scores by roughly 0.25 standard deviations. However, the study lacked sufficient power to detect effects on diarrheal disease in children.

Health Impacts Beyond Diarrhea – Nutritional Status and Parasitic Infection

Recently, nutritionists including Jean Humphries have hypothesized that reducing a child's fecal bacteria exposure during the first years of life through improved sanitation (and/or handwashing or water treatment) may improve gut function (the ability of the gastrointestinal tract to absorb nutrients) and subsequent growth. The prenatal period and the first 2 years of life are a critical window for intervention in growth and development: infection and poor nutrition during this window can negatively impact an individual's long-term cognitive development and lifetime physiologic trajectory. The new hypothesis is that nutritional supplementation seems to be necessary but not sufficient to eliminate growth shortfalls because chronic infection and colonization of the gut by fecal bacteria, spread via poor conditions, impedes nutrient absorption and creates low-level immune system stimulation, a condition called environmental (or tropical) enteropathy.

If the environmental enteropathy hypothesis were to be correct, this would significantly alter our understanding of the health benefits associated with sanitation, and increase the estimated cost-effectiveness of these interventions. The change would likely be very large, because of the lifetime gains associated with better nutrition in early childhood.

Recent rigorous research suggests that avoiding worm infections in childhood brings not only better health outcomes, because of reduced anemia, but also better nonhealth outcomes. In an article with the memorable title 'Worms at Work,' randomized control trial data show that children without worms are less fatigued who go to school more and ultimately have higher incomes as adults. Complete sanitation services certainly reduce worm loads and infection rates; however, it is uncertain whether partial sanitation coverage is sufficient to do this. To the extent that feasible, affordable sanitation interventions reduce worm infections, the benefits associated with these sanitation investments may be much greater than suggested by health benefit calculations alone because of the associated lifetime schooling and wage increases.

Nonhealth Benefits of Sanitation

Limiting the gains from sanitation to health benefits, however, ignores a growing body of evidence that indicates that people realize substantial nonhealth benefits from improved sanitation, such as convenience, safety, and dignity. Lack of facilities for defecation is a problem faced by everyone, but differing norms for behavior and modesty of women can make this especially problematic for them. Women and girls may be expected to defecate only when it is dark, which can increase urinary tract infection rates, chronic constipation, and

psychological stress. Leaving the home for secluded areas after dark also makes women and girls vulnerable to physical assault. The challenges of menstrual management and the symptoms of the postnatal period compound these problems. Measuring the quality of life benefits for women from reduced stress or shame when sanitation services are available is very hard to do. Women and children in particular are targeted as primary users of sanitation for reasons including their privacy and security.

Suggestive evidence from the economic and sociological literature demonstrates that women's participation is important for providing and managing local public goods. These frequent associations between women, sanitation, and public goods imply a need for a greater understanding and further research on both women's and men's roles in sanitation provision and behavior change.

Elastic Demand and the Subsidy Debate

This section considers the case for subsidies in the water supply and sanitation sector, with a particular focus on sanitation. Willingness to pay for water quantity has been well established, including in the setting in Morocco discussed above. Evidence on valuation of water quality has been summarized elsewhere. Subsidies for sanitation are currently at the center of a policy debate because of a new push to meet the MDGs and rethink old ways of doing business in that sector.

Supply-side interventions along with hardware subsidies have been the typical approach to rural sanitation. Traditional public finance reasoning supports such an approach on both efficiency and distributional grounds. Subsidizing sanitation hardware has been justified on the grounds that the public benefit far outweighs the private one. In addition, the high upfront costs of sanitation infrastructure necessitates subsidies for the credit-constrained poor. Even with hardware subsidies, the extra transportation and construction costs associated with latrine building may still be prohibitive for the extremely poor. One study in Mozambique found that the additional transportation and construction costs for a latrine made the already subsidized cost (only 5% of the household's average monthly income) into a 'medium' cost which was too burdensome majority of the poor population.

Recent funding trends have begun to disavow subsidies in the sanitation sector. Community-led total sanitation, for example, is a new participatory methodology for sanitation behavior change which discourages the use of subsidies and emphasizes cost sharing by households instead. There are several nonrandomized, cross-sectional studies that have been frequently cited in the gray literature as evidence to support the case for cost recovery, rather than subsidies. One example of this comes from a report conducted by the Water and Sanitation Program in South Asia that compiled lessons learned from eight case studies of rural sanitation programs in Bangladesh, India, and Pakistan. Six of the eight case studies examined the TSC in India. The report compares programs offering full hardware subsidies (e.g., Andhra Pradesh TSC) to programs offering only partial subsidies (e.g., West Bengal TSC) and programs with full cost recovery (e.g., Plan Bangladesh). The analysis relied on data from interviews with key stakeholders and observations at selected villages that were included in the program and villages that were not included in the program. As emphasized above, such a methodology does not create a credible counterfactual. The study concludes that there is an association between high subsidies and poor program performance: the two worst performing programs (Andhra Pradesh TSC and Pakistan's Lodhran Pilot Project) had the highest hardware subsidies. The report goes on to say that high hardware subsidies 'reduce the sense of ownership by those that receive the heavily subsidized facilities' and that there is 'increasing evidence that (subsidies) tends to result in low toilet usage and wasted investments.' Others also argue charging a fee for sanitation infrastructure will induce adoption, ownership, and more use.

There are three assumptions underlying the argument that cost recovery increases usage. First, higher prices may act as a 'screening' mechanism for those who most need the product because households will self-select into purchase. Second, positive prices are interpreted as a signal of quality. And third, purchase will increase use because households rationalize purchases *ex post* because of a 'sunk-cost' effect. The sunk-cost effect implies that the household pays a psychological cost whenever it buys a product that it subsequently does not use. Several researchers use similar methodologies to exploit variation in offer prices and purchase prices for water treatment products and bed nets, respectively, to test for evidence of the screening and the sunk-cost effects. Both studies agree that cost sharing drastically reduced demand and does not target those most in need. For bed nets, cost sharing did not reduce wastage. Higher willingness to pay is associated with a greater propensity to use the water treatment product. These two studies add to a growing body of empirical evidence which refutes the simple claim that a positive price effectively targets households who are more in need of a produce or makes use of the product more likely.

Whether and how much to subsidize sanitation falls into a much broader debate about cost sharing for health products in general. The empirical evidence points to an income elasticity of demand for health that is positive and above one in both developed and developing countries, which implies that even a small increase in income would result in a very large increase in the demand for the good.

Another consistent finding in the experimental literature is that there is a very steep demand curve for preventative health products, such as bed nets, water treatment, or deworming pills. The price elasticity of demand around zero is very large for people in lower income groups, meaning that even a small change in price can create a very large effect on demand for the good. For example, it was found that demand for deworming drugs dropped from 79% to 19% when the price was raised from 0 to 30 cents. Similarly, others found that raising the price of bed nets from 0 to 60 cents lowered demand by 60% points in Kenya and that a 13 cent increase in the price of water treatment lowered demand for the product by 30% points in Zambia. These dramatic findings would seem to defend full subsidies of health products with positive externalities for poor households.

The theoretical literature on externalities and the empirical evidence discussed above would seem to suggest that sanitation should continue to be subsidized. Subsidies may also

have potential downsides, and these drawbacks in the sanitation sector need to be rigorously tested. Subsidies may lead to inefficient allocation in two ways. First, households may delay their decision to purchase and install sanitation infrastructure because of the expectation of receiving a future subsidy. And second, subsidies that follow purchase or construction may lead to overconsumption of the good to benefit from the subsidy. For example, a review of a sanitation progress in Andhra Pradesh, India, found that households had built expensive toilets to receive the subsidy, but abandoned them soon after. In addition, subsidization of sanitation infrastructure has been blamed for distorting the private supply market and artificially inflating hardware prices. And finally, in practice, elite capture of construction subsidies has meant that the transfer is not always received by the intended beneficiary.

Conclusion

Further research on the health externalities of improved sanitation and water quality would provide policymakers with the evidence they need to decide on whether and how much to subsidize these interventions. How subsidies might be best provided is another area for exploration, so that the pitfalls identified above can be minimized or avoided. An investigation of households' valuation for improved sanitation, like the research that has been done on water quality and bed nets, would better inform policymakers in this debate.

Understanding how water and sanitation service bundle public and private benefits is also important in determining how to provide these goods. The majority of nonhealth benefits of sanitation, including reduced shame and stress, are likely what economists call 'private benefits.' Water quantity provides many private benefits, in terms of quality of life, whereas water quality may have a more public health character. Sanitation likely combines both attributes. Individuals are typically considered to be best placed to allocate limited resources between competing goals, to the extent that they are the sole beneficiaries of those goods, and thus it is often argued that donor, or public funds should be reserved for funding those investments that provide public benefits, not private ones, no matter how attractive the attributes of the private goods may be.

However, the case for investment in private goods can be stronger if a donor values the welfare of women and girls more than decision-making processes within households might. Despite the fact that women benefit disproportionately from sanitation and water services, if they have little ability to control how resources are spent, unmet demand may persist even if nominally affordable or seemingly attractive options are available. A donor may wish to support providing services that women want as a way of redistributing resources toward women. Untangling these issues remains a fruitful area of research.

Welfarism and Extra-Welfarism

J Hurley, McMaster University, Hamilton, ON, Canada

Glossary

Capabilities The set of all possible physical and social functionings for a person.
Consequentialism The normative tenet that any policy or action be judged solely in terms of the resulting, or consequent, effects.
Extra-welfarism A normative framework of economics which holds the evaluation of a policy or resource allocation that should be based on a larger set of information than the utilities attained by members of society solely.
Functioning A person's ability to engage in private and social activities, frequently also taken to include emotional and psychological states of health.
Individual sovereignty A tenet of welfare economics that holds individuals are the best judges of their own welfare.
Pareto criterion An efficiency criterion that holds a resource allocation is efficient if it is not possible to reallocate resources so as to increase one person's utility without decreasing another person's utility.
Potential Pareto criterion An efficiency criterion in economics that holds an allocation is preferred to another if the gains to the winners are sufficiently large to compensate the losers and still leave the winners better off.
Social welfare function A function that maps from the levels of utility attained by members of society to the overall level of welfare for society.
Utility It is variously defined in the history of economics. Two dominant interpretations are hedonistic utility, which equates utility with pleasure, desire-fulfilment, or satisfaction; and preference-based utility, which defines utility as a real-valued function that represents a person's preference ordering.
Welfarism A tenet of welfare economics that holds the evaluation of a policy or resource allocation should be based solely on the utilities attained by members of society.

Introduction

Welfarism and extra-welfarism are alternative normative economic frameworks for ranking resource allocations. By normative, we mean economic analysis intended to answer questions such as, What 'ought' we to do? or Which resource allocation is the best? or Is policy A preferred to policy B? Normative analysis unavoidably rests on value judgments regarding, for example, as to what constitutes a benefit. Normative economic analysis contrasts with positive economic analysis in that, by answering questions such as, What will be the effect of policy A on the allocation of resources among the members of the society?, it attempts to describe what will happen without making any judgment as to the goodness or desirability of the predicted effects.

Welfarism is one element of the welfare-economic framework that dominates normative analysis in economics. It dictates that the only information relevant for ranking alternative allocations of resources is the utilities attained by the individuals in a society.

Extra-welfarism, in contrast, argues that normative economic analysis should be based on a larger set of information than simply the utilities attained by individuals in the society. Different variants of extra-welfarism emphasize different types of information to either supplant or supplement utility information.

As noted, normative economic analysis is conducted to rank-order policy options. Each policy generates a particular allocation of goods and services within the society and an associated distribution of well-being among the members of the society. The policies considered can be quite narrowly defined and generate relatively circumscribed effects, such as would be the case when comparing alternative dosages of a drug used to treat a relatively rare, minor ailment, or they can be broadly defined with wide-ranging, profound effects on resource allocation, such as would be the case when comparing alternative systems of health-care finance, which may affect labor markets, income distribution, health-care consumption, and other economic activities. In either case, the term 'resource allocation' refers simply to who gets what in society, including health-care goods and services, other government goods and services, private consumption goods and services, and so forth. Hereafter, we use the terms 'policy' and the associated resource allocation created by a policy interchangeably.

Welfarism and the Welfare-Economic Framework

The mainstream welfare-economic framework is built on four central tenets: utility-maximization, individual sovereignty, consequentialism, and welfarism.

Utility-maximization refers to the behavioral assumption that individuals choose rationally: given a set of choice options, an individual chooses the most preferred option among them according to the defined notions of consistency. Utility has been interpreted variously in the history of economics and continues to have multiple interpretations. The two dominant interpretations are hedonistic utility and preference-based utility. Hedonistic utility, which derives from classical utilitarianism, equates utility with the pleasure, happiness, or satisfaction that an individual derives from a good or an activity. It is a psychological construct and an individual is assumed to choose and act so as to maximize his utility.

In contrast, the preference-based definition of utility eschews a psychological interpretation and defines utility as a function that represents a preference ordering: those goods or activities that an individual chooses are assigned a higher utility value than those that are not chosen. Utility therefore simply represents preferences: it makes no assumptions as to the reasons why one thing is preferred to another. Modern microeconomic theory adopts this preference-based interpretation of utility. At times, some have argued that utility is defined only over goods and services, but in modern economics, utility can be defined over goods, services, activities, and virtually any phenomenon on which an individual can express a preference.

Individual sovereignty (sometimes referred to as 'consumer sovereignty') is the maxim that individuals are the best judges of their own welfare. Any judgment regarding an individual's welfare should be based on the person's own assessment. Individual sovereignty explicitly rejects paternalism – the notion that a third party may know better than the individual what is best for himself or herself. It dictates that individual preferences be respected in the process of evaluation.

Consequentialism holds that any policy must be judged exclusively in terms of the resulting, or consequent, effects. The motivation for or intention behind the policy does not matter; ethical imperatives such as duties, rights, and obligations do not matter. All that matters is the effects that flow from the policy.

As already noted, welfarism holds that the goodness of any resource allocation is to be judged solely on the basis of the utilities attained by the affected individuals. No other aspect of the situation matters. Together, these four tenets require that any policy be judged solely in terms of the resulting utilities achieved by individuals, as assessed by the individuals themselves.

The final ranking also depends on the criterion used to rank alternative policies based on this utility information. Early Neoclassical Welfare Economic Theory assumed (like classical utilitarianism) that utility was cardinally measurable and interpersonally comparable, and defined the best allocation as the one that maximized total utility (i.e., the sum of individual utilities) for the population. Modern welfare economics assumes that utility is ordinally measurable and noninterpersonally comparable, and it replaces the utility-maximizing criterion with the Pareto criteria: an allocation of resources is judged to be Pareto optimal if it is not possible to reallocate resources so as to increase one person's utility without decreasing another person's utility. Although many economists prefer the Pareto criterion to the sum-maximizing criterion because it makes less restrictive assumptions regarding utility and it makes weaker ethical assumptions, the Pareto criterion suffers some important limitations for applied welfare analysis. For a given set of resources, each of the many possible allocations can be Pareto optimal: the Pareto criterion does not necessarily lead to full ranking that identifies a single allocation as best. Besides, as nearly all real-world policy changes hurt at least one individual, organization or group in a society, strict application of the Pareto criterion leads to policy paralysis in which no policy can be judged better than the *status quo*.

These limitations of the Pareto criterion led to the development of the potential Pareto criterion (also call the hypothetical compensation test), which states that one allocation is preferred to another if the gains to the winners are sufficiently large to enable them to (hypothetically) compensate the losers while are still leaving the winners better off. Crucially, however, compensation does not have to be paid to the losers, so the losers are in fact still worse off. The potential Pareto criterion is the basis for much normative economic policy analysis.

Neither the sum-maximizing criteria of classical utilitarianism nor the Pareto criterion are sensitive to how utility is distributed among the members of a society. Welfare economics has tried to incorporate distributional concerns through the concept of a social welfare function. A social welfare function maintains the welfarist assumption that rankings depend solely on the utilities attained by the members of the society, but includes a measure of the society's aversion to inequality. Hence, even if the total utility is the same under both the policies, and if the society is averse to inequality the policy under which utility is distributed more equally among individuals would be preferred.

Welfare-economic analysis has been importantly shaped by the two fundamental theorems of welfare economics. The first theorem states that a well-functioning market (where this has a specific meaning) leads to a Pareto optimal allocation of resources. The second theorem states that, given the right initial distribution of income in society, any Pareto optimal allocation (including those judged to be equitable) can be achieved through market allocation. When combined with the claim that questions of distribution are fundamentally political rather than economic, the second theorem has led economists to focus on issues of efficiency, effectively separating the analysis of efficiency from the analysis of distribution. In addition, given that any allocation can, in principle, be achieved through a system of well-functioning markets, market-based allocation serves as the reference standard for judging efficiency. Hence, within the welfare-economic framework government intervention in a market can be justified by equity concerns (e.g., income inequality) or by market failure, a situation in which deficiencies in the market cause market allocation to be inefficient. The latter, however, has dominated economic analyses on the role of government policy. As a corollary, within this framework the objective of any corrective public policy is to achieve the allocation that would have resulted from a well-functioning market.

Empirical Welfare Analysis

Using this welfare-economic framework as a guide to empirical normative analysis presents a number of challenges. The methodology of applied welfare analysis is called cost–benefit analysis. The goal of cost–benefit analysis is to determine whether the adoption of a policy will be more efficient than a specified alternative policy, where efficiency is defined by the potential Pareto criterion. Within cost–benefit analysis, utility is measured using a money metric. Benefit to a member of a society is defined as the amount of money a person is willing to pay for the effect achieved by a policy (e.g., improved health). As both benefits and costs are measured in monetary units, a policy is deemed efficient (relative to the alternative

against which it is being compared) if the net benefit (incremental benefits–incremental costs) is positive. The goal of cost–benefit analysis is to mimic for government policies the allocation of resources that would have resulted from a well-functioning market.

Extra-Welfarism

At its most general sense, extra-welfarists argue that normative assessment should be based on a wider set of information than solely the utilities attained by individuals. Although utility information may be relevant, it is insufficient and additional, or extra, information should be incorporated into the analysis. Extra-welfarism is not strongly prescriptive as to what this additional information is; indeed, many extra-welfarists argue that the relevant information depends on the context. As extra-welfarism is, in part, a reaction against the dominant welfarist paradigm in economics, it tends to be more eclectic as different extra-welfarist writers have reacted against different elements of welfarism and proposed different ways of addressing welfarism's limitations. As a result, it is perhaps easier to articulate what extra-welfarism is not than what it is. Still, although extra-welfarism continues to develop within heath economics, it embodies a sufficient set of foundational principles and ideas as to define a coherent normative framework distinct from welfarism (Hurley, 2000; Brouwer *et al.*, 2008).

Extra-welfarist ideas have existed within health economics since long before the term 'extra-welfarism' was coined. Much of the work of extra-welfarists in health economics has been to integrate these ideas into a framework with deeper conceptual foundations. The work of Culyer (1990) – who coined the term 'extra-welfarism' – has been particularly important in this respect. These extra-welfarist tendencies in health economics arose for a number of reasons:

- Health economists have traditionally worked closely with noneconomist health professionals, including clinicians, epidemiologists, bioethicists, decision scientists, and others not schooled in welfare economics and who found some of its elements unpalatable. In particular, a primary outcome of health-care interventions is improved health, and notably, 'lives saved.' Many noneconomists objected to assigning a monetary value to lives saved. This gave rise to the use of cost-effectiveness analysis rather than cost–benefit analysis in the evaluation of health-care interventions. Cost-effectiveness measures outcomes in natural units (e.g., life-years gained and cases detected) and refrains from assigning a monetary value (or indeed any explicit social value) to the health gains produced by a health intervention.
- Government health policy commonly rejects the welfare-economic view that the desired allocation of health-care resources is the one that would follow from market forces based on people's willingness to pay. The explicitly stated objective of many governments is to improve population health based on allocation of health-care resources according to 'need', regardless of a person's ability to pay or willingness to pay. This requires that access to health care be independent of a person's income or wealth. Even if the society could somehow get the distribution of income 'correct' (as envisioned in most of the welfare-economic analysis), it would be very difficult to achieve this objective through market-based allocation of health care using prices. Instead, the objective requires allocation based on nonmarket principles.
- Health economics has been heavily influenced by the 'decision-maker' approach to cost–benefit analysis, which rejects the individualistic, welfarist foundations of traditional cost–benefit analysis. The decision-maker approach instead emphasizes the objectives (and weights) of high-level policy decision makers. This approach has strong affinities with the view within decision sciences that the role of the analyst is to assist a decision-maker in achieving the decision-makers stated goals. Combined with the point above regarding the stated objectives of most of the health policies, this perspective led health economists to develop methods of evaluation in which health – rather than utility – is the primary measure of benefit.
- The demand for health care derives from the demand for health. This derived demand for health care means that health care is an input into the production of health, which permits normative assessments of health-care consumption using supply-side notions of efficiency, unlike other sectors of the economy in which individuals demand goods for their direct effects on utility. This underlying production relationship enables a third-party analyst to use evidence regarding the impact of a health-care service on health (generated, for instance, by clinical studies) to assess the efficiency of health-care consumption: it cannot be efficient to consume a service known to be ineffective in producing health. This perspective on normative assessment in the health sector reinforces a focus on health as the main outcome of interest.

Extra-welfarism in health has been shaped importantly by the work of the Nobel-Prize winning economist Amartya Sen. Sen broke sharply with welfarism and has developed an alternative framework based on the concepts of human functionings and capabilities (e.g., Sen, 1999). Sen argued that welfarism was an insufficient basis for normative economic analysis because utility focuses too narrowly on people's mental and emotional reactions to circumstances and not enough on what they can achieve with their material and other resources. Welfarism, for instance, suffers from the problem of adaptation. A person born into poverty, who adjusts his/her life expectations to conform to his/her limited life possibilities may, as measured by utility, be better off than a well-off person given every advantage and opportunity in life but whose expectations exceeded what his/her was able to realize and who therefore ends up disappointed. Welfarism also either ignores nonutility aspects of a situation, such as whether basic human rights are being violated, or, to the extent that they are captured by the analysis, they enter only through the metric of utility. In the end, Sen argues that neither utility – whether defined in traditional hedonistic terms as desire-fulfillment or pleasure or in modern terms as preference satisfaction – nor a person's material possessions can serve as a proper basis for assessing alternative social policies.

Sen argued that, instead, evaluation should focus on functionings and capabilities. The central ideas of his approach can be briefly summarized as follows. He begins with commodities – goods and services – that can be under a person's command and which have characteristics: a bicycle is a commodity whose salient characteristic is that it can provide transportation; health care is a commodity whose salient characteristic is the potential to improve a person's health. Commodities and their characteristics do not depend on features of the person who possess them. A functioning is what a person succeeds in doing with the commodities at his or her command; it is what the person manages to do or to be. Bicycling is a functioning. The functionings possible for a person depend on the commodities at the command of a person and features of the person and their environment. A quadrapalegic with a standard bicycle cannot achieve the functioning of bicycling. Functionings range from the trivial (enjoy ice cream) to the profound (form meaningful relationships with others). The set of all possible functionings for a person, which Sen calls their capabilities, depends on their feasible set of commodities available and, given their personal characteristics and social institutions, the feasible set of means available to them to transform commodities into functionings. Alternative states of the world should be evaluated based on the people's capabilities in that world; that is, the functionings open to them. Sen emphasizes a nonconsequentialist perspective that the evaluation be based not on the functionings a person actually achieves, as these may depend on personal choices not of concern to normative assessment, but rather on what was possible for the person – the life prospects that were available to them given the social arrangements and their place in society. Sen's framework is commonly referred to as the 'capabilities' approach within extra-welfarism.

As noted, Culyer was one of the earliest health economists to recognize the potential for adapting Sen's ideas to the health sector. The concept of need, for example, is widely used by health professionals, health scientists, and, historically by health economists, though it does not fit easily into the individualistic, welfarist framework of traditional welfare economics in which people are characterized only by utility; and mainstream economics has in fact been hostile to the concept, seeing it largely as an attempt by some to gain privileged status for their preferences. Yet, the concept of need for health care fits easily into the capabilities approach wherein health care is a commodity that is essential for (and needed by) an ill-person to become healthy and thereby be able to realize many different types of functionings.

Within a broad welfarist framework, functionings and capabilities could, in principle, be valued using a metric of utility. Indeed, among welfarists who believe that preferences extend over any aspect of life, there is no concern of extra-welfarism that could not, in principle, be captured through preferences. The point of extra-welfarism, however, is that preferences are the wrong metric by which to value such outcomes. The extra-welfarist criticism of utility is not that it can only be applied to a limited range of outcomes; rather the criticism is that it provides a limited valuation of all those outcomes to which it is applied.

Though Sen's capabilities approach is a particularly influential source of extra-welfarist thought in health economics, it is only one variant of extra-welfarism. Brouwer *et al.* (2008) represents perhaps the most comprehensive attempt to articulate the scope and definition of extra-welfarism in the health sector, and in particular ways in which extra-welfarism differs from the welfarist normative framework. They emphasize four ways in which extra-welfarism differs from the welfarist framework: (1) extra-welfarism permits the use of outcomes other than utility; (2) extra-welfarism permits the use of sources of valuation other than the affected individuals; (3) extra-welfarism permits the weighting of outcomes (whether utility or other) according to the principles that need not be preference-based; and (4) extra-welfarism permits interpersonal comparisons of well-being in a variety of dimensions, thus enabling movement beyond Paretian economics. Below we summarize some of the main elements of extra-welfarism in the health sector, discussing these and other points related to extra-welfarism.

Extra-welfarism emphasizes the use of nonutility information in normative economic analysis. Conceptually, extra-welfarism does not reject a possible role for utility information – it simply argues that utility information alone is insufficient. The predominant nonutility outcome of interest within health economics is health status. The focus on health derives from a number of factors – the influence of the decision-maker approach and the fact that health policy-makers emphasize health as the outcome of interest; the fact that health is observable and, within certain bounds, interpersonally comparable; and the fact that health can be integrated into Sen's capability approach. Extra-welfarism can also accommodate other types of nonutility information such as rights, dignity, and other ethical concerns. Indeed, it places no restriction on the type of nonutility information that can, in principle, be included in an analysis. Some have argued, however, that a shortcoming of how extra-welfarism in the health sector has developed in practice is a near-exclusive focus on health as the outcome of interest in evaluation. To the extent that this is true, extra-welfarism has simply substituted one restrictive definition of the outcome space – utility – with another – health.

Health status can be measured in numerous ways depending on the specific question under consideration, and the emphasis on health as the outcome of concern has spurred economists to develop health measures with desirable properties. The dominant health-related outcome measure for the evaluation of health programs, services, and technologies is the quality-adjusted life-year (QALY). The QALY illustrates well that extra-welfarists do not completely reject the use of utility information and utility-based methods, but that they often use utility information in ways not consistent with welfare economics. The QALY is designed to capture the effect of a health intervention on both the quantity and quality of life-years. It is defined simply as the quality-weighted sum of life-years: $\sum_i Q_i Y_i$, where Y_i is the number of years spent in health state i and Q_i is a quality weight for health state i that takes on a value between 0 and 1, where the weight for full health is 1.0 and the weight for being dead is 0. The quality weights used to construct a QALY measure are often constructed using methods derived from utility theory; that is, the quality weights underlying the QALY are elicited using the methods drawn from utility theory.

This fact has led to considerable confusion and debate regarding the interpretation of a QALY, and this debate reflects

important issues in the debate on welfarism and extra-welfarism. The confusion stems from the fact that a QALY can be interpreted differently depending on the auxiliary assumptions one is willing to make. Under certain assumptions regarding the nature of people's utility functions, a QALY can be interpreted as a measure of individual utility or preferences. These assumptions are restrictive, however, and do not accord well with evidence on the actual structure of people's utility functions. Hence, welfarists – for whom utility is the outcome of interest – have criticized the QALY because it does not represent well people's preferences over health states. Extra-welfarists, however, have argued this criticism is misguided: although preference information is used in the construction of a QALY, the QALY is not intended as a measure of preferences but instead it is a measure of health, or perhaps as more commonly stated, health-related quality of life. Hence, the fact that QALYs do not accurately map preferences over health states is not a weakness. Finally, some extra-welfarists have explored the potential for interpreting the QALY as a measure of the value of an individual's capability set. Doing so requires making the rather strong assumption that the QALY can represent all of an individual's well-being rather than making the more traditional assumption that QALY represent only one component of an individual's well-being (the health-related component). Regardless of the specific interpretation one may adopt, the point is that the QALY illustrates one way extra-welfarists integrate utility information in unconventional ways, and, in addition, that one cannot understand certain debates in health economics without being attuned to subtle distinctions between welfarist and extra-welfarist approaches.

Unlike welfare economics, extra-welfarism permits sources of valuation other than the individuals affected by a policy. Extra-welfarism is comfortable with certain types of paternalism. Acting as agents for the members of the society, decision-makers are not assumed to act in the way they think individuals would act, but rather as they think individuals ought to act. The potential sources of value are many. The valuation could be based on empirical information drawn from the general public, but it may include information other than preferences, it may even include preferences but aggregated in ways inconsistent with individualistic welfare-economic analysis, it may gather information in ways inconsistent with preference measurement such as deliberative process and consultations of various types, or it could be responses to questions quite different from preference information. Valuation could be reasoned argument that has no basis in empirical measurement.

Extra-welfarism and welfarism differ importantly in a number of ways pertaining to the aggregation of costs and benefits across individuals. Extra-welfarism is more accommodating of interpersonal comparisons of well-being. Sen has argued in particular for frameworks that admit more possibilities than the two extremes of complete rejection of interpersonal comparability (as in modern welfare economics) and the assumption of full interpersonal comparability (as in classical utilitarianism). He emphasizes the scope for limited degrees of comparability that allow for at least partial orderings of the different possible states of the world. Such partial orderings are all that the analysis requires in many situations. The shift to nonutility outcomes such as health also provides greater scope for assuming degrees of interpersonal comparability. Again, even if one recognizes that it is not possible to conclude which of the two people have greater health in all situations, it often is possible to make relatively uncontested judgments regarding relative levels of health across individuals. The same is true for pivotal concepts such as the need for health care.

Extra-welfarism provides greater scope than welfarism for integrating equity concern. Both the Pareto criterion of analytical welfare economics and the net-benefit criterion on cost–benefit analysis are completely insensitive to distributional concerns. Extra-welfarism, however, allows for the integration of nonunitary equity weights that reflect the fact that society may value health gains among certain groups in society more than others. The equity weights constitute a type of nonutility information that may be derived from a number of sources. Some examples include differential weighting by age (greater weight to the young), by one's role in society (e.g., greater weight to caregivers, especially those caring for children), by the extent to which one is responsible for one's ill-health (lesser weight to those who are at least in part responsible for their ill-health), or by baseline health status (greater weight to those with more severe health conditions). The use of such weights also implies breaking with the welfare-economic assumption of anonymity, which holds that no characteristic of an individual matters for evaluation except their value with respect to the outcome of interest.

Extra-welfarism is also more accommodating of equity concerns beyond distributional equity, such as procedural equity. Procedural equity emphasizes fairness in the process by which resources are allocated, respect for the rights of individuals, and related matters that may not bear on the actual final distribution of resources. Although welfarist approaches have developed the idea of 'process utility' to capture some of these types of concerns, such an approach values them only to the extent that they affect utility, whereas many argue that aspects of procedural equity lie outside the logic of a consequential calculus.

Empirical evidence consistently demonstrates that among the general public concerns regarding equity weigh heavily in judgments on the allocation of health-care resources. People are willing to reduce the total amount of health produced in order to achieve a more equal distribution of health among the members of the society. Moreover, although extra-welfarism can readily accommodate such attitudes, some analysts have been critical of the fact that, as a pragmatic matter, a good deal of extra-welfarist evaluation in health has adopted a health-maximization criterion: that is, the best option is that which maximizes the amount of health produced, in a manner analogous to the classical utilitarian approach within welfarist economics. As with the concern regarding a near-exclusive focus on health in the outcomes space, the issue is not what extra-welfarism embodies in principle, but rather what happens on the ground in actual practice.

Extra-Welfarism in Empirical Normative Analysis

There is no single 'extra-welfarist' approach to empirical normative analysis. In the area of health technology assessment, extra-welfarist ideas are incorporated into cost-effectiveness and cost–utility analyses. In the normative analysis of broader

health system policies extra-welfarist ideas manifest themselves in a focus on health as the outcome of interest rather than willingness to pay as measured by the demand curve for health-care services. Two brief examples below illustrate how selected aspects of extra-welfarism translate into empirical normative analysis, and especially how these aspects differ from the welfare-economic approach. The first illustrates, in the context of health technology assessment, how extra-welfarism draws on sources of valuation distinct from the individualistic approach of welfarism. The second illustrates how a focus on health rather than willingness to pay can change the normative conclusions regarding the optimal policy to combat insurance-induced moral hazard in the health services market.

Sources of valuation in extra-welfarism

Consider the economic evaluation of a new health-care technology the only effect of which is to reduce the probability of dying within a given period. Under the welfare-economic framework, these additional life-years would be valued according to the amount each affected individual was willing to pay to reduce the chance of death, so some (e.g., the wealthy) would be willing to pay more than others (e.g., the poor). The new technology would be deemed efficient if the net benefit was positive. If, instead, a cost-effectiveness analysis (CEA) is conducted, the analyst refrains from placing a value on the additional life-years produced by the new technology. The efficiency of the intervention is expressed using the incremental cost-effectiveness ratio (ICER), which indicates the additional cost incurred per life-year gained. Although CEA allows the analyst to avoid placing a monetary value on a life-year gained, if the results of the CEA are to be used as the basis for an adoption decision, the decision-maker must decide whether the additional cost per life-year is above or below the amount the *society* is willing to pay-that is, are the extra benefits worth the extra costs. The extra-welfarist CEA bases the decision on the social value of the health benefit (e.g., life-year gained), which may be set by the decision-maker, by community consultation, or by some other process. Although, as noted above in the discussion of equity weights, the social value of the health gain may differ across the groups of individuals in a society, the social value does not depend on the individuals' own valuation of the health gain.

The evaluation of policies to combat moral hazard

The analytic importance of using health rather than willingness to pay as a measure of social value can be illustrated with an example adapted from Reinhardt (1998). Consider two families with identical preferences and full insurance for physician visits, the Chens, who are wealthy, and the Smiths, who are poor. Each family has just had a baby. Baby Chen is healthy but Baby Smith is sickly. With full insurance, the Smiths demand nine physician visits during the period and the Chens demand six. To combat moral hazard, the insurer seeks to reduce total visits by five. To do so, it imposes a copayment equal to $15 per visit. Under cost-sharing, both families demand five visits per period, for a reduction of five visits overall (from 15 to 10). Within the standard welfare-economic analysis, the reductions of four and one, respectively, for the Smiths and the Chens are the optimal way to reduce total visits by five because it imposes the lowest welfare loss as measured by willingness to pay. However, because Baby Smith is sickly while Baby Chen is healthy, the marginal health gain of a physician visit is always greater for the Smiths than for the Chens. If we measure benefit by the health effects rather than willingness to pay, then to reduce overall visits by five in a way that minimizes health effects, Baby Chen's visits should be reduced from six to two whereas the Baby Smith's are reduced from nine to eight. Such a reduction cannot be achieved by a single user-charge policy. Consequently, this extra-welfarist analysis indicates that moral hazard should be combated by an alternative policy that can selectively reduce the visits that have the least health gain.

Current Issues in Extra-Welfarism

Extra-welfarism continues to develop in health economics, and we highlight just a few areas of the ongoing development. One active area of work seeks to translate Sen's capability approach into a practical, empirical method. Capability sets, as noted above, include not only the functionings a person actually achieves, but all the possible functionings a person could have achieved. Hence, a major challenge is how to measure these potential functionings that were not achieved by an individual, and in particular to distinguish those that were available but not chosen from those that were not available due to some social or economic barrier in society. A second area focuses on the relationship between extra-welfarism and welfarism. Brouwer *et al.* (2008) argue that welfarism is simply a special case of extra-welfarism. Much of the literature has tended to focus on the two polar cases – welfarism which limits the outcome space to utility – and extra-welfarist approaches that ignores utility in the outcome space (even if it has used elements of utility in constructing indices such as the QALY). Less well developed is systematic thinking regarding the rich middle ground that admits both utility and nonutility outcomes, and in particular, principles that can guide the role of each in an analysis. The nature of the outcome information included, for instance, might depend on the level of aggregation at which a decision is being made. At high levels of aggregation, such as a central ministry allocating resources to regional authorities responsible for their respective populations, the concepts of need and health likely dominate considerations of possible differences in preferences. However, in the design of programs at the local level, the role for preferences may be larger as the program has more direct dealings with those receiving services. Similarly, it is natural to ascribe a larger role for preferences (especially over process aspects of care delivery) in those contexts in which differences in health and other outcomes are small. Finally, there is ongoing tension between the emphasis in extra-welfarism on diversity, flexibility, and adaptability of methods and standardization of methods both to increase comparability across studies and to improve quality in those aspects for which there may be generally recognized 'better' methods (e.g., of certain aspects of measurement). This tension is an inherent feature of extra-welfarism. Only by attending carefully to its demands can extra-welfarism avoid the pitfalls of, on one hand, lacking sufficient shared, core

principles required for a coherent, distinct vision and, on the other, a type of standardized rigidity against which extra-welfarism is in part a reaction.

Acknowledgment

The author would like to thank Junying Zhao for many stimulating discussions regarding extra-welfarism, and especially on the ideas of A. Sen.

What Is the Impact of Health on Economic Growth – and of Growth on Health?

M Lewis, Georgetown University, Washington, DC, USA

Introduction

Health status improvements over the past 400 years have been steady, with a surge over the last century that is nothing short of spectacular, and a period during which economic progress has soared. Vaccines, antibiotics, and other medical advances have contributed to reductions in illness (morbidity) and mortality. Economic growth has shown equally impressive gains catapulting much of the world into higher income status with all of the associated consumption and health benefits that higher incomes allow. Richer people are better educated and nourished, and can afford investments that improve population health (3.9 Cutler and Lleras-Muney).

With economic advances and health status moving in tandem, the question is: Do health improvements spur growth, or do income increases determine progress in population health, or both? The evidence is mixed and hampered both by the lack of an acceptable and universal measure of health status and by the empirical difficulties inherent in controlling for reverse causality as well as nonlinearities.

Measurement of both growth and health pose challenges for both empirical estimation and for policy implications. For growth, the measurement is either of a static level of income, itself difficult to measure, or the dynamic of economic growth. Both may drive improvements in health, or serve as proxies for other achievements of higher-income countries such as education, effective public health interventions, or strong institutions, all of which correlate with improved health status.

The existing health metrics are inadequate to the task of effectively measuring the links between growth and health. No single measure exists to capture mortality and morbidity. Mortality only occurs once and is therefore a rare event. Common reliance on infant mortality reflects the high concentrations of deaths in the first year of life, and the availability of accessible and comparable data across countries. As infant mortality effectively captures differences across population health it is the measure of choice (1.1 Murray). Life expectancy serves a similar purpose but fails to capture health status as effectively, relegating its use to comparing broad national trends. More recent measures include life satisfaction and emotional well-being, malnutrition, and stunting (a measure of long-term malnutrition).

Accumulated evidence on the relationship between health and growth indicates that both directions of causality are plausible but neither is definitive. Existing evidence from cross-country macroeconomic studies analyze country-level relationships. More heterogeneous, microeconomic investigations provide analytic underpinnings for interpreting the findings of macroeconomic empirics and offer insights into some of the causal pathways of the relationships between health and growth and growth and health. These are discussed here.

How Have We Become so Healthy?

Mankind has become increasingly healthier over the past four centuries, and significantly so since 1900. Life expectancy at birth in the USA rose from 46 years and 48 years for men and women, respectively, in 1900, to 75 years and 81 years in 2010; a shift mirrored elsewhere in the industrialized countries, and observed in many developing countries as well. The major factors driving progress include improved nutrition, rising education, and advances in public health (1.7 Sahn). In contrast, health care investments have had far more modest effects on population health.

On the basis of his Nobel winning historical research on food production, malnutrition, and productivity Fogel (2004) estimates that improvements in the quantity and quality of food contributed to 40% of observed mortality declines since 1700, much of it during the twentieth century. Better nutrition raised agricultural output stemming famines and undernutrition. Parallel public health investments combined to steadily raise health status. Together labor productivity rose spurring economic growth.

Hygiene has also played a major role. In examining the explanation for mortality declines in England and Wales during the nineteenth and twentieth centuries historical research finds that immunizations, expanded access to piped water and sanitation, separation of water and sewerage, and better nutrition enhanced citizens' abilities to ward off infections, thereby reducing morbidity and mortality levels. Scientific knowledge of disease transmission contributed importantly to public health, and led to reductions in transmission of water and foodborne diseases that further improved health status (4.1 Cookson and Suhrcke, 4.3 Mills). Again, the evidence shows no measurable effect of medical interventions on survival.

Over the centuries both health and economic growth have improved. The question is the possible causal relationship between them to inform policy on raising both health status and incomes. One important conclusion is that health investments have valuable social and household benefits; whether these benefits translate into faster economic growth is simply a search for further benefits.

Correlates of Population Health and Income

The first empirical estimation of the relationship of income and health status was offered by Preston (1975) using life expectancy as a proxy for health status. More recent data confirm his finding of a concave relationship between gross domestic product (GDP) and life expectancy (**Figure 1**) and show the same relationship as his original results, with the relationship becoming stronger over time as poor countries catch up to the wealthier world in life expectancy.

 doi:10.1016/B978-0-12-375678-7.00602-7

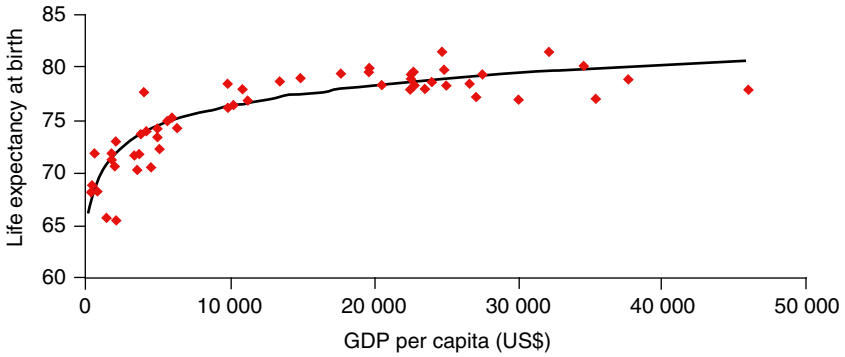

Figure 1 The Preston curve, 2001. Reproduced with permission from World Bank, World Development Indicators.

For the lowest income countries, small shifts in income lead to disproportionately higher life expectancies, often reflecting the first moves toward the demographic transition, as well as progress in public health. Preston attributed declines in mortality less to income and more to public health interventions and has suggested the combined importance of adequate calories, income, and education, echoing Fogel and others' historical conclusions.

Extending Preston's cross-sectional evidence with longitudinal data Deaton (2006) shows divergence among GDP, life expectancy, and infant mortality suggesting that the relationship between growth and health does not hold within countries over time. Each of the curves in Figure 2 is the standard deviation of the variable relative to its value in 1960. Thus, although country-level health indicators have converged per capita incomes have progressively diverged. If that is indeed the case then changes in income appear to be unrelated to health status measures.

Other researchers have argued for a strong and consistent relationship between growth in per capita incomes and reductions in infant and child mortality, and life expectancy based on cross-country, time-series data, and they point to poor economic performance as a cause of child mortality. They conclude that causality moves from income to health. Research examining the impact of income on emotional well-being in the US drawing on the Gallup-Healthways Well-Being Index shows that emotional well-being rises with log income but only to an annual income of US$75 000 after which there is no association. So income buys increasing well-being but at the lower end of the income scale.

Macroeconomic studies under the World Health Organization's (WHO) 2001 Commission on Macroeconomics and Health initiative produced evidence of the link between health and economic growth concluding that health investments will make countries richer. The evidence affirms correlations, but causality remains elusive due to the inability to adjust for reverse causality, and the problem of omitted variables. There are a number of variables that affect both health and growth such as climate and disease prevalence complicating efforts to measure the effects of one on the other.

Subsequent research on the relationship between health and changes in income explore the dynamics of health and income shifts. In a highly controversial study geography is used as an instrumental variable for health status to address the endogeneity problem. The study finds a high correlation between population health and economic growth. Subsequent research reviewed 13 studies of cross-country regressions and all repeat the same strong results. Considerable debate and challenge has ensued on the appropriateness of geography (distance from the equator) and its importance to growth. Subsequent empirical studies from multiple researchers show that once the effect of geography on a country's choice of institutions is controlled for, geography has little independent effect on growth.

Creative efforts were made to address the endogeneity problem including examination of twentieth-century breakthroughs in science such as drug therapies and insecticides and new global institutions such as WHO, but none find any independent effect on income growth though these new interventions did contribute to increases in population. Recent efforts to include microeconomic measures on the impact of health on productivity in a macroeconomic accounting framework find some modest gains in GDP. Incorporating general equilibrium effects to account for the diminished returns to labor with rapidly rising population have little effect as improvements in life expectancy do not lead to increases in per capita income or worker productivity.

Thus, despite creative approaches the controversy on whether health spurs growth remains a conundrum.

Individual Health and Productivity

Examining the same sets of relationships between income and health at the household level allows insights into how the factors interrelate to produce better health or higher incomes, and results in more robust findings. The downside of microeconomic studies is their limited generalizability, given the importance of different contexts in explaining effectiveness of interventions.

Morbidity and Income

Illness undermines productivity, in patterns similar to those Fogel identified between malnutrition and productivity. This cost-of-illness approach examines the short and longer term impacts of illness on education, labor productivity, employment, and economic activity.

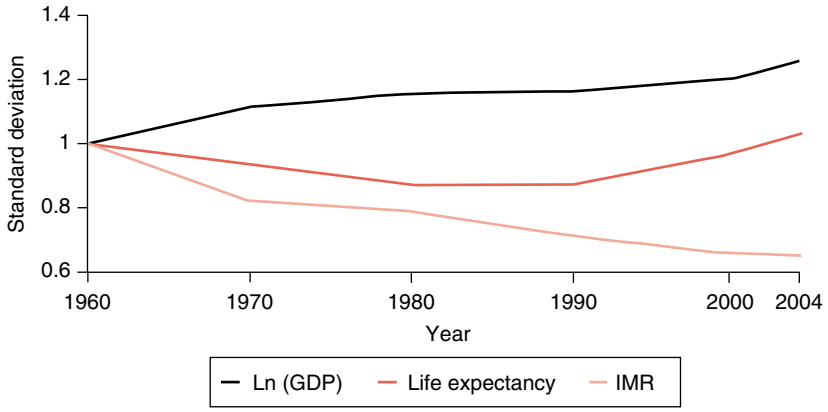

Figure 2 Normalized cross-country standard deviations of health and income, 1960–2004. The infant mortality rate (IMR) measures the number of children born who die before their first birthday per 1000 births. The standard deviation of the under-five mortality rate shows a similar evolution and is not presented in this figure. The IMR is a significant factor in life expectancy calculations, because, particularly in countries with high death rates, a significant portion of a country's deaths occur in the first year of life. Reproduced with permission as indicated in the NBER paper, Deaton, A. (2006). Global patterns of income and health: Facts, interpretations, and policies. *NBER Working Paper No. W12735.* Cambridge, MA: National Bureau of Economic Research.

A study of hookworm eradication in the American South tracking the impact of local infection control on education enrollment, attendance, and literacy suggests the importance of vector control in both education and incomes over lifetimes. The phasing in of hookworm control allowed an assessment of the patterns and extent of responses to eradication. Areas with higher pre existing infection rates saw bigger improvements after eradication. A parallel set of studies for malaria in the US c. 1930 and in Brazil, Colombia, and Mexico in the 1950s traced the effects of eliminating childhood exposure to malaria on adult literacy and earnings. The study concludes that "persistent childhood malaria infection reduces adult income by 40 to 60 percent." Similar but less dramatic effects emerged from malaria eradication across Indian states in the 1950s, where literacy and primary completion rates rose by 10% in malaria-free areas (1.12 Cohen).

More recent experiments suggest the potential value of targeted treatment measures on schooling and earnings. In a study of randomly assigned deworming treatment for school children in western Kenya a 25% increase in student attendance was found among those receiving medication, although there was no effect on school performance, possibly due to the lack of any change in other inputs at the school.

Expanded access to antiretroviral treatment in many countries of sub-Saharan Africa has offered a laboratory to test the impact of interventions. In western Kenya those under treatment are 20% more likely to join the labor market and increase their weekly hours worked by 35%. In another study in the tea-growing region of western Kenya human immunodeficiency virus (HIV)-positive tea pickers with 6 months on antiretroviral treatment increased their number of days worked and therefore their wages. Wage earnings rose from 75% to 89% of the wages of non-HIV-positive workers, thereby almost regaining the lost earning levels.

The impact of potential and actual parental death from HIV has shown some unexpected effects. In areas of high HIV prevalence across southern Africa children are less likely to go to school, take longer to go through school, and are less likely to graduate from primary school. More than half of the explanation is attributed to the expectations of a shorter life of parents, which will affect life chances of children rendering schooling of marginal benefit to future income. This complements evidence on the life chances of orphans emanating from an analysis of 10 Demographic and Health Surveys. Orphans in sub-Saharan Africa are significantly less likely to be in school as compared with their peers. Similar results emerge for Indonesia. However, country-level evidence is inconsistent in Africa. In Tanzania no impacts on schooling of HIV deaths of parents were found, perhaps because extended family members take on parenting roles for orphans (1.13 de Walque; 1.27 Thirumurthy).

A related and dramatic achievement in reducing the cost-of-illness is the multidonor program in the Niger Delta in West Africa where since the late 1990s pesticide spraying has controlled the black flies that had rendered the area uninhabitable. A total of 25 million hectares of rich agricultural land has been recultivated in reclaimed areas demonstrating yet again the value of public health interventions (1.16 Grépin).

All of these studies document augmented productivity and impacts on education or output from improvements in health status, or measure the costs of poor health on these same indicators. Interventions at the household level as well as targeted regional investments in public health activities can have important effects on education and productivity (3.9 Cutler and Lleres-Muney).

Limited evidence exists on the link between income and health. Analysis of a unique data set for South Africa permits quantification of the impact of old-age pensions in South Africa on health status. Where households pool income, including pensions, the overall health status of the household improves through positive effects on nutrition, living conditions, and stress levels of adults. Surveys typically fail to capture income pooling, and this study allows good insights into how pooled incomes can influence investments that enhance health status.

Investing in Early Childhood Development and Adult Performance

Targeted investments and the impact on economic well-being have received increasing attention with particular focus on children. Mounting multisectoral evidence from economics, psychology, and neuroscience makes the case that investments in disadvantaged young children have profound effects on learning, earnings, and adult health. Recent overviews point to factors such as maternal undernutrition, poverty, poor health, and unstimulating home environments as strongly associated with adult cancer incidence, mental illness, lower incomes, and lower birthweight of offspring. A review of microeconomic studies concludes that nutrition and possibly other dimensions of health compromise productivity. Heckman (2007) emphasizes the economic importance of noncognitive skills and their importance in future economic and social behavior, which in turn influence productivity and earnings. The US research suggests that the economic rate of return to preschool attendance among disadvantaged children dwarfs returns to other, later academic investments (3.1 Royer and Bauer; 4.13 Karoly).

Longitudinal studies provide strong evidence of the value of early childhood interventions. Low birthweight negatively affects long-run adult outcomes such as height, intelligence quotient (IQ), educational attainment, and earnings. Bolstering early nutrition interventions translate into greater cognitive development, physical stature and strength, greater learning, higher adult productivity, and healthier offspring. A 35-year longitudinal study in Guatemala traced adult participants who had received a randomly distributed nutrition supplements as school children. Women had 1.17 more years of schooling, their children were 179 g heavier at birth, and their children were 30% taller as adults compared with the children of those who had not received the supplement. Men in the treatment group earned an average wage of 46% above those who only received the calorie-based supplement (1.3 Soares; 1.7 Sahn).

Consistent, robust evidence on returns to early childhood investments confirms the importance of targeted interventions for disadvantaged children. Although often difficult because many young children remain at home, targeted early childhood programs have a clear payoff in higher productivity and earnings over a lifetime and better health in adulthood. They also offer the possibility of breaking the intergenerational cycle of poverty.

Health-Related Interventions and Health: Implications for Policy

If economic progress simply solved the problems of mortality and morbidity, then public policy would no longer be concerned with public health and health care needs would be met. Similarly, if investments in health provided the needed impetus for growth resource allocation decisions would be straightforward. However, circumstances are more complex and targeted policy decisions influence economic growth and population health.

Part of the interest in the growth to health link is to determine whether economic progress means more investments in health. A panel study of all countries in the 2010 WHO database examines the elasticity of public health spending with respect to national income controlling for demographics, source of financing, and other characteristics. A dynamic model using a lagged dependent variable adjusted for endogeneity shows results consistent with earlier studies in that GDP and public health expenditures move in tandem, but contrary to other studies finds significant elasticities below 1.0 for all but the lowest income countries, and lower values for the dynamic model results. So under this specification, income growth does not translate into commensurate increases in health spending.

If greater health investments could assure both better health status and rapid economic growth, then spending on health would need to be a priority given the large social and economic benefits. However, ample evidence suggests that spending alone falls short of even achieving health goals. The link from health spending to health outcomes is weak, and cross-country evidence shows minimal correlation between spending and health outcomes. As global access to important preventive and treatment technologies does not differ dramatically and funding is on the rise, it suggests that institutions and other factors such as education underpin the divergence between spending and outcomes. Chronic absenteeism, inadequate budget execution, illegal payments, and poor management combined with a severe lack of accountability translate into absence of the very technologies that can save lives at the point of service, such as drugs, supplies, and equipment, which in turn means low returns on investment. Poor governance in service delivery suggests government failure, effectively government interventions that have gone wrong. Without sound institutions, public health investments will not improve health, let alone economic growth (1.22 Government Regulation and Corruption – no author).

So despite advances in technology, countries experience marginal gains where countries lack institutions that can ensure effective delivery and financing of health care services. However, the discrepancy extends to the Organization for Economic Cooperation and Development (OECD) countries, where studies of survival rates for specific diseases do not correlate with either total or public spending.

Debate on the path to better health and economic growth will continue given the inconclusive nature of the evidence. Better research and measurement will help to hone the findings and provide stronger policy guidance; but stronger institutions to ensure effective health care delivery will require equal attention.

Willingness to Pay for Health

R Baker, C Donaldson, and H Mason, Glasgow Caledonian University, Glasgow, UK
M Jones-Lee, Newcastle University Business School, Newcastle upon Tyne, UK

Introduction

The 'willingness to pay' (WTP) method was first applied in the health area in the famous study of WTP to avoid heart attacks, by Acton (1973). WTP for health is an issue in individual (personal) and societal (public) decision making about health care. The term usually refers to individuals' willingness to spend money personally, i.e., 'out of pocket,' to obtain health gains for themselves or to avoid health losses or reduce health risks for themselves. WTP in this sense can be observed both in actual behavior and in responses to hypothetical questions. In either case, WTP is interpreted as an indicator of how much personal satisfaction or well-being (often called 'utility') individuals derive from (or believe they derive from) different health outcomes. It is thought that aggregate WTP out of pocket in a group of people benefiting from a program may be used as an indicator of how much money society should be willing to spend on the program, although this depends on the funding arrangements (whether health care is publicly or privately financed) and who is asked (patients or the public).

The satisfaction and well-being individuals derive from health outcomes may be measured in different ways. Most of these, including quality-adjusted life-years (QALYs) and disability adjusted life years (DALYs), aim at measuring the value of different health outcomes relative to each other with a view to aiding priority setting within given health budgets. The special property of measurements in terms of WTP is that they purport to establish the value of health outcomes relative not only to each other but also to other goods and services. In principle, WTP data may thus inform decisions not only about priority setting within given health budgets but also as to how much money should be allocated to health services versus other goods and services.

In the following, the authors' focus is first on the meaning and measurement of individual WTP and the aggregation of this across individuals. Actual WTP for different technologies and programs in a public health service can be different from the simple individual aggregate, most notably because of various concerns for equal access and equity. The authors return to this important point in the Issues section at the end.

Welfare Theoretical Background and Application (in Principle) to Health Technology Assessment

What is 'WTP'?

In standard welfare economics, maximum WTP represents the theoretically correct measure of 'strength of preference' for, or value of, a commodity. In areas of public-sector activity, such as health care, in which conventional markets do not exist, decisions still have to be made about how best to use limited resources. This requires valuation of both resource costs of interventions and their benefits (the benefits being health gain and other sources of well-being). This can be elicited either in surveys by use of hypothetical WTP questions – essentially, the contingent valuation approach in which respondents state values for the good in question – or revealed as a result of observing real market-based choices. Owing to the rarity of the latter in health care, the contingent valuation method tends to be relied on more than revealed preference.

WTP focuses on the valuation of benefits, whereby a health care option may be described to a respondent and the person is asked what is his/her maximum WTP for it. In principle, with this type of information, the combination of interventions in cash-limited publicly funded systems could be chosen, which maximizes the value of benefits (possibly distributionally weighted) to the community. In privately funded systems, WTP information would more likely be used to assess whether aggregate WTP for a particular health care intervention exceeds costs; if it does, the implication is that this intervention can be added to the benefits package. In each of these cases, WTP is necessarily treated as a cardinal measure of value, i.e., a measure which captures strength as well as direction of preference.

It is important to distinguish WTP, as a measure of benefit, from the price of a good. In many cases, people would be willing to pay more than the market-clearing price of a good. For any individual, the difference between benefit, as represented by his/her maximum WTP for the good, and the price paid by him/her for the good represents a gain in well-being from having the good provided at the market price.

WTP and Levels of Decision Making

WTP methods have been used at three main levels of decision making in health care. The first level is that of patients within a clinical area being asked to choose between close substitutes of the sort that might be evaluated within a randomized trial. It could be argued that when making such choices between therapies, the people best placed to judge are patients who will receive the therapies. The second level is that where geographically defined health authorities have to prioritize across such clinical areas in a publicly funded system (e.g., as in one study, by Olsen and Donaldson (1998), comparing helicopters, hearts, and hips). Here, it could be argued that those best placed to decide are taxpayers (or those who paid taxes in the past). In more insurance-based systems, where the decision might be about whether to add a program to the benefits package, those same people might be asked about their WTP for that program alone, the decision being based on whether the aggregate WTP is greater than the costs of said program. The different scenarios that emanate from these contextual backgrounds, and the ways that WTP can be used within them, have been laid out by O'Brien and Gafni (1996) and Shackley and Donaldson (2000).

Internationally, the advent of Health Technology Assessment (HTA) agencies has now taken WTP methodology to the national level. Many of the recommendations made by HTA organizations involve considerations of the costs and benefits of single interventions, where there is no obvious basis for a comparison between alternatives, apart from with the costs and effects of treatments that constitute current practice or the status quo. In such cases, the decision about whether to provide the intervention is not obvious and hence gives rise to the question of what monetary value to place on a gain of one QALY.

All of the above scenarios also give rise to the question of whether WTP can be used to value wider benefits of health care (e.g., location of care and process utility) over which people have preferences but which might not be captured easily by narrower, health-focused methods, such as QALYs.

Measurement of Individual WTP and Estimation of Aggregate Value

In 1963, the first empirical application of WTP, published in a journal, was in the area of environmental policy evaluation. During the 1970s, the method was further developed in studies of the valuation of saving lives, as applied to safety and transport policies, largely through the work of Jones-Lee (1974) and Jones-Lee *et al.* (1985). This latter body of work is of great relevance to the issues faced currently in health as the development of methods to elicit a value of saving a life has strong parallels with the challenge of valuing a QALY (or 'healthy year'). Therefore, in this section, the authors commence with an introduction to measurement methods by focusing on lessons learned in area of safety (especially the issue of how to estimate the value of a prevented fatality, or VPF), before moving to how these lessons have been built on in deriving estimates of the value of a QALY.

Revealed Preference versus Contingent Valuation in Safety

Basically, the revealed preference approach involves the identification of situations in which people actually do trade-off income or wealth against physical risk – for example, in labor markets where riskier jobs can be expected to command clearly identifiable wage *premia*. By contrast, the contingent valuation approach applied to safety typically involves asking a representative sample of people more or less directly about their individual WTP for improved safety (or, sometimes, their willingness to accept compensation for increased risk).

The difficulty with the revealed preference approach when applied to labor market data is that it depends on being able to disentangle risk-related wage differentials from the many other factors that enter into the determination of wage rates. The approach also presupposes that workers are well informed about the risks that they actually face in the workplace. In addition, those whose jobs do carry clearly identifiable wage *premia* for risk may not be representative of the work force as a whole, in that such people almost certainly have a below-average degree of risk-aversion.

The great advantage of the contingent valuation approach is that it allows the researcher to go directly and unambiguously to the relevant wealth/risk trade-off – at least, in principle. However, the contingent valuation approach has the disadvantage of relying on the assumption that people are able to give considered, accurate, and unbiased answers to hypothetical questions about typically small changes in already very small risks.

Aggregation

So, under what has naturally come to be known as the 'WTP' approach to the valuation of safety, one first seeks to establish the maximum amounts that those affected would individually be willing to pay for (typically small) improvements in their own and others' safety. These amounts are then simply aggregated across all individuals to arrive at an overall value for the safety improvement concerned (see example in following paragraph). The resultant figure is thus a clear reflection of what the safety improvement is 'worth' to the affected group, relative to the alternative ways in which each individual might have spent his or her limited income. Furthermore, defining values of safety in this way effectively 'mimics' the operation of market forces – in circumstances in which markets typically do not exist – insofar as such forces can be seen as vehicles for allowing individual preferences to interact with relative scarcities and production possibilities to determine the allocation of a society's scarce resources.

To standardize values of safety that are derived from the WTP approach and render them comparable with values obtained under other approaches (such as gross output – see Jones-Lee (1994)), the concept of the prevention of a 'statistical' fatality or injury is applied. To illustrate this concept, suppose that a group of 100 000 people enjoy a safety improvement that reduces the probability of premature death during a forthcoming period by, on average, 1 in 100 000 for each and every member of the group. The expected number of fatalities within the group during the forthcoming period will thus be reduced by precisely one, and the safety improvement is therefore described as involving the prevention of one statistical fatality. Now suppose that individuals within this group are, on average, each willing to pay £w for the 1 in 100 000 reduction in the probability of death afforded by the safety improvement. Aggregate WTP will then be given by £$w \times 100\,000$. This figure is naturally referred to as the WTP-based value of preventing one statistical fatality (VPF) or alternatively as the value of statistical life (VOSL). So, for instance, if w=£10, VOSL=£1 000 000 in our example.

Clearly, in the above example, average individual WTP, £w, for the average individual risk reduction of 1 in 100 000 is a reflection of the rate at which people in the group are willing to trade-off wealth against risk 'at the margin,' in the sense that the trade-offs typically involve small variations in wealth and small variations in risk. Empirical work on the valuation of safety thus tends to focus on these individual marginal wealth/risk trade-off rates.

On a somewhat more cautionary note, it is extremely important to appreciate that, defined in this way, the VPF is not a 'value (or price) of life' in the sense of a sum that any given individual would accept in compensation for the certainty of his or her own death – for most of us, no finite sum

would suffice for this purpose so that in this sense life is literally priceless. Rather, the VPF is an aggregate WTP for typically very small reductions in individual risk of death (which, realistically, is what most safety improvements really offer at the individual level).

In valuing safety it is also useful to have a valuation of an averted statistical injury (VSI). The VSI is generally pegged against the VOSL rather than estimating WTP for an injury. To do this, a standard gamble exercise can be used to calculate the marginal rate of substitution (MRS) of an injury against death. The value of preventing this injury is then the fraction of the VOSL that is given by the MRS, i.e., if the MRS is 0.09, the value of preventing this injury will be 9% of the VOSL.

Recent Developments in Valuing Life

Viewed from an historical perspective, both quantitative and qualitative research have tended to cast doubt on the reliability and validity of WTP values for safety derived through the direct contingent valuation method. As well as sequencing and framing effects, a prominent issue has been the lack of ability of the method to account for embedding and scope. That is, respondents tend to view safety improvements as a 'good thing' and, therefore, will often state much the same WTP for different sizes of risk reduction, whether for fatal or nonfatal injuries. It may be unreasonable to expect respondents to give accurate answers to hypothetical questions, which involve direct trade-offs between wealth and small reductions in risk.

In view of these difficulties with the direct contingent valuation approach, Carthy *et al.* (1999) suggested a less-direct, 'chained' approach, which breaks down the valuation process into a series of more manageable steps. More specifically, respondents are first presented with a question asking them about their WTP for the certainty of a complete cure for a given nonfatal road injury and their willingness to accept compensation (WTA) for the certainty of remaining in the impaired health state. On the basis of reasonable assumptions concerning underlying preferences, it is then possible to obtain an estimate of each respondent's marginal rate of substitution of wealth for the risk of the nonfatal injury as a weighted average of his/her WTP and WTA responses. Respondents are then presented with a 'standard gamble' (SG) question aimed at determining the ratio of individual marginal rates of substitution of wealth for risk of death relative to the corresponding marginal rate of substitution for risk of the nonfatal injury. The monetary value from the first stage can then be combined with the ratio from the second stage to obtain a WTP for reduced risk of death.

The approach is, perhaps, more realistic in that most people can relate to giving a monetary value for avoiding a nonfatal injury of the sort they are likely to have experienced, and people are not asked directly to place a monetary value on a small risk reduction. The method has shown promise in terms of being subject to less marked embedding effects and other biases than earlier approaches.

Linking Safety and Health: Modeling the Value of a QALY

As noted, the most common measure of benefits applied in health economic evaluation is the QALY. Although the cost per QALY gained for technology 'A' can be compared with the cost per QALY gained of technology 'B' (and hence the *relative* efficiency of A vs. B can be assessed), weighing up costs (measured in monetary terms) and health benefits (measured in QALYs) for a single technology is problematic. As a result, health care decision makers have tended to invoke decision rules (such as cost per QALY limits above which technologies are unlikely to be recommended for adoption). To generate research evidence to underpin such decision rules, there has been international interest in the estimation of the monetary value of a QALY. If such a value could be estimated, then costs and benefits could be compared using the same metric (i.e., money), and one could more readily judge whether benefits offset costs. Existing evidence from the economics of safety literature is a natural starting point for such a project.

A straightforward way to combine work on health and safety valuation is to take the well-established VOSL based on research into road safety and, from it, attempt to model the monetary value of an year of life. This can reasonably be interpreted as the value of a healthy year, which is the same as a QALY. Indeed, this is what was attempted in the UK Social Value of a QALY (SVQ) project and more recently in the European Value of a QALY project (EuroVaQ). A simplified version of the method of transforming the VPF into a value of a QALY is presented in **Box 1**. However, the value resulting from this would reflect a particular QALY type. By QALY type, the authors mean that QALYs can be generated in at least two ways, these being by adding years to life expectancy or by

Box 1 Modeling the value of a QALY

A straightforward way to compute the value of a QALY is to start with the well-established roads VPF for the UK. For example, if a representative death is taken avoided as being that of a person aged 35 years, assume that the VPF is £1.4 m (or $£1.4 \times 10^6$) and that the person concerned would have lived for another 40 years, a rough calculation of the value of a life year gained by that person would be as follows:

$$V = \frac{£1.4 \times 10^6}{40}$$
$$= £35\,000$$

However, if one were to assume that not all of the 40 years gained would be spent in full health (especially later years) and a discount rate applied, the denominator would fall, thus raising the value of a QALY above £35 000. For example, if the discount rate was taken to be 3.5%, then the annualized sum that would have a discounted present value of £1.4 m over 40 years would be £77 300.

In SVQ, similar approaches were used to model the value of QALYs resulting from extending life and from quality-of-life enhancement only. For example, the latter is based on UK values for four different scenarios of serious injury. Each health state was broken down into three phases; in hospital effect (valued at 0.69 or 0.16 on the EQ-5D tariff, depending on severity of injury and generally modeled as lasting for 1 month), initial after effects (generally for 2 months and valued at 0.76) and longer term effects (for remaining life and valued at either 0.76 or 0.3, again depending on severity). Assuming that any given injury would occur at the mean age of the UK population, with 26 expected remaining QALYS, an overall total QALY loss for each scenario has been calculated. The VSI of £150 000 then has been divided by the total QALY loss for each scenario and computed a weighted average based on probability of each scenario occurring.

enhancing the quality of remaining life years without extending life. The former can be further subdivided into avoiding immediate threats to life – hereafter called 'life saving,' or adding years to the end of one's life – hereafter called 'life extension.' The procedure outlined in Box 1 reflects the first of these, although a more-sophisticated approach, still using the VOSL as a basis, was also employed to model the value of a QALY arising from life extension as opposed to life saving.

Valuing Improvements in Quality of Life

WTP procedures have been used directly by the UK Department for Transport to derive the value of preventing a serious injury (VSI). From such data, the monetary value of health gains (as measured by instruments in the QALY field) can be estimated. But one can also combine a monetary value for a health gain with health state utility scores to achieve values for different improvements in quality of life. The simplest way to do this is to use established utility tariffs in instruments such as the EQ-5D, the Health Utilities Index, the 15-D, etc. For instance, if a survey respondent was willing to pay a maximum of £3000 WTP for a move from a more-impaired health state for 1 year to a less-impaired state for the same period, where the tariff difference between the states is 0.1, then the WTP for a QALY implied by this would be £30 000 (i.e., £3000/0.1) for that individual. If repeated over several respondents and scenarios, a representative WTP for a QALY could be derived (Gyrd-Hansen, 2003).

Others have combined WTP questions and utility scores in the same survey, for example, in the social value of a QALY studies in the UK and Spain, the feasibility of doing this was assessed by presenting members of the public with appropriately framed valuation questions in a survey – see Box 2 for example health states, and Box 3 for example question to illustrate how changes in quality of life and WTP were estimated and combined (each from the UK study).

From Box 3, it can be seen that any individual respondent would be faced with a set of WTP and standard gamble questions, the two sets then being combined in different ways to arrive at values of a QALY. The reason for having respondents undertake a health state utility assessment exercise, rather than combine WTP values with a preexisting tariff (such as that which exists for the EQ-5D quality-of-life system), was that the researchers wanted each respondent's WTP value to be combined with their own personal health state utility value for purposes of internal consistency.

Box 2 Stomach and head health states

Stomach: 3 months

Initially you will have severe stomach pains, diarrhea, vomiting, and fever for 7 days, severe enough to interfere with most of your usual activities.

Things then improve, but for up to 1 year from initial onset you will suffer an episode of stomach discomfort and sickness every couple of weeks, with each episode lasting for 2–3 days. These episodes are not so severe but may interfere with some of your usual activities.

(*Half of the respondents were given stomach health state descriptions of 3 months, 12 months, and lifetime durations.*)

Head: 3 months

One will have episodes of throbbing pain across the front of your head and will feel sick and may occasionally be sick. One will feel like he/she wants to lie still in a darkened room.

During the next 3 months one will suffer an episode of head pain and sickness every couple of weeks, with each episode lasting between 8 h and 2 days. These episodes will interfere with many of your usual activities. After 3 months he/she returns to the current health with no further effects from this illness.

(*The other half of the respondents were given head health state descriptions of 3 months, 12 months, and lifetime durations.*)

Examples of Applications in Safety and Health

Values of Life

Turning to the question of the figures that are actually applied in practice, WTP-based values of safety are currently used in road project appraisal in the UK, USA, Canada, Sweden, and New Zealand, with several other countries employing values that have been substantially influenced by the results of WTP studies. More specifically, in the UK, the Department for Transport currently employs a figure of £1.64 million in June 2007 prices for the prevention of a statistical fatality in its roads project appraisal. In turn, the Department's values for the prevention of serious and slight, nonfatal injuries are £185 220 and £14 280, respectively, again in 2007 prices.

In the USA, the US Department of Transportation currently values the prevention of a statistical road fatality at US$6 m (approximately £3.96 m). In turn, Transport Canada applies a WTP-based value for the prevention of a statistical fatality of Cdn$ 4 m (approximately £3.22 m) based on a survey of the literature. The WTP values used in Sweden and New Zealand were derived under the contingent valuation approach and in 2010 prices are SEK 18.5 million (approximately £1.8 m) and NZ$ 3.56 million (approximately £1.7 m).

WTP for a QALY: Estimates from Modeling Studies

Table 1 gives a typical set of values of a QALY that have arisen from the UK-based modeling study described above (see Box 1). It would seem that different 'QALY types' would imply different values. Based on WTP for life saving (to reduce the risks of life-threatening events), values close to £70 000 per QALY were produced, as compared to values approximately £35 000 for a life-extending QALY (at the end of life). Estimating gains from improvements in quality of life, with no increase in number of remaining years, produced a lower value of approximately £10 000 per QALY. These differences are striking, and further studies are needed to clarify them.

Box 3 Valuing a QALY via surveying the general public

The value of a QALY is derived via a 'chaining' procedure. In the initial part of the chain, the respondent is asked about whether she/he would be prepared to pay anything to avoid being in this state, and, if so, what is the maximum amount she/he is willing to pay.

In the second part of the chain, the respondent would be asked a 'standard gamble' question involving a choice between two options. In the standard way of deriving a QALY index, one option would leave the respondent in the stomach/head condition for certain for the remainder of his/her life, whereas the other option would involve a gamble with varying probabilities of a better or worse outcome. 'Better' usually means a return to full health for the rest of one's life, whereas worse is usually characterized as immediate death. Visual procedures are used to guide the respondent through the process, and the index is derived from the point at which the respondent feels it is difficult to choose between the outcome for certain and the gamble.

Let us assume that, for one respondent, the probability at which she/he finds it difficult to choose between the head condition for certain and taking the gamble is 0.95, and that his/her WTP to avoid a year in the stomach condition was £1000. Dividing £1000 by 0.05 (which comes from subtracting 0.95 from 1) would give a value of a QALY for that person of £20 000. This can be done across several individuals to arrive at an average value of a QALY for a population.

For either head or stomach conditions, each respondent was asked two WTP questions (to avoid the 3-month state and the 12-month state) and three standard gamble questions (3 months for certain vs a gamble with outcomes of return to current health or 12 months in the state; 12 months for certain vs a gamble with outcome of return to current health or rest of life in the state; and rest if life for certain vs gamble with outcomes of current health or immediate death). In fact, slightly more WTP and standard gamble questions were asked of each respondent, but these are not relevant to this paper.

Table 1 Values of a QALY via alternative calculations from modeling based on VPF and VSI

Basic modeling approach	*Value of a QALY (£)*
Life saving	70 000
Life extending	35 000
Quality-of-life enhancing	10 000

Source: Reproduced from Donaldson, C., Baker, R., Mason, H., et al. (2011). The social value of a QALY: Raising the bar or barring the raise? *BMC Health Services Research* **11**, 8. doi:10.1186/1472-6963-11-8.

The issue of WTP for QALY types has been explored recently in subsequent surveys on the 'European value of a QALY' (see the EuroVaQ website at http://research.ncl.ac.uk/eurovaq/). It is also worth noting that the VPF itself is just over nine times the value of preventing a statistical injury. That there is no single value of a QALY is in line with other published views, the lowest value also being reflective of earlier published studies, which looked at the value of QALY gains arising from quality-of-life enhancement only.

A small number of other studies have modeled the value of a QALY from a Value of a Statistical Life. Using Australian data Abelson (2003) reported a value of AUS$108 000 (approximately £59 000). In Sweden, a value of US$90 000 (approximately £64 000) was reported by Johannesson and Meltzer (1998), whereas Hirth *et al.* (2000) calculated a value of US$161 305 (approximately £115 000).

Values of a QALY from Survey Research

Because the surveys referred to above from the UK and Spain (see Baker *et al.* and Pinto Prades *et al.* in further reading list) were intended only as feasibility studies, they were based on small samples not necessarily representative of the population as a whole. Nevertheless, the work suggests that it is feasible to conduct a survey to elicit monetary values for a QALY from a representative sample of the public so long as the procedure is broken down into manageable steps. However, it also became apparent that the mean estimates produced by such questions are particularly prone to the influence of 'outlier responses,' and that great care is therefore required in the selection of central-tendency measures. The most common example of an outlier was that many people were willing to take only very small risks of a more adverse outcome to avoid the stomach and head health states in the standard gamble questions or were even not willing to gamble at all. As well as such 'floor' effects respondents may also have a WTP ceiling (or budget constraint), an amount they express whether for a small or large perceived gain. Thus, when WTP values and health state utilities are combined in such circumstances, the implied WTP per QALY for such individuals can be so high as to lead to an implausible population average WTP per QALY across the whole sample. This was indeed the case in these studies, with the value running into several millions of pounds/euros! Other ways of managing the data can be used, however. For example, if mean WTP and mean QALY loss are combined (a 'ratio of means' as opposed to 'mean of ratios' approach), much more conservative values of a QALY emerge.

Issues

WTP and Ability to Pay

On the face of it, it would seem that it is problematic to use WTP measures to inform decisions about the allocation of resources for commodities, such as health care, for which such allocation is supposed to be on the basis of (some notion of) need. This is because WTP is obviously associated with ability to pay. However, Government departments in the UK and in other countries employ WTP-based values for the prevention of a statistical premature fatality (VPF) that are based on central-tendency measures (typically arithmetic means) of the population distribution of individual WTP for risk reduction. The fact that these VPFs are then applied uniformly to all groups in society whatever the income levels of members of the group clearly entails the implicit use of inverse-income distributional weights and further overcomes the challenge of ability to pay influencing WTP.

It would also appear that there is already a precedent in public-sector decision making for (at least implicitly) applying distributional weights to individual WTP for reductions in risks to life in order to arrive at an overall value in the form of a population mean (or possibly median) of individual values. This represents the state of the art of dealing with any such biases.

Validity and Scope

A major focus in the environmental WTP literature with respect to validity has been on scope effects: especially whether respondents are willing to pay more for greater amounts of the good being valued than for smaller ones, as one would expect. Carson (1997) showed that most studies (31 of 35 reviewed) reveal sensitivity to scope. Despite such positive results, doubts still remain about WTP values elicited through hypothetical surveys, and scope tests have taken on the status of being the 'acid test' for any particular study. As in other areas of application, results in health have been mixed (Smith, 2001; Olsen *et al.*, 2004). Also, this has led to more qualitative methods being used to examine the thought processes underlying respondents' stated values, a trend which will likely (and justifiably) continue.

Valuing Others

So far only passing reference has been made to people's concern – and hence WTP – for others', as well as their own health and safety. Insofar as people do display such 'altruistic' concern, then one would naturally expect that it would be appropriate to augment the WTP-based VPF to reflect the amounts that people would be willing to pay for an improvement in others' safety. However, it turns out that under plausible assumptions about the nature of people's altruistic concern for others' safety on the one hand and their material well-being on the other (the latter being reflected by their wealth or consumption), augmenting the VPF to reflect WTP for others' safety would involve a form of double counting and would therefore ultimately be unjustified. For example, suppose that individual A is concerned not only about individual B's safety but also about the latter's wealth or consumption. Furthermore, suppose that individual A's altruistic concern for B is 'pure,' in the sense that it respects B's preferences. Although A will then regard a reduction in B's risk of premature death as a 'good thing,' he/she will also regard the increase in B's taxation (or other expenditure) required to finance the risk reduction as an exactly offsetting 'bad thing.' Taking account only of A's WTP for B's safety improvement would therefore quite literally involve double counting. Thus, the issue of whether and how people's concern for others' safety ought to be taken into account under the WTP approach hinges on the essentially empirical question of the relationship between such concern and concern for others' wealth or consumption. Detailed discussions of the issue of altruism and safety exist in the literature, and it would seem that similar arguments apply to societal WTP values elicited in the health field.

Actual WTP in a National Health Service with Concerns for Equity

As noted above in the Section on Valuing Improvements in Quality of Life, WTP for improvements in quality of life can be estimated by combining WTP with individual utility scores for health states (measured on the 0–1 scale used in QALY calculations). For instance, if a national health service's WTP for a gained healthy year is £30 000, the WTP for improving a person's health (utility) by 0.1 for 1 year may be estimated to be $0.1 \times 30\,000 = £3000$. But this presupposes that individual utilities for health states correctly reflect societal preferences for priority setting – and hence correctly indicate societal WTP. There is much evidence that this assumption does not hold in societal decisions about resource allocation among groups of patients with different degrees of severity of disease and among groups with equal interests in treatment but different capacities to benefit from treatment. Most notably, in several jurisdictions the general public and societal decision makers have been shown to value utility gains more the more severe the initial condition is (Nord, 1999; Shah, 2009). To use conventional utilities from the QALY field to estimate what would be reasonable for a national health service to be willing to pay for technologies and programs that improve quality of life is thus problematic.

To capture concerns for equity, Nord (1999) suggested a type of priority weights for life years with a structure that is different from that of utilities normally used in QALY calculations. In principle, such weights can be used instead of conventional utilities when combining with a public health service's WTP for gaining a healthy year to estimate WTP for improvements in quality of life. This is an area of continuing research. There is at present no universal agreement as to what would be the right alternative weights to use for this purpose.

A similar point about equity can be made regarding WTP for gained life years. Even if a national health service indicates a WTP of, for instance, £30 000 for one gained healthy year (one QALY), it does not follow that N gained years should give a WTP of $N \times 30\,000$. A national health service may for instance consider that this would lead to unjustified age discrimination in priority setting in surgery and other one-time treatments of life-threatening conditions. It does not follow that a gained life year in a state of reduced health, say at utility level 0.8, should give a WTP of only $0.8 \times 30\,000 = £24\,000$, as this by many would be regarded as unfair discrimination against people with chronic disease or disability.

Conclusions

Measurements of individual WTP for health benefits are potentially useful to examine whether the individual welfare gains from health programs outweigh their opportunity cost, i.e., outweigh the welfare gains that could have been obtained by spending the resources on other goods and services instead. In this, the WTP approach has an advantage over approaches that use QALYs or DALYs. As with other approaches to valuation of health care, there are various methodological challenges associated both with measurement and aggregation of WTP. There is also an important distinction between estimating aggregate individual WTP and determining what should be the WTP in a national health service that strives for both efficiency and equity in health care. Further research on WTP measurements will help to clarify the potential and the role of the WTP approach in health care resource allocation.

Index

This index is in letter-by-letter order, whereby hyphens and spaces within index headings are ignored in the alphabetization, and it is arranged in set-out style, with a maximum of four levels of heading. Location references refer to the volume number, in bold, followed by the page number. Page numbers suffixed by *F* and *T* refers to figures and tables respectively. vs. indicates a comparison.
