Input markets in health care have own specific characteristics as well. Training healthcare professionals, in particular medical doctors, takes a long time and it is highly costly. Allocation of doctors to training vacancies and specialties is an important issue in many countries. Doctors are special input factors as they determine demand (when acting as agents for patients) and provide services (as suppliers of healthcare services). But also nurses and other professions have markets for their services, and the scope of health professions is changing in response to market forces. As an example of these changes there is the ability, in some places, of qualified nurses to prescribe pharmaceuticals for common health problems of the population. Or the issues associated with dual practice by doctors, especially when both public and private healthcare provision coexist (and compete). The way training and tasks of health professions evolve will potentially change market equilibrium in input markets, influencing the supply side of healthcare provision. Market equilibria will change as well in provision of healthcare services and ultimately in health insurance markets.

Many forces shape market equilibria and regulation in health care. Understanding the economics of markets in health care is an unfinished task, and future research will certainly develop issues addressed in the Encyclopedia (and likely open new areas of research as well).

Markets with Physician Dispensing

T Iizuka, University of Tokyo, Tokyo, Japan

Introduction

In many countries, physicians play the dual role of prescribing and dispensing medicines. Although this practice is mostly prevalent in Asia, it also exists in some regions of Europe and in some African countries. In these regions, the dispensing physicians profit from selling medicines to their patients. Policy makers have long been concerned about this practice because financial incentives can distort physicians' prescription decisions. This article examines markets in which the physicians dispense medicines by reviewing the experiences of three Asian healthcare systems, Japan, South Korea, and Taiwan, all of which implemented policies to separate prescribing and dispensing. Interestingly, each of these governments responded to this challenge differently, providing valuable insights on the economic consequences of physician dispensing.

Potential Conflict of Interest

In Asia, physicians have long played dual roles as both prescribing physicians and dispensing pharmacists. It is a tradition in Oriental medicine to not differentiate the roles of physicians and pharmacists and for patients to receive drugs directly from their physicians. Healthcare systems in Asia, including China, Hong Kong, Japan, South Korea, Taiwan, Thailand, and Malaysia have followed this tradition. In these healthcare systems, although retail prices (or reimbursement prices) are commonly regulated by the government, wholesale prices (or purchase prices) are not. This situation allows physicians to legally profit from the margin between the retail and wholesale prices. In fact, pharmaceutical companies routinely set a wholesale price that is below the regulated retail price in an attempt to induce demand for their medicines. This practice creates the natural concern that these financial incentives could distort a physician's prescription decisions. Physicians may not choose the best medicine for their patients in terms of efficacy, safety, and/or cost; instead, they may choose a medicine that provides them with the highest margin.

The margin received by physicians can affect their prescribing decisions in three ways. First, the physician's margin can induce therapeutic substitution between brand-name drugs with different active ingredients, all of which could be used to treat the same disease. In such a case, the physician may choose a drug with a higher profit margin even when the drug is suboptimal for the patient. The second possibility is generic substitution, which involves the substitution between brand-name and generic drugs with the same active ingredients. The difference in the physician's margin between the two versions may affect the physician's decision to prescribe and dispense generics. The third possibility is overprescribing. Physicians can increase their profits by simply prescribing and dispensing more medicines to their patients. In some cases, physicians may prescribe and dispense medicines even when none are necessary. All these concerns are realistic; it may be difficult for patients and insurers to verify the appropriateness of the physician's choice even after the patient has taken the medicine.

Governments have been aware that physician dispensing can create a serious conflict of interest between physicians and their patients or payers. However, separating prescribing and dispensing is often difficult because physicians are highly dependent on the profit from dispensing medicines to their patients. In all the three healthcare systems that is discussed below, physician fees have been set relatively low, and profits from dispensing drugs have been a major source of income. Accordingly, physicians have been against the separation policy. An extreme case occurred in South Korea, where a series of nationwide boycotts by physicians occurred when the government mandated the separation of prescribing and dispensing starting on 1 July 2000.

Physician Dispensing in Japan

As in other Asian healthcare systems, physician dispensing is deeply rooted in Japanese society. Following the tradition of Kampo medicines, physicians have customarily prescribed and dispensed medicines to their patients. Although the Meiji government in 1874 considered the separation of prescribing and dispensing as one of the goals of the modern healthcare system in Japan, the actual separation of prescribing and dispensing was virtually nonexistent before the 1970s (Kosaka, 1990; Jeong, 2009).

Prescription drug prices are regulated in Japan. Specifically, although the retail price (or reimbursement price) is regulated by the government, the wholesale price (or physician's purchase price) is not. Thus, physicians can earn margins by both prescribing and dispensing drugs. Moreover, doctors are paid on a fee-for-service basis. Therefore, physicians can increase their profits by overprescribing and dispensing high-margin drugs. As in other healthcare systems in Asia, physicians were highly dependent on the profits from dispensing medicines. Government surveys showed that on average physicians' margins accounted for approximately 25% of the reimbursement price in the early 1980s (Tomita, 2009).

The potential incentive problem created by physician dispensing was not unnoticed. However, the physicians' association (the Japan Medical Association) and the pharmaceutical companies were against any drastic reforms, which made it difficult for the government to mandate the separation of prescribing and dispensing. Instead, the government has instituted two types of incentives to induce physicians not to dispense medicines. First, the government adjusted its price-control rule so that physicians' margins were reduced. The government updates the regulated retail price in April every alternate year, based on both the previous period's retail price

and the average wholesale price. Specifically, the retail price for drug k at year $t+1$ follows the pricing formula below, assuming that the retail price is revised in year $t+1$:

$$P^R_{kt+1} = P^W_{kt} + R_t \times P^R_{kt} \quad [1]$$

where P^R_{kt} and P^W_{kt} denote the retail price and the average wholesale price for drug k at time t, respectively. The government does not allow the retail price to increase over time: if the computed retail price at $t+1$ exceeds the retail price at t, the retail price at $t+1$ is set equal to the retail price at t.

To reduce the physicians' margins, the government has reduced the value of R_t in eqn [1] over time. To see how R_t may affect the physician's margin, M_{kt}, note that M_{kt} is simply the difference between P^R_{kt} and P^W_{kt}. Then, eqn [1] can be rewritten as follows:

$$P^R_{kt+1} = P^R_{kt} - M_{kt} + R_t \times P^R_{kt} \quad [2]$$

Equation [2] implies that if the physician's margin, M, is greater than $R \times P^R$ at t, the retail price for drug k has to decline in the next period. The government reduced R_t from as high as 0.15 in the early 1990s to 0.02 in recent years. The reduction of R_t makes it difficult for pharmaceutical companies to offer a deep discount without substantially lowering the retail prices in the next period. Indeed, as the government hoped, average margins declined over time as R_t decreased, from as high as 25% of the retail price in the early 1990s to approximately 7% in recent years.

Second, to reduce physician dispensing, the government substantially increased prescription-issuing fees, which physicians receive when they write a prescription to be filled at an outside pharmacy. Prescription-issuing fees were 100 yen (approximately $1.3) per prescription in the early 1970s but increased to 500 yen in 1974. The fees were approximately 700 yen (approximately $9.1) in 2005.

Although no existing analysis formally quantifies the effects of these policies on separating prescribing and dispensing, a large number of physicians have stopped dispensing medicines from their offices during the past few decades. To examine whether the reduction in physician dispensing has resulted in lower drug spending, Graph 1 shows how pharmaceutical spending changed between 2001 and 2010, focusing on outpatient office visits. According to the Japan Pharmaceutical Association, the percent of drugs dispensed by pharmacists increased from 45% to 63% during this period. The graph shows that as the separation of prescribing and dispensing increased, pharmaceutical spending at pharmacies doubled, whereas the amount of drugs dispensed by physicians decreased by approximately 20% during the same period. Thus, as expected, the separation policy substantially increased the role of pharmacists. Total outpatient drug spending, which does not include dispensing fees, has increased by 2.4% annually, which is higher than the annual rate of increase in national health expenditures (1.8% between 2001 and 2009).

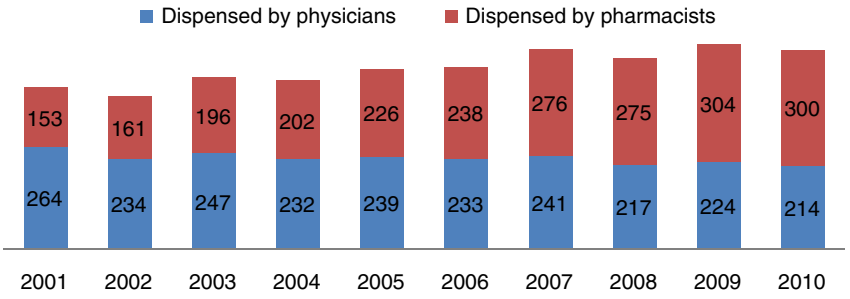
Although these simple comparisons suggest that the separation policy has not necessarily reduced pharmaceutical spending, it is difficult to isolate the impact of the separation policies from the impact of other healthcare policies, such as healthcare financing and provider payment reforms. In the section Overprescribing and Therapeutic Substitution, studies that examine more directly the impact of physician dispensing on pharmaceutical spending and medical expenditures are reviewed.

Overprescribing and Therapeutic Substitution

As noted previously, policy makers have been concerned that physician dispensing may result in overprescribing and substitution toward higher margin drugs. The latter situation results when the physicians' margins differ across drugs. Iizuka (2007) considered these possibilities by empirically examining the Japanese hypertension drug market, which consists of more than 40 brand-name drugs. The data were aggregated at the product level and covered the period between 1991 and 1997, when a majority of physicians dispensed medicines from their offices. Iizuka (2007) assumed that the physician acts as an agent for his/her patient and chooses a hypertension drug from more than 40 brand substitutes.

To examine whether financial incentives lead to overprescribing and substitution toward high-margin drugs, it is necessary to have data on the physicians' margins. Although no official data exist for the physician's margins, Iizuka (2007) calculated them by taking advantage of the pricing rule (i.e., eqn [1]). Specifically, in eqn [1], retail prices at t and $t+1$ (P^R_{kt} and P^R_{kt+1}, respectively) are publicly known. It is then easy to determine the average wholesale price at t (P^W_{kt}) using only the publicly available data. An average physician's margin at time t for each medicine can be obtained simply by taking the

Graph 1: Drug spending in Japan (2001–10)
Outpatient visits only. June of each year (billion yen)



Source: Survey of medical care activities in public health insurance, ministry of health, labour and welfare, 2001–2010.

difference between the retail price and the wholesale price at time t. It should be noted, however, that physicians' margins can be obtained only on average, and if the bargaining power of medical institutions differs substantially, this approach may not be valid.

Utilizing the obtained physicians' margins, Iizuka (2007) estimated a utility-based random coefficient discrete choice model, in which physicians choose one hypertension drug from more than 40 alternatives. Physicians were assumed to choose a drug by taking into account the patient and utility of each drug. In addition to physician's margin, other factors, such as the patient's out-of-pocket cost and the attributes of the drug, were also considered in the estimation. The results indicated that physicians respond to the size of the margin associated with each drug, suggesting that financial incentives created by physician dispensing distort the physicians' prescribing patterns.

To understand the magnitude of the distortion that the physicians' margins create, using the estimated parameter values, Iizuka (2007) conducted a counterfactual analysis in which prescribing and dispensing are hypothetically separated. This analysis was conducted by simply removing the physician's margin from their objective function. Under the assumption that the retail price and other factors do not change, it was shown that the elimination of the physicians' margins reduces total prescribing and pharmaceutical spending by 10.6% and 15%, respectively. This finding implies that the current spending on hypertension drugs is inflated 4.4% from substitution with high-price, high-margin drugs and 10.6% by overuse of drugs. These results support the ongoing concern that physician dispensing results in overprescribing and substitution toward high-margin drugs.

Although the simulation is valuable for quantifying the extent of the distortion potentially created by physicians, at least three issues exist that are outside the model but are important to actual policy making. First, it is likely that when the separation of prescribing and dispensing is mandated, physicians will be compensated for their lost income by, for example, higher physician fees. In turn, this may increase total medical expenditures. Second, the counterfactual simulation assumed that pharmaceutical prices would stay the same after the separation of prescribing and dispensing. However, this may not be true because the government may need to fund any additional payments to physicians by lowering reimbursement prices for pharmaceuticals. Third, as in Japan, the government may attempt to induce the separation by increasing prescription-issuing fees, resulting in overprescribing and higher medical expenditures. Policy makers need to carefully evaluate these possibilities when implementing policies.

Generic Substitution

Although Iizuka (2007) provided valuable insights regarding the effects of physician dispensing on both overprescribing and therapeutic substitution, the analysis is limited because it examines physician decisions only at the aggregate level. Moreover, it does not take into account the dynamic nature of the prescription process, and it does not examine whether physician dispensing affects generic substitution. Iizuka (2012) attempted to overcome these shortcomings by using rich, micro-level panel data covering more than 360 000 observations of over 40 drugs that faced generic competition after 1998. In this study, physician heterogeneity, such as a physician's general preference for generic drugs or whether the physician dispenses a drug from his/her office, is observable. Using this detailed microdata and estimating dynamic probit models, Iizuka (2012) examined the factors that affect the choice between brand-name versus generic drugs with the same active ingredient. As in Iizuka (2007), a physician was assumed to be an agent for his/her patient and to take into account both his/her own and the patient's utility when making a decision regarding which version of the drug to prescribe. During the data period (i.e., August 2003–December 2005), generic substitution was not allowed in Japanese pharmacies. Thus, the study focuses on physicians' generic adoption decisions. The patient's out-of-pocket costs, the physician's margin from each version, state dependence, and patient–physician heterogeneity were also considered as factors that could affect patient and/or physician utility from generic drugs. The physicians' margins were computed in the same way as in Iizuka (2007).

Based on a simple tabulation, Iizuka (2012) showed that generic drugs are more frequently used in small clinics (as opposed to large hospitals). Among the small clinics, generics are more often used by dispensing physicians (as opposed to nondispensing physicians). While dispensing physicians chose generic drugs 50.1% of the time, nondispensing physicians chose generics only 18.5% of the time. In terms of the margins that brand-name and generic drugs offer, the study found that generic drugs typically provide the largest margins immediately after they enter the market, and these margins are substantially larger than those for brand names during the period. However, the generics' advantage in margins quickly disappears after the first period, so the margins offered by brand-name and generic drugs no longer differ substantially. Iizuka (2012) argued that this phenomenon is a direct consequence of the government's price-control rule, as given by eqn [1]. That is, the rule makes it difficult for generic firms to continuously provide large margins because offering a large margin in one period reduces the room for a price discount in the next period.

Estimation results indicated that the dispensing physician's choices are affected by the difference in the margins between brand-name and generic drugs. Thus, as in the case of therapeutic substitution, financial incentives matter in generic substitution. In contrast, the study showed that when prescribing and dispensing are separated, physician prescription choices are not influenced by the difference in margins. This result is expected because nondispensing physicians do not earn the margins and therefore should not be affected by them. The results also indicated that, while dispensing physicians are responsive to patient costs, nondispensing physicians fail to internalize patient costs. This partly explains why substantially cheaper generic drugs are infrequently adopted in Japan. Iizuka (2012) speculated that dispensing physicians are more price sensitive because they directly purchase drugs from wholesalers and thus know more about the price difference between brand-name and generic drugs than do

nondispensing physicians. One implication of this result is that the separation of prescribing and dispensing reduces physician price sensitivity, which, in turn, may increase pharmaceutical spending when pharmacists do not have incentives to substitute generics for brand names. Physicians were also found to differ substantially in their preference for generic drugs, and this heterogeneity plays an important role in the choice between brand-name and generic drugs.

Physician Dispensing in South Korea

As in Japan, physicians in South Korea have long prescribed and dispensed medicines to their patients. However, an interesting difference has existed. In South Korea, not only physicians but also pharmacists have prescribed and dispensed medicines to their patients. On 1 July 2000, the South Korean government implemented a law for mandatory separation between the roles of physicians and pharmacists. After the implementation, physicians no longer dispensed drugs, and pharmacists no longer wrote prescriptions. The policy was intended to address the ongoing concern that physician dispensing (and pharmacist prescribing) induces overprescribing and inappropriate use of medicines, as seen in other Asian healthcare systems. The South Korean government expected that the separation policy would reduce the cost and misuse of medicines and improve drug efficiency (Kim and Ruger, 2008).

South Korea's experience is unique; unlike Japan and Taiwan, it was able to switch from a full integration of prescribing and dispensing to a complete separation of the two functions. Jeong (2009) argued that the president's political leadership and progressive civic groups have played key roles in the drastic reform. The radical change may make it possible to infer the impact of the reform on the outcomes related to our interests. However, existing studies do not employ rigorous identification strategies and simply compare the outcomes before and after the separation policy. Thus, care should be taken when interpreting the results.

With this caveat in mind, the following sections review the literature that examined the effects of the separation policy in South Korea on (1) therapeutic and generic substitution, (2) overprescribing, (3) pharmaceutical spending, and (4) health outcomes.

Therapeutic and Generic Substitution

Evidence indicates that after the separation policy, physicians shifted away from cheaper drugs and toward more expensive drugs (Kim and Ruger, 2008; Kwon, 2009). According to Kim and Ruger (2008), high-priced prescriptions for outpatients increased their market share from 16.0% (in March 2000) to 34.4% (in March 2001) at clinics and from 59.4% to 73.2% at general professional hospitals. The authors also reported that, as a result, sales by multinational companies rose consistently after the reform. Regarding generic substitution, several authors noted that physicians shifted away from cheaper generic drugs toward more expensive brand-name drugs after the separation policy.

These substitution patterns appear to indicate that before the separation policy, lower-priced brand-name and generic drugs provided higher margins for physicians than their substitutes. This conjecture is supported by Iizuka (2007), who demonstrated that when the physicians' margins are eliminated, pharmaceutical demand will shift away from former high-margin drugs toward low-margin drugs. Although no systematic evidence exists on the extent of the margins for drugs in South Korea, Kim *et al.* (2004) noted, "Physicians no longer had any incentive to prescribe cheaper drugs to outpatients after the policy was implemented" (p. 272), which also supports the conjecture. The observed shift away from low-priced drugs after the implementation of the policy makes sense if these drugs provided higher margins for physicians before 2000.

Alternatively, the shift toward more expensive drugs can be explained if physicians became less price sensitive after the separation policy. To the author's knowledge, no empirical study on the South Korean market has shown this relationship. However, as noted previously, Iizuka (2012) showed that, in the Japanese market, dispensing physicians are responsive to price differences, whereas nondispensing physicians are not. This result supports the hypothesis that physicians become price insensitive after the separation policy was implemented.

Overprescribing

Kim and Ruger (2008) reported that the number of prescribed medicines per visit declined approximately 4.8% between 1999 and 2001. Similarly, Kim *et al.* (2004) noted that the prescription rate of antibiotics declined by approximately 4.7% after the separation policy. These results indicate that the quantity of medicine dispensed declined after the separation policy. This is not surprising because the separation of prescribing and dispensing removes any financial incentives to overprescribe, holding all other factors constant. In fact, these numbers may underestimate the impact of the separation policy. After the separation policy, the South Korean government introduced a separate prescription-issuing fee, which created a new incentive to write more prescriptions (Kwon, 2009).

Pharmaceutical and Medical Spending

The above evidence indicates that, on one hand, the separation policy in South Korea reduced overprescribing, but, on the other hand, it caused a shift away from cheaper brand-name and generic drugs. Because these effects potentially cancel each other out, in theory, the total impact of the separation policy on pharmaceutical spending is ambiguous. However, authors agree that pharmaceutical spending increased dramatically after the separation policy was implemented. Kim *et al.* (2004) noted that compared to the first half of 2000, drug spending for outpatient visits increased by 41.6% in the first half of 2001, whereas drug spending for inpatients increased by 22.5%. Kwon (2009) showed that the rapid increase in drug spending continued until 2006. The fact that total drug spending increased after the separation

policy suggests that the shift toward more expensive drugs outweighed the cost savings because of a reduction in overprescribing.

The reader may note that this increase in pharmaceutical spending is not consistent with the counterfactual simulation presented by Iizuka (2007). In the Japanese case, Iizuka (2007) showed that the separation of prescribing and dispensing would reduce pharmaceutical spending both by reducing overprescribing and by increasing the use of less expensive drugs. The latter occurred because of the price-control rule in Japan; high-priced drugs generally provide higher margins to physicians than low-priced drugs. It is difficult for low-priced drugs to continuously provide high margins to physicians because doing so will substantially reduce the retail price of the drug in the following period. This comparison also suggests that the effect of a separation policy on pharmaceutical spending is likely to depend on which drugs provided higher margins to physicians before the implementation of the separation policy.

From the perspective of medical expenditures, it is also important to examine whether the separation policy affected nondrug expenditures, including physician consultation fees. If the latter are raised in exchange for a reduction in drug spending, total medical expenditures may increase. This is an important issue because physicians strongly resisted the separation policy because of their dependence on the profits from drug sales. Kwon (2009) noted that the revenue from drugs typically accounted for over 40% of total revenue. To compensate for the lost income, the South Korean government increased physician consultation fees five times between November 1999 and January 2001 (Jeong, 2009), for a total fee increase of 49%. Kim and Ruger (2008) found that medical expenditures, as a percentage of the gross domestic product, drastically increased after 2000, from approximately 4.5% before 2000 to approximately 6.0% in 2005. Although it is not clear how much of this sharp increase is because of the implementation of the separation policy, concerns were raised that health care expenditures in South Korea were out of control (Kim and Ruger, 2008).

Health Outcomes

As noted previously, one of the objectives of the separation policy was to reduce the inappropriate use of medicines. It was widely known that South Korean physicians and pharmacists were prescribing excessive amounts of antibiotics to their patients (Park *et al.*, 2005; Kim and Ruger, 2008). Before the separation policy, the rate of antibiotic resistance in South Korea was one of the highest in the world, and the overuse of antibiotics was considered to be the main cause (Kim and Ruger, 2008). By reducing the incentive to overprescribe drugs, governments hoped that the inappropriate use of drugs would be reduced.

Park *et al.* (2005) examined whether the separation policy reduced the inappropriate use of antibiotics. They looked at physician prescription choices in January of 2000 and 2001 and examined whether antibiotic prescribing in cases of viral illness, for which antibiotics are inappropriate, declined after the reform in comparison to cases of bacterial illness, for which the use of antibiotics may be justified. The author found that antibiotic use declined in both groups, but the reduction was larger for patients with viral illness (from 80.8% to 72.8%) than for patients with bacterial illness (from 91.6% to 89.7%). Kwon (2009) also reported that, before the separation policy in January 2000, 57.7% of prescriptions included antibiotics, but that number decreased to 45.6% after the separation policy in January 2002. These numbers appear to indicate that the separation policy had reduced antibiotics usage. However, the use of antibiotics remains very high among patients with viral illness, even after the separation policy. Moreover, to the author's knowledge, no direct evidence has shown that the separation policy improved health outcomes. Clearly, the impact of physician dispensing on health outcomes is understudied, suggesting the need for additional research on this important issue.

Physician Dispensing in Taiwan

As in Japan and South Korea, physicians in Taiwan have traditionally prescribed and dispensed medicines to their patients and have thus earned margins. The physicians' margins in Taiwan appear to be large. Chou *et al.* (2003) noted that unofficial estimates indicate that physicians' margins represent half of drug reimbursement prices. Patients pay copayments, but they are relatively low (Liu *et al.*, 2009).

The Taiwanese government has been concerned that financial incentives might lead to an excessive use of medicines. In 1997, the government implemented a separation policy that prohibits physicians from directly dispensing drugs to their patients. However, as in other countries, physicians were against the separation policy because they were dependent on the revenue generated by dispensing medicines. To gain support from physicians and pharmacists, the government increased physician consulting fees and pharmacist dispensing service fees. Furthermore, the government made a major concession as part of the separation policy: physicians were allowed to dispense drugs from their offices if they hired an on-site pharmacist. This is in contrast to the South Korea's separating policy, which prohibited all medical institutions from employing pharmacists or having on-site pharmacies (Kim *et al.*, 2004). As a result, although almost no clinics in Taiwan had on-site pharmacists before the separation policy, nearly 60% of them subsequently hired on-site pharmacists (Chou *et al.*, 2003). Thus, a large number of clinics continued to dispense drugs even after 1997.

An important aspect of the separation policy in Taiwan was that the policy was phased in between 1997 and 2000, which allowed researchers to rigorously examine the impact of the separation policy by implementing the difference-in-differences approach. This approach identifies the effect of a policy through a before-and-after comparison with a control group. Chou *et al.* (2003) conducted such a study and reached the following three findings. First, the separation policy reduced the drug prescription rate and drug spending per visit by 17–34% and 12–36%, respectively, for visits to non-dispensing clinics relative to the control group. This shift is consistent with the studies previously discussed and indicates

that the separation of prescribing and dispensing reduced prescribing. The reduction in drug spending largely results from the reduction in number of drugs prescribed, suggesting that no clear shift occurred toward either more or less expensive drugs in Taiwan.

Second, in contrast to the effect of the separation policy on drug spending, Chou *et al.* (2003) did not find that the policy had an impact on medical expenditure, which includes drug prices, lab tests and diagnostic expenses, dispensing fees, and consultation fees. This lack of impact implies that the reduction in drug spending was offset by physician fees and dispensing fees, both of which were intentionally raised to gain support for the policy from physicians and pharmacists (Chou *et al.*, 2003).

Third, the study found that the separation policy had no effect on drug spending for the clinics that hired on-site pharmacists. By permitting physicians to hire on-site pharmacists, the separation policy failed to alter physician prescribing behavior. This example demonstrates that, as Hsieh (2009) argued, it is critical to break the link between profit margins and physician prescribing behavior to prevent the inappropriate use of medicines.

Research Agenda

As reviewed in this article, a growing number of papers have examined the impact of physician dispensing on physician prescribing patterns, pharmaceutical spending, and medical expenditures. This frequency is not surprising given the prevalence of physician dispensing in Asia and its potential impact on health outcomes and medical expenditures. However, most existing studies simply compare the outcomes before and after the separation policy without controlling confounding factors that would also influence the outcomes. Because other policy reforms, such as healthcare financing, provider payments, or pharmaceutical pricing reforms may occur simultaneously, these studies face difficulties in isolating the effects of the separation policy. Only a limited number of studies have rigorously quantified the impact of physician dispensing on physician prescribing behavior and medical expenditures. Clearly, more research is needed to improve our understanding of this important issue.

Research that examines the impact of physician dispensing on health outcomes is even more scarce. A major concern regarding physician dispensing is that physician dispensing could adversely affect health outcomes as a result of overprescribing or inappropriate medicine choices. The literature that most directly investigates these issues consists of studies that examined whether physician dispensing increased the rate of antibiotics prescriptions (e.g., Park *et al.*, 2005). As previously noted, important progress has been made on this front. To the author's knowledge, however, it is still unknown whether physician dispensing practices ultimately affect health outcomes. Given the importance of this issue, more research is needed to clarify the effect of physician dispensing on health outcomes. Indeed, without such analysis, one has to be very careful about discussing the welfare implication of physician dispensing.

Conclusions and Lessons Learned

This article examined markets with physician dispensing, focusing on the impacts of physician dispensing on their prescribing patterns, drug and medical expenditures, and health outcomes. The experiences of three Asian healthcare systems, Japan, South Korea, and Taiwan, were reviewed. Although these systems faced the same concerns that physician dispensing could lead to overprescribing and inappropriate use of medicines, the governments intervened in the markets differently, providing valuable insights on the impact of physician dispensing.

Japan did not ban physician dispensing but instead created financial incentives to encourage physicians to refrain from dispensing drugs. That is, the physicians' margins were gradually reduced, whereas prescription-issuing fees were raised. As a result, according to Japan Pharmaceutical Association, the percent of drugs dispensed by pharmacists increased from 12.0% in 1990 to 20.3%, 39.5%, 54.1%, and 63.1%, in 1995, 2000, 2005, and 2010, respectively.

Although it is apparent that physician dispensing has decreased over the past 20 years, it is not clear whether the reduction in physician dispensing has reduced overprescribing, drug spending, or medical expenditures. To induce the separation of prescribing and dispensing, the government has substantially increased the prescription-issuing fees, which may have encouraged overprescribing and resulted in higher medical expenditures. Dispensing fees for pharmacists were also substantially raised, further increasing medical expenditures. Thus, the total impact of the separation policy on drug spending and medical expenditures is not clearly known.

In contrast to the gradual approach taken in Japan, South Korea enforced the separation of prescribing and dispensing, making physician dispensing illegal after 1 July 2000. This drastic approach faced strong protests by physicians and resulted in substantial fee increases for them. Evidence also indicates that after the separation policy, physicians shifted away from low-priced drugs toward high-priced drugs, which substantially increased pharmaceutical spending. Both of these changes appear to have contributed to the sharp increase in pharmaceutical and medical expenditures after the separation policy.

Beginning in 1997 Taiwan also made physician dispensing illegal. However, when faced with the strong opposition of physicians, Taiwan created a major loophole: clinics were allowed to continue dispensing as long as they hired an on-site pharmacist. The majority of clinics were therefore allowed to continue both prescribing and dispensing medicines, even after 1997. As a result, the separation policy had little impact on physician prescribing behavior. For the small number of physicians who stopped dispensing drugs, the separation policy appears to have reduced total prescribing. However, the reduction in drug spending was offset by higher physician fees, resulting in little change in total medical expenditures.

The lessons for policy makers can be summarized as follows. First, consistent with an ongoing concern, evidence indicates that physician dispensing distorts physician prescribing decisions by creating financial incentives to both overprescribe and substitute toward higher margin drugs. Thus, holding everything else constant, eliminating the physicians' margins

will mitigate these distortions. As a result, separating prescribing and dispensing can potentially improve health outcomes.

Second, although the separation policy may remove the incentive to overprescribe and to substitute toward high-margin drugs, it does not necessarily reduce pharmaceutical spending. For example, by eliminating the physicians' margins, demand for cheaper brand-name and generic drugs could decline if these drugs provided higher margins before the separation policy. Alternatively, physicians could become less price-sensitive after the separation policy because they would no longer purchase drugs directly from the wholesalers. Thus, if the goal of the separation policy is to reduce drug spending, additional policies – such as global budgets, which will increase the price sensitivity of physicians – may also have to be implemented.

Third, the experiences of the three healthcare systems suggest that the aforementioned assumption that 'everything else is constant' does not usually hold true. That is, if the physicians' margins are eliminated, the physicians' lost income must be compensated by, for example, higher physician fees or prescription-issuing fees, both of which increase medical expenditures. Moreover, if the prescription-issuing fees are set higher than the marginal cost of writing a prescription, overprescribing will be encouraged even when the physicians' margins are eliminated, further increasing drug spending. Because pharmacists are assuming new tasks, separate fees may also have to be paid to the dispensing pharmacist. Policy makers should be aware that this additional spending is difficult to avoid. Unless this spending is funded by a reduction in pharmaceutical spending, separation policies may result in a substantial increase in total medical expenditures. Reduction in drug spending can be achieved, for example, by a decrease in overprescribing or by reducing pharmaceutical prices. The latter may be justified because the pharmaceutical companies will no longer pay margins to physicians.

This discussion indicates that the success of a separation policy critically depends on how policy makers construct the details and take into account the interdependence of healthcare policies, such as physician dispensing, pharmaceutical pricing, and provider payments. The author hopes that this short article helps policy makers anticipate the key issues to be considered before designing policies related to physician dispensing.

Measurement Properties of Valuation Techniques

PFM Krabbe, University of Groningen, Groningen, The Netherlands

Introduction

In medical decision analysis and economic evaluation of health care, states of illness or disability (hereafter called 'health states') are commonly valued on a scale from zero to unity. A value of 0 is assigned to the state of being dead (or a state equivalent to being dead), whereas a value of 1 is assigned to 'full health.' The values are called preference scores or utilities and may be used to weigh life years in evaluations of health outcomes. Several techniques can be used to elicit values for health states from individuals, including the standard gamble (SG), time trade-off (TTO), rating scale, magnitude estimation (ME), person trade-off (PTO), Thurstone scaling, and extensions of this latent scaling model, the class of discrete choice (DC) models. They are based on different theoretical assumptions and stemming from different disciplines (e.g., health economics, psychology, and public health). Empirical studies on the relationship between the outcomes of these valuation techniques have shown that there are differences in the values elicited by the different valuation techniques and in their measurement properties. So far, there is little agreement about which technique is the most appropriate.

For health state values to be useful to decision makers, the numbers should accurately represent the genuine value or attitude of the subjects from whom they were elicited toward the health states in question. The extent to which this is the case depends on the psychometric or measurement properties of the elicitation techniques used to establish the values. In the context of health economics, the most salient psychometric properties are validity and reliability. From the area of clinimetrics the concept 'responsiveness' has been introduced as an important property of health outcome measures. More general is the idea of 'level of measurement,' which is related to the field of measurement theory, and that is more directed on the information level of the responses captured by various measurement approaches. This article explains what is meant by each of these and reviews the valuation techniques mentioned above with respect to these properties.

This overview is only dealing with valuation of health states derived from a group of respondents. In the area of clinical decision making, often individual patients are involved in eliciting values for health states that concerns possible outcomes related to their own disease and optional treatment modalities. The measurement properties of these patient values will not be discussed and presented in this article. The main reason for refraining to incorporate these types of values is because many measurement properties cannot be (directly) estimated on an individual basis or are rarely performed.

Validity

Validity refers to the degree to which an instrument really measures what it intends to measure. Another definition used in educational and psychological testing is that it is an overall assessment of the degree to which evidence and theory support the interpretation of the scores entailed by proposed uses of the instrument. Validity is thus concerned with the nature of 'reality' and the nature of the entity being measured. Especially for (partly) subjective phenomena, such as the valuation of health states, the determination of validity seems to be a process that involves the incremental accumulation of evidence rather than one definitive comparison. As opposed to outcomes such as temperature, blood pressure, or survival, health status is not directly observable and its appraisal is to some extent normative.

Validity encompasses three main aspects each with a rather broad scope: content validity, criterion-related validity, and construct validity. Content validity refers to the question: 'Is the instrument really measuring what we intend to measure?' For the purpose of this study, this implies a discussion about the 'real' meaning and interpretation of values elicited by valuation methods. Are they really representing individual expressions of health state preferences? Criterion-related validity is only applicable if one method can be identified as superior, i.e., a 'gold standard.' As these issues are part of an ongoing debate, content and criterion-related validity are not addressed. Here convergent validity which may be regarded as a type of construct validity is primarily dealt with. In convergent validity research, the degree of association (i.e., correlation coefficients) between measures of constructs that theoretically should be related to each other is estimated, that is, patterns of intercorrelations among measures are looked at. Correlations between theoretically similar measures should be 'high.' A detailed discussion about the validity in valuation techniques, which revolves around the content of the HRQoL concept, would go beyond the scope of this article.

Convergent Validity

A variety of relationships between values from different valuation techniques has been reported in the literature. From these studies it is clear that the different valuation techniques produce different value functions. In general, SG and TTO values are all higher than visual analog scale (VAS) values. Under highly controlled experimental circumstances, a study by Krabbe *et al.* (1997) showed that in students the SG and the TTO are producing equivalent valuations to a large extent, despite their apparent conceptual difference. Results from this study can be compared with the few existing studies that have examined this issue, taking into consideration (**Figure 1**) that in the latter studies the numbers of health states and/or participants have usually been small and the statistical techniques rather global. A paper by George Torrance published in 1976 showed a coefficient of determination (R^2) of 0.95 between SG and TTO. These coefficients are based on the mean values of only six health states assessed by local alumni of McMaster University. In Torrance's study, the very bad and the very good

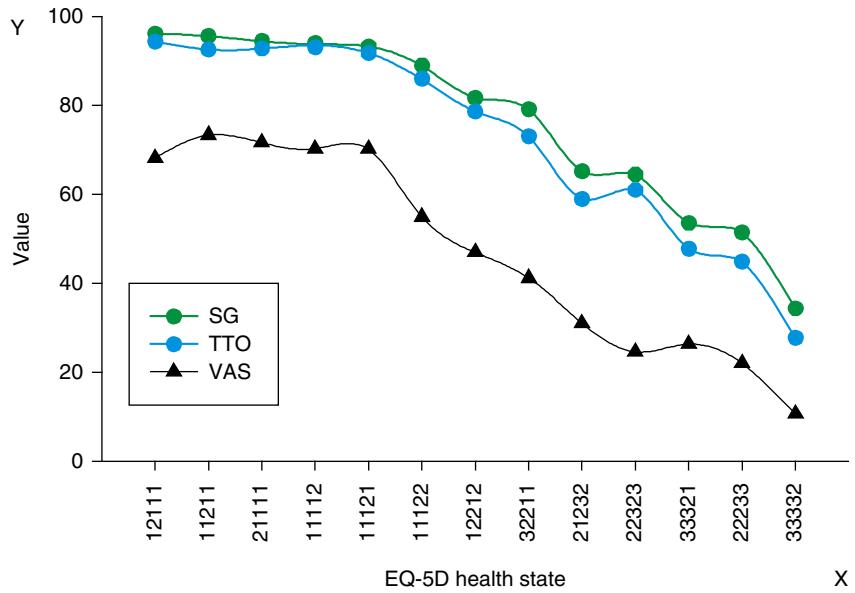

Figure 1 Valuations (means) for 13 EuroQol health state descriptions elicited by three valuation techniques (ordered by SG values). Reproduced from Krabbe, P. F. M., Essink-Bot, M. L. and Bonsel, G. J. (1997). The comparability and reliability of five health-state valuation methods. *Social Science & Medicine* **45**, 1641–1652.

health states were excluded, which may have improved the coefficients. Comparison of mean values obtained (from a set, N = 52, of physicians, therapists, family members, and patients) with the SG and the TTO for 35 disability levels in a study conducted by Alan Wolfson and colleagues in 1982 resulted in an R^2 of 0.84. In 1984, Leighton Read and colleagues presented a Pearson correlation coefficient of 0.65 between the SG and the TTO based on assessments made by 67 physicians. Their study was based on the valuation of only two health states. John Hornberger and colleagues in 1992 reported a Spearman rank correlation of 0.31 between the SG and the TTO. Their results were based on 58 individual patients' valuations of their own health. Comparisons of these methods are inevitably problematic as the techniques used vary across studies (study design, framing) as well as mechanisms for transforming raw values, such as done not only for the TTO (states worse than dead) but also for the VAS (based on position of 'dead').

In the earlier mentioned study of Krabbe *et al.* (1997), valuations based on a VAS (a type of rating scale) were distinct from, but strongly related to, values derived from the two trade-off methods. A simple one-parameter power function sufficed to transform VAS values to SG or TTO. A smaller study by Eric Bass and colleagues from 1994, focused on deriving values for health states in gallstone disease, demonstrated a consistent and substantial difference between values derived by a rating scale technique and those obtained by an SG technique.

In the rise of health state valuation techniques (late 1970s and early 1980s), some studies have been investigating ME. The most well known one is probably the study by Rachel Rosser and Paul Kind from 1978. However, in this study, ME was not compared with another valuation technique. One year later in 1979, Robert Kaplan and colleagues showed that ME responses are compressed at the lower end of scale near death, which seems inconsistent with their VAS results.

In one of the rare studies focused on the comparison of PTO with other valuation methods, Joshua Salomon and Christopher Murray performed in 2004 a head-to-head study in which they calculated the following Spearman's rank correlations based on responses from 69 public health professionals: PTO versus VAS 0.85, PTO versus TTO 0.84, and PTO versus SG 0.86. For the other combinations they found: VAS versus TTO 0.94, VAS versus SG 0.94, and TTO versus SG 0.92.

Benjamin Craig and colleagues applied in 2009 a secondary analysis on data for 8 countries collected by the EuroQol Group, which enabled them to compare VAS, TTO, and DC values (derived from rank data). They observed between VAS and TTO coefficients ranging from 0.61 to 0.80 (Kendall's tau) and ranging from 0.60 to 0.92 for the strength of the relationship between VAS and DC. In a recent study published in 2010, Stolk *et al.* (2010) observed a convergent validity of 0.93 (ICC; intraclass correlation coefficient) between TTO and values derived under a DC model. Responses in this study were collected from 209 students (**Figure 2**). Another study from the Netherlands by Denise Bijlenga and colleagues in 2009, based on participation of 97 community persons, found convergent validity of 0.72 (ICC) between VAS and TTO. For the comparisons DC between TTO and VAS they transformed the values of these two methods into binary scores (to create data comparable to raw DC input data, e.g., preference data). Coefficients were 0.79 between VAS and DC (Cohen's kappa) and between TTO and DC 0.77 (Cohen's kappa). In an explorative study, Joshua Salomon performed in 2003 a secondary analysis on the original the Measurement and Valuation of Health, University of York, 1995 data that were used to construct the EuroQol-5D valuation function. Transforming this data into rank data followed by DC modeling, a very high similarity between the original TTO data and the DC-derived values was reached: 0.97 (ICC).

Reproduced from Stolk, E. A., Oppe, M., Scalone, L. and Krabbe, P. F. (2010). Discrete choice modeling for the quantification of health states: the case of the EQ-5D. *Value in Health* **13**(8), 1005–1013.

Reliability

Reliability deals with the stability of measurements, all other things being equal, and with the congruence between raters in the case of the assessment of stimuli (e.g., health states). To a large extent, achieving reliability is a technical matter (e.g., larger samples sizes, repeated measurements, and increasing number of health states). Two distinct types of reliability coefficients can be distinguished in the field of health state valuation: test–retest and interrater. Test–retest reliability is dealing with the reproducibility of a method. If a method is reliable, it should evoke the same outcomes on a second occasion if there is no alteration due to change expected. The most appropriate way of testing this is by computing the ICC between the test and retest. The interrater (or interobserver) reliability seems less suitable for valuation methods, as here assessment is focused on the scaling of health states. Hence, health states that are related to each other with an underlying natural ordering on a unidimensional scale yields another type of data. However, from a more fundamental measurement perspective the interrater reliability can be used as an indicator for the fulfillment of basic measurement requirement in general. In the following, various data on the reliability of individual responses are reported. The reliability of mean responses in groups of people can be much greater, depending on the size of the group, because random variations in individual responses go both ways and tend to cancel each other out.

Test–Retest

In 1976, George Torrance reported in one of the earliest studies involving both SG and TTO a test–retest reliability coefficient (Pearson correlation based on replications) of 0.77 for both SG and TTO. Test–retest was also studied by Donald Patrick and colleagues in 1973 for the rating scale (numbers from 1 to 11) and produced in a group of health leaders a coefficient of 0.79 (Pearson correlation).

There is little evidence for the test–retest reliability of ME and PTO techniques. Of these two techniques, ME would appear to be most promising in terms of reliability. Rosser and Kind reported test–retest reliability for ME at 97% (percentage of agreement). But it is not clear from their publication whether this is done for the real ME tasks or only for the preceding ranking task. In one of the earliest valuation studies, Patrick and his colleagues applied ME for which they presented a test–retest reliability of 0.74.

In 1995, Erik Nord reported relatively poor test–retest findings for the PTO at the individual level, 40% measured by the percentage of agreement, but stressed that group-level reliability could, nevertheless, be satisfactory. In 1997, Christopher Murray and Arnab Acharya reported a lowest correlation coefficient of 0.87 among 9 different groups that performed the same PTO task. Of course, this statistic is only an approximation for the test–retest as not the same individuals were applied.

The classical method of Thurstone scaling (or paired comparison) has been studied in the area of quantifying health states by Paul Kind and David Hadorn in the early days of health-state valuation. Kind applied the classical Thurstone model and an extension of it, the Bradley–Terry–Luce model, in 1982. However, neither reliability statistics nor comparisons (validity) with other methods were performed. Hadorn and colleagues performed in 1992, a Thurstone scaling analysis, but based on an incomplete and selective design

of 54 (59%) of the total number of pairs. In addition, this response mode and analytical steps seem a bit different than the standard approach. Nevertheless, they reported test–retest correlation of 0.79 for Thurstone scaling as well as for the rating scale.

Denise Bijlenga and colleagues also explored a DC model in their 2009 study; the researchers found test–retest results of 0.77 for the VAS (ICC), 0.70 for TTO (ICC), and 0.78 (Cohens's kappa) for DC values.

Interrater

Item Response Theory models, and in particular the Rasch model, are built to deal with 'objective' measurement of subjective phenomena. The most important claim of the Rasch model is that due to the mode of collecting response data in combination with the conditional estimation procedure of the model, the derived measures may fulfill the invariance principle. This is a critical criterion for fundamental measurement. Invariance means that the comparison between two (or more) health states should be independent of the group of respondents that performed the comparisons, and judgments among health states should also be independent of the set of health states being compared.

This invariance principle is closely related to an (implicit) assumption made in the field of health state valuation, namely, that in general people evaluate health states similarly, which permits the aggregation of individual valuations to arrive at group or societal values. The invariance principle seems also related to the IIA assumption (independent of irrelevant alternatives) made in DC models. Therefore, it is important to determine how similar people's judgments actually are for particular valuation techniques, as heterogonous responses (or even distinct response structures) of individuals may indicate that a valuation technique is less appropriate as it may not yield unidimensional responses. Such an analysis can be performed with intraclass correlation statistics (interrater reliability) or specific mathematical routines closely related to factor analysis.

For these reasons, the author wants to assess, additional to test–retest reliability, the consistency across subjects in their task of rating health states (i.e., group level). This type of reliability is indicated as interrater reliability. To compute this reliability coefficient for all health states together, based on a variant of analysis of variance, a global interrater coefficient can be estimated. Formally, this coefficient is a simple adaptation of the conventional Cronbach's alpha (internal consistency measure); instead of multiple items, multiple raters are now being investigated. Although the interrater reliability is formally a statistic that expresses the homogeneity of the responses among raters, this statistic may also be seen as evidence for the content validity. Because a high interrater coefficient may only be expected if most of the raters have a rather similar understanding of the valuation task and in addition come up with comparable preference scores for the valued health states.

By the use of Generalizability Theory, a specific application of analysis of variance, Krabbe *et al.* (1997) were able to reveal various sources of measurement error in the elicited values for health outcomes. Although all the methods to some extent seem to be biased, the valuation methods yield health state valuations that were satisfactorily reliable at the group level: SG 0.58, TTO 0.65, and VAS 0.77. These findings support the validity of constructing societal values for health states based on aggregated data. In an earlier postal survey, which was also conducted using EuroQol health-state scenarios, VAS interrater reliability coefficients in the range 0.77–0.84 were observed by Marie-Louise Essink-Bot and colleagues in 1993. Both results confirm the relatively good properties of VASs with regard to the interrater reliability of the responses. It should be noted that Leighton Read and colleagues in their 1994 study also applied a type of analysis of variance analysis that approximates the G-theory approach. They also found that the variability of responses among respondents is considerably greater for SG than for VAS. Denise Bijlenga and colleagues estimated interrater ICCs for the VAS (0.73), TTO (0.33), and the DC (0.64).

The independency of the set of health states (invariance principle) to be positioned on the VAS has been rejected in two Dutch studies by Han Bleichrodt and Magnus Johannesson in 1997 and Paul Krabbe and colleagues in 2006. Both studies clearly showed that different values will be collected with a multiitem VAS for a fixed set of health states if these are part of varying other states. It is reasonable to assume that these biases may even be larger in the case of measuring health states on a VAS state by state.

Responsiveness

The concept of responsiveness (or sensitivity) has arisen over the past 20 years and refers to the ability of an outcome measure to reflect change. To be of value, an instrument should be stable when no change occurs, although reveal differences in case of improvement or deterioration of a person's health status. The concept of responsiveness has drawn considerable attention among the users of descriptive HRQoL instruments (questionnaires). Most of these users are working in the field of medicine, where responsiveness is part of the clinical framework of health measurement, called 'clinimetrics.' This term was coined to describe an approach to scale development in the area of health that is ostensibly different from the more traditional approach known as 'psychometrics.' These two approaches differ from both in a conceptual and a methodological viewpoint.

Many within the field of descriptive HRQoL or patient-reported outcomes research agree that responsiveness is important, yet there is no consensus on how to quantify it. The confusion even extends to the conceptualization, study design, and measurement of responsiveness. Conspicuously absent is a theory on its relationship to the two classic psychometric concepts, reliability and validity. Responsiveness seems to have a bearing on validity because an instrument first has to measure what it was designed to measure in order to measure accurately. Responsiveness also seems to have a bearing on reliability; if an instrument is unreliable it will not be responsive to changes. Formal research fields in the social sciences (e.g., psychometrics, mathematical psychology, and measurement theory) offer no empirical, theoretical, or mathematical support for the notion of responsiveness. Nevertheless, responsiveness is used here as a theoretical construct that can only be examined by means of

comparison with other measurement instruments and practical experiences.

So far, it seems that the responsiveness has not been investigated for preference-based instruments. This is to some extent explainable as most often valuation techniques are used to quantify certain health states or conditions. They are far less applied to measuring changes between two measurement occasions (in the case of estimating the test–retest property, everything is done to reduce possible changes in the health status of individual). Accordingly, for the applications of the valuation methods there are arguments why this has not been done. Of course, for the use of the so-called preference-based multiattribute systems, such as the EuroQol-5D (EQ-5D), the Health Utility Index Mark III, and the Short-Form 6D it is more informative and more important to have results about the responsiveness of these systems.

Level of Measurement

Apart from theoretical and methodological differences between the valuation techniques, the general underlying assumption is that individuals possess implicit preferences for health states that range from good to bad and that, in principle, it should be possible to reveal these preferences and express them as quantitative or semiquantitative values. The implication of this is that the values should be characterized as interval level data or cardinal data. So, differences between health states should reflect the increment of difference in severity of these states. For that reason, informative (i.e., metric) outcome measures should be at least at the interval level. This means that measures should lie on a continuous scale, whereby the differences between values reflect true differences (i.e., if a patient's score increases from 40 to 60, this increase is the same as from 70 to 90).

Although there have been interest from the onset of quantifying health states in the classical psychometric reliability statistics (validity remains a difficult factor in this area of subjective measurement), far less attention have been directed on the basics of measurement theory in general. Unfortunately, it seems that certain crucial conditions of measurement are hardly recognized by scientists working in the field of quantifying health states. In particular, to arrive at health state values that are characterized as having cardinal or interval level measurement properties, certain basic conditions are required. This involves the invariance principle in collecting response data, but another requirement is unidimensionality of the measurement scale.

Economists tend to claim that responses to the TTO and the SG have interval scale properties, whereas responses to rating scales, including the VAS, tend not to have interval scale properties, given that in the latter, no trade-offs are expressed. Around 1990, Erik Nord and Jennifer Morris/Allison Durand published two papers showing that when subjects locate a set of health states on a straight value line ranging from 0 to 100, most subjects do not intend to express more than ordinal preferences. In a later attempt to find empirical evidence to support that mean health state values collected with a (multiitem) VAS can be characterized roughly as interval data, based on a rank-based scaling model (unfolding), Heleen van Agt and colleagues observed in 1994 a very strong relationship that support the interval property of the raw VAS data. Confirming results were found in a study by Paul Krabbe and colleagues in 2007 that applied nonmetric multidimensional scaling on data (metric and ranks) that were derived from VAS values. Parkin and Devlin (2006) argued that there is no more evidence for interval scale properties in TTO responses and SG responses than in VAS responses.

In a paper by George Torrance and colleagues in 2001, results are presented of a more detailed analysis between the relationship of SG and the VAS. Based on their own study outcomes and incorporating studies from other published studies (all aggregated group means), they show that there is a clear concave curve that passes through 0 and 1 (**Figure 3**). Similar results were also found for the relationship between TTO and VAS. In fact, if the relationship between two different valuation techniques is nonlinear, this implies that at least one of these two methods cannot be regarded as a true metric scale (cardinal or interval differences between the mean values of the health states).

Based on the results of one of the earliest studies to derive health state values based on DC modeling, Salomon concludes that predicted health state valuations derived from a model of ordinal ranking data can provide a close match to observed differences between cardinal values for different states. The model may be used to generate robust predictions on an interval scale, with predictive validity rivaling that of a model estimated directly from TTO values.

To find empirical evidence to support that health state values are overly representing a unidimensional structure, Paul Krabbe in 2006 used a basic mathematical routine to dissect valuation data into underlying dimensions. This study revealed deviating response behavior among the respondents in their health state valuation elicited with the TTO, whereas a

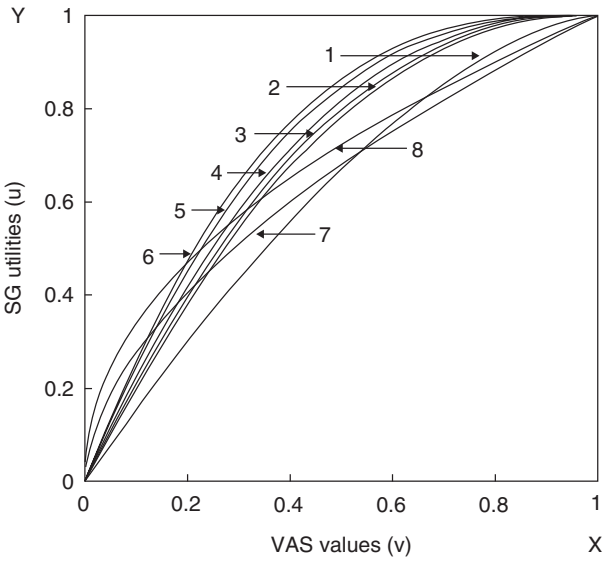

Figure 3 Relationship between mean SG scores and mean VAS scores for health states. Reproduced from Torrance, G. W., Feeny, D. and Furlong, W. (2001). Visual analog scales: do they have a role in the measurement of preferences for health states? *Medical Decision Making* **21**(4), 329–334.

similar analysis on VAS data showed a single dimension. A logical explanation for the absence of unidimensionality of the TTO is that this method is measuring two distinct phenomena (health states and longevity) simultaneously.

Conclusion

It is not surprising that the results found by the author are heterogeneous. Most studies about comparing different valuation techniques were conducted years ago. Certainly in the beginning, most studies were relatively small, often clinically oriented, and there was less harmony about the way valuation methods should be performed. Moreover, in each valuation technique the subjects are faced with a cognitive task that differs from that used with other techniques. In addition, several of the techniques exist in different versions that frame the decisions in different ways. In general, studies focused on comparing different valuation techniques can be differentiated in terms of the type of descriptions of the health states, selection of study population, number of health states, and types of health states. Health states can be divided into hypothetical states and actual or hypothetical health states pertaining to treatment outcomes or particular stages of disease.

Conventionally, the values for different health states used in economic evaluations are derived from a representative community sample. Subjects who value the hypothetical health states need not be familiar with specific illnesses. However, it is reasonable to assume that in many situations healthy people may be inadequately informed or lack good imagination to make an appropriate judgment about the impact of (severe) health states. Many authors assert that individuals are the best judges of their own health status instead of unaffected members of the general population. Numerous studies have found discrepancies in valuations for health states between the general population (healthy people) and people who actually experience illness (patients). Several of these discrepancies can be explained by referring to adaptation mechanism made by patients, but for the frequently applied TTO, it is above all the central element time that likely induce different values for different respondents.

Introduction

Health economics is a relatively young subdiscipline, and the measurement of inequalities in the health domain has only relatively recently received attention from health economists. Nevertheless, and perhaps unsurprisingly, the topic has a very long history outside health economics, in particular in public health, demography, sociology, and epidemiology. The notion of a 'gradient in health' across measures of socioeconomic status has been the subject of empirical analysis and speculation regarding its causes for more than a century. For example, in the mid-nineteenth century, William Farr proposed a law relating mortality with population density. At around this time, the famous political economist William Stanley Jevons examined variation in the rate of mortality in different English cities, attributing differences to the proportion of poor Irish immigrants (Jevons, 1870). In the early part of the twentieth century, there were also several empirical examinations of income-related gradients in mortality, including analyses by Hibbs (1915) and Woodbury (1924) of the gradient in infant mortality in the US using information collected from household surveys. A key issue then (as now) was whether the relationship between health and income was purely a correlation, or implied some form of causation. However, most of these early studies reported the health–income gradients only in a tabular or graphical form and did not apply any of the measures the authors examine here.

In this article, the authors give a nonexhaustive overview of the techniques that economists have developed to measure inequality and inequity in health and health care. These measures have their origins in univariate measures such as the Gini coefficient and the Lorenz curve that were developed in the early twentieth century to measure income inequality. Economists also developed bivariate inequality measures, particularly for quantifying the distribution of categories of expenditure across income (Wiśniewski, 1935). Some of these early studies used measures such as concentration curves and indexes to examine health care spending as a component of household expenditure at different levels of income (Iyengar, 1960; Ghezelbash, 1963).

It has only been in the past few decades that these measures have been used specifically for health economics applications. Probably the first proposal for the use of the Gini coefficient in a health economics context can be attributed to Chen (1976), who formulated the K index as a proxy measure of health care quality. The rationale for using this measure was as a way of penalizing situations where avoidable morbidity was concentrated in a small number of individuals rather than being spread more evenly across a community. Le Grand (1987) also applied the Gini coefficient to quantify inequalities in age at death in his international comparisons across a range of high and middle income countries. However, more recent applications of the Gini are less common than studies focusing on bivariate inequality, i.e., the correlation between health and measures of socioeconomic status such as income. Here, the measure traditionally adopted is the concentration index, stemming from proposals of Wagstaff *et al.* (1991), which has been widely employed in international inequality comparisons (e.g., *see* Van Doorslaer *et al.*, 1997). In the past few years, there has been a considerable interest in developing new uni- and bivariate health inequality measures, in part to address some of the aspects of health such as the bounded nature of many health measures (e.g., rates of mortality must fall in the 0–1 range).

The authors' overview focuses on the most important contributions since 2000 and is intended primarily as a catalog of what is available at present. They therefore confine themselves to a short presentation of the various measurement techniques developed by economists; for more in-depth discussions or the literature on the causal mechanisms linking health and income the authors refer to the literature list at the end of this article. The remainder of this article contains four sections. The authors discuss the measurement of inequality in the next section. Next, the authors deal with decomposition methods and introduces methods to measure health inequities. The final section concludes. For brevity, the authors refer to health variables in what follows, but all methods described in this article can be applied to any variable measuring health, health care use, and health care expenditures.

Measurement of Inequality

Measurement of Total (i.e., univariate) Health Inequality

The initial focus of this entry is measurement of the degree of inequality within a given health distribution. The literature on the measurement of this type of health inequality borrows heavily from the literature on the measurement of income inequality.

Throughout this entry, the authors consider a population of n individuals that are ranked by their health levels, i.e., each individual $i=1,\ldots,n$ is characterized by a health level h_i and $h_1 \leq h_2 \leq \ldots \leq h_n$. They always assume that the health variable h_i has a well-defined, finite lower bound $h^{\min}$. With regard to the upper bound, they distinguish between the infinite and finite case, i.e., the authors have either $h_i \in [h^{\min}, +\infty]$ or $h_i \in [h^{\min}, h^{\max}]$. When the health variable is of the ratio-scale type, they assume that $h^{\min}=0$.

 doi:10.1016/B978-0-12-375678-7.00205-4

For ratio-scale variables with an infinite upper bound, the most popular inequality indicator is the Gini index, which can be written as a weighted sum of health shares (Lambert, 2001):

$$G(h) = \frac{1}{n}\sum_{i=1}^{n}\left[\frac{h_i}{\overline{h}}\left(2R_i^h - 1\right)\right] \quad [1]$$

where $\overline{h}$ denotes average health and R_i^h is the fractional rank of individual i (in the absence of ties we have $R_i^h = (i - 0.5)/n$; in the presence of ties the definition is slightly different). The Gini index is a relative inequality index: it focuses on the relative health differences between individuals. If one wants to stress the absolute differences between individuals, one could use the generalized Gini index, which is an absolute inequality index obtained by multiplying the Gini index by average health:

$$GG(h) = \frac{1}{n}\sum_{i=1}^{n}\left[h_i\left(2R_i^h - 1\right)\right] \quad [2]$$

In principle, any relative or absolute inequality index used for the measurement of income inequality can also be used for the measurement of health inequality. But there is an important caveat: because the health variable is not necessarily of the ratio-scale type, one should not take for granted that indicators developed for ratio-scale variables generate meaningful information when applied to other types of variables, such as nominal, ordinal, or cardinal health variables. Depending on the nature of the variable, different inequality indicators are called for. For instance, Abul Naga and Yalcin (2008) have derived a class of indicators tailored to measure inequality for ordinal health variables.

The situation also changes when the health variable has a finite upper bound, for example, a maximum value of 100%. In that case, one can look either at attainment levels, measured by the health variable h_i, or at shortfall levels, measured by the ill-heath variable $s_i = h^{\max} - h_i$. Recent publications (Erreygers, 2009b; Lambert and Zheng, 2011) have explored what this implies for health inequality measurement. These studies start from the idea that the attainment and shortfall indicators should be complementary, which in its strongest form imposes that attainment inequality is always equal to shortfall inequality. As far as the Gini family is concerned, the strong complementarity criterion leads to the following corrected version of the Gini indicator (Erreygers, 2009b):

$$CG(h) = \frac{4}{n}\sum_{i=1}^{n}\left[\frac{h_i}{\left(h^{\max} - h^{\min}\right)}\left(2R_i^h - 1\right)\right] \quad [3]$$

A similar correction can be applied to the coefficient of variation family. As shown by Lambert and Zheng (2011), the combination of a weak version of complementarity and decomposability points in the direction of the variance as a measure of inequality.

Measurement of Socioeconomic Health Inequality

The dominant strand in the health inequality literature deals with bivariate inequality, and focuses on the correlation between health and socioeconomic status. The most popular measure in this field is the concentration index. Suppose that y_i is a variable which measures the socioeconomic status of individuals; this variable can be occupation, education, income, wealth, etc. Let R_i^y be the fractional rank of an individual according to the chosen socioeconomic variable. The concentration index can be written as (Wagstaff *et al.*, 1991):

$$C(h;y) = \frac{1}{n}\sum_{i=1}^{n}\left[\frac{h_i}{\overline{h}}\left(2R_i^y - 1\right)\right] \quad [4]$$

Observe that the socioeconomic variable need not be of the ratio-scale type; the index only requires information on the socioeconomic rank, which can also be obtained from an ordinal variable.

Different variants of the standard concentration index $C(h;y)$ have been introduced over the years. If one wants to focus on absolute, rather than relative, health differences between individuals, one can use the generalized concentration index $GC(h;y) = \overline{h}C(h;y)$. It is also possible to express different degrees of sensitivity to inequality by using the extended concentration index (Wagstaff, 2002). Again, the authors have a different story when they are dealing with bounded health variables (Clarke *et al.*, 2002). The counterpart of the strong complementarity criterion, which the authors mentioned in the previous subsection, is the 'mirror' condition. This requires that the measured degree of socioeconomic inequality of health should be the reverse of the measured degree of socioeconomic inequality of ill health. Recently, two indicators, which satisfy the mirror condition, have been suggested. The first (Wagstaff, 2005) is defined as:

$$W(h;y) = \frac{1}{n}\sum_{i=1}^{n}\left[\frac{h_i\left(h^{\max} - h^{\min}\right)}{\left(h^{\max} - \overline{h}\right)\left(\overline{h} - h^{\min}\right)}\left(2R_i^y - 1\right)\right] \quad [5]$$

and the second (Erreygers, 2009a) as:

$$E(h;y) = \frac{4}{n}\sum_{i=1}^{n}\left[\frac{h_i}{\left(h^{\max} - h^{\min}\right)}\left(2R_i^y - 1\right)\right] \quad [6]$$

Because both have the mirror property, the level of socioeconomic inequality in health and ill health is identical, except for the sign, i.e., $W(h;\ y) = -W(s;\ y)$ and $E(h;\ y) = -E(s;\ y)$, but in other respects the indices are very different. Erreygers and Van Ourti (2011) provide an in-depth discussion of the properties of these two indicators, in the context of a more general examination of the applicability of rank-dependent indicators.

Decomposition Methods

In the previous sections Measurement of Inequality, the authors covered the most popular inequality indices in the health economics literature. These indices have frequently been used to compare inequality levels between countries or within countries over time but do not allow to infer what lies behind these differences in (socioeconomic) inequality. Decomposition methods – first developed in labor economics and in the income inequality literature – are a useful tool to align the analysis more with an explanatory approach.

Factor Decompositions

Wagstaff *et al.* (2003) were the first to highlight the usefulness of applying existing decomposition methods to the health domain, in particular to the concentration index. When health can be written as a linear function of K factors (e.g., socioeconomic status, demographics, lifestyles, …), one can express socioeconomic health inequality as a weighted sum of the socioeconomic inequalities in these factors. This is most easily seen from combining eqn [4] with a regression model that associates health linearly to K factors x_{ik}:

$$h_i = \alpha + \sum_{k=1}^{K} \beta_k x_{ik} + \varepsilon_i \qquad [7]$$

where α and $\beta_1,\beta_2,\ldots,\beta_K$ are coefficients and ε_i an error term with zero mean. After some algebra, the following result emerges:

$$C(h;\gamma) = \sum_{k=1}^{K} \left[\left(\beta_k \frac{\overline{x}_k}{\overline{h}} \right) C(x_k;\gamma) \right] + \frac{2\mathrm{cov}\left(\varepsilon_i, R_i^{\gamma}\right)}{\overline{h}} \qquad [8]$$

which shows that socioeconomic health inequality is affected (a) by the magnitudes of the impact of the K factors on health – measured by the average elasticities $\beta_k \overline{x}_k / \overline{h}$ – and (b) by the socioeconomic inequalities in each of the contributing factors – measured by the concentration indices $C(x_k; \gamma)$. There is also a residual term summarizing the covariance between the error term of eqn [7] and the fractional socioeconomic rank. Similarly, one can derive decompositions of the other univariate and bivariate indices discussed in the previous sections Measurement of Inequality. The authors refer interested readers to O'Donnell *et al.* (2006), Erreygers (2009a) and Van Doorslaer and Van Ourti (2011). Readers interested in subgroup decompositions should consult Clarke *et al.* (2003).

Longitudinal Decompositions

A factor decomposition unravels the link between (socioeconomic) health inequality and its associated factors, but in many occasions the authors are interested in the difference between two inequality indices. They now describe decompositions of the change of (socioeconomic) health inequality over time. Note that many of these methods can also be used to decompose differences between countries.

Wagstaff *et al.* (2003) describe an Oaxaca–Blinder decomposition of the change in the concentration index that starts from eqn [8]. It reveals whether changes in (socioeconomic) health inequality are mainly driven by changes in socioeconomic inequalities in the associated factors x_k or by changes in the associated elasticities η_k.

$$\Delta C = \sum_{k=1}^{K} \eta_{kt} [C(x_{kt};\gamma_t) - C(x_{kl};\gamma_l)] + \sum_{k=1}^{K} C(x_{kl};\gamma_l)[\eta_{kt} - \eta_{kl}] + REST \qquad [9]$$

where ΔC denotes the difference between two concentration indices in period t and l; and REST is a residual term.

Van Ourti *et al.* (2009) have adapted the Oaxaca–Blinder decomposition in eqn [9] in order to reveal the relation between the change in income-related health inequality, income growth, and the change in income inequality. This decomposition starts from eqn [7] but allows for a nonlinear association between income (included in x_k) and health. The health elasticity of income turns out to play a crucial role; if this elasticity is increasing with income, then proportional income growth will lead to higher income-related health inequality, and vice versa.

Allanson *et al.* (2010) have recently developed a related longitudinal decomposition that extends the work of Jones and López Nicolás (2004). Jones and López Nicolás (2004) study concentration indices based on short-run (cross-section) and long-run (panel averages) measures of health and socioeconomic status using insights from the literature on income mobility (Shorrocks, 1978), and show they diverge when there are systematic differences in health between those whose socioeconomic status is upwardly and downwardly mobile. An important trademark of their decomposition is that it allows to show whether socioeconomic health inequalities are persistent over time. However, it cannot illustrate whether health changes are more/less pronounced for those with high relative to low socioeconomic status. Allanson *et al.* (2010) show that the change in socioeconomic health inequalities can be written as the sum of 'socioeconomic health mobility' (i.e., the extent to which health changes accrue to those with an initial high relative to low socioeconomic status) and 'health-related socioeconomic mobility' (i.e., the extent to which socioeconomic status changes are larger/smaller for the initially healthy or unhealthy). The same authors have also studied the effects of deaths in longitudinal decompositions (Petrie *et al.*, 2011).

Measurement of Inequity

Until now, the discussion has been mainly confined to ways of measuring and decomposing (socioeconomic) health inequality. Although this is totally in line with having 'the numbers tell the tale', it is not clear whether society at large is concerned about all (socioeconomic) health inequalities. It seems highly plausible that people are concerned about some causes/drivers of inequalities, but less about others. The former is usually denoted as inequity and is the focal point of this section.

Measurement of Horizontal Inequity

The dominant inequity concept is that of horizontal inequity, which states that equals should be treated equally. The concept of vertical equity – which states how unequally unequals should be treated – is as important, but has received far less attention in the literature due to empirical difficulties to estimate the vertical equity norm (Sutton (2002) is a noteworthy exception).

When measuring horizontal socioeconomic inequity in health, one should start by defining whether variation in health attributable to certain factors is equitable or inequitable.

The typical stance in the literature is to consider the variation due to age and sex as equitable and all other variation as inequitable. This is much in line with the practice of standardizing health for age and sex that is popular in public health and epidemiology, but in principle the subdivision between equitable and inequitable health variation allows for a broad range of value judgments (including e.g., the case where equality of health outcomes is inequitable). Two procedures have become popular in the health economics literature (Wagstaff and Van Doorslaer, 2000; Gravelle, 2003; Fleurbaey and Schokkaert, 2009). The first, denoted 'direct standardization', boils down to calculating the predicted value of eqn [7] keeping those factors that lead to equitable health variation fixed (e.g., fixing age and sex at a specific value). The resulting index of socioeconomic inequity $HI^{dir}(h;\ \gamma)$ calculates the socioeconomic inequality in these predicted health values:

$$HI^{dir}(h;\gamma) = C\left(\hat{h}_{|\overline{a},\overline{s}};\gamma\right)$$

$$= C\left(\hat{\alpha} + \sum_{k=1}^{K-2}\widehat{\beta_k}x_{ik} + \widehat{\beta_a}\overline{a} + \widehat{\beta_s}\overline{s} + \widehat{\varepsilon_i};\gamma\right) \qquad [10]$$

where ^ denotes an estimate, and age and sex have been fixed at their average values $\overline{a}$ and $\overline{s}$. The second approach, 'indirect standardization', boils down to calculating the difference between the actual socioeconomic inequality in health and the hypothetical situation where socioeconomic inequality reflects only variation due to equitable variables (which is obtained by fixing the values of the variables that lead to inequitable health variation in eqn [7]):

$$HI^{ind}(h;\gamma) = C(h;\gamma) - C\left(\hat{h}_{|\overline{x_k},\overline{e}};\gamma\right)$$

$$= C(h;\gamma) - C\left(\hat{\alpha} + \sum_{k=1}^{K-2}\widehat{\beta_k}\overline{x_k} + \widehat{\beta_a}a_i + \widehat{\beta_s}s_i;\gamma\right) \qquad [11]$$

where the inequitable variables and the error term are fixed at their average values $\overline{x_k}$ and 0.

The horizontal inequities obtained from eqns [10] and [11] are similar because eqn [7] is linear. Owing to the linearity of eqn [7], it is also straightforward to see that there is an exact link between the factor decomposition of the concentration index and indices of horizontal inequity: in other words, by rearranging the decomposition in eqn [8] – i.e., moving the contributions of age and sex to the left hand side – eqns [10] and [11] are obtained. However, in many empirical applications a nonlinear functional form is preferred for eqn [7] due to the skewed distribution of health. In the latter case, the exact link with the decomposition in eqn [8] is lost, but as long as the variables leading to equitable and inequitable health variation are additively separable, eqns [10] and [11] are still similar. When additive separability no longer holds – which occurs, for example, when the health effect of medical supply (an inequitable variable in our example) depends on the age of the individual (an equitable variable) – eqns [10] and [11] will give different estimates of horizontal inequity. In the next section, the authors discuss this difference in a more general setting and highlight the ethical positions underlying the indirect and direct standardization procedures.

Methodology of Fleurbaey and Schokkaert (2009): Insights from Social Choice

In this section, the authors very shortly introduce a recent contribution to the literature on health equity measurement that is not based on the concentration index. Fleurbaey and Schokkaert (2009) have discussed how the theory of fair allocation (Fleurbaey, 2008) – a social choice theory – could be used to measure health and health care inequities. The most important difference with approaches based on the concentration index (or other related rank-dependent inequality indices) is that it consists of a two-step approach. In the first step, the sole and ultimate goal should be to estimate the 'best' empirical model that links health to its determinants. In a second and independent step the inequities in health are measured, and the procedure is similar whether the underlying equation linking health and its determinants is linear, nonlinear, or not additively separable in the equitable and nonequitable variables. It boils down to subdividing the list of variables into those causing equitable and inequitable health variation (much like before), and next calculates all inequities related to the variables that lead to inequitable health variation. This is different from the methods based on the concentration index that focus on socioeconomic inequity only; and hence the theory of fair allocation allows the measurement of inequities along a broader spectrum of ethical stances.

The first step consists of modeling how health relates to its determinants, i.e., an exercise in pure positive economics. Preferably, a structural econometrics model that disentangles how determinants affect health directly and indirectly (via other endogenous variables such as income, medical care, lifestyles, and so on) is used, but in this section the authors stick to a reduced form to illustrate the most basic version of the approach of Fleurbaey and Schokkaert (2009):

$$h_i = f(x_i) \qquad [12]$$

where $f(.)$ links health to the vector of regressors x_i.

Once $f(.)$ has been estimated, the researcher (or the outcome of a public debate) should subdivide the vector of regressors into a set of variables that lead to equitable (x_i^{eq}) and inequitable health variation (x_i^{in}). Although the description is based on the reduced form in eqn [12], it should be clear that a structural model might be extremely useful in guiding the subdivision, as it allows the distinction of the direct and indirect effects of explanatory variables (e.g., think of a case where the indirect impact of gender on health via unhealthy behavior is considered equitable, whereas the direct impact of gender on health might be considered inequitable). The subdivision allows to introduce two concepts that have been developed in the theory of fair allocation and that are closely related to the two standardization approaches the authors introduced in previous section Measurement of Horizontal Inequity. 'Direct unfairness' is in the same vein as 'direct standardization' and proceeds by fixing the value of x_i^{eq} at a reference value $h_i^{dir} = f\left(\tilde{x_i^{eq}}; x_i^{in}\right)$. The alternative procedure compares actual health with a 'fair' distribution of health where x_i^{in} is fixed, i.e., $h_i^{fg} = h_i - f(x_i^{eq}; (\tilde{x_i^{in}}))$. Next, one calculates inequity in health by measuring inequalities in h_i^{dir} or h_i^{fg}. Fleurbaey and Schokkaert (2009) argue in favor of using an absolute inequality index.

Several things are worth pointing out. First, if socioeconomic status is considered as the only determinant leading to inequitable health variation, these methods conceptually coincide with the approach based on the concentration index; but as soon as other choices are made with respect to the subdivision of factors leading to equitable and inequitable health variation, both approaches will diverge. Second, the approach translates an inherently multidimensional problem into a one-dimensional inequality problem. In contrast, approaches based on the framework of concentration indices are multidimensional in nature. Third and similarly to the discussion of the two standardization procedures in the previous section Measurement of Inequality, the functional form of $f(.)$ is crucial. When additive separability applies so that $h_i = f(x_i) = g(x_i^{ed}) + h(x_i^{in})$, inequalities in 'direct unfairness' and the 'fairness gap' are identical, but when this is not the case inequalities diverge. The theory of fair allocation can however guide the choice between 'direct unfairness' and the 'fairness gap'. 'Direct unfairness' imposes that health differences due to factors leading to equitable health variation are not reflected in estimates of inequity, whereas the 'fairness gap' imposes that absence of inequity in health coincides with an absence of inequitable health variation. Both requirements seem plausible but cannot be jointly true when the function linking health to its determinants is not additively separable in the factors leading to equitable and inequitable health variation. For more discussion, the authors refer to Fleurbaey and Schokkaert (2009).

Conclusion

This article gives a nonexhaustive overview of techniques to measure inequality and inequity in health and health care. The authors have focused on the most important health economics contributions since 2000, but they have also acknowledged that this literature is embedded in a long tradition of research on the socioeconomic health gradient that dates back to more than a hundred years. In fact, the recent research can be seen as revival interest in bivariate as opposed to univariate measures of inequalities.

The first part of the article has dealt with the measurement of univariate inequalities in health. Special attention was paid to bounded health variables; and the implications for health inequality measurement. Next, the authors covered the concentration index and related indices that have been popular to measure bivariate socioeconomic health inequalities.

The second part of the article introduced decomposition methods that are useful to align the analysis more with an explanatory approach. The authors subsequently covered factor decompositions and longitudinal decompositions. The first allows the contribution of separate health determinants to health inequalities to be disentangled; the second is useful to understand what drives changes in health inequalities over time (or between countries) and whether it is always the same people in poor or good health.

In the final part of the paper the authors have moved from inequalities to inequities, i.e., that share of total inequalities that is found to be inequitable. They have covered the traditional approach in health economics that focuses on horizontal socioeconomic-related inequities; and introduced a new and promising approach – derived from social choice theory – that allows to calculate health inequities along a broad set of ethical positions.

Measuring Health Inequalities Using the Concentration Index Approach

G Kjellsson and U-G Gerdtham, Lund University, Lund, Sweden

Introduction

Health inequality can be defined as variations in health status across individuals within a population. To compare inequalities between countries or over time periods, it may be, for example, interesting to know how much more healthy the healthier individuals are than the unhealthy individuals. However, it may be more interesting to know how health is distributed in relation to a socioeconomic variable. Any version of the concentration index (C) measures inequality in the distribution of a health variable in relation to a socioeconomic rank attached to each individual. Although there are other measures of socioeconomic-related health inequalities (e.g., epidemiologists frequently use absolute and relative range and the population attributable risk), health economists generally use the C. The popularity is probably due to the illustrative and intuitive interpretation. In addition, the C takes the whole population into account rather than only calculating differences between the extremes.

The remainder of this article is a short overview of the recent discussion on how to use different versions of the C to measure socioeconomic health inequalities. The next section defines and discusses the standard C and the related generalized C (GC). These indices are related to the (generalized) GINI coefficient, which is popular within the income inequality literature. Herein, lie parts of the problem of using the C as a measure of health inequalities: health is rarely measured on the same scale as income. Measurement Properties of Health Variables therefore considers the measurement properties of different health variables. Desirable Properties of Inequality Indices discusses desirable properties of an inequality index: the recent literature suggests that an index should be invariant to arbitrary transformations of the health variable. Recent Corrections of Concentration Index (a) presents the recent corrections of C that satisfies these properties and (b) discusses how one may relate to inequality indices for health variables that have different measurement properties from income. Guidelines for Practitioners compiles this literature into a guideline for practitioners and provides an illustration using European Survey of Health, Ageing and Retirement (SHARE)-data.

Concentration Index and the Generalized Concentration Index

Definitions

Just as the GINI coefficient is derived from the Lorenz curve, C is derived from the Concentration Curve (CC). Although the Lorenz curve plots the fraction of the total income concentrated in a fraction of the population ranked by income, CC plots the fraction of the total sum of a health variable that is concentrated in a fraction of the population ranked by a socioeconomic variable (e.g., income). For example, in Figure 1 the poorest 10% possess only 2.5% of the total health that is distributed within the society. As the line at 45° represents a perfectly equal distribution (i.e., the poorest 10% of the individuals possesses 10% of the total accumulated health), it is referred to as the line of equality (LE).

The GINI is equal to twice the area between LE and the Lorenz curve. However, as CC, in contrast to the Lorenz curve, can be both above and below LE, C is defined as twice the area below LE and above CC (i.e., area a in Figure 2) subtracted by twice the area above LE and below CC (i.e., area b). Equivalently, C may be expressed as a ratio between the area $a-b$ and total area below the LE (i.e., $a+c$). Thus, C attains values between -1 and 1. A negative value suggests that the health variable is concentrated among the poor, whereas a positive value suggests that the health variable is concentrated among the rich. Thus, if the health variable is expressed positively in terms of health, a positive (negative) index suggests a pro-rich (pro-poor) distribution. The opposite applies if the health variable is expressed negatively in terms of ill-health. In the former case, C attains its maximum value when all health is concentrated to the richest individual. In the remainder of the article, this will be referred to as the most pro-rich state.

In a finite sample, the C may be formally expressed as:

$$\mathrm{C} = \frac{2}{n\mu}\sum_{i=1}^{n} h_i(R_i - 1)$$

where n denotes the number of individuals, h_i is health of individual i, μ is the mean of h, and $R_i = n^{-1}(i - 0.5)$ is the fractional socioeconomic rank ranging from the poorest to the richest.

The related GC is analogously derived from the GCC, which plots the fraction of the mean of the health variable that is concentrated in a fraction of the population. As GC equals μC, it is not bounded between -1 and 1.

Absolute and Relative Value Judgment

C and GC are sensitive to different types of health changes. C is unaffected if health increases proportionally for all individuals, whereas GC is unaffected if health increases with an equal amount for all individuals. This difference relates to the clash in the income inequality literature between a relative and an absolute view of inequalities (e.g., Kolm, 1976). The degree of inequality can be preserved either if relative differences (ratios) or absolute differences remain the same. However, although income is always unbounded and measured on a ratio scale, health variables can be measured on different scales and can be either bounded or unbounded. It is therefore not appropriate to directly apply the value judgments from the income inequality literature to all health variables. Further elaborations on this question requires a discussion of the differences between health and income.

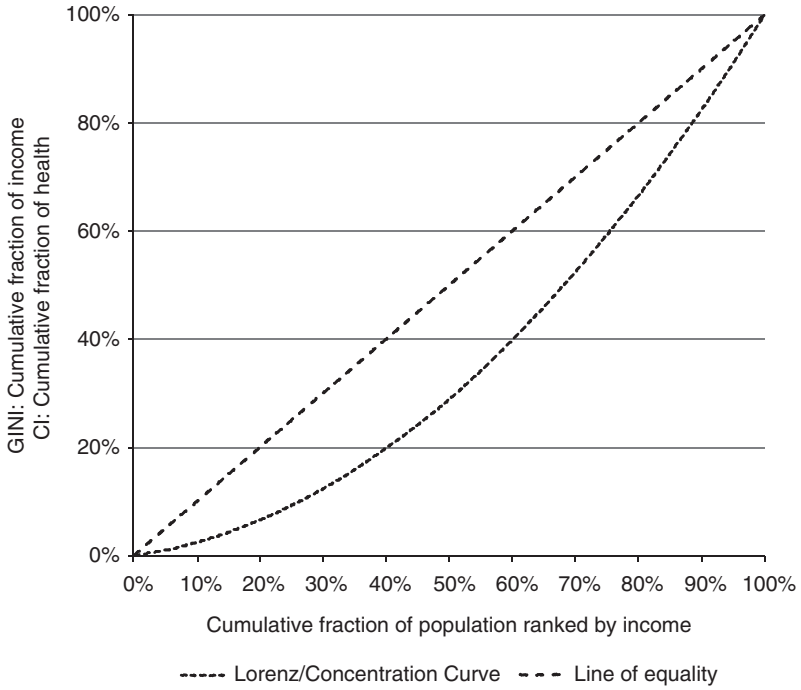

Figure 1 The Lorenz Curve and the CC.

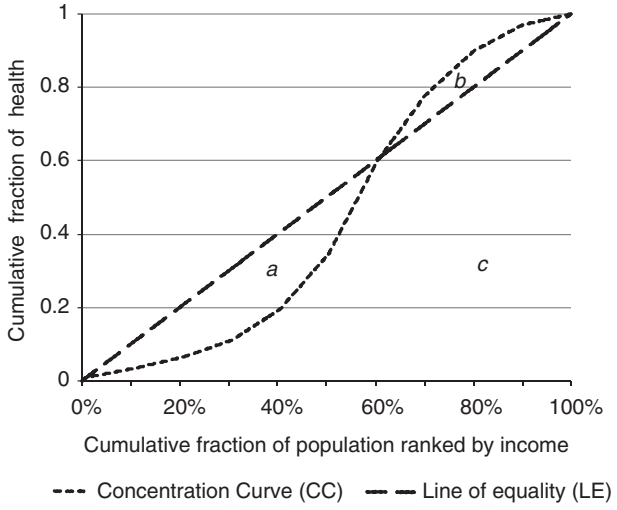

Figure 2 The concentration index. *Note*: Using a graphical representation, C may be defined as $2 \times (a - b)$ in **Figure 2** or as $(a - b)/(a + c)$ in either **Figure 2** or **Figure 3**.

Measurement Properties of Health Variables

Erreygers and van Ourti (2011a) categorize health variables by two dimensions: their measurement scale and boundedness. In principle, health variables can be measured on five different scales:

- Nominal, that is, a scale that allows for classifying, but not ordering, individuals (e.g., type of sickness).
- Ordinal, that is, a scale that allows for ordering individuals but not measuring differences between them (e.g., self-assessed health graded from very bad to excellent).
- Cardinal, that is, the zero point is fixed arbitrary and does not have an intuitive interpretation of total absence, one may meaningfully calculate differences but not ratios (e.g., body temperature or Health Utility Indices (HUIs); The HUI is in the quality-adjusted life-years literature generally anchored between 0 and 1, representing being dead and perfect health respectively, and interpreted as if it was ratio scaled).
- Ratio scale, that is, the zero point corresponds to complete absence and ratios can be meaningfully measured (e.g., health care expenditures).
- Unique, that is, the zero point corresponds to complete absence, and it is not possible to scale the variable (e.g., number of general practitioner (GP)-visits).

Unless one circumvents the meaningless ordinal or nominal differences by projecting the health indicator on a cardinal or ratio scale (e.g., binary variables may always be interpreted as a ratio-scaled variable of average prevalence at the level of deciles/percentiles), one cannot use the C approach for nominal or ordinal scales. Therefore, the remainder of this article only considers health variables that are cardinal, ratio scaled, or unique.

The other dimension in which health variables and income may differ is that while there is no upper bound on income, health variables can be either unbounded or bounded. A bounded variable ranges from a theoretical lower bound $h_{\min}$ to a theoretical upper bound $h_{\max}$. Therefore, one may – in

contrast to unbounded variables – measure both attainments h_i and shortfalls s_i of such a health variable (i.e., $s_i = h_{max} - h_i$). This has crucial implications for the desirable properties and value judgments of the indices, discussed in the sections Desirable Properties of Inequality Indices and Value Judgment for Bounded Variables.

Desirable Properties of Inequality Indices

The literature discusses several possibly desirable properties for health inequality indices. This section considers the most important ones. Although the transfer property and scale invariance are relevant, and indisputably desirable, for all health variables, the mirror condition is only relevant for bounded variables.

The transfer property suggests that if health is (hypothetically) transferred from a poorer to a richer individual, then the inequality index becomes more pro-rich and vice versa.

Scale invariance suggests that the inequality index is unaffected by the scale of the variable (e.g., Erreygers and van Ourti, 2011a). For example, it is desirable that the measured degree of inequality is the same if health spending is measured in Euros or Dollars. For the same reason, it is desirable that the measured degree of inequality remains the same for different cardinal scales.

The mirror condition requires that the measured degree of inequalities is the same for shortfalls and attainments, i.e., the inequality index of attainments should be equal to the inequality index of shortfalls but have the opposite sign. As there is no general consensus of whether it is appropriate to measure inequality in shortfall or attainment, Clarke *et al.* (2002) highlight that the mirror condition may be desirable as it assures that the ranking between populations is the same irrespective of the chosen perspective. However, although the first two properties are indisputable, the mirror condition implies an implicit value judgment that is only desirable if one truly considers inequalities in shortfalls and in attainments to be two measures of the same concept.

Both C and GC satisfy the transfer property as long as the health variable is nonnegative. Moreover, GC satisfies mirror but is not scale invariant for any measurement scale (other than for a unique scale). Conversely, C does not satisfy mirror but is scale invariant for ratio-scaled (but not cardinal) variables. As neither C nor GC satisfies all properties for all type of variables, further corrections of C have been proposed.

Recent Corrections of Concentration Index

Definitions

This section presents and discusses three corrections that have recently been suggested. The first correction applies for cardinal variables (bounded or unbounded). Erreygers and van Ourti (2011a) suggest modifying the C as:

$$\text{Modified C} = \frac{\mu}{(\mu - h_{min})}\text{C} = \frac{2}{n(\mu - h_{min})}\sum_{i=1}^{n} h_i(R_i - 1)$$

which is equivalent to computing C of a transformed health variable m_i for which the minimum value are set to zero (i.e., $m_i = h_i - h_{min}$). Thus, this modification of C satisfies scale invariance for cardinal variables (which indirectly also implies that the index satisfies the transfer property even if h_i attains negative values).

The other two corrections are specifically developed for bounded variables and satisfy the mirror condition as well as scale invariance for cardinal variables. Wagstaff (2005) corrects C as:

$$W = \frac{(h_{max} - h_{min})}{(h_{max} - \mu)(\mu - h_{min})}\text{C}$$

and Erreygers (2009a) corrects C as:

$$E = \frac{4}{(h_{max} - h_{min})}\mu\text{C}$$

Although these three corrections of C satisfy scale invariance for cardinal variables, one still cannot directly apply the value judgments from the income inequality literature. Therefore, the next section reviews the recent discussion in the literature of how one may relate to these inequality indices for bounded (cardinal) variables (**Table 1**).

Value Judgments for Bounded Variables

In the ongoing discussion on inequality indices for bounded variables, Erreygers and van Ourti (2011a,b) advocate a redefinition of the relative and absolute value judgments, whereas Wagstaff (2005, 2009, 2011a) suggests an approach that compares

Table 1 Properties of the indices

how far the health distribution is from the most pro-rich state. This section presents the two views, starting with the former.

Scale invariance implies that, without changing the measured degree of inequalities, any bounded health variable can be represented by a standardized health variable h_i^* ranging from zero to one, that is, $h_i^* = (h_i - h_{\min})/(h_{\max} - h_{\min})$. As differences in such a standardized variable always represent real health differences and are not an effect of changing the unit of measurement, Erreygers and van Ourti (2011a) define the value judgment for bounded variables based on inequality preserving changes of this variable. Still, the bounds of the variable act as constraints for some inequality preserving changes, that is, for some health distributions it is technically impossible to add an equal amount of health or to proportionally increase the health for all individuals without exceeding the upper bound of the variable. Erreygers and van Ourti (2011a) therefore redefine the value judgments so that an index embodies a specific value judgment if it is invariant to the corresponding inequality preserving change given that such a change is feasible.

Following this definition, Erreygers' correction of C (E) captures an absolute value judgment; it is invariant to equal increments of the standardized health variable but not to proportional changes. However, for the relative value judgment, the transition to bounded variables is not as straightforward. As (the modified) C is invariant to equiproportionate changes of the standardized variable, it captures a relative value judgment. But C does not satisfy the mirror condition. In fact, Erreygers and van Ourti (2011a) show that it is impossible to combine the mirror condition with a relative value judgment.

Wagstaff's normalization of C (W) satisfies the mirror condition but captures neither a relative nor an absolute value judgment. For an equal increment, W increases if the mean of the standardized health variable is larger than 0.5 but decreases if the mean of the standardized health variable is smaller than 0.5. This seemingly strange and counterintuitive behavior is a result of Wagstaff's solution to what he refers to as 'the bounds issue.' For bounded variables, the maximum and minimum value of C depends on the mean of the health variable; as C tends to one when only one single individual is in possession of all the health available in the society, the most pro-rich society cannot be reached unless there is only one individual in full health. This issue complicates comparisons between populations with different mean health. As a solution, Wagstaff normalizes C by the maximum value of the index (i.e., C of the most pro-rich state possible) given the level of health in the society (see **Figure 3**). Thus, in a society with a population of n individuals where the sum of h_i^* is equal to m, W attains the value of one when the richest m individuals have full health, whereas everyone else has no health. How a health change affects W reflects whether the society moves closer or further away from the most pro-rich state and, consequently, W may be interpreted as the answer to the question of how far the society is from that state (Wagstaff, 2009, 2011a).

Kjellsson and Gerdtham (2013) points out that C and E may also be interpreted as answering a similar question. However, the indices differ in their definition of the most pro-rich state; C attains its maximum value when the richest individual has all the health, and E attains its maximum value when only the upper half of the income distribution have full health and the lower half has no health.

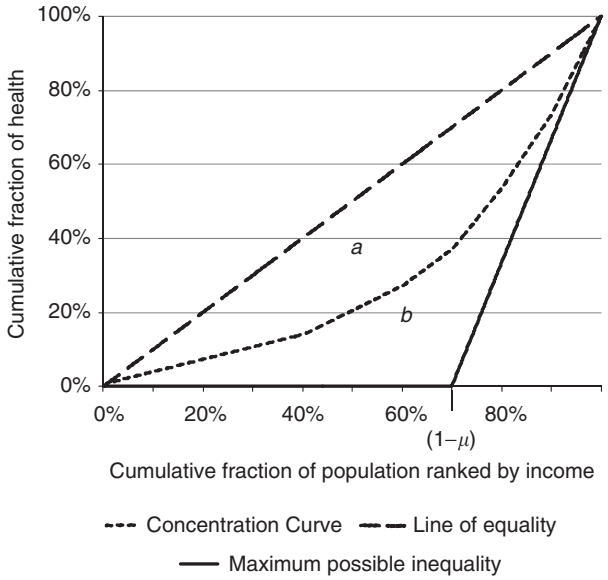

Figure 3 Wagstaff's normalization of C. *Note*: Using a graphical representation, we may define Wagstaff's normalization of C as: $W = C/(1-\mu) = a/(a+b)$.

Having reviewed the two approaches of how to measure health inequalities for variables of different measurement properties, the authors are now ready to compile the literature into a guideline for practitioners and follow the guideline in an empirical illustration.

Guidelines for Practitioners

Which Index to Use and When?

Simplifying the guidance from Erreygers and van Ourti (2011a), **Table 2** summarizes the possible choices for a researcher or practitioner depending on the measurement scale and the boundedness of the health variable. To be eligible, the index has to satisfy transfer and scale invariance.

As scale invariance is not an issue for unbounded variables measured on a unique scale, one may apply either GC or C depending on the value judgment that one wants to impose. However, for unbounded variables that are either ratio scaled or cardinal one is constrained to apply a relative value judgment as (the modified) C is the only index that satisfies scale invariance.

For bounded variables, the choice boils down to the following three alternatives. First, one may choose to impose the mirror condition and apply an absolute value judgment by using E to answer the question of how far a society is from a state where the upper half of the income distribution has full health and the lower part has no health. Second, one may take the level of health in the society into account, but depart from a pure relative judgment, by using W to answer the question of how far a society is from a state where the richest m individuals have full health and everyone else has zero health. Third, one may choose to relax the mirror condition, not address the bounds-issue that Wagstaff highlights, and apply a relative value judgment, that is, using (the modified) C. However, applying a relative value judgment for bounded variables requires a decision of whether it is appropriate to measure inequalities in shortfalls or attainments.

The current advice in the literature is to accept that the relative value judgment and mirror condition are incompatible and either use a relative or an absolute value judgment (Erreygers and van Ourti, 2011a,b; Wagstaff, 2011b). Erreygers and van Ourti (2011a,b) advocate the attractiveness of the mirror condition and, thus, prefer E. They also stress that E satisfies two additional possibly desirable properties. The first property is as follows: if starting with an unequal health distribution and gradually decreasing the health of all individuals toward zero (i.e., in the limit all the health of individuals is zero, which implies a perfectly equal distribution), then E tends to zero. Neither C nor W shows this tendency. The second property is: if the health of a rich individual, i.e., an individual from the upper half of the income distribution, increases, then E always increases. Neither C nor W satisfies this property.

Conversely, Kjellsson and Gerdtham (2013) and Wagstaff (2009, 2011a) claim that these two properties are a result of the absolute value judgment. In a recent note, Wagstaff (2011b) also advocates abandoning the mirror property (and thereby also his own correction) for the relative value judgment. However, this literature provides no guidance on the choice between attainments and shortfalls. The bottom line of this discussion is that any index inevitably enforces a value judgment that the researcher needs to be aware of and explicitly consider.

Empirical Illustration

For illustrational purposes, this section uses three health variables from the second wave of SHARE to compute inequality indices that, depending on the measurement properties of the variable, satisfy scale invariance and the transfer property. All the three variables, a health index, out-of-pocket payments, and GP-visits, differ in respect of their measurement properties. For a comparison between these results and the work of the ECuity group (e.g., van Doorslaer and Koolman, 2004; van Doorslaer *et al.*, 2004, 2006) horizontal inequity indices are calculated by indirectly standardizing for age, sex, and, when appropriate, health (see O'Donnell *et al.*, 2008).

The health index is a cardinal variable ranging from 0 (being dead) to 1 (perfect health) and is similar to the HUI in van Doorslaer and Koolman (2004) but is specifically developed for the SHARE-data (Jürges, 2007; Jürges, 2005). **Table 3** shows the value of the indices that satisfy scale invariance and the transfers property for bounded cardinal

Notes: HI indicates that the index has been standardized for age, sex, and health. The countries are ranked by the index value for either payments or GP-visits (i.e., highest value equals rank 1). Bold figures indicate a significant result on the 5% level. Indices and standard errors are calculated using the convenient regression method (O'Donnell *et al.*, 2008) and the imputation methods developed for SHARE (Christelis, 2011).

variables, i.e., (the modified) C of both shortfalls and attainments as well as W and E. As seen, the reranking of countries between the different inequality index is limited. Generally, the ranking varies less between the inequality indices when there is less variation in average health between countries. However, high average health generates a pattern where the ranking diverge into two groups: C of shortfalls and W; and C of attainments and E. A similar pattern would appear if one was to apply all four indices to 1996 European Community Household Panel in van Doorslaer and Koolman (2004). van Doorslaer and van Ourti (2011) confirm that the ranking is similar for C of attainments and E, whereas the authors encourage the reader to verify for oneself that using W or C of shortfalls will rerank countries in a similar manner as in their example. This reranking stresses on the importance of being aware of the value judgment that a particular index implies.

According to the nonstandardized indices, Denmark, Sweden, and the Czech Republic are ranked as the three most unequal countries, whereas the Netherlands, Poland, Greece, Switzerland, and Italy are the least unequal. However, when accounting for the demographics (i.e., standardize for age and sex), Sweden becomes relatively less unequal whereas Austria moves in the opposite direction. The positions of two of the extremes, Denmark and the Netherlands, are consistent with the findings in van Doorslaer and Koolman (2004).

As out-of-pocket payments, which is the sum of all the individuals' out-of-pocket health spending (excluding insurance premiums) is a ratio-scaled variable, C is the only index that satisfies scale invariance and the transfer property. Therefore, one can only apply a relative value judgment. The results (Table 4) show that, except for Sweden, Poland, Greece, and the Czech Republic, the richer individuals pay a larger fraction of the out-of-pocket payment. The standardization increases the index for all countries, that is, the fraction the poorer individuals pay decreases when controlling for need (i.e., standardizing for age, sex, and the health index).

As the number of GP-visits is measured on a unique scale, it implies that both C and GC may be applied as both indices satisfy the necessary properties. The inequality indices of a utilization variable such as GP-visits measure inequality in access to care. When standardizing for age, sex, and health, the interpretation of the index is a measure of horizontal inequity. The overall tendency of the results (Table 4) is that the indices are negative even after controlling for the above, that is, there is a pro-poor discrimination of access to care. The notable differences between the rankings of C and GC again stress the importance of considering the value judgment. However, regardless of the value judgment, the pro-poor discrimination appears to be strongest in Spain and weakest in Poland. Although the results overall differ to some extent, the finding of Spain having the strongest pro-poor discrimination is in line with the work of the ECuity group (van Doorslaer *et al.*, 2004, 2006).

Conclusion

This article reviews the recent literature on measuring socio-economic health inequalities using the concentration index approach. The authors have briefly discussed when the different corrections of C are appropriate to use depending on the measurement properties of the health variable and value judgment one wants to impose. For an in-depth discussion of the topic see the articles in the further reading list.

Measuring Vertical Inequity in the Delivery of Healthcare

L Vallejo-Torres and S Morris, University College London, London, UK

Glossary

Concentration index A measure of the degree of income-related inequality in health. Where there is no income-related inequality, the concentration index is zero. A negative value indicates a disproportionate concentration of ill-health among the poor.

Equity It relates in general to ethical judgments about the fairness of the distribution of things such as income and wealth, cost and benefit, access to health services, exposure to health-threatening hazards and so on, not necessarily to be identified with equality or egalitarianism. Although not the same as 'equality', for some people, equity frequently involves the equality of something (such as opportunity, health, access).

Horizontal equity It refers to treating equally those who are equal in some morally relevant sense. Horizontal equity principles include 'equal treatment for equal need' and 'equal treatment for equal deservingness'. Applied to insurance, the notion that two individuals facing the same risks should have access to the same coverage at the same premium.

Inequity It refers to treating unequally those who are equal in some morally relevant sense or treating equally those who are unequal in some morally relevant sense.

Need The most frequently met practical measures of need at the community level are morbidity and mortality data. They plainly imply a need for health though not necessarily a need for health care (which may not be effective in altering either for the better). Other concepts include capacity to benefit from health care and the resources that are necessary to reduce capacity to benefit to zero (i.e. to the point at which the marginal benefit falls to zero).

Resource allocation It refers to societal or individual decisions about the equitable distribution of available resources.

Socioeconomic status A description of a person or group of people having a similar social, political and economic position in society.

Vertical equity It refers to treating unequally those who are unequal in some morally relevant sense. Vertical equity principles include 'higher contributions from those with greater ability to pay', 'more resources for those with greater need'.

Introduction

Equity in the delivery of health care is an important policy objective in many countries, and some, such as Australia, Canada, Sweden, and the UK, distribute healthcare resources on the basis of explicit equity objectives. Such objectives often subscribe to egalitarian goals, which suggest that health care should be distributed according to need and financed according to ability to pay.

Egalitarian goals can include horizontal and/or vertical equity principles. The horizontal equity principle requires that individuals with the same needs receive the same treatment. The vertical equity principle requires that those with different needs receive appropriately different treatment. Taken together, these principles suggest not only that patients with the same needs should receive the same treatment irrespective of, for instance, their social class or place of residence, but also that those with greater needs should be appropriately prioritized in receiving health care.

In the literature, little attention has been paid to vertical equity in the delivery of health care. This is probably because measuring vertical equity requires strong value judgments regarding the way healthcare delivery ought to vary amongst individuals with different levels of need. Most empirical work considers horizontal equity, though the importance of vertical equity is increasingly being emphasized. When considering the role that health care might play in reducing inequalities in health, some authors have argued that accounting for vertical equity in the delivery of health care addresses health inequalities that will not be addressed by focusing only on horizontal equity. For example, it has been suggested that horizontal equity is not relevant when dealing with individuals with substantial differences in health status. The Marmot review (Marmot, 2010) concluded that in order to reduce the steepness of the social gradient in health, ''actions must be universal, but with a scale and intensity that is proportionate to the level of disadvantage.'' The review named this principle 'proportionate universalism,' which is related to the principle of vertical equity.

Crucial to the measurement of vertical equity are measures of 'healthcare delivery' and 'need.' 'Healthcare delivery' is a broad term that can be used to refer to the receipt of treatment, the use of, or access to, healthcare services, or to the allocation of healthcare resources between individuals or areas. In economic studies of equity, healthcare delivery typically refers to the use of healthcare services by individuals or to the allocation of healthcare resources to areas.

Although a wide variety of definitions of need have been developed, economists often define need in terms of 'capacity to benefit' – the ability to benefit from healthcare provision. In empirical studies, however, need is usually defined in terms of ill-health, where people who are ill are deemed to have greater need than those who are not. This is an imperfect measure, because unlike capacity to benefit, it does not account for the

instrumentality of need, i.e., that needs for health care when ill only exist if there is health care available that can improve health. Although it is a limitation, this definition is used for pragmatic reasons in that measures of ill-health are often directly available in datasets used to measure equity, whereas measures of capacity to benefit are not available.

Another limitation, also commonly adopted for pragmatic reasons, is that empirical studies usually measure ill-health and healthcare delivery contemporaneously, when ideally need would be measured prior to utilization so that its causal impact on utilization could be assessed.

When investigating inequity in healthcare delivery, it is common to distinguish between 'need variables' which ought to affect healthcare delivery and 'nonneed variables' which ought not to. Inequality in healthcare delivery can be associated with both need and nonneed variables. There is horizontal inequity when healthcare delivery is affected by nonneed variables, so that individuals with the same needs consume different amounts of care. There is vertical equity when individuals with different levels of need consume appropriately different amounts of healthcare. The categorization of variables, such as age, gender, income, and ill-health, as need or nonneed variables is crucial to testing for horizontal and vertical inequity. The measurement of horizontal and vertical equity rests on value judgments as to what are need and nonneed variables and what constitutes an appropriate level of health care.

Notably, there are methodological challenges associated with measuring vertical equity, and as a result few studies have investigated this issue. Among these studies, there is considerable variation in the methods used and in the assumptions underpinning the analyses. In this article, these methods are reviewed and appraised; approaches taken outside the field of health care to measure vertical equity are also examined.

A Simple Model of Vertical Equity

Gravelle *et al.* (2006) have described the conditions for the identification of and distinction between vertical and horizontal inequity in healthcare delivery, and have highlighted the main challenges faced by economic studies of equity in health care. They place equity analyses in the context of welfare maximization. For example, let v be the individual welfare accruing to individual i from the consumption of health care q, from k need characteristics N, and from the cost of accessing health care, c:

$$v_i = v(q_i, N_{ki}, c_i) \quad [1]$$

The aim of the policy maker is to enable individuals to choose utilization levels q that maximize an aggregate welfare function W subject to the constraint that total utilization cannot exceed total supply S:

$$W = \sum_i v(q_i, N_{ki}, c) \quad s.t. \sum_i q_i \leq S \quad [2]$$

In the optimal allocation, which meets the horizontal and vertical equity principles, healthcare consumption is not affected by nonneed variables, and the effects of the need variables on consumption reflect the appropriate difference in treatment that individuals with different levels of need ought to receive. Consider a model of actual health care use given by

$$q_i = \alpha + \sum_k \beta_k N_{ik} + \sum_j \delta_j Y_{ij} + u_i \quad [3]$$

where Y_j denotes a set of j nonneed variables that ought not to affect healthcare use. The condition for horizontal equity is $\delta_j = 0$, i.e., use is not affected by nonneed variables. The conditions for vertical equity are $\beta_k = \beta_k^*$ and $\alpha = \alpha^*$, where β_k^* and α^* denote the appropriate effect of the need variables on healthcare use, however, defined, and the optimum base level of consumption from the optimal healthcare allocation, respectively.

Vertical Equity in Healthcare Delivery

In this section, different approaches that have been taken to measure vertical equity in healthcare delivery are reviewed. Following Gravelle *et al.* (2006), the criteria for assessing the different approaches are based on: distinguishing between need and nonneed variables; testing the potential impact of omitted variables; disentangling horizontal and vertical equity; and measuring the extent of vertical inequity. The different approaches to defining the appropriate way in which healthcare consumption ought to vary for individuals with different levels of needs is also considered.

Separation between need and nonneed variables depends largely on value judgments on what counts as a need variable and what counts as a nonneed variable. It is commonly accepted that measures of health status and morbidity ought to affect healthcare use. In individual-level analyses with health and morbidity data, socioeconomic indicators are generally considered to be nonneed indicators. In the case that needs are not comprehensively measured, socioeconomic indicators may be picking up the effects of unobserved need factors, such as unmeasured severity levels. In that case, the analysis would be affected by an omitted variable problem. Although the extent to which needs are captured depends largely on the availability of the data, one criteria for assessing the different approaches is the ability of such approaches to account for needs comprehensively.

The exploration of vertical equity requires estimating the appropriate way in which healthcare consumption ought to vary for individuals with different levels of needs. Without the knowledge about the optimal effect of needs on healthcare delivery, conclusions about whether individuals with different needs are being appropriately treated cannot be made. In addition, the separation between vertical and horizontal aspects is not straightforward. This is because both need and nonneed variables are likely to be related. For instance, if on average, healthy individuals consume more health care than they ought to (i.e., there is evidence of vertical inequity favoring the relatively healthy – prohealthy vertical inequity) and there is a positive correlation between health and income, then probably on average, richer individuals will consume more health care than they ought to; there is horizontal inequity favoring the rich (prorich horizontal inequity). More generally, if health and income

Abbreviations: HI, horizontal inequity; NA, not applicable; SES, socioeconomic status; VI, vertical inequity.

are positively correlated, prohealthy vertical inequity will tend to benefit those on higher incomes, leading to prorich horizontal inequity. Conversely, propoor horizontal inequity will tend to mean that the sick have higher than expected levels of use, leading to prosick vertical inequity. Therefore, separation of vertical and horizontal inequity aspects is an important challenge in measuring vertical equity in healthcare delivery.

Finally, the simple model described in Section A Simple Model of Vertical Equity can be used to identify vertical and horizontal inequities in healthcare delivery, but it does not allow measurement of the extent of inequity; it is not possible to measure this purely on the basis of the size of α and β in eqn [3]. However, this is of interest because it permits comparisons over time and between areas, which is helpful both to identify trends and for policy evaluation.

Approaches to Measuring Vertical Equity in Healthcare Delivery

The following eight approaches, summarized in Table 1, have been used to measure vertical equity in healthcare delivery. Each of them has been explained, moving from the simplest to the more complex, and the limitations of each approach are assessed.

Approach 1: The association between socioeconomic status and healthcare delivery

This approach assumes that vertical equity is identified by a positive association between socioeconomic status (SES) and the delivery of health care. The assumption underpinning this approach is that individuals in lower socioeconomic groups

have higher needs and they should therefore receive more health care in order to meet the vertical equity principle.

Let q_i denote the quantity of healthcare delivery and Y_i the SES for individual i. Higher values of q and Y denote greater healthcare use or resources and higher SES, respectively. Note that in this approach Y is used as a proxy for need and not as a nonneed variable. The test for vertical equity is based on the relationship between q_i and Y_i:

$$q_i = \alpha + \delta Y_i + \varepsilon_i \quad [4]$$

$$\frac{\partial q_i}{\partial Y_i} = \delta < 0 \quad [5]$$

There is vertical equity if SES is negatively correlated with healthcare use (i.e., $\delta < 0$). Among the studies that have used this approach, the relationship between SES and healthcare delivery has been explored by different bivariate measures such as unadjusted odd ratios, ratio analysis, concentration curves, and correlation coefficients (Table 1).

In the absence of good epidemiological data, area-level analyses often rely on socioeconomic indicators as need variables. However, the choice of SES as a need variable is contested, and in many other studies, SES is defined as a nonneed variable. Although the correlation between SES and health is well documented, it does not imply that differences in SES will only be reflecting differences in needs. Moreover, there may be needs that are not correlated with SES that will not be picked up by an analysis of this kind. Therefore, the interpretation of the association between SES and healthcare delivery is ambiguous. These analyses are also not able to distinguish between vertical or horizontal inequity, as they cannot judge whether individuals receive different amounts of health care because of their different needs or because of same needs but different nonneed variables (e.g., SES). Even if SES was an appropriate need variable, this type of analysis cannot identify whether or not the differences in treatment received by those in lower SES is appropriate to meet their relatively higher needs. Nor can it measure the extent of vertical equity. Therefore, this approach is of limited use for analyzing vertical equity in healthcare delivery.

Approach 2: Comparison of the ranking of observations according to both needs and healthcare delivery

This approach assumes that vertical equity is identified by a positive correlation between the ranking of healthcare delivery and that of need. The method is thus based on a comparison of the hierarchy of observations when ranked according to both needs and the delivery of health care received. For example, this approach involves creating a need index based on health status, ranking observations with respect to need, and comparing this ranking with another ranking based on some measure of healthcare delivery. A measure such as Kendall's coefficient of concordance between the two rankings could be used to indicate vertical inequity.

Inappropriate ranking in the allocation of health care with respect to needs could be due to deviation from either the horizontal or the vertical equity principles. Therefore, this method cannot distinguish between horizontal and vertical aspects of inequity, nor does it control for nonneed factors. Furthermore, although the method provides a framework for testing if the delivery of health care is ordinally appropriate, it fails to account for whether or not the allocation is cardinally appropriate. The measurement of vertical equity requires that the size of the differences in healthcare delivery between observations is sufficient to account for their relative differences in needs. Hence, this method is also of limited use for measuring vertical equity in healthcare delivery.

Approach 3: The association between need and healthcare delivery

This approach assumes that vertical equity is identified by a positive correlation between healthcare delivery and need variables, usually measured by one or more health measures, after controlling for nonneed variables, commonly measured in terms of SES. It focuses on the idea that a positive association between healthcare delivery and ill-health is a necessary condition for vertical equity. Following from eqn [4], let N denote a measure of ill-health for individuals i, so that the test for vertical equity in healthcare delivery is that $\beta > 0$, i.e., the need variable has a positive association with use:

$$q_i = \alpha + \beta N_i + \delta Y_i + \varepsilon_i \quad [6]$$

$$\frac{\partial q_i}{\partial N_i} = \beta > 0 \quad [7]$$

Most studies using this approach have tried to incorporate some assessment of vertical equity by looking at the coefficients of the need variables that have been included in their regression models testing for horizontal inequity.

The approach is a simplified version of the test for vertical equity presented in eqn [3]. The main limitation of this approach is that it cannot discern whether or not the higher levels of use by those with higher levels of need adequately meets their relative need when compared with the healthy; hence the condition described by eqn [7] is at best a necessary but not a sufficient condition for vertical equity. Moreover, it is not possible to measure the extent of vertical inequity using this approach.

Approach 4: The effect of socioeconomic status on healthcare use at different level of needs

This approach assumes that vertical equity is identified by differences in the impact of nonneed variables on healthcare use in groups with different needs. One approach that has been used is to explore whether or not nonneed variables affect healthcare delivery at different levels of health. This is achieved by the interaction between need and nonneed variables, for example, by extending eqn [6] to

$$q_i = \alpha + \beta N_i + \delta Y_i + \sigma N_i \times Y_i + \varepsilon_i \quad [8]$$

In this approach, there is said to be vertical equity if $\beta > 0$ and $\sigma = 0$. An alternative approach would be to run separate models for groups with different levels of nonneed variables and testing if the impact (β) of the need variables on healthcare delivery is the same for every group. This is a test for vertical equity because differences in healthcare delivery between groups with different levels of need cannot be regarded as appropriate as long as they are affected by differences in nonneed characteristics, such as income. An extension to this

approach involves including an additional condition that in order to meet the vertical equity principle, the response of utilization to need in every SES group should be the same as that observed in a predefined reference group, which is thought to be (more) vertically equitable.

This approach to measuring vertical inequity is problematic because it has also been proposed in the literature as a means of testing for horizontal inequity, on the grounds that, for example, if sick individuals when they are rich receive more health care than the sick when they are poor, the horizontal equity principle is not met. Significant interactions between need and nonneed variables cannot be separated into horizontal and vertical aspects, so this approach cannot be used to test for either vertical equity or horizontal equity in isolation.

Approach 5: Health outcomes derived from unequal treatment across nonneed groups

This approach assumes that vertical equity is identified by a significant association between healthcare use and a nonneed indicator, but with the same health outcomes in different nonneed groups. The idea behind the approach is that there is vertically equity if different groups, defined in terms of one or more nonneed variable, receive different levels of healthcare delivery and so are treated unequally, but achieve the same health outcomes. In the general framework, where H_i stands for the health outcome of individual i:

$$q_i = \alpha_0 + \delta_0 Y_i + \varepsilon_i \quad [9]$$

$$H_i = \alpha_1 + \delta_1 Y_i + \varepsilon_i \quad [10]$$

the delivery of health care is considered to be vertically equitable if $\delta_0 \neq 0$ in eqn [9], and $\delta_1 = 0$ in eqn [10]; therefore, different SES groups are treated differently, but their outcomes are the same.

One limitation of this approach is that differences in health outcomes are assumed to be a result of differences in the treatment received. There may be a range of reasons why individuals receiving different treatment end up having same health outcomes that do not relate to their treatment but to other factors such as inefficiencies in the provision of health care or to nonhealth-care factors, for example, other social determinants of health. This could be tested directly by including q as an additional covariate on the right hand side of eqn [10]. In addition, and similarly to previous methods, this method is not able to quantify the extent of vertical inequity.

Approach 6: Comparing the actual effect of need indicators on use with the target effect of need indicators

This approach assumes that vertical equity is identified by need variables having the appropriate effect on healthcare use. Studies using this approach search for the appropriate effect of the need variables such that individuals with unequal needs receive appropriately unequal treatment. Once the appropriate effects, for example, in terms of regression coefficients, have been derived, they can be compared with the actual effects in order to assess whether the allocation was vertically equitable. Therefore, based on a model such as the one described in eqn [6], this approach tests whether or not the estimated effect of the need variables on healthcare delivery equals the target effect, i.e., if $\hat{\beta} = \beta^*$, where β^* is the target effect of the need variable.

Approaches to identifying values of β^* could include eliciting society's preferences, calculating the actual effect of the need variables on healthcare delivery in different subgroups of the population, and using the largest value as the target effect.

This approach provides the basis for a test of vertical inequity as described by Gravelle *et al.* (2006) in eqn [3]. However, it is not capable of measuring the extent of vertical equity. It therefore precludes the quantification of inequity over time and/or between areas and does not assist in monitoring efforts to reduce vertical inequity.

Approach 7: Healthcare gap between actual and target health care

This approach assumes that vertical equity is identified by the distribution of healthcare gaps (HCG), which are defined as the distance between the target level of healthcare delivery and the actual level of healthcare delivery. The target level of healthcare delivery might be exogenously set by policy makers as the minimum level of healthcare delivery that individuals or areas should receive given their levels of need. For example, HCGs x for each individual i are given by:

$$x_i = \max(q_i^* - q_i; 0) \quad [11]$$

where, q_i^* is target healthcare use and q_i is actual healthcare use. $x = 0$ when $q \geq q*$, i.e., the HCG has a zero value when individuals receive more health care than the targeted level (the focus of the analysis needs to be reversed to consider the distribution of individuals receiving more than targeted level of health care). The HCGs can be combined across individuals or areas, for example, using poverty indices or standard inequality measures, making value judgments regarding the relative weight of the HCGs in different groups, to provide an aggregate measure of deviations from target levels of healthcare delivery.

The main limitation of this approach, in terms of measuring vertical inequity, is that it is not capable of disentangling horizontal and vertical inequity aspects because the difference between the target level of healthcare delivery and the actual level is affected by deviations from both vertical and horizontal inequity principles. Moreover, this measure only captures healthcare inequity among individuals receiving less than the target level of health care unless we reverse the focus and consider individuals receiving more than the target level. This implies that situations in which individuals receive more than their target level of health care would not be deemed inequitable. Therefore, it is not possible to derive a measure that considers both sides simultaneously and provide a meaningful estimate of the extent and direction of inequity.

Approach 8: Measuring the difference between target and need-expected healthcare delivery across socioeconomic status

This approach assumes that vertical equity is identified and measured by the difference between the distribution of the target and the need-predicted health care use with respect to

SES. The approach applies similar methods to those now widely used to measure horizontal inequity using concentration indices. Let $\hat{q}_i$ denote the predicted value of healthcare delivery from eqn [6] based on the estimated effect of the need variables ($\hat{\beta}$); and $\hat{q}_i^*$ the predicted values of healthcare delivery based on the target effect of the need variables (β^*), however defined. In both equations, SES is set equal to the mean value $\overline{Y}$ in order to neutralize its effect (as a nonneed variable) in the prediction.

$$\hat{q}_i = \hat{\alpha} + \hat{\beta} N_i + \hat{\delta}\overline{Y} \quad [12]$$

$$\hat{q}_i^* = \alpha^* + \beta^* N_i + \hat{\delta}\overline{Y} \quad [13]$$

Equation [12] gives the need-expected (also referred to as need-predicted) allocation of health care; eqn [13] gives the target allocation of health care based on the optimal effect of the need variables and the intercept; α^*, β^*. Sutton (2002) has proposed this methodology to measure the extent to which the gap between the target and the need-expected allocation falls disproportionally on specific SES groups. The target allocation of health care is created by imposing across the whole need distribution the (strictly positive) level of β found in the subpopulation with the lowest levels of need. The method involves computing the concentration index (CI) of the need-predicted and target allocation of health care with respect to SES. The estimate of vertical inequity is the difference between the two. Following Wagstaff (2002), the formula for the CI of socioeconomic inequality can be written as follows:

$$CI = 1 - (2*(1 - R_i)) \sum_{i=1}^{n} \frac{q_i}{Q} \quad [14]$$

where Q is the total healthcare use across the sample and $R_i = i/n$ is the fractional rank in the income distribution of the ith person, with $i = 1$ for the poorest and $i = n$ for the richest. Therefore, the CI is one minus the weighted sum of the share of the healthcare variable of each observation, where the weight is given by the position of the individual in the SES distribution of that population. The CI provides a summary measure of the magnitude of socioeconomic-related inequality in a health variable of interest, and by comparing a set of indices one can derive a clearer ranking when trying to compare inequality across a number of countries, regions or time periods.

Vertical equity is then measured as the difference between the CI of the need-predicted healthcare allocation and the CI of the target allocation, i.e., the divergence in the allocation of health care that relates only to the difference between the actual effect and the appropriate effect of the need variables:

$$VI = CI_{\hat{q}_i} - CI_{q_i^*} \quad [15]$$

These methods control for nonneed indicators in order to appropriately separate the effect of need factors; they provide the comparison between the actual and the target effect of the need variables; and, in particular, they allow for the measurement of vertical inequity by looking at the distributional consequences across the income distribution. However, the focus of this approach is on the measurement of socioeconomic-related vertical equity in healthcare delivery, which although of interest, may be only part of the vertical inequity which is present in a healthcare system. The reason for this is that vertical inequity arises when individuals with unequal needs do not receive appropriately unequal treatment, and this definition does not rely on the inequity being identified with respect to the socioeconomic dimension solely. Thus, this approach measures what Gravelle *et al.* (2006) described as the consequences of vertical equity for the groups identified by horizontal inequity, i.e., across the socioeconomic distribution.

As mentioned above, Sutton (2002) derived the target allocation by imposing the value of β found in one part of the health distribution (among the healthy) on to respondents across the whole health distribution. This assumes that the relationship between changes in ill-health and changes in use among the unhealthy ought to be the same as this relationship among the healthy. The underlying requirement for choosing this target was that the effect of the need variable ought to be positive across the full range of the health distribution. The imposition of a strictly positive effect of need on utilization may not be appropriate for specific types of services or patients.

Adapting Measures Used in Other Fields

Approaches to measuring vertical equity have also been considered in other fields, including: healthcare financing; poverty alleviation programs; the transport sector; aid allocation; and, education funding programs.

Most of these methods are of limited usefulness for measuring vertical equity in the delivery of health care. In the case of poverty alleviation programs, transport sector policies and part of the methodology for measuring vertical inequity in finance, the focus is on relative measures, assessing whether or not a variable was redistributed in a more or less vertically equitable way following a policy change. These methods could be applied to assess the relative impact of policies to reduce vertical inequity in healthcare delivery, but do not provide a static measure. A potential difficulty with adapting these approaches to our context is that they require an assessment of the extent to which a particular healthcare policy contributes to the observed redistribution of healthcare delivery.

There are two measures that could be used to capture vertical equity in healthcare delivery – Kakwani's progressivity index and the ratio of the estimated coefficient to the optimal coefficient of the need indicator. The details of these approaches are summarized in Table 1. Kakwani's progressivity index, which is widely used in the tax and healthcare finance literature, focuses on the measurement of how far health care is financed according to ability to pay. It is defined as the difference between the CI of payments with respect to income, and the Gini coefficient for prepayment income:

$$\Pi_k = CI_{\text{payments}_i} - G_{\text{preincome}} \quad [16]$$

where the CI is defined as in eqn [14], but now q_i represents healthcare payments and R_i is the fractional rank in the prepayment income distribution of the ith person. The Gini coefficient G is analogous to this index where q_i stands for the prepayment income. The Kakwani index equals zero if

payments as a proportion of income are constant across the income distribution; if payments as a proportion of income increase with income, the index is positive, and the finance source is considered to be vertically equitable or progressive.

This index could be used to measure the extent to which healthcare delivery as a proportion of need increases with needs. However, it could only discern whether or not healthcare delivery is 'progressive.' It is not capable of assessing whether the system is 'responsive enough' or whether it 'overmeets' the needs of the population being served. In this sense, it is similar to Approach 3 described above, with the same limitations.

Applying Toutkoushian's and Michael's (2007) method developed for the context of school funding, vertical equity in healthcare delivery could be measured as the ratio of the estimated coefficient, $\hat{\beta}$, to the optimal coefficient of the need factors, β^*, in healthcare utilization equations, such as eqns [12] and [13]. Vertical equity would be achieved when VE defined below equals 100%.

$$VE = \frac{\hat{\beta}}{\beta^*} \times 100\% \qquad [17]$$

Toutkoushian and Michael do not provide a method for estimating the target effect of the need variables, other than suggesting (in an education funding context) to use the monetary amounts prescribed by the state's foundation program in the setting of per pupil revenues. In the context of the delivery of health care, this would be similar to obtaining policy makers' or medical experts' opinion about how health service use ought to increase with needs. If this information were available, this method would permit a summary in one measure of how far the estimated coefficient is from the optimal effect. The ratio could also be compared over time and across different geographies. As with Approach 6 described above, this ratio does not measure the redistributive impact of the difference between the estimated and target allocation across the whole distribution, because it is focused on only what happens on average in a population.

Conclusions and Implications

In this article, different approaches to measuring vertical equity in healthcare delivery have been described. At the outset, it has been noted that although vertical equity considerations seem to be gaining momentum in the context of addressing inequalities and inequities in health and health care, vertical inequity analysis are rarely undertaken. Therefore, existing techniques to investigate vertical inequity have been appraised and assessed, and areas suitable for further work have been identified.

Methods were classified into different approaches and the validity of each was assessed. Approaches used to measure vertical equity outside the field of healthcare delivery were also explored, though none of these approaches was considered to provide any advantage over the methods already used in the field.

Of all the methods considered, Sutton's (2002) approach using CI techniques was found to provide the most comprehensive analysis of vertical equity in the delivery of health care. However, this approach was developed to measure socioeconomic-related vertical equity only. Emphasis on the socioeconomic dimension of inequity has been the norm in the analyses of horizontal inequity in health care, which is appropriate given that the aim is usually to identify systematic variations in the treatment of those with equal needs but are from different socioeconomic backgrounds. However, in the context of vertical inequity, this approach is possibly rather restrictive. Vertical inequity arises when healthcare delivery is not allocated appropriately according to differences in needs. This definition therefore does not require inequity to be measured with respect to a socioeconomic dimension, but emphasizes the need dimension. Further work is necessary to extend this methodology for ensuring that the consequences across the need distribution have been accounted for. This could be accomplished, for example, by computing the concentration indices with respect to the needs variable rather than with respect to SES.

Quantifying the extent to which healthcare delivery ought to vary at different levels of needs is a major challenge when investigating vertical inequity. In the absence of information from policy makers regarding how much more high need individuals ought to receive as compared with those with lower needs, the literature on vertical equity has suggested different approaches. These include asking the community, identifying areas within a country that are more responsive to the needs of their populations, and imposing the positive effect of ill-health on use as found in one part of the health distribution (where the effect has been found to be strictly positive) onto respondents across the whole health distribution. One alternative approach could involve using external evidence regarding subgroups of the population more likely to achieve a vertically equitable allocation (i.e., subgroups more likely to receive the health care they ought to, given their needs, or geographical areas where performance indicators suggest an allocation of resources that align resources appropriately with needs). Another alternative could be to identify the use of services for a set of clearly defined needs that are based, for example, on clinical guidelines for a particular medical condition. This may be of limited use, especially for studies looking at vertical inequity across healthcare services generally, but could be appropriate if considering a specific service.

In conclusion, the importance of incorporating vertical equity considerations in the way healthcare resources are allocated is being increasingly emphasized. The few empirical studies that have investigated vertical equity in healthcare delivery have used a variety of methods with different underlying assumptions. In this article, some light has been shed on the differences and the validity of the approaches being used has been discussed. Also, areas for further work have been highlighted with a view to improving methods for measuring vertical equity in the delivery of health care.

Medical Decision Making and Demand

S Felder, Universität Basel, Switzerland
A Schmid and V Ulrich, Universität Bayreuth, Germany

Introduction

Ever since medicine has been practiced, medical decision making has been conceptualized. Informal and formal rules have been in place to guide physicians in the therapeutic process – the Hippocratic Oath is a very early example. Probably up until the late nineteenth century the patient had little say in the physician's decision making, and a rather paternalistic relationship between the two prevailed.

The twentieth century brought two important developments. First, the recognition of informed consent as a fundamental ethical requirement strengthened the patient's role in the decision making process. Patients today are frequently characterized as responsible clients and customers who make informed decisions. Second, medical decision making was formalized and its scope extended beyond the direct patient–physician relationship, for example, to questions of public health and reimbursement.

Nowadays, the term medical decision making refers to a wide range of decisions in health care, with a special focus on the methods applied in the decision making process. The point of view from which such analyses are conducted can vary and includes the perspective of an individual physician or patient as well as the perspective of the policy maker. As the concern here is with the relationship between decision making and demand, the natural perspective is the patient's.

Depending on one's point of view, the criteria for assessing decision outcomes may differ and different theories and analytical methods may be applied. The field of medical decision making is characterized by a strong quantitative focus and covers a range of aspects from health economic evaluation to the analysis of cognitive processes and psychological factors. This article adheres to a very narrow definition of medical decision making, focusing on the role of formal decision analysis. This is well-suited to the fundamental concepts of health economics, which rely strongly on utilitarian principles.

Medical decision making and the analysis thereof is driven by the fact that decisions in medical care are in most cases characterized by two attributes: A varying, but frequently high degree of uncertainty and the availability of more than one alternative. Uncertainty arises from a number of sources. First of all, the onset of illness is a seemingly random event and can hardly be predicted. Furthermore, the presence of a sickness in a patient is uncertain; hence the decision maker faces a diagnostic risk. Then there is the therapeutic risk, as there is uncertainty over the effects of a specific therapy on a particular patient. At the same time, the patient himself knows neither how his body will react to the medication prescribed nor how the individual risk factors his genetics expose him to play into it. Another source of uncertainty is the fallibility of diagnostic tests, introducing the possibility of error at this stage of the treatment process.

Medical Decision Making

Basic Model

A formal analysis of medical decision making can help structure very complex problems. The structure of decision processes are typically represented by decision trees in which probabilities, outcomes, and sometimes other parameters are formalized and quantified. This makes all assumptions explicit and enables decision makers to draw informed conclusions. The aim is to identify the treatment strategy which yields the highest expected utility. Decision analysis is thus merely a tool for making informed decisions – the decision itself is still up to the decision maker, who decides how utility is defined and which components are taken into account. This means that legal, ethical, and professional considerations as well as patient preferences and other factors can have an influence. The contribution of formal decision analysis is to provide structure, explicitness, and quantitative measures in this process and thereby facilitate an informed discussion (cf. Weinstein *et al.*, 1980).

A basic model of medical decision making is developed, beginning with the decision over medical treatment under diagnostic risk. For simplicity, there is no differentiation between physicians and patients as decision makers in this model, but rather the assumption that physicians decide purely in the interest of their patients. The patient's health state H_i is unknown; one can be sick or healthy, $i = \mathrm{s}, h$. p describes the *a priori* probability of the sick state. The decision maker must decide whether to treat the patient ($j = +$) or not ($j = -$). $U(H_i^j)$ is the utility function which values health in its different possible states. Expected utility as a function of the treatment decision j becomes

$$EU^j(p) = pU\left(H_{\mathrm{s}}^{\,j}\right) + (1-p)U\left(H_{\mathrm{h}}^{\,j}\right) \qquad [1]$$

The decision maker can also use diagnostic tools and make the treatment decision dependent on the test outcome, i.e., treat if the test is positive and not treat if it is negative. Therefore, j, $j = +, -$, is used, for the test outcome as well as the treatment decision. It follows that $H_{\mathrm{h}}{}^{-}$ indicates the health state after a true negative test result and $H_{\mathrm{h}}{}^{+}$ the health state after a false positive test result, whereas $H_{\mathrm{s}}{}^{+}$ stands for the health consequences of a true positive test result and $H_{\mathrm{s}}{}^{-}$ for those of a false negative test result.

The expected utility of a diagnostic test, $EU^{Dx}(p)$, can then be written as follows:

$$\begin{aligned} EU^{Dx}(p) = {} & p\left[Se \cdot U\left(H_{\mathrm{s}}{}^{+}\right) + (1-Se)U\left(H_{\mathrm{s}}{}^{-}\right)\right] \\ & + (1-p)\left[Sp \cdot U\left(H_{\mathrm{h}}{}^{-}\right) + (1-Sp)U\left(H_{\mathrm{h}}{}^{+}\right)\right] \end{aligned} \qquad [2]$$

where 'Se' is the sensitivity or true positive rate, $1-Se$ is the false negative rate, 'Sp' is the specificity or true negative rate, and $1-Sp$ is the false positive rate of the test.

 doi:10.1016/B978-0-12-375678-7.00808-7

The decision tree in Figure 1 illustrates the decision maker's choice. Squares represent decision nodes and circles indicate chance nodes.

It is useful to define:

$$G = U(H_s^+) - U(H_s^-) > 0 \quad \text{and}$$
$$L = U(H_h^+) - U(H_h^-) < 0 \qquad [3]$$

as the decision maker's utility gain from treatment in the sick state and one's utility loss from treatment in the healthy state.

Three threshold probabilities can now be derived at which the decision maker is indifferent between two actions, as introduced by Pauker and Kassirer (1975, 1980):

$$\tilde{p} = \frac{1}{1 - G/L} \qquad [4]$$

$$\tilde{p}^{Dx} = \frac{1}{1 - LR^+ G/L} \qquad [5]$$

and

$$\tilde{p}^{Rx} = \frac{1}{1 - LR^- G/L} \qquad [6]$$

where $LR^+ = Se/(1 - Sp)$ denotes the positive and $LR^- = (1 - Se)/Sp$ the negative likelihood ratio of the test. $LR^+ > 1$ and $0 \le LR^- < 1$ holds for useful tests (i.e., $Se + Sp > 1$).

The first threshold $\tilde{p}$ is called the therapeutic threshold, at which the decision maker is indifferent between treating and not treating the patient in a situation where no diagnostic test is available. At the test threshold, $\tilde{p}^{Dx}$, one is indifferent between not treating and testing (followed by the treatment decision depending on the test outcome). At the treatment threshold, $\tilde{p}^{Rx}$, the decision maker is indifferent between testing and treating without prior testing. Because $LR^+ > 1 > LR^- > 0$ and $-G/L > 0$, $\tilde{p}^{Dx}$ is located below the therapeutic threshold and $\tilde{p}^{Rx}$ above it: $\tilde{p}^{Dx} < \tilde{p} < \tilde{p}^{Rx}$.

These thresholds allow us to characterize the decision maker's optimal test and treatment strategy. At low *a priori* probabilities of sickness, $0 \le p \le \tilde{p}^{Dx}$, the optimal decision is not to use the test and not to treat. The dominant aspect in this situation is the utility loss resulting from a false positive test result. At intermediate *a priori* probabilities of sickness, $\tilde{p}^{Dx} < p < \tilde{p}^{Rx}$, the optimal strategy is to test and then to treat if the test outcome is positive. With a negative test outcome not treating is indicated. Finally, at high *a priori* probabilities, $\tilde{p}^{Rx} < p < 1$, not testing is optimal and immediate treatment is indicated. The utility loss stemming from a false negative test outcome is the dominant factor here.

The Value of Information

Medical decisions often involve the use of diagnostics. The optimal use of the information gleaned can be conceptualized using the value of information as introduced by Gould (1974). The value of diagnostic information is defined as the additional expected utility resulting from the use of the test. This requires considering the optimal decision when no test is available. This reference situation is characterized by the expected utility of not treating at $p < \tilde{p}$ and the expected utility of treating at $p \ge \tilde{p}$. Given eqns [1]–[3], we can solve for the value of information of a diagnostic test and find

$$VI(p) = \begin{cases} \max(p \cdot Se \cdot G - (1-p)(1-Sp)L, 0) & \text{for } 0 \le p < \tilde{p} \\ \max(-p(1-Se)G + (1-p)Sp \cdot L, 0) & \text{for } \tilde{p} \le p \le 1 \end{cases} \qquad [7]$$

Figure 2 shows the value of information and the three thresholds discussed above. The value of information is positive between the test and treatment thresholds and reaches its maximum at the therapeutic threshold. At *a priori* probabilities of sickness below the test threshold or above the treatment threshold the value of information is zero: in these ranges the information technology should not be used in the treatment decision.

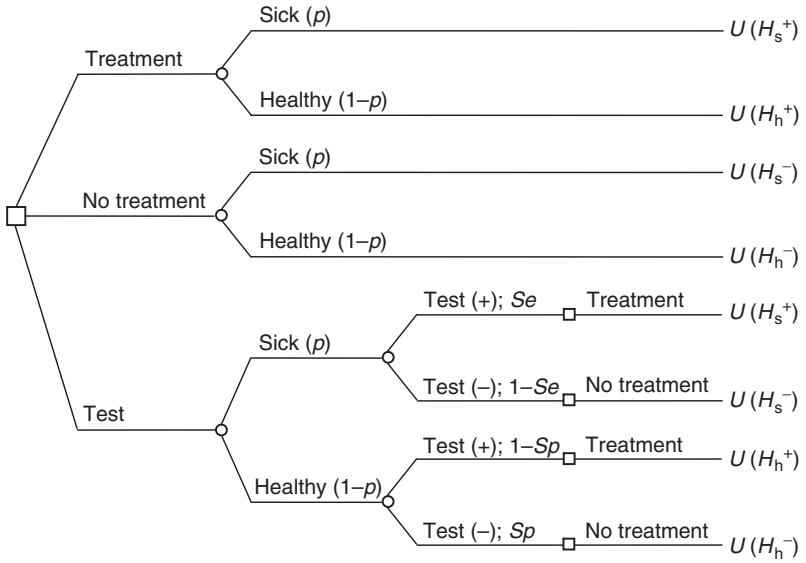

Figure 1 Decision tree for the test treatment decision.

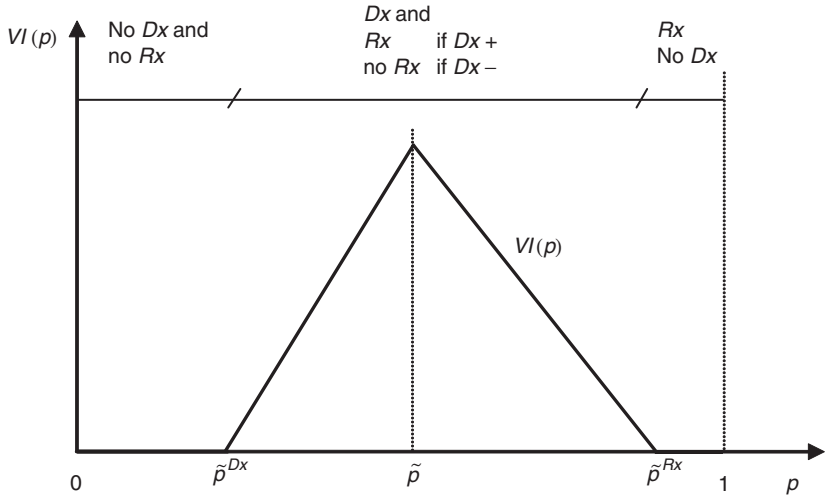

Figure 2 The value of information of a test.

The value of information concept can be applied to situations in which several tests are available and the decision maker has to choose which one to use. It allows the evaluation of the decision maker's marginal rate of substitution between sensitivity and specificity. The decision maker chooses the optimal test dependent on his preferences and the given *a priori* probability of sickness.

Equation [7] leads to

$$dVI(p) = 0 \text{ implies } p \cdot dSe \cdot L = -(1-p) \cdot d(1-Sp) \cdot G \text{ or}$$

$$\left.\frac{dSe}{dSp}\right|_{dVI=0} = \frac{1}{p/(1-p) \cdot (G/L)} \qquad [8]$$

This equation was derived by McNeil *et al.* (1975) and Metz (1978), though without reference to the value of information concept. The marginal rate of substitution between sensitivity and specificity is decreasing in p. In other words, at high *a priori* probabilities of sickness the decision maker chooses a test with high sensitivity, whereas at low *a priori* probabilities one favors tests with high specificity. In the first situation, the benefits of treating the patient dominate, whereas in the second situation, the benefits of not treating become more relevant. The marginal rate of substitution is also decreasing in G/L. Hence, if either G increases or L decreases (in absolute terms), tests with high sensitivity are more attractive. Inversely, if either G decreases or L increases (in absolute terms), tests with high specificity are favorable.

Risk Aversion

Medical decision analysis often implicitly assumes a decision maker to be risk neutral. This is consistent with the practice of measuring intervention outcomes in terms of changes in mortality. New research also investigates the effect of higher order risk preferences on medical decision making. Consider the effect of risk aversion on the test and treatment thresholds. For a decision maker with a concave utility function, i.e., marginal utility of health decreasing in the level of health, it is easy to show that G, the gain from treatment in the sick state, increases and L, the loss from treatment in the healthy state, decreases in absolute terms as compared to a decision maker with linear utility. With this, the decision maker's test and treatment thresholds decrease (all $\tilde{p}$ are decreasing in $(-G/L)$). Intuitively, if either the potential benefit from treatment increases or the potential harm decreases, the treatment option becomes more attractive. The risk averse decision maker uses his test and treatment strategy as an insurance device (it reduces the spread between the possible health states) by opting for testing and treatment at lower prevalence rates than a risk neutral decision maker. In situation where the decision maker can choose between several tests he will tend to favor those with high sensitivity if he is risk averse. This can be seen in eqn [8] because the marginal rate of substitution between sensitivity and specificity is increasing in $(-G/L)$.

The decision maker's risk preferences are only partially described by risk aversion. Higher-order attitudes such as prudence and temperance also appear to play a role in decision making under uncertainty (Kimball, 1990; Eeckhoudt and Schlesinger, 2006). Felder and Mayrhofer (2013) analyze higher-order risk preference in a medical setting by adding a comorbidity risk to a specific index condition, or primary illness. They show that the effects of risk aversion on the test and treatment thresholds are reinforced when prudence and temperance are taken into account. Risk attitudes may explain why screening activities in very low *a priori* probability ranges are observed (for instance, the prostate-specific antigen (PSA)-test for prostate cancer in asymptomatic middle-aged men) where under risk neutral decision making would not be expected.

The above example covers some of the basic concepts of formal decision analysis in the context of medical decision making. The focus is exclusively on the utility derived from the patient's health status. (The utility of health states is often quantified and thus made comparable across illnesses by means of the quality-adjusted life-years concept.) Depending on the aim of the analysis the model will incorporate further information, for example, relating to treatment costs. The analysis can also pertain to a supply rather than a demand

decision. In the following, we elaborate on a model which puts a stronger focus on the patient's perspective and his demand for medical care.

Health Care Demand

Medical decision making can be integrated into a conventional demand framework. So far the gain from treatment, i.e., $h = H_s^+ - H_s^-$, was exogenous to the decision model. However, the effect of a treatment depends on the type and amount of medical inputs M that are used. A health production function $h = f(M)$ describes this relationship.

The utility maximizing decision maker faces a limited budget, which he can spend on medical inputs M or on other consumption goods C. The utility function is thus $U(C,H)$, which is strictly positive and strictly increasing in both M and C. Marginal utility is decreasing, implying that the individual is risk averse. To ensure that a change in consumption does not have an effect on the marginal utility of medical inputs and vice versa, the mixed derivatives must be zero.

To include h – the health gain produced by medical inputs – explicitly in the utility function, $H = H_s^- + h$ is noted. (To keep this illustration simple, healthy patients and the potential issues they raise are disregarded.) The utility function can then be written as

$$U = U(C, H_s^- + h) = U(C, H_s^- + f(M)) \quad [9]$$

Demand for health services now becomes a derived demand, as it is driven by the underlying demand for health. All prices except for medical inputs are set equal to one. With income Y, the budget constraint is

$$C + p_M M = Y \quad [10]$$

Solving the Lagrangean function $L(C,M,\lambda) = U(C, H_s^- + f(M)) + \lambda(C + p_M M - Y)$, where λ indicates the marginal utility of income, a combined first-order condition is derived for the utility maximizing demand for consumption and health care:

$$U_H / U_C = p_M / f'(M) \quad [11]$$

The right side of the equation can be interpreted as the marginal cost of investing in health. By rewriting this equation the following equation is obtained:

$$U_H f'(M) / p_M = U_C \quad [12]$$

which can be interpreted intuitively: In the optimum, the last monetary unit spent must generate the same marginal utility whether it is spent on medical care or on consumption.

Conducting a comparative static analysis can investigate the effects of changes in the exogenous variables on the demand for health. Let us first look at technological innovation and assume that $h = \varphi M^{\alpha}$, where $\varphi > 0$ reflects the productivity parameter. If innovation increases the productivity of medical inputs, this is reflected in an increase in the marginal product of medical inputs $f'(M) = \varphi \alpha M^{\alpha - 1}$. In other words, the marginal cost of producing health diminishes. This results in higher demand for health and medical inputs. The opposite effect is caused by higher prices for medical inputs. Although higher income also results in a higher level of demand, a higher initial health level does not have a clear positive or negative effect. In this model, the probability of survival, which is included in the expected utility function, has no influence on demand.

This model can be extended to include the aspect that health care demand is often directed toward preventing early death. A simple approach to modeling survival is to introduce an initial probability of survival π_0 which can be increased by medical inputs: $\pi(M)\pi_0 + g(M)$ with $g'(M) > 0$ and $g''(M) < 0$. This extension permits the evaluation of the demand for health as a function of initial survival. It can be shown (see Felder and Mayrhofer (2011)) that the demand for health care is inversely related to the initial survival rate, which is tantamount to the famous dead-anyway effect (Pratt and Zeckhauser, 1996).

Double Moral Hazard under Two-Sided Asymmetric Information

This article began by outlining a basic model of medical decision making which assumes that the physician acts as a perfect agent for the patient. In the second model the focus was on the patient's view. In practice, both perspectives have to be combined. A primary reason is that patients have become increasingly involved in treatment decisions. They want to participate in the decision making process and physicians want them to understand the implications of the decisions that have to be taken. Second, even disregarding an ideal-type shared decision making process, the outcomes for physicians and patients are interlinked.

A model that characterizes this relationship must also map out the underlying two-way moral hazard structure. A simplified model would contain only one stage, in which a utility maximizing physician makes a treatment decision based on factors such as the patient's health status, coinsurance, and his remuneration. However, the health outcome depends not only on the treatment, but also on the patient's health-related behavior, even beyond the narrowly defined notion of compliance. This creates strategic interdependence between the levels of utility realized by the physician and the patient. Both sides suffer from information deficits. The patient either does not know whether the physician is sharing all relevant information or simply lacks the capability to understand all the information that is given. Furthermore, they cannot easily verify the quality of the treatment. On the other side, the physician does not know everything about the patient's health-related behavior. This behavior, however, affects the health outcome. Thus, health outcomes can be interpreted as the result of both the physician's medical services and the patient's behavior.

The physician's treatment decision and the patient's health-related behavior can interact in three key ways: Medical services and health behavior can be strategically independent, implying that the level of medical services does not affect the marginal productivity of the patient's compliance and vice versa. Alternatively, the two components can be strategic complements, i.e., if one factor is increased this has a positive effect on the other factor. Finally, they might be strategic

substitutes, so that a lower level of health care services can be compensated – at least so some extent – by better health-related behavior. These three types of interaction between physician decision and patient behavior yield different results. There is some evidence that there is indeed a strong mutual influence of the demand for health and the provision of health care services (Schneider and Ulrich, 2008).

Concluding Remarks

The expected utility theory of von Neumann and Morgenstern is the fundamental building block of most models in medical decision making under uncertainty. However, it has been criticized for its failure to predict individual behavior. Alternative non-expected utility theories such as rank-dependent choice models have been suggested to reflect actual behavior more precisely. One aspect, for instance, is that decision makers tend to overweight small probabilities and underweight large probabilities, which leads to an inverse S-shaped probability transformation which has been confirmed in empirical studies (Abdellaoui, 2000; Bleichrodt and Pinto, 2000).

Recent research, in turn, has challenged the validity of rank-dependent theory. Among others, List (2004) showed that individuals with extensive experience behave largely rationally, or in accordance with the expected utility theory. Physicians take decisions on tests and treatments as a matter of routine – and they are expected to make unbiased estimations of probabilities and take coherent decisions.

The use of the expected utility theory is also warranted in the prescriptive realm of medical decision making. If an optimal policy has to be chosen or recommended, "the expected utility is the best theory to determine which decisions to undertake" (Wakker, 2008, p. 687).

Medical Malpractice, Defensive Medicine, and Physician Supply

DP Kessler, Stanford University, Stanford, CA, USA

Introduction

An efficient system of medical malpractice liability law should induce physicians to supply precautionary medical treatments as long as the benefits exceed the costs. In practice, the US malpractice system may deviate from this ideal along two dimensions. First, it may create incentives to supply cost-ineffective treatments based on fear of legal liability – to practice 'defensive medicine' (Kessler, 2011). Defensive medicine can take many forms: too many diagnostic tests, specialist office visits, and even unnecessary surgeries. One recent paper estimates the cost of defensive medicine in the US to be 2–3% of health spending, or over US$50 billion per year (Mello *et al.*, 2010).

Second, it may create incentives to decline to supply cost-effective treatments. This phenomenon is sometimes described as 'negative defensive medicine,' to distinguish it from its counterpart above. Negative defensive medicine can also take many forms, including physician avoidance of high-risk patients or procedures, reduction of hours of work, relocation, or exit from the profession altogether. All of these involve a restriction in the supply of physicians' services that is not in society's interests.

Thus, the impact of the US malpractice system on physician supply is an important policy issue. This article summarizes the empirical research on this topic. In general, the research finds that higher levels of malpractice liability lead to lower levels of supply. This finding is strongest and most robust for specialists, other physicians who are most likely to be at high risk for a malpractice claim, and for physicians in rural areas. However, the consequences of malpractice-induced reductions in supply on the cost of care and patient health outcomes – and hence on social welfare – remains largely an open question.

The article begins with an overview of the operation of the US malpractice system and a theoretical framework in which its effects on supply can be evaluated. It then summarizes the empirical evidence. It concludes with a discussion of the implications of these findings for social welfare and suggestions for future research.

The US Malpractice System and Physician Supply

In general, malpractice claims are adjudicated in state courts according to state tort laws. (The text in this section borrows heavily from Kessler (2011).) These laws generally require three elements for a successful claim. First, the claimant must show that the patient actually suffered an adverse event. Second, a successful malpractice claimant must establish that the provider caused the event: the claimant must attribute the injury to the action or inaction of the provider, as opposed to nature. Third, a successful claimant must show that the provider was negligent. Stated simply, this entails showing that the provider took less care than that which is customarily practiced by the average member of profession in good standing, given the circumstances of the doctor and the patient (Keeton *et al.*, 1984). Collectively, this three-part test of the validity of a malpractice claim is known as the 'negligence rule' (see Budetti and Waters (2005), for a layperson's explanation).

Even though they share the same basic structure, states' liability laws differ in terms of the level of liability they impose on providers. In particular, several states have changed their laws in ways that reduce liability relative to its historical levels – to adopt 'tort reforms.'

The consequences of malpractice law and tort reforms for the supply of physician services are theoretically indeterminate. An early model by Danzon *et al.* (1990) illustrated why it is so difficult to assess the impact of malpractice law on supply a priori. Suppose that physician markets are monopolistically competitive, and states' liability regimes impose both fixed and variable costs on providers. In this context, the model shows that the extent to which decreases in liability costs lead to increases in supply depends on the magnitude of costs, the extent to which they are fixed or variable, and the effect of variable costs on physicians' profits. If liability costs are primarily fixed, then decreases in costs would lead to higher profits in the short run and ultimately to increased supply. If liability costs are primarily variable, however, and the market-wide elasticity of demand for physician services is low, then tort reform would lead to a decrease in price with a minimal change in quantity, and hence little change in profits and ultimately supply.

As Matsa (2007) pointed out, extensions of this model suggested that malpractice law may have very different effects across specialties and geographic areas. Malpractice insurance premiums, perhaps the most important cost imposed on providers by the liability system, differ dramatically along these dimensions. For example, in 2009, premiums in Suffolk County, New York, for specialists in internal medicine and obstetrics were US$33 000 and US$178 000, respectively, whereas premiums in Colorado were approximately one-third as much (Medical Liability Monitor 2009). In the Danzon *et al.* (1990) framework, such differences could imply very different supply responses to similar tort reforms.

Empirical Assessment of the Effects of the Malpractice System and Tort Reforms

The extent to which changes in malpractice law lead to changes in supply is, thus, an empirical question. Empirical research on the effects of malpractice law on supply is of three types. The first arm of the literature surveys physicians about their opinion of the role of the malpractice system on their scope of practice, hours of work, or likely future labor force participation (e.g., Mello *et al.*, 2005). Although opinion surveys indicate that physicians believe that the malpractice system has a significant effect on supply, this approach only

 doi:10.1016/B978-0-12-375678-7.01106-8

provides information about physicians' perceptions, which may or may not be closely related to their economic decisions.

A second arm examines the correlation between supply and measures of malpractice costs such as insurance premiums, claims rates, or average payments per claim. Baicker and Chandra (2005) estimated the relationship between the change in the number of physicians per capita from 1993–2001 by specialty, age, and rural location and the change in these measures of costs across US states. They found that the overall size of the physician workforce does not respond to increases in costs, although in rural areas, the response of the size of the workforce is small but statistically significant. Dranove and Gron (2005) found that the incidence of a high-risk procedure (craniotomy) and women's travel time for a high-risk delivery did not change in Florida contemporaneous with that state's dramatic increase in premiums in the early 2000s. Mello *et al.* (2007) reported similar findings about physicians scope of practice in Pennsylvania contemporaneous with that state's dramatic increase in premiums, but documented a decline in the number of practicing obstetricians there. In a recent working paper, Reyes (2010) found that increases in malpractice premiums lead to increased specialization among US obstetrician–gynecologists, with some physicians concentrating more in obstetrics and others in gynecological surgery.

However, the possibility that unobserved determinants of supply are correlated with premiums, claims rates, or payments qualifies the results of all these studies. The malpractice costs in a particular area may be increasing because the patients are particularly sick (and hence prone to adverse outcomes and malpractice claims), because the patients have more 'taste' for medical interventions (and hence more likely to disagree with their provider about management decisions), or because of many other factors. To the extent that these factors are not captured fully in observational data, estimates of the impact of malpractice costs in the studies above would tend to understate the magnitude of the true effect.

The third arm of the literature addresses this concern by identifying the effect of malpractice costs on supply with variation in tort reforms across states and over time. As Kessler (2011) pointed out, this technique yields unbiased assessments of the impact of the malpractice system under the assumption that the adoption of reforms is uncorrelated with unobserved determinants of supply (see US Congress, Congressional Budget Office (2006) for a criticism of this assumption).

Kessler *et al.* (2005) estimated the effect of reforms on the number of physicians using individual–physician-level data from the American Medical Association's Physician Masterfile, matched with data on US states' tort laws and state demographic, political, population, and health care market characteristics. They grouped reforms into two types – 'direct' and 'indirect' reforms. Direct reforms directly reduced malpractice awards. The most important reforms of this type are caps on damages that limit a defendant's financial liability (or some element of liability, like pain-and-suffering or punitive damages) in a successful lawsuit. As the research discussed in Kessler (2011) showed, direct reforms reduce the frequency and size of claims, and insurance premiums. Other reforms that only affect awards indirectly, such as reforms imposing mandatory periodic payments (which require damages in certain cases to be disbursed in the form of annuity that pays out over time), limits on joint and several liability, or limits on the contingent fees that plaintiffs' attorneys can charge have had a less consistent impact on malpractice costs. They find that 3 years after adoption, direct reforms increase physician supply in the US by 3.3%, all else held constant. They also find that direct reforms had a larger effect on the supply of most (but not all) specialties with high malpractice insurance premiums, on states with high levels of managed care, and on supply through retirements and entries than through the propensity of physicians to move.

Newer work examines the supply response to reforms for different subgroups. Using county-level data from 1985–2000, Encinosa and Hellinger (2005) showed that caps on pain-and-suffering damages lead to increases in supply, especially in rural areas. Using county-level data from 1970–2000, Matsa (2007) found no aggregate effect of caps on damages, but large effects for rural physicians and especially rural specialists; he hypothesized that this is because rural doctors face greater uninsured liability costs and a more elastic demand for medical services. Using state-level data from 1980–2001, Klick and Stratmann (2007) found that caps have a significant effect on the number of doctors per capita, and that this effect is concentrated among the specialties that face the greatest exposure to malpractice risk.

Two other studies assess the extent to which reforms affect physician avoidance of high-risk patients and hours of work. In the only study of its kind, Dubay *et al.* (2001) examined the effect of tort reforms on the supply of prenatal care for pregnant women. They found that reforms result in prenatal care beginning earlier in pregnancy, especially for women with low socioeconomic status, who may be more likely to file a malpractice claim. Helland and Showalter (2009) showed that reform-induced reductions in liability costs lead to increases in hours, especially for physicians aged 55 years and older.

Conclusions

The small but growing literature on the effect of malpractice law on physician supply reaches two main conclusions. First, tort reforms that directly reduce the costs imposed by the US malpractice system have a small, statistically significant positive effect on the number of physicians per capita, on the order of 2–4%. Second, although there is some debate about the robustness of this result for the overall physician population, there is almost universal agreement that reforms increase supply of certain subgroups that are likely to be sensitive to malpractice incentives. These subgroups include specialists who face substantial exposure to malpractice risk; rural physicians who may be less able to increase their markups to recover the costs of malpractice from their patients; and physicians who serve patient populations that are more likely to file a claim.

If markets for physician services functioned perfectly, these results would imply that tort reforms improve social welfare. Suppose that patients had perfect information about the risks of treatment, and physician services were priced at their marginal cost. In this case, as long as the liability system imposed no transactions costs, tort reforms should not affect supply.

Patients and their physicians would make optimal decisions regardless of the level of liability, and any reductions in awards for malpractice would be completely offset by increases in prices. Reductions in liability would only increase supply if the liability system consumed real resources, which would mean that it was, by definition, inefficient.

Of course, there are many reasons why physician markets might not reflect this ideal. Most important, if patients don't have perfect information about risks, then liability-induced reductions in supply might be optimal. Physicians might not take appropriate precautions in the absence of liability, which could lead to an equilibrium quantity of physician services that was too large. Liability-induced reductions in supply might be optimal for another reason: the widespread prevalence of health insurance, which means that neither patients nor physicians bear the full costs of care in any particular case. Such moral hazard could also lead to a socially excessive supply of services, which might be mitigated by liability costs. The fact that markets for physician services are unlikely to be perfectly competitive adds a third source of indeterminacy. Even simple models of monopolistic competition showed that the free-entry outcome can involve socially too few or socially too many suppliers (Spence, 1976; Tirole, 1988).

Any assessment of the welfare implications of liability-induced reductions in physician supply must therefore examine their consequences for health care costs and health outcomes. To date, only two studies have attempted to do so, and their findings are inconclusive. Dubay *et al*. (2001) found that tort reforms lead to prenatal care beginning earlier in pregnancy, although they fail to reject that this increase in supply led to improved infant health. Along the same lines, Klick and Stratmann (2007) found that reforms lead to an increase in the supply of high-risk specialties, but reported that the effects of reform on infant mortality were mixed.

Investigation of the links between physician supply, costs, and outcomes is therefore an important topic for future research. Future research might also investigate the effect of other, nontraditional reforms to the liability system on physician supply. Kessler (2011) discussed several of these, including restricting the legal discoverability of information gathered as part of private, voluntary efforts to reduce medical errors; allowing evidence of compliance with clinical practice guidelines as an affirmative defense to negligence; and expanding the use of alternative dispute resolution, no-fault, and administrative compensation systems.

Medical Tourism

N Lunt and D Horsfall, University of York, Heslington, York, UK

Introduction

The notion of traveling abroad for the purposes of health and well-being is well established. The spas of Hungary, baths of Turkey, and geysers of Sweden have long been popular destinations for those seeking convalescence. Where surgical care was required, the direction of travel generally saw the wealthy citizens of poorer nations traveling to the richer, more medically advanced countries. However, international travel for the purposes of medical treatment is no longer the preserve of political and economic elites. Contemporaneously the whole spectrum of medical treatment is offered in destinations around the world as part of a global market in health care. This treatment spans the full range of medical services, but most commonly includes dental care, cosmetic surgery, elective surgery, and fertility treatment. Medical value travel or 'medical tourism' as a term has come to represent situations where consumers elect to travel across international borders with the intention of receiving some form of medical treatment. Differences between medical and health tourism focus on the type of intervention, setting, and particular inputs involved. Setting the boundary of what is health and counts as medical tourism for the purposes of trade accounts is not straightforward. Within this range of treatments, not all would be included within health trade. Cosmetic surgery for esthetic rather than reconstructive reasons, for example, would be considered outside the health boundary.

At first sight medical and tourism are curious terms to run together. Medical and surgical treatment can involve risk, pain, and discomfort; tourism is associated with relaxation and pleasure albeit associated with travel. Although some treatment destinations are those associated with sun, scenery, and sightseeing, it is not clear the extent to which such local attractions are important in the patient's decision.

A range of nomenclature is used in the health services literature, including international medical travel, outsourcing, and refugees. Although the term medical tourism is increasingly being employed, there are a number of commentators who are critical of its use. Their criticisms center on the notion somehow devaluing the rather serious procedures that such patients are often undertaking.

Arguably, however the concept of medical tourism does have analytical purchase – capturing the health sector element as well as the wider economic impact of such travel. Although it must be acknowledged that medical tourism may have little to do with general tourism rationale, the term is useful because it points toward the commodification and commercialization of health travel. Hence, the role of the industry, issues of advertising, and supplier-induced demand are brought to the fore.

The Nature and Scope of Medical Tourism

Although there is a general consensus that the medical tourism industry has burgeoned over the past decade, there remains disagreement as to the current size of the industry. Figures that are regularly reproduced in the literature draw on data collected and projections made by Deloitte, which places the number of US citizens leaving the country in search of treatment at 750 000 in 2007. The main objection to Deloitte's figures come from McKinsey and Co who suggests that, although the potential for such large numbers exist, a more accurate worldwide figure would be between 60 000 and 85 000 medical tourists per year. In large part, very significant disparity may be due to different definitions of medical tourism.

The numbers of medical tourists proffered by McKinsey still appear rather small, particularly in the context of a US population of 360 million, and even the 50 million uninsured. Given that even the most conservative estimates of inward medical tourism to India place the number of tourists at 200 000, alongside figures between 200 000 and 350 000 for Singapore, and 200 000 for Cuba, it would seem that McKinsey's numbers are understated.

This lack of clarity extends beyond not only the numbers of medical tourists but also their profile, the process of becoming a medical tourist, and the aftereffects of medical tourism. It is assumed that different drivers exist for higher and lower income patient groups traveling from North America and Western Europe. But relatively little is known about sociodemographic profile, age, gender, existing health conditions, and status in attempting to map the composition of the medical tourism market.

Such numbers and insights are important to quantify economic impact and also to assess potential risk to source health systems. Given this gap in knowledge, the discussion within the article is inevitably limited in terms of the literature base from which it can draw upon.

Why do People Travel?

As would be expected, globalization has played a significant role in the development of medical tourism. Developments in medical tourism mirror the expansion of markets in health care and embedding of neoliberalism on the world stage. Precipitating the rise of what is seen as a consumerist age marked by lower levels of social solidarity, globalization has advanced the commodification of health care. At the most basic level the advent of the Internet and lowering of travel costs has undoubtedly played a vital role in not only raising awareness of the opportunities for surgery abroad but also making the pursuit economically viable. The freeing of medical services from their traditional territorial boundaries reflects a more transnational and international role for health policy development, with partnerships developing between organizations in established and developing medical markets, transnational companies with an increasing stake in health care in multiple countries, and an emerging role developing for supranational bodies.

In terms of the medical tourism market, the free movement of goods and services under the auspices of the World Trade Organization and its General Agreement on Trade in Services has accelerated the liberalization of the trade in health services, as have developments with regard to the use of regional and bilateral trade agreements. As health care is predominantly a service industry, this has made health services more tradable, global commodities. But that it is easier to travel abroad for care does not fully explain why patients become medical tourists.

The most common explanatory factor cited is that of cost. Indeed it is clear that for those in the US and Western Europe who feel the need to 'go private,' the potential cost savings of traveling abroad are huge, with any review of prices showing a potential saving between 30% and 90% depending on the treatment sought (see **Boxes 1–4**). In terms of familiarity, expatriates often have medical care on their visits back to their 'home' country, which would also show up as medical tourism; for example, the large Indian Diaspora in the UK, and the 2nd Generation Mexicans living in the US (see **Boxes 4** and **5**). In addition, some treatments may not be available or may be subject to a wait in the home country, including the latest technology and techniques. Moreover, some treatments may not be legal in the country of origin. The desire for privacy and wish to combine traditional tourist attractions, hotels, climate, food, cultural visits with medical procedures are also thought to be key contributing factors to the growth in this market. Each of these factors, on their own or in combination, has shifted the direction of medical travel. In the present day not only are India and Thailand top destinations for complex elective procedures but also the very tourists visiting their hospitals, along with those in Poland, South Africa and beyond, are traveling from countries with established and often championed health care systems. Conversely, these championed health systems continue to treat medical tourists at facilities with long-standing reputations (see **Box 5**).

Marketing Medical Tourism

At the most basic level, prospective medical tourists are faced with a level of information that is at once overwhelming and also relatively unhelpful. Internet sites marketing destination and providers are relatively cheap to set up and run, and contributors may post information without being subject to clear quality controls or advertising standards. Medical tourist sites promote benefits and downplay the risks, and the lack of clear regulation regarding what information can be presented on the Internet to prospective medical tourists is then compounded by deeper issues of credibility, trust, and perceptions of risk. As with all medical treatments, an element of risk exists to the patient's health, which is supposedly outweighed by the potential benefits resulting from the treatment. What can be gleaned from the literature concerning risk and safety-related incidents for medical tourism is limited. Although there is evidence regarding, for example, the occurrence of adverse events in the UK hospitals, there is little similar overseas/international data for medical tourist destinations.

Evidence of clinical outcomes for medical tourist treatments is limited and reports are difficult to obtain and verify. Little is known about the relative clinical effectiveness and outcomes for particular treatments, institutions, clinicians, and organizations. There is scant evidence on long- or short-term follow-up of patients dispersing to home countries following treatments at the range of destinations. That positive treatment outcome should result is important not least because typically the patient's local health care takes on the responsibility and funding for postoperative care including treatment for complications and to remedy side effects.

Two particularly interesting stakeholders in the medical tourism industry are brokers/facilitators and providers. There has been a steady rise in the number of companies and consultancies offering brokerage arrangements for services and providing web-based information for prospective patients

Box 1 Case study 1

Brazil

Estimated size of industry	50 000 Inward medical tourists per year
Key procedures offered	Cosmetic, reproductive, and bypass
Estimated cost saving – for the consumer	45–60%
Key pull factors	Cost, quality of care, and range of procedures
Role of state	Limited

The Brazilian medical tourism market centers on cosmetic surgery. Indeed there are more plastic surgeons per capita in Brazil than any other country in the world. Studies suggest that the patient-centered nature of care in Brazil, the willingness to offer procedures not available elsewhere, and the reputation for quality are key pull factors in addition to cost. This perceived high level of quality is undoubtedly aided by the proportion of accredited clinics (more facilities accredited than any country other than the US) and partnerships with organizations such as the International Hospital Corporation, which is based in the US.

The Brazilian government plays only a limited role in promoting the industry. Indeed, although health tourism was recognized in the Brazilian National Tourism Plan (2007–10), it was not identified as an area of focus or potential revenue. This undoubtedly reflects the fact that most medical tourists are catered for in private clinics and that as yet, it is estimated that the financial benefits of even the long-established cosmetic industry are relatively modest.

Box 2 Case study 2

Hungary

Estimated size of market	Estimated 40% share of European dentistry tourism market. Has been estimated between 400 000 and 1 million medical tourists
Average potential cost saving for the consumer	45%
Major clinical areas	Dentistry
Key pull factors	Cost, quality, reputation, and location
Role of government	Keen to promote the industry and reduce regulatory road blocks

Hungary is an exporter country within the medical tourism market. Its reputation for high quality and low costs makes it, along with countries such as Poland, a genuinely accessible and affordable option close to Western European countries such as Germany and Austria. It has been labeled the dental capital of the world, with a much higher dentist per capita ratio than can be found in neighboring Austria, Germany, or the UK. Indeed it is estimated that between one in two and one in three of all Austrians travel to Hungary to meet their dentistry needs. The Hungarian government has offered much in the way of support for the medical tourism industry, expanding domestic incentives to travel to wellness locations to the foreign tourist market, proclaiming 2003 as The Year of Medical Tourism, and even using its premiership of the EU to promote the medical tourism industry.

Recent years have seen an expansion into the cosmetic surgery market as well as the general medical surgery market. The expansion into other clinical areas is still at a relatively early stage.

Box 3 Case study 3

Thailand

Estimated size of the market	Between 350 000 and 1 million visitors per year
Average potential cost savings for the consumer	From 30% to 90% depending on the procedure
Main clinical areas	Cosmetic, fertility, dental, gender reassignment, and cardiac
Major pull factors	Cost and quality
Role of state	Key role in promoting the industry. Legislative role in reducing barriers to the industry

The Thai medical tourism industry is part of the first wave of Asian medical tourism markets to open up and along with Singapore and India represents one of the biggest exporters of medical tourism services. As with most other Asian countries, cost is a key driver of medical tourism with cardiac, cosmetic, and gender reassignment procedures between 60% and 90% cheaper than US prices.

Both business and the government have played major roles in marketing Thailand as a cheap, safe, and relaxing country in which to get the highest standard of treatment. On a practical level, the Thai government has eased visa restrictions on medical tourists and provided funds to support the development of a medical hub in and around Bangkok. Thai hospitals meanwhile have sought to market themselves to the wider world by placing a heavy emphasis on high rates of Thai Joint Commission International accreditation and the reputations of established hospitals such as the Bumrungrad and Bangkok Hospitals.

about available services and choices, which can be attributed to the transaction costs associated with medical tourism, where individuals have to assemble their own information and negotiate any treatment. Typically brokers and their web sites tailor surgical packages to individual requirements: flights, treatment, hotel, and recuperation. Brokers may specialize in particular target markets or procedures (treatments such as dentistry or cosmetic surgery), or destination countries (e.g., Poland and Hungary). Medical tourist facilities will often target particular cultural groups – Bumrungrad in Thailand, for example, has a wing for the Middle East patients. Within the wide picture of medical tourism there is a diversity of participating providers. Relatively small clinical providers may include solo practices or dual partnerships, offering a full range of treatments. At the other end of the scale are extremely large medical tourism facilities (e.g., Bumrungrad, Raffles in Singapore, and Yonsei Severance Hospital in South Korea) where clinical specialism is the order of the day. Providers are primarily from the private sector, but are also drawn from some public sectors (e.g., Singapore and within Cuba).

Box 4 Case study 4

India

Estimated size of the market	Conservative estimates suggest an inflow of at least 200 000 medical tourists, though much higher estimates are available
Average potential cost savings for the consumer	From 30% to 90% depending on the procedure
Main clinical areas	Cosmetic, fertility, orthopedic, and cardiac
Major pull factors	Cost and quality
Role of state	Key role in promoting the industry. Legislative role in reducing barriers to the industry

The Indian medical tourism industry is a major exporter of medical tourist services. Initially built around treating medical tourists from West Asia and the Middle East, India is beginning to attract an ever-increasing number of European and American medical tourists.

As with most other lower-middle income countries provider countries, cost is a key driver of inward medical travel – cardiac, cosmetic, and even dental procedures can be found between 60% and 90% cheaper than US prices.

Central to the expansion and dominance of the Indian medical tourism market have been both private and public endeavors. The Indian government has relaxed visa laws, introducing a special visa category – an M visa – to cater for the growing number of medical tourists as well as allowing tax breaks to providers. In the private domain, the Apollo Group controls some 50 hospitals and markets these rigorously on the basis of their quality, safety, and in many cases accreditation or partnership with US hospitals. One particular advantage the Indian market has over its Thai and Singaporean counterparts is the large Indian Diaspora, which is increasingly being targeted by marketing campaigns.

Hospitals may be part of large corporations (the Apollo Group, e.g., has 50 hospitals within and outside India), and ownership itself may lie primarily in the higher income countries from where patients mostly originate.

Countries seeking to develop medical tourism have the options of growing their own health service or inviting partnerships with large multinational players. Individual hospitals may develop relations with travel agencies or wider brokerage companies. Securing accreditation from international programs may be a part of the development of services. In addition to accreditation, other approaches to raising the profile of countries and their health facilities have been used. For example, partnerships and oversight by overseas hospitals and universities, most often from the American private sector, can fulfill a similar role. Formalized linkages with widely recognized medical providers and educators (such as Harvard Medical International and Johns Hopkins Hospital) are becoming increasingly popular among hospitals in middle-income countries catering for medical travelers. A long-standing approach of the Cleveland Clinic, is to train foreign physicians as house staff and fellows to encourage later patient referrals back to the US once they are practicing medicine in their home countries.

The Role of State Support

A range of national government agencies and policy initiatives have sought to stimulate and promote medical tourism in their countries. Many countries see significant economic development potential in the emergent field of medical tourism. Thai, Indian, Singaporean, Malaysian, Hungarian, and Polish governments have all sought to promote their comparative advantage as medical tourism destinations at large international trade fairs, via advertising within the overseas press, and official support for activities as part of their economic development and tourism policy (see **Boxes 2–4**).

Government support does manifest itself slightly differently across the medical tourism map. However, common features are the relaxation of visa regulation, promotion of medical tourism within the central ministries of tourism, support for hospitals to achieve accreditation from bodies such as the Joint Commission International (JCI), and a willingness to provide funding. Useful examples can be found in both Singapore and India. Since 2003, SingaporeMedicine has been a multiagency government–industry partnership aiming to promote Singapore as a medical hub and destination for advanced patient care. It is led by the Ministry of Health, and has the support of the Development Board (new investments and health care industry capabilities); International Enterprise Singapore (growth and expansion of Singapore's health care interests overseas); Singapore Tourism Board (branding and marketing of its health care services) (see **Box 4** for details on India).

As the case studies illustrate, some places may be simultaneously acting as countries of origin and destination in the medical tourism marketplace (e.g., the US). High income countries may service overseas elites, whereas at the same time their citizens choose to travel as medical tourists to lower and middle-income countries for treatments (e.g., India and Thailand). Thus, Harley Street in the UK and facilities including the Mayo Clinic and Cleveland Clinic in the US have long-standing reputations in the international provision of health care. Conversely, the emergence of lower cost

Box 5 Case study 5

USA

Estimated size of the market	An estimated 43 000–103 000 foreigners travel to the US and 50 000–121 000 US residents travel out. Estimates are as high as 500 000 for outward flows
Average potential cost saving for the consumer	Costs in the US are among the highest in the world
Main clinical areas	Cosmetic, fertility, orthopedic, and cardiac
Major pull factors	Quality
Major push factors	Cost and access

The US medical tourism market is more complex than any other, owing much to the fact that it is both an importer and exporter of medical tourists. There are three main import drivers. The first is access to health care within the US. With an estimated 46 million uninsured Americans and one of the most expensive health care systems in the world, many Americans can simply not afford surgery at home. Estimates are as high as half-a-million Americans leave the US as medical tourists every year, largely to Central and South America, but also increasingly to India and the East Asia.

Second, the large number of immigrants in the US, many of whom have demonstrated a preference to return to their home country for care. In particular, the large Mexican Diaspora is an increasing source of outward medical tourists, with some US-based companies even extending their health care cover to procedures undertaken in Mexico.

Third, changing attitudes as seen with the increasing outsourcing of the US medical industry. Although the use of foreign-based radiologists to provide overnight cover for US radiologists may not be directly bound to burgeoning medical tourism market, it is indicative of the changes occurring within the US market and shifting perceptions. There is an increasing acceptance that lower costs elsewhere do not necessarily signal lower quality. A range of employers are sanctioning its employees to seek medical care abroad within the coverage of their health care policies. Many of the facilities treating American medical tourists abroad are controlled by or in partnership with US corporations, many of which are providers of domestic health care.

The motivations for non-US citizens traveling to the US vary, however the high quality of care, international reputation of flagship health care facilities, and high waiting times in neighboring Canada are thought to be key drivers.

treatments in Thailand, India, or parts of Europe will attract individuals from higher income countries who pursue treatments on the basis of cost. The remainder of the article discusses the impacts on health systems for exporter and importer countries. A country imports if their patients go overseas to receive care, and exports if they themselves provide care to inward medical tourists.

Implications of Importing Medical Tourist Services

There are a range of potential financial impacts for publicly funded health care in countries importing medical treatments. Costs may result from overseas cosmetic surgery or dental work that requires emergency or remedial treatment within home countries. Infection outbreaks resulting from travel will also bear upon the public health system. Similarly, there may be health and social care costs that arise from multiple births, as a result of overseas fertility treatments, particularly if facilities use more 'risky' procedures. Domestic private health activity may also experience costs, given that they potentially lose business to overseas providers, for example, cosmetic surgery and fertility treatment. National regulators may incur associated costs of patients traveling overseas caused by monitoring advertising and providing detailed information and advice to support potential or actual medical tourists. But overall, there has been little systemic collection of evidence or attempts to estimate system costs and knowledge is fragmented.

Large numbers of medical tourists traveling overseas will impact on the source country's own health system, perhaps increasing trends that are encouraged by the current domestic private provision. For example, outflows of high-income patients from low- and middle-income countries will reduce revenue and dilute political pressure for investment in particular facilities and technology. Indeed, outflows of medical tourists for treatments that could be provided locally could signal a failure of policy and delivery in sender countries. There are suggestions that the target market for South Africa's breast cancer treatment is a growing pool of middle-class women drawn from across the African region with financial means, but who experience failed domestic policy. Regarding travel from higher income countries, if eligibility for services such as fertility or dental work is tightened, then those with private resources may choose to travel overseas to maintain access. The ability to circumvent waiting times raises issues of equity. However, travel overseas for treatments that are not provided or are illegal within the source country may normalize such treatments and generate debate about the importance of providing them locally (e.g., latest fertility treatments, gender reassignment, organ transplantation, or even euthanasia services).

In countries where Third Party insurers are exploring medical tourism as a provider option, outflows of patients

may benefit employers and employees contributing to health plans, and the public insurance system itself. Opportunities for financial benefit may be consolidated if medical tourism becomes an outsourcing option. For the US, research has estimated that 15 treatments would show savings of US$1.4 billion annually if one in ten US patients chose to undergo treatment abroad. Similarly, a recent study looking at possible bilateral medical tourism trade between the UK and India demonstrated substantial savings could accrue to the UK National Health Service from sending its patients to India, both financially and in alleviating waiting lists. If one takes the waiting lists for a selected number of procedures suitable for medical tourism, and compares the cost of sending those patients (plus an accompanying adult) to India, with the costs of getting treatment in the UK, the savings would be of £120 million. Some subsets of the population, such the Indian Diaspora, may prefer to go back 'home' for treatment, and may be happy to cross-subsidize some of the costs.

There are arguments that some medical systems are inefficient and face restrictive barriers to entry. A development such as medical tourism can potentially exert competitive pressure on systems importing health care and help drive down the costs and prices offered in domestic systems. Medical tourism may encourage economies to maximize their comparative advantage across labor costs, utilization of technology, and spare capacity. Indeed the US employers are said to be encouraging workers to travel domestically for medical care – a development prompted by deals struck with overseas providers being used as leverage. The possibility of medical tourism resulting in underused capacity in American hospitals has also been raised.

One of the implications of globalization is the increased flow of clinical and ancillary staff around the globe. Individuals may fully or part-train in their home country and move overseas to continue their training and gain experience with a particular specialism. Of major concern has been the flow from low to high income countries. Medical tourism may provide opportunities for professional migrants to return home – so-called 'reverse brain drain' or 'brain circulation.' This may be a disbenefit for developed countries which have long relied on such expertise to underpin their health system.

System Implications for Exporting Countries

The main exporting countries (those who provide the services to medical tourists) are located across all continents, including Latin America, Eastern Europe, Africa, and Asia. Countries have specialized in certain procedures. For instance, Thailand and India specialize in orthopedic and cardiac surgery (Boxes 3 and 4), Brazil is famous for cosmetic surgery (as outlined in Box 1), and Hungary (Box 2) and Poland are hotspots for dental surgery. As the US case illustrates, all countries may possibly be source and destination countries for medical tourists. However, here we frame low- and middle-income countries as the destination, and high-income countries as source. The magnitude of the possible effects being discussed is largely unknown – typically the potential or actual occurrence of these effects has been observed, but the scale of effect, and how this scale may differ between countries is an unknown quantity.

Economic Impacts

Delivering care to medical tourists will likely increase the level of direct foreign exchange earnings coming into a country and improve the balance of payments position. There are suggestions that Thailand benefits between US$1.5 and 2 billion from medical services and approximately US$0.5 billion from related tourism – overall total value added is 0.4% of gross domestic product. Income from foreign patients can be used within hospitals and national systems to cross-subsidize care for domestic patients, or could be used to help fund capital investment for use by all patients within the hospital or health system. Similarly, there are suggestions that the Cuban experience is to reinvest income from foreign patients into the national system for broader public good. International patients will have multiplier effects – a RAND study of Cleveland's metropolitan economy highlighted the economic benefits that the Cleveland Clinic added to the local economy.

Economic implications vary depending if international patients are simply using spare capacity or competing with domestic patients. For instance, the push by Thailand to be a hub for medical tourists in the 1990s was a result of the economic crisis in Asia generating a fall in domestic private patients and hence spare capacity in their private sector. In this case, increasing foreign patients entailed a net benefit to the private health system with substantial income and little real opportunity cost. However, where capacity has to be developed, there are substantial potential costs not only in financial terms but also in the wider context of concerns around equity, access, and human resources.

Although medical tourism generates income for the health sector (physicians hospitals, medications, and medical devices), general increases in tourist income (airfares, food, hotels, and souvenirs) are also important. There is a substantial level of expenditure by medical tourists, and their companions, that is not related to medical care. For example, it is estimated that companions would spend approximately twice as much on hotels and tourism as the patient. As discussed earlier, the promise of these earnings often drives the government involvement in investing directly or indirectly (tax incentives) in private hospitals and actively promoting medical tourism. Sectors other than medical care – especially those associated with hospitality and travel – may benefit to some degree from increased medical tourism, as will the government more centrally through increased taxation revenue. However, global business models and the involvement of Transnational Corporations may result in profits from medical tourism and ancillary activities being remitted overseas.

In many instances, medical tourists are either Diaspora or patients who have previously visited the country and are likely to visit again (an estimated 2.2% of foreign travelers and 10% of nonresident Indians visited India with the objective of health treatment). Thus, they are 'regular' visitors who on one trip incorporate an element of medical care. In this situation clearly the additional income generated by the 'medical' element of medical tourism is far more limited.

There are financial costs associated with promoting medical tourism – including upgraded infrastructure, both within the health sector (e.g., hospital facilities) and beyond (roads, airports, and telecommunications). There are also likely to be costs concerned with the appropriate staffing of facilities (including taxpayer's subsidized education and training), and possible accreditation schemes. For instance, 48 countries have been granted accreditation from the US-based JCI, the international arm of the Joint Commission, which accredits US hospitals. India has already sought and obtained JCI accreditation for 17 hospitals, and Thailand for 14. Other international accreditation bodies include the Australian Council for Healthcare Standards, the Canadian Council on Health Services, and QHA Trent Accreditation. However, there are costs associated with ensuring compliance with these various criteria, maintenance of these accreditations, and the processing costs themselves.

Trickle Down Benefits

There are arguments around 'trickle down' of best practice and technological diffusion as benefitting countries providing medical tourism. The increased ability to purchase the latest technology, for example, and treating foreign patients may broaden the case-mix for staff, or increase throughput to enable them to become more skilled. Medical tourism may be linked to temporary secondments to overseas facilities, which may lead to enhancement of human capital. Increased quality may result through ensuring compliance with (higher) international standards for care.

However, there is the possibility of resources being diverted from the domestic population and invested into private hospitals; such as driving investment toward urban tertiary care rather than rural primary care centers, which more appropriately reflect domestic population needs. It is argued that a number of young professionals are drawn to specialist facilities catering for medical tourists. The focus of resources on high technology orthopedic, dental, and reproductive care, rather than more basic public health measures to tackle infectious disease may be disadvantageous for the local population.

Human Resource Implications

There are arguments that medical tourism provides exporting countries the opportunity to attract back to their home country health workers who had emigrated, thus reversing the 'brain drain' of professional mobility. Hospitals treating medical tourists can offer higher salaries and wider opportunities more comparable with overseas institutions. International patients are more likely to trust doctors who have trained or practiced in their countries of origin, as well as ensuring that human resources are brought back to the country or are less persuaded to leave. The empirical veracity of this effect remains unclear however.

There are concerns that medical tourism will cause an internal brain drain, with health professionals abandoning the public health system to work for the hospitals that attract medical tourists, lured by better salaries and work opportunities. There are longer consultation times for foreigners – so generating additional demand for physicians (mostly specialists). Suggestions are that for India there is a shortage of 600 000 doctors, 1 million nurses, and 200 000 dental surgeons. Thus medical tourism would decrease the quality of the public health system and doctor-to-patient ratio. (Given that medical education in countries such as Thailand is heavily tax subsidized, the medical tourism market also presupposes state activity and investment.) As with other aspects of medical tourism, there is little empirical evidence of whether this is happening, and to what extent; and what there is unclear.

Two-Tier System

Do foreign patients benefit from sophisticated private hospitals with a high staff-to-patient ratio and expensive, state-of-the-art medical equipment, whereas the local population only has access to basic, under-resourced health facilities? Certainly there is the potential for medical tourism to have effects in terms of the distribution of health care resources for the less well-off local population. There have been various accusations that in some countries private sector medical tourists may be accumulating medical resources and taking health care services and personnel away from the local population and by driving up prices in the private sector. State regulation can mitigate impacts; however, there is potentially incoherence between trade and health policy that promotes both medical tourism and universal coverage.

Although private hospitals in India may have a responsibility under the Public Trust Act to provide free health care to the extent of 20% of resources, there are no checks undertaken to ensure that this occurs and others have suggested that Indian hospitals renege on promises to provide free health care. Nonetheless, as with much in this area, there is no strong evidence that medical tourism exacerbates a two-tier system.

Conclusion

Medical tourism for source countries may alleviate waiting lists and reduce health care costs, but there is a quality of care risk. The impact of medical tourism on health care systems is not well understood for destination countries: finance, delivery, organization, and regulation. Evidence is limited and there is a necessity to develop a robust empirical base on a number of these issues. In compiling data we must scrutinize sources and surveys used to provide numbers, including the role of national agencies and private facilities. Extrapolating from a country to a more global perspective is difficult, as is ensuring 'the count' is appropriate (do we count patients or treatment episodes; day treatments or in-stay treatment; expatriates and those funded by their multinational employers; only large and accredited providers?).

Beyond health policy and management there are also key legal and ethical issues for medical care abroad – informed consent, liability, and legislating for clinical malpractice. Choosing an overseas treatment center brings a number of challenges – difficulties in assessing comparative quality and

performance of alternative providers, differences in legal liability and knowledge concerning the processes of how to pursue complaints and receive redress. There are complexities regarding who or what could be subject to legal proceedings – product advertising, initial Internet consultation, a brokerage service, surgery itself, and various mixes therein – the jurisdiction of hearing any case, and the country's law that should govern any case.

Research and evaluation has not kept pace with the development of medical tourism. The lack of data is significant because countries face difficulties keeping fully informed about the significance (potential or actual) of medical tourism for their health systems. Mechanisms are needed that help us track the balance of trade around medical tourism on a regular basis. This would allow us to add to the evidence-base by assessing who benefits and loses out at the level of system, program, organization, and treatment.

Medicare

B Dowd, University of Minnesota, Minneapolis, MN, USA

What is Medicare?

The US Medicare program began in 1965 to address issues of access to care for three groups of Americans: the aged, the disabled, and people with end-stage renal disease (ESRD) or amyotrophic lateral sclerosis (ALS or Lou Gehrig's disease). (The Medicaid program, also begun in 1965, covers low-income Americans.) Enrollees in Medicare are referred to as beneficiaries. Some beneficiaries are eligible for both Medicare and Medicaid and are referred to as dually eligible beneficiaries.

Beneficiaries become aged eligible for Medicare at the age of 65 years. Those under the age of 65 years can qualify for Medicare if they are entitled to disability benefits under the Social Security Disability Insurance (SSDI) or Railroad Retirement. ESRD eligibility is open to Americans who have ESRD or ALS and who have met the required work credits for, or are receiving, Social Security or Railroad Retirement benefits, or are the spouse or dependent child of a person receiving those benefits.

The Medicare program is divided into four different 'Parts,' due largely to historical and political influences. Part A covers primarily hospital charges, but also home health, hospice care, and care in skilled nursing facilities. Part B covers primarily medical expenses (including many physician charges incurred during hospitalization). Part C covers the payment of private health plans in Medicare – originally referred to as Tax Equalization and Fiscal Responsibility (TEFRA) risk plans, then Medicare + Choice, and now Medicare Advantage (MA) plans. For many years, Medicare did not cover outpatient prescription drugs, except through some MA plans. That changed with the introduction of Medicare Part D in the 2003 Medicare Modernization Act (MMA) legislation. Part D coverage was first offered in 2006. Long-term nursing home stays are not covered by any part of Medicare.

The basic Medicare entitlement benefit package reflects health insurance coverage in the USA in 1965. In 2013, beneficiaries face a deductible of $1184 per hospital stay during a 'benefit period,' plus $296 per day for days 61 through 90, $592 per 'lifetime reserve day' over day 90 for each benefit period up to a maximum of 60 lifetime reserve days. Part D has a complex coverage structure that includes a coverage gap (referred to as a donut hole) that extends from total spending equal to $2970 to $6733.75 in 2013.

The entitlement benefit package, which reflects typical insurance benefits in 1965 when the program was established, has been criticized for its meager level of coverage. Medicare beneficiaries face the possibility of unlimited out-of-pocket expenses. As a result, approximately 90% of beneficiaries in fee-for-service (FFS) Medicare purchase private supplementary insurance or 'Medigap' policies that cover the coinsurance and deductibles for Medicare-covered services. These policies add to total Medicare costs because the effect of supplementary insurance is to reduce point-of-purchase cost sharing – in some cases to zero. The result is increased demand for services, and the Medicare program picks up approximately 80% of that additional cost, whereas the premiums for supplementary insurance reflect only the 20% paid by the supplementary insurer. Reform of the Medigap market is a topic of perennial policy interest, but there have been no substantial changes till date.

Although Medicare often is thought of as a 'public' insurance plan, its administration and delivery of services occur primarily through private health-care providers, health plans, and claims-processing firms under government contract. The traditional Medicare program contracts with private firms to pay health-care providers on a FFS basis and thus is referred to as FFS Medicare. Beneficiaries enrolled in MA plans are referred to as MA enrollees. Part D coverage is offered either through MA plans or by private stand-alone companies selling outpatient prescription drug coverage.

MA enrollees pay the same Part B premiums as beneficiaries in FFS Medicare, and MA plans receive a per-capita rate for each beneficiary they enroll. The level of capitation payment has been a source of controversy over the years. MA and Part D plan switching is limited to annual open enrollment periods.

How is the Medicare Program Financed?

There are two trust funds through which Medicare funds flow: the Hospital Insurance (HI) and Supplementary Medicare Insurance (SMI) trust funds. Part A expenses and the costs of program administration appear in the HI Trust Fund, whereas expenses for Parts B and D appear in the SMI Trust Fund. Administrative costs of running the Medicare program are represented in trust funds. The trust funds are administered by a Board of Trustees for Medicare that issues annual reports describing the state of the funds.

The trust funds are used solely for accounting purposes. Revenue and expenses do not actually flow through the trust funds. However, the HI Trust Fund balance is 'real' in the sense that Part A Medicare payments cannot be made if there are not adequate funds credited to the HI Trust Fund.

Part A is financed primarily through payroll taxes. The current payroll tax rate is 2.9%. Parts B and D are financed primarily through general taxes and beneficiary premiums. Beneficiary premiums are set at 25% of Part B and Part D costs. Part B premiums are means tested (increase with income) for beneficiaries whose incomes exceed $85 000 or $170 000 for a couple. The base-level monthly Part B premium in 2013 was $104.90 but rose to $335.70 for beneficiaries with incomes greater than $214 000, or couple with incomes greater than $428 000. The Part B deductible in 2013 was $147 per year.

Because Part A revenue is limited by the total level of taxable payroll income for the nation's workers, it is technically possible for the Part A trust fund to become insolvent. Parts B

and D have access to general tax revenue and thus they cannot become insolvent in the same sense as Part A, although increased Part B and Part D spending can limit other types of government spending. Thus, the most closely watched portion of the annual trustee report is the projected number of years until Part A payments will exceed the amount of money credited to the HI Trust Fund. That time span has varied from as little as 2 years in the early 1970s to the high 20s in early 2000s.

Since the introduction of capitated private health plans in the mid-1980s, payments to MA plans have been based roughly on a percentage of the cost of caring for beneficiaries in traditional FFS Medicare in the same county, adjusted for a set of risk factors. Because the average cost of caring for beneficiaries in FFS Medicare varies dramatically from one county to another, even when the counties are geographically proximate and after adjusting for the health risk of beneficiaries, government payments to MA plans also have varied dramatically.

MA plans must provide the entitlement benefit package, but are free to use any excess revenue to offer additional supplementary benefits to their enrollees. As a result, the amount of supplementary benefits offered by MA plans also varies dramatically from one county to another. In counties with low FFS spending levels, beneficiaries must pay an additional out-of-pocket premium above and beyond the Part B premium for the same benefits received for free by beneficiaries in counties with high FFS spending. The geographic disparity in government-financed benefits is a source concern due in part to issues of equity and in part to the lack of evidence that higher FFS spending is associated with either higher health risk or better health outcomes among FFS Medicare beneficiaries.

Expenditures and Cost Trends in Medicare

In 2010, approximately one-third of Medicare spending was for services covered only by Part A, whereas one-fifth was for services covered only by Part B. Payments to MA plans accounted for 23% of spending and Part D expenditures were approximately 11% of spending. Areas of particularly high growth in recent years have been home health-care and imaging services.

Cost concerns surfaced in the earliest days of the Medicare program. In 2012 Medicare's unfunded obligation over the next 75 years was $27.2 trillion. The US federal debt currently exceeds the US gross domestic product. As the mass of Americans born after World War II ('baby boomers') begin to reach the age of 65 years, the Medicare population will roughly double. Taxable income, particularly payroll income, will fall dramatically as the 'boomers' retire, as will the number of workers per Medicare beneficiary.

The geographic variation in FFS Medicare costs remains a controversial topic. Some analysts have found that much of the variation in cost is unrelated to either the health status or health outcomes of beneficiaries, whereas others find that sociodemographic characteristics explain a large proportion of the variation.

There have been several important responses to cost concerns over the life of the Medicare program. During the early 1980s, Medicare switched from cost-based reimbursement for inpatient care to a prospective rate per admission for Part A expenses. The Resource-Based Relative Value Scale introduced in the late 1980s was an attempt to reweight the fee schedule toward the work performed by primary care physicians.

Payments to providers and MA plans were reduced significantly in the Balanced Budget Act (BBA) of 1997, but some of the cuts were restored in subsequent legislation. The 1997 BBA legislation introduced the sustainable growth rate (SGR) legislation that mandated across-the-board reductions in physician fees if expenditures on physician fees grew too rapidly. Physician fees actually were cut by 5.4% in 2002, but since then, Congress has found ways to circumvent the mandated cuts. As a result, the SGR legislation now requires roughly a 30% cut in physician fees. A fee cut of that size likely would reduce physicians' willingness to see Medicare patients. Thus, each round of budget negotiations includes discussion of ways that the SGR 'problem' could be 'fixed.' Doing so, of course, would add to Medicare's projected unfunded deficit.

There was some hope in the 1980s that the introduction of capitated private plans would reduce the rate of cost growth in Medicare. Instead, paying MA plans a percentage of FFS Medicare costs, coupled with an inadequate risk adjustment system, resulted in private plans costing the program more money – a problem that continued through the 2000s, when private plans in low-cost areas were given supplementary payments in response to the geographic disparity in supplementary benefits offered by MA plans.

Options for cost reduction are more limited in FFS Medicare than in private health plans. FFS Medicare lacks the statutory authority to intervene in the patient care process, for example, by installing disease management programs except as demonstration experiments. Medicare does have an approval process for new technology, but continues to pay for many treatments that have been shown to provide no medical benefit to beneficiaries. Early attempts to design preferred provider systems in FFS Medicare – systems that featured varying coinsurance rates favoring lower cost or higher quality providers – were stymied by pervasive Medigap insurance that protected beneficiaries from the effect of coinsurance. Medigap also exacerbates FFS Medicare's cost problems by eliminating point-of-purchase cost sharing, thereby increasing the demand for services, and FFS Medicare pays approximately 80% of the cost of those additional services rather than having them reflected in Medigap premiums paid by beneficiaries.

The MMA of 2003 required an annual computation of the percentage of Medicare program revenues that come from general tax revenues. If that percentage was projected to be greater than 45% over the subsequent 7-year period, the Board of Trustees must issue a warning. If such a warning is issued for two consecutive years, the President must propose legislation to reduce the projected percentage to 45%. Although such warnings have been issued every year since 2007, Congress has taken no action.

Future Policy Options

Medicare faces daunting fiscal challenges in the coming years due to inefficiencies in the way the program is administered

and inadequate accumulation of revenue to cover the expenses of the mass of Americans who are beginning to become aged eligible for benefits. Medicare's unfunded obligation is an important part of the entitlement problem in the USA and a major contributor to long-run growth in the federal debt.

Current policy proposals cover the full range of revenue-increasing and cost-reducing options. Tax increases are a contentious alternative during a recession. However, the payroll tax was increased in January 2013, and further increases plus increases in beneficiary out-of-pocket premiums and cost sharing, as well as more aggressive means testing, remain viable but controversial options.

Cost-reducing options must operate through a reduction in the number of beneficiaries or the cost per beneficiary, which in turn is a function of the services delivered to each beneficiary times the unit prices of those services. One way to reduce the number of beneficiaries is to raise the age of eligibility. Current estimates suggest that the savings would be modest. Current legislation calls for significant reductions in provider fees or the rate of increase in provider fees. Hospitals will be penalized for excessive readmissions and hospital-acquired conditions. Payments to 'disproportionate share hospitals' will be cut, as will payments for graduate medical education. Official assessments of the fiscal health of the Medicare trust funds are required to assume that Congress and the administration will adhere to the laws that Congress has passed, even though few analysts actually believe that is the case.

Medicare fees currently average approximately 80% of fees paid by private insurers in the commercial (private) insurance market, whereas fees under the Medicaid program for low-income Americans typically are lower than Medicare fees. The 2010 Patient Protection and Affordable Care Act is estimated to add 33 million Americans to the ranks of the insured, and many of the newly insured will be purchasing private insurance. At the same time, there is no significant change to the supply of services by health-care professionals. Thus, a dramatic increase in the privately insured could result in severely reduced access for Medicaid beneficiaries, followed by difficulties for Medicare beneficiaries.

Although large across-the-board fee cuts in the Medicare program may prove infeasible, there are three other alternatives. The first is increased use of 'bundled payments'; for example, bundling postacute care into the prospective payment for hospital admissions is an approach to reduce excessive use of services. The implementation of prospective hospital payment into diagnosis-related groups adjusted for medical severity (MS-DRGs) provides an encouraging precedent. Of course, the ultimate 'bundle' is capitation payment, as implemented in the MA program. Accountable care organizations (ACOs) are another attempt to place providers at greater risk for the cost of care. One difficulty with the ACO approach in the traditional FFS Medicare program is that beneficiaries remain free to see any provider they like, despite the ACO provider being at some risk for the cost of their care.

A second alternative payment reform is competitive bidding for some health-care services. The Medicare program has had some demonstrated success with competitive bidding for durable medical equipment.

The third alternative is 'value-based purchasing.' The PPACA legislation requires the Medicare program to design value-based purchasing programs for hospital and physician services. Limiting fee increases to providers who meet certain cost and quality benchmarks could provide a way to reduce average fees without compromising access or quality. Assessment of physician quality may improve with full implementation of the Physician Quality Reporting System (PQRS) that allows physicians to report clinical outcomes such as the patient's blood pressure on a standard claims form. Participation in the PQRS system has been voluntary since its inception in mid-2007, and physicians were paid a bonus for participating. Beginning in 2015, however, nonparticipating physicians will face a financial penalty.

The PPACA legislation also establishes the Independent Payment Advisory Board (IPAB), a federal board charged with making recommendations to limit the growth in Medicare spending. Although IPAB has considerable power and discretion – either its recommendations must be implemented by the Department of Health and Human Services, or uHCongress must substitute equivalent cost saving – the scope of measures that it can recommend is severely limited. For example, it cannot recommend denial of care, or changes in eligibility standards, taxes, or beneficiary cost sharing.

There are numerous proposals that involve more basic restructuring of the Medicare program. Medicare beneficiaries currently are entitled to both a specific package of benefits (coverage) and the traditional FFS delivery system with out-of-pocket premiums limited to the national Part B premium, regardless of the actual level of FFS costs in their local market area. Conversely, MA enrollees face an additional out-of-pocket premium in areas with low FFS spending levels and subsequently low MA payment rates. One policy option is to retain the entitlement benefit package but to have both MA plans and FFS Medicare submit bids for that package and set the government's contribution to premiums equal to the lowest or second lowest bid in each county. That would mean that beneficiaries might have to pay an additional premium above and beyond the Part B premium for FFS Medicare, as they do now for MA plans in some market areas. In such a 'competitive pricing' or 'premium support' system, MA plans might have an advantage in areas where high FFS costs were due to inappropriate overuse of services that could be reduced through more aggressive selection of efficient providers or more careful management of care. However, FFS Medicare might have an advantage in areas with higher provider market concentration and subsequent market pricing power, if FFS Medicare's administratively determined fee levels were substantially lower than the prevailing rates charged to private insurers.

Although the list of policy options is broad, its ability to produce a significant reduction in Medicare spending per capita is limited by the resolve of elected officials to make difficult decisions. The history of congressional self-discipline through initiatives such as the SGR and '45 percent rule' is not encouraging. In fairness, however, congressional resolve is limited by the voter's preferences. The US Medicare program faces many of the same long-term challenges as government-provided benefits in other countries – a discrepancy between public demand for more generous benefits and the public's

willingness to pay for those benefits. The problem in the USA is exacerbated by the high unit prices paid by the government and the government's inability to control utilization. The result, to date, has a massive projected unfunded deficit that, in the absence of serious reform, will have to be paid by future generations, born and unborn, who are not able to vote on current policy.

Glossary

Dysregulation of mood An emotional response that is not within the conventionally accepted range of responses.
Perceived stress The degree to which general situations in life are judged by individuals to be stressful. This is in contrast with measures of the frequency or types of stressful events experienced by individuals.
Psychotic disorder A severe mental disorder that causes abnormal thinking and perceptions. Symptoms include delusions and hallucinations.
Unipolar depressive disorder A mental disorder characterized by episodes of low mood with a loss of interest or pleasure in normally enjoyable activities.

Introduction

Mental illness is a common occurrence. Epidemiological evidence reveals that mental disorders are prevalent across more- and less-economically developed countries (WHO World Mental Health Consortium, 2004), and some mental health problems have been understood as being an illness since the time of Hippocrates. Mental disorders are known to have major consequences for longevity, quality of life, and productivity. For instance, the World Health Organization estimates that unipolar depressive disorders account for the third-largest share of lost disability-adjusted life years worldwide. There is a growing recognition that mental health disorders are also associated with reduced life expectancy. Recent estimates from the US suggest that 26% of nonelderly adults experienced a diagnosable mental disorder in the past 12 months (Kessler *et al.*, 2005a). In the US, individuals with a mental health disorder die on average approximately 8 years younger than individuals with no mental health disorder, and 95% of these deaths were from internal causes (i.e., cardiovascular disease, cancer, pulmonary disease). Less than 5% of deaths were from external causes of suicide, homicide, or accidents, similar to the rate in the population reporting no mental health disorder.

A comprehensive multidisciplinary overview of the determinants of mental health, including genetic and other neurological bases for disease, is covered in the landmark Surgeon General's report on mental health (US DHHS, 1999). Although the authors briefly review some of these concepts, their focus in this article is on the contributions of economists to this literature.

Mental illness includes a broad range of specific disorders, which are distinct from many physical health disorders in that there is no definitive diagnostic test for mental illness. Rather, mental illness is defined by the existence and severity of a set of symptoms that may include inappropriate anxiety, disturbances of thought and perception, dysregulation of mood, and cognitive dysfunction. The authors briefly review some of the more common and prominent examples of mental illness.

Anxiety disorders (including phobias, panic attacks, and generalized anxiety) are characterized by an individual's anxiety responses to a given situation substantially exceeding what is emotionally and/or physiologically appropriate. Psychotic disorders (such as schizophrenia) involve serious disruptions of perception and thought process, which manifest in symptoms of hallucination, delusion, disorganized thoughts, flat affect, and inability to think abstractly. Mood disorders include depression, which is characterized by persistent symptom of sadness that is often associated with physical symptoms of insomnia, decreased appetite, and low-energy, and bipolar disorder, which is characterized by extreme fluctuation between depressed mood and elated mood. Impulse-control disorders include attention-deficit and hyperactivity disorder, and are frequently associated with childhood and adolescence. Cognitive disorders affect the ability to organize, process, and recall information. Perhaps the most prominent example is Alzheimer's disease which is progressive and generally is associated with aging (often more so than with broader mental illness).

There is an important difference between mental illnesses such as schizophrenia, where there is a clear binary categorization of having versus not having the disease; from other types of mental disorders such as depression, anxiety, or attention-deficit disorder, where the symptoms lie along a continuum from manageable and self-limiting to profoundly and persistently disabling. Analogous physical health conditions are, respectively, cancer, where there is a clear difference between people with and without the disease, and back pain, where many people experience symptoms, but only relatively few have their functioning disrupted by those symptoms. Nevertheless, all categories of mental disorders include conditions that range in severity, from relatively mild to profoundly severe.

Some view mental health status and happiness as lying along a common continuum. This article treats mental illness as a disease. This conceptual distinction is especially important in the context of studying economic issues in mental illness, as the idea of happiness is closely linked with the notion of utility that underlies classical consumer theory. This distinction is made clear by explicitly considering the idea of a mental health production function.

The pioneering work on health production functions (Grossman, 1972) was formulated from the perspective of physical health conditions but one needs to consider how it

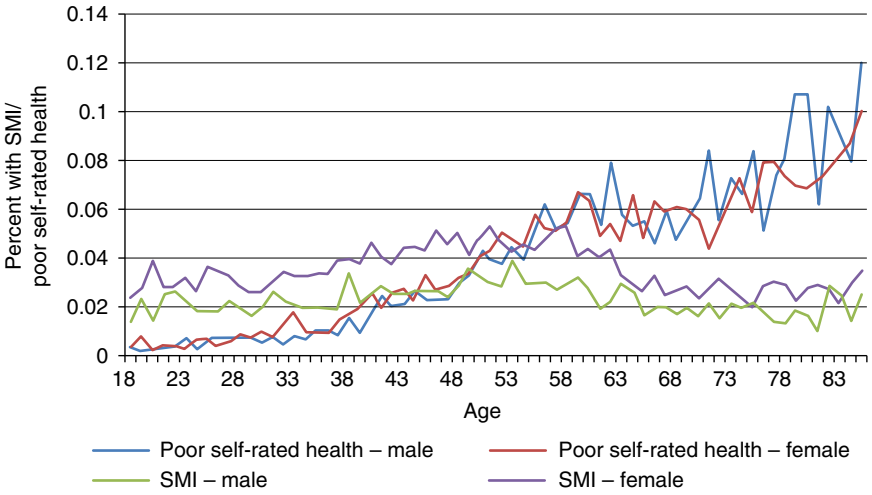

Figure 1 Percent with SMI/poor self-rated health, by age and gender. National Health Interview Survey, 2000–09. SMI determined by K6 score.

can be applied to mental health. Individuals are posited to have been born with an initial endowment of health capital. Health capital is a durable capital stock with two types of value: as a consumption good, where good health directly improves current utility, and an investment good, where health status affects other economic activity (such as employment). The stock of health capital at a point in time is determined by the stock of health capital at the previous point in time, health investments (including both behaviors and medical care), random shocks, and a depreciation term.

Physical health and mental health share some similarities in the context of this model, yet have some differences. Similar to the case of physical health, there is evidence of heterogeneity in initial endowment of mental health. For example, economists are beginning to contribute to an existing body of psychology and neuroscience research on the effects of stress *in utero*. Research finds that stressful conditions during pregnancy (particularly the first trimester) lead to significant increases in subsequent mental health problems. One study finds that maternal stress during pregnancy doubles the risk of schizophrenia in offspring (Malaspina *et al.*, 2008). In addition, similar to physical health, a range of treatment technologies exist which can improve mental health status between time periods.

Nevertheless, mental health contrasts in some important ways from physical health in the context of this model. The notion of intertemporal depreciation does not fit neatly with mental health. The Grossman model assumes that health depreciates at an increasing rate with age. This assumption fits the data fairly well for the case of physical health, as illustrated in Figure 1 (measured here as the proportion of the population reporting poor self-rated health). However, mental health (measured here as the proportion of the population with severe mental distress) exhibits a relatively flat, inverse U-shaped pattern in age, consistent with epidemiological studies that find that most mental illnesses first occur early in life. On average mental health depreciates only moderately until the mid-50s, and then improves moderately at older ages.

Another way that mental health departs from the classic health capital model is in the type of health investment inputs. Similar to general health, health care can affect mental health in ways that are broadly similar to physical health with many evidence-based treatments available. For example, pharmaceutical treatments can improve symptoms of anxiety, major depression, and schizophrenia as well as other mental health disorders. Brief psychotherapy is also effective in treating acute cases, as well as extending periods of remission. Also, like general health conditions, health behaviors (e.g., exercise) can affect mental health. Yet, it is believed that psychosocial stress plays a relatively larger role in the production of mental health than of physical health. Psychosocial stress has been studied extensively by research in psychology and sociology, and a review of this literature is outside of the scope of this article. But in brief, these fields have produced striking evidence on the effects of psychosocial stress on mental disorders, and have identified moderators and mediators of this relationship. More recently, some sources of psychosocial stress have been studied by economists, as described below in section Employment.

Finally, it is noteworthy that any economic model of health status that is derived from classical consumer theory is faced with the challenge that in many cases, mental illness represents a break from 'rational' behavior. Indeed, the departure from an individual's normal capacity for decision making (e.g., the compromised perception and thought processing that are common in psychosis) and changes to an individual's preferences (e.g., not caring about the future is a symptom of major depressive disorder and can be interpreted by an economist as a change to one's discount rate) are hallmarks of mental illness and can violate the axioms of expected utility theory.

Economists have focused most of their interest on three specific (related) determinants of mental health: income, labor market participation, and macroeconomic conditions. In the rest of this article the authors discuss findings related to these inputs. Like other health disorders, although risk factors have been documented, much of the heterogeneity in mental health disorders and outcomes remains unexplained.

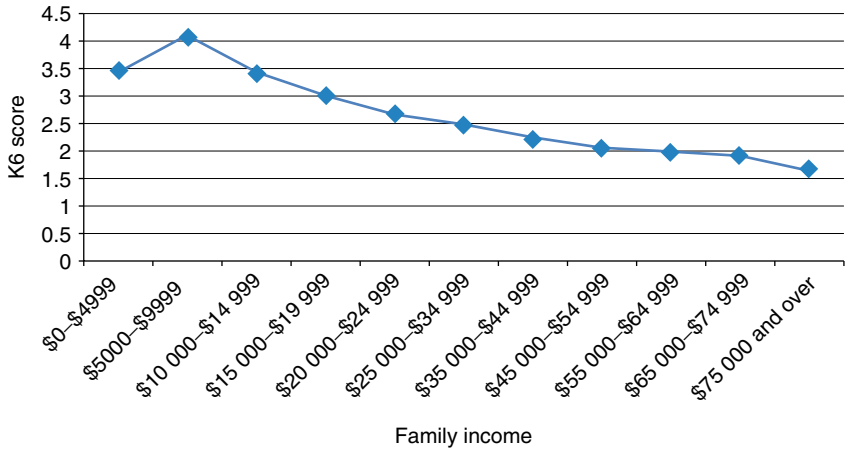

Figure 2 K6 scores, by income. National Health Interview Survey, 2000–06.

Income

Disentangling the effects of income on mental health from the reverse effect is difficult because mental health disorders, like other health conditions, are also likely to have a direct effect on income through labor market outcomes, and perhaps household formation. **Figure 2** uses data from the National Health Interview Survey to examine the correlation between mental health (measured by K6 score) and household income in the US. This figure illustrates the strong correlation between income and mental health. However, epidemiological evidence suggests that although the within country correlation between income and mental health is strong, there is a weaker correlation between income and mental health across countries and some evidence suggests a higher prevalence of mental disorders in higher-income countries. Evidence from quasi-natural experiments and randomized experiments suggests a causal relationship with income having a direct effect on mental health. Evans and Garthwaite (2010) examine the effects of the US Earned Income Tax Credit (EITC) expansions on maternal mental health. Comparing low-income mothers with two children, who received substantially more in benefits, with mothers with one child, they find that mothers with two children had significantly fewer days with poor mental health over the previous 30 days. In Canada, Milligan and Stabile (2011) find strong evidence that additional income through child benefits has significant positive effects on maternal mental health and children's mental health. Although these studies suggest an effect, one cannot necessarily extrapolate these findings to other populations, including populations with higher incomes.

Case (2004) finds that members of South African households that include a pensioner are less depressed than members of other households, again suggesting a causal effect of income on mental health. Fernald *et al.* (2008) find that the effect of giving loans to previously rejected applicants reduced depressive symptoms in men, despite increased perceived stress.

Economic theory has also been applied to suicide, leading to the prediction that as with mental health in general, suicide will decrease with permanent income (Hammermesh and Soss, 1974) and population-level data on suicide rates are generally consistent with that prediction. Recent work suggests that relative income may affect suicide risk. For example, Daly *et al.* (2012) finds that, holding own income constant, a 10% increase in county income was associated with a 4.5% increase in suicide hazard, suggesting that lower social status increases suicide risk.

Macroeconomic Conditions

A consistent finding from the economic literature on macroeconomic effects on health is that physical health is countercyclical, which is commonly explained by individuals investing greater time in physical-health promoting activities when the opportunity costs of time are lower. Interestingly, the relationship between macroeconomic conditions and mental health appears to be procyclical. The research literature uses unemployment rates (measured at various level of aggregation) as a measure of local macroeconomic conditions. In periods of higher unemployment levels of suicides, various measures of mental distress, and other disabling mental disorders increase, even though measures of physical health (i.e., acute health conditions and disability) improve. For example, Ruhm (2003) finds that a 1% increase in unemployment was associated with a 7.3% decline in nonpsychotic mental disorders. Economists find that Google searches for mental health-related terms increase with unemployment rates, providing further, novel evidence of the procyclicality of mental health. Less is known about how and why macroeconomic conditions affect mental health. Three nonmutually exclusive hypotheses are that poor macroeconomic conditions reduce individuals' mental health by reducing income, by increasing rates of job loss, and by increasing overall levels of psychosocial stress.

Employment

The direct and indirect effects of unemployment on mental health have been compared with large and significant direct

effects found. Although the direct effects of unemployment are much greater than indirect effects, when measuring the consequences of unemployment at a population level, Helliwell and Huang (2011) find that the indirect effects dominate because a much larger population is affected. This work suggests the nonpecuniary effects of being unemployed on mental health are 5.5 times greater than the effects due to loss of income. They also find that higher unemployment benefits (as measured by the benefits replacement rate) do not mitigate the effect of unemployment on mental health. On the other hand, Salm (2009) examines exogenous involuntary job loss, as measured by business closures, and finds little evidence of an effect of job loss on the mental health outcomes studied.

Others have looked specifically at the effect of retirement on mental health outcomes. Dave *et al.* (2008) find significant negative effects of retirement on mental health. Again, they find that income is not the dominant mechanism by which retirement affects mental health. They explore the mechanisms for this effect and find evidence for the importance of declines in social interactions and physical activity.

Can public programs alleviate life events that affect mental health? Economic studies have failed to find significant effects of declining US welfare caseloads on maternal mental health; though there is some evidence that length of maternity leave may affect the severity of depression. Kling *et al.* (2007) examined the effect of being offered housing vouchers on health. They find being randomly assigned to receive a housing voucher did lead to lower poverty rates and residence in safer neighborhoods 4–7 years postrandom assignment. Although no significant effects were found on adult physical health outcomes, large positive effects on adult mental health outcomes were found, with a 45% reduction in relative risk of serious mental illness.

The existing literature on determinants of mental health finds that psychosocial stress negatively affects mental health, and that important psychosocial stressors can emerge from individual and societal economic conditions. Experimental research, including animal studies, identifies the causal effect of psychosocial stress on mental health in controlled laboratory settings. Observational research links individual and societal economic conditions to levels of stress, and correlates stress with mental health without identifying a causal effect of stress, per se. Economists have recently bridged the gap between these two broad areas of research by applying the tools of empirical microeconomics to the study of mental health outcomes. This economic research generally suggests that individual and societal economic conditions do affect mental health, in some cases substantially. Yet, few evaluations of policies to affect economic conditions consider these effects when evaluating the costs and benefits of programs. Generally, existing literature suggests including mental health as an outcome measure in these evaluations is likely to increase the benefits of these policies.

Mergers and Alliances in the Biopharmaceuticals Industry

H Grabowski, Duke University, Durham, NC, USA
M Kyle, Toulouse School of Economics, Toulouse, France, and Center for Economic Policy Research, Toulouse, France

Introduction

Over the past few decades, the pharmaceutical industry has been characterized by both significant consolidation of large pharma firms as well as the vertical disintegration of the R&D process. The latter is associated with considerable entry into the discovery and development process by early-stage biopharmaceutical firms. Since the early 1990s, an evolving marketplace for new technologies through licensing agreements and joint ventures has emerged, accompanied by the growth of contract research organizations that specialize in implementing clinical trials for new drug candidates.

To put some of these changes in historical perspective, it is useful to chronicle some of the key dynamic forces affecting the pharmaceutical industry. The prevailing company structure that dominated the industry from the end of World War II through the 1980s was the large, vertically integrated multinational firm with R&D laboratories, production facilities, and marketing departments. These firms generally financed their R&D investment through internally generated funds, emphasized growth through company-developed pipelines (Grabowski, 2012; Scherer, 2010). Although entry from new start-ups began in earnest in the 1970s, most drug products associated with new technologies such as recombinant technology were in the early stages of development and years away from reaching the market.

Although the 1980s was a period of rising prices and profits for the industry, integrated multinational drug firms also faced many challenging developments. These changes included rising R&D costs (DiMasi *et al.*, 1991, 2003), the expiration of patents on major commercial products, and the beginning of intensive price competition from generics. The passage of the Waxman-Hatch Act in 1984 was a key legislative change that substantially reduced entry costs for generic firms. Generics may now enter the market by demonstrating only bioequivalence, and can rely on the clinical data provided by the originator to show safety and efficacy (Grabowski, 2007). These dynamic forces intensified in the 1990s with the rise of buyer-side market power in the form of managed care organizations and pharmacy benefit managers in the USA, and increasingly stringent price controls in other major world markets. Market and political pressures have caused declining growth in sales and profits that have been particularly evident on an industry-wide basis since the mid-1990s.

There has been increasing attention over recent years to whether the pharmaceutical industry is now in an R&D productivity crisis. Several observers have pointed to a pattern of rising R&D expenditures accompanied by a declining trend in new molecular entities since the mid-1990s. The productivity crisis idea is subject to various qualifications relating to the quality of new molecular entities, the long lags that characterize the R&D process in pharmaceuticals, and a gradual shift to a new R&D paradigm based more on biology than chemistry (Cockburn, 2006). Nevertheless, the declining trend in new products from the R&D labs, along with continuing patent expirations on prior 'blockbuster' products, has created a replacement problem for many large pharma firms.

Large-Scale Mergers

The structural response to these dynamic forces has included both large horizontal mergers as well as a growing number of development-stage agreements between large pharma firms and smaller, research-based biopharmaceutical firms. The first merger wave began in 1989–90. The annual value of pharmaceutical mergers in these two years exceeded that of any prior year in the 1980s by a considerable margin (Ravenscroft and Long, 2000). This was followed by an even larger merger wave beginning in the mid-1990s and continuing into the 2000s (Danzon *et al.*, 2007; Koenig and Mezick, 2004). After a lull of several years, two large-scale merger deals were consummated in 2009 (Pfizer–Wyeth and Merck–Schering). Combinations have included not only mergers between large pharma firms, but also the acquisitions of biotech firms by pharma firms and mergers between firms of different sizes in the emerging biotech sector.

Table 1 shows how the global market shares in the pharmaceutical industry have changed between 1989 and 2009. It shows the global market shares of the top 18 ranked

Table 1 Global shares and mergers in pharmaceuticals, 1989–2009

Rank	*2009*		*1989*	
	Company	*Share (%)*	*Company*	*Share (%)*
1	Pfizer	7.6	Merck	4.0
2	Merck	5.2	BMS	3.5
3	Novartis	5.1	Glaxo	3.1
4	Sanofi-Aventis	4.7	SKB	3.0
5	GlaxoSmithKline	4.7	Ciba-Geigy	2.9
6	AstraZeneca	4.6	AHP	2.7
7	Roche	4.4	Hoechst	2.4
8	J&J	3.6	J&J	2.3
9	Lilly	2.7	Bayer	2.3
10	Abbott	2.6	Sandoz	2.1
11	Teva	2.1	Lilly	2.1
12	Bayer	2.1	Pfizer	2.0
13	Boehinger Ing	2.0	Roche	1.9
14	Amgen	2.0	Schering-Plough	1.6
15	Takeda	1.9	MMD	1.6
16	BMS	1.9	Upjohn	1.5
17	Daiichi Sankyo	1.2	Boehringer Ingel	1.5
18	Novo Nordisk	1.1	Warner Lambert	1.4

firms by sales in 1989 and 2009. All of the eight top-ranked firms in 2009 engaged in large-scale mergers as well as many small-scale acquisitions over this 20-year period. Correspondingly, several of the leading firms in 1989 have been consolidated into larger entities. The firms with asterisks beside their names in 1989 have all been acquired by, or merged into, larger surviving entities.

The top ranking firm in 2009, Pfizer, completed three major mergers over this period (involving Warner Lambert, Pharmacia-Upjohn, and Wyeth). Other top-ranked firms consummating large-scale mergers over this period include GlaxoSmithKline (merging Glaxo, Burroughs Wellcome, and SmithKline-Beecham), Sanofi-Aventis (merging Hoechst, Marion Merrell Dow, Aventis, Rhone-Polenc, and Sanofi-Synthelabs), Novartis (merging Ciba-Geigy and Sandoz), and Roche (merging Syntex and Genentech).

Some of the prominent mergers in the earlier merger waves involved cross-border mergers (e.g., Pharmacia-Upjohn, AstraZeneca, and SmithKline-Beecham). Cross-border mergers exhibited positive gains in market valuation in the event studies conducted by Ravenscroft and Long (2000). International integration of pharmaceutical activities provide benefits by allowing firms to obtain faster global uptake of new drugs in the growth phase of the pharmaceutical life cycle, and coordinating firm strategies on a multinational basis. At the same time, integrating disparate corporate cultures and headquarters can lead to substantial challenges and implementation costs (Belcher and Nail, 2000). Nevertheless, mergers have been an important factor contributing to a multinational business structure and strategic approach in pharmaceuticals. Many of the firms that were regional in nature in 1989 are now part of larger enterprises with global R&D, manufacturing, and marketing capabilities.

The share of global sales of the top 18 firms increased to 59% by 2009, compared with 41% in 1989. Despite the merger activity and increased concentration, the pharmaceutical industry is still relatively unconcentrated compared with many other industry sectors. Antitrust authorities have rarely raised concerns about the potential for increased market power, only occasionally requiring the divestiture of some product lines. Changes in company rankings also occur over time as a result of both new product introductions and patent expirations. This is reflected by the rapid growth of dedicated biotech firms like Amgen and Genentech (now part of Roche). In addition, firms whose dominant business is generics, such as Teva, have grown to a sizeable presence, reflecting the increased utilization of generic drug products over these two decades as well as their entry into specialty branded products.

Figure 1 depicts the number of mergers or acquisitions and the average deal size over the period 1990–2011. This chart is based on data from Recombinant Capital. Since 1990, there has been a dramatic upward trend in the number of reported mergers in the pharmaceutical industry, consistent with the consolidation observed in Table 1. However, there is a decline in the number of deals since 2007, reflecting in part the downturn of overall global economic activity. The average deal size line shows considerable volatility with peaks around periods of large-scale horizontal merger activity. At the same time, however, there has been a downward trend in average deal size since 2004, reflecting an apparent move away from 'mega-mergers' and toward more acquisitions of development-stage firms by pharma firms and mergers between smaller biotech firms.

Alliances

The pharmaceutical industry has made extensive use of 'markets for technology' since the late 1970s. The term refers to the licensing of ideas or technology platforms, R&D alliances, or joint ventures between firms. Markets for technology allow a vertical disintegration of the product development process, with some firms specializing in early-stage work and others in the execution of clinical trials, preparation of regulatory dossiers, and marketing. These relationships, which is generally referred to as alliances, can be a substitute for mergers and

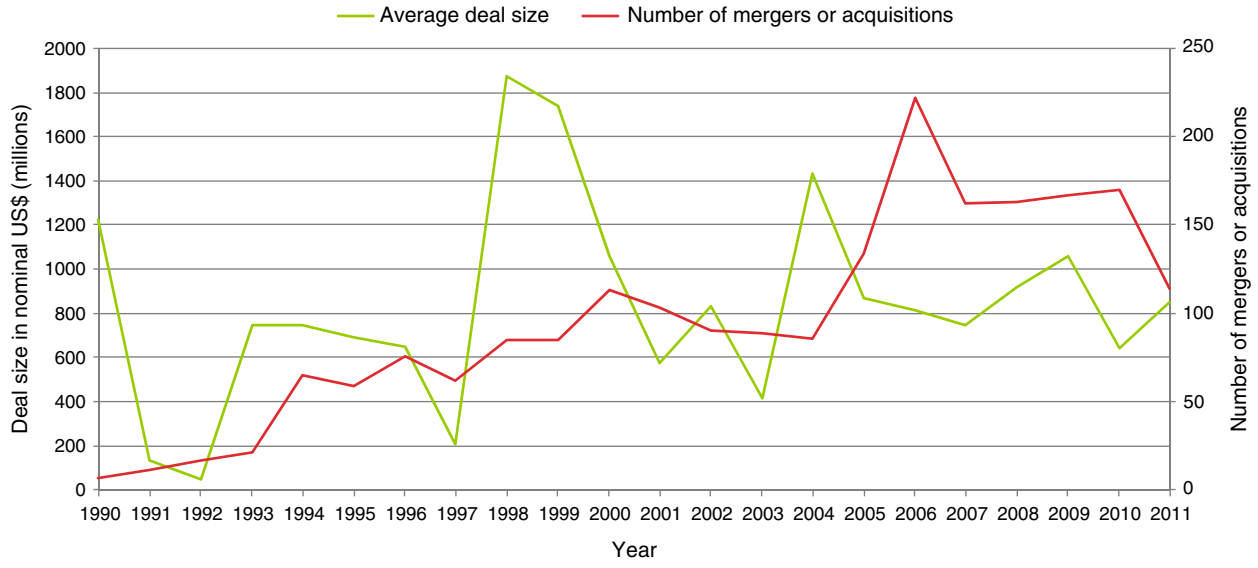

Figure 1 Merger activity and size.

acquisitions: that is, they may be a more efficient alternative to the vertical integration resulting from a merger or acquisition. However, they can also be a form of extended due-diligence during which the firms learn about whether a future merger or acquisition between partners would be desirable. A prototypical development-stage agreement would involve payments of milestones and/or royalties and some sharing of R&D expenses in the exchange for rights to develop and/or market the new products covered under the agreement. The extent of integration at the R&D stage associated with these agreements varies considerably, ranging from true joint development agreements, to transfers of development-stage products from licensors to licensees, to marketing options in exchange for development-stage funding and future payments.

Although large, horizontal-style mergers have tended to occur in waves, there has been a steady upward trend in the number and values of R&D stage alliances in the pharmaceutical industry between the mid-1990s and the onset of the global recession in 2008. During this period, the number of such alliances with market valuations of $100 million or more increased several fold in value (Recombinant Capital, 2008). With the onset of the global recession in 2007–08, however, the number of collaborative R&D deals has moderated, with a downward trend in average deal value. This downward trend reversed in 2011, perhaps signaling a return to growth in the annual number of deals and values (Cartwright, 2012).

For a subset of licensing deals, Recombinant Capital has access to the contracts themselves. Because this information is reported for only a subset of deals, it may not be representative. **Figure 2** presents a summary of how contract terms have evolved over the past two decades. There has been a pronounced increase in milestone payments relative to other deal terms, such as upfront fees and equity positions. The preference for milestone payments over upfront fees likely reflects 'lemons problem' concern; partners prefer to see results before they pay. However, the ability of R&D firms to accept these terms indicates that their financial position is more secure and they are less desperate for cash from partners.

Figure 3 shows a shift toward licensing later in the development process. Because there is a much larger set of projects available for license at early stages (the high failure rates significantly reduce the number of projects that survive until Phase II or III), most deals are in the development or preclinical stage. But by 2011, almost half of the deals were Phase I or later, and the share of Phase III or later was more than 20%. Again, this trend is consistent with both the desire to avoid financing a lemon as well as reduced financial constraints for R&D firms, who are capable of financing development through more stages than in earlier years.

The geographic coverage of licenses has been more limited recently, as is shown in **Figure 4**. This figure corresponds to the reach of licensor rights as assigned in the agreement. The 'worldwide' category includes licenses that have no geographic restriction; the remaining categories refer to the specific geographic region for which the licensor has rights. The trend toward more restricted geographic coverage is somewhat surprising, given the prevalence of multinationals with a presence in most markets and the global nature of research. It may reflect a move toward licensing arrangements whose primary focus is marketing, rather than R&D. However, it points to the continued salience of country-specific knowledge and capabilities within firms.

In the next section of the article, the motives for pharmaceutical mergers and related empirical studies on the determinants of M&A activity are considered. Section 'The Effects of Pharmaceutical Mergers and Alliances' summarizes evidence concerning the effects of mergers and alliances on different outcome measures including R&D productivity and innovation. Section 'Policy Issues' discusses current policy issues involving mergers and alliances. The final section

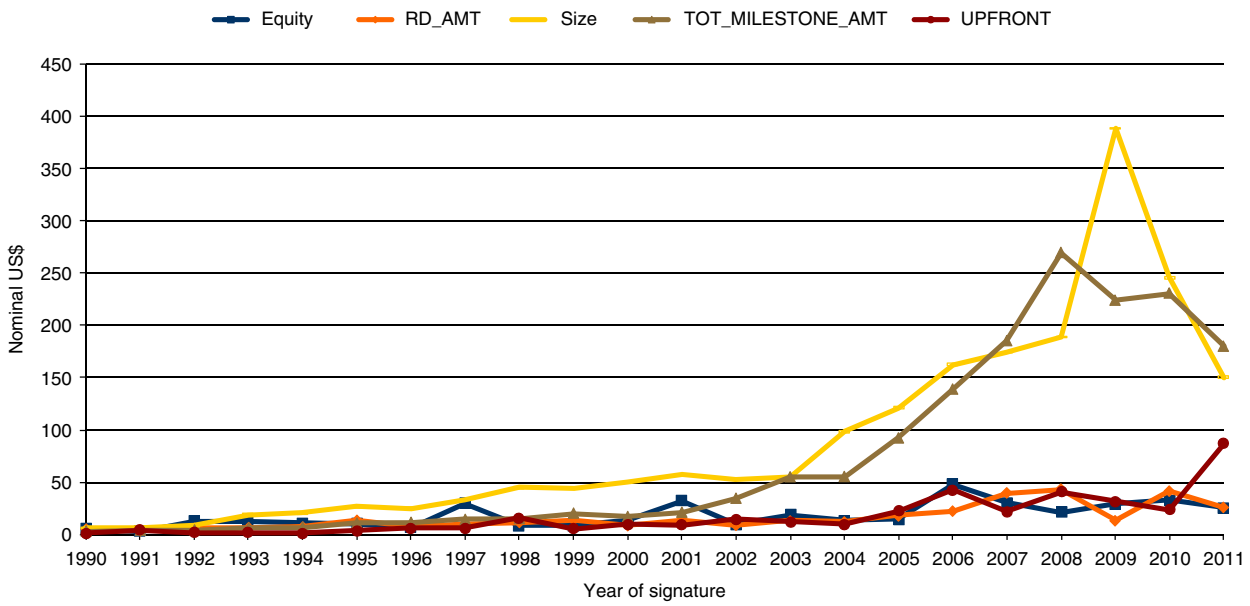

Figure 2 Average deal terms of licenses.

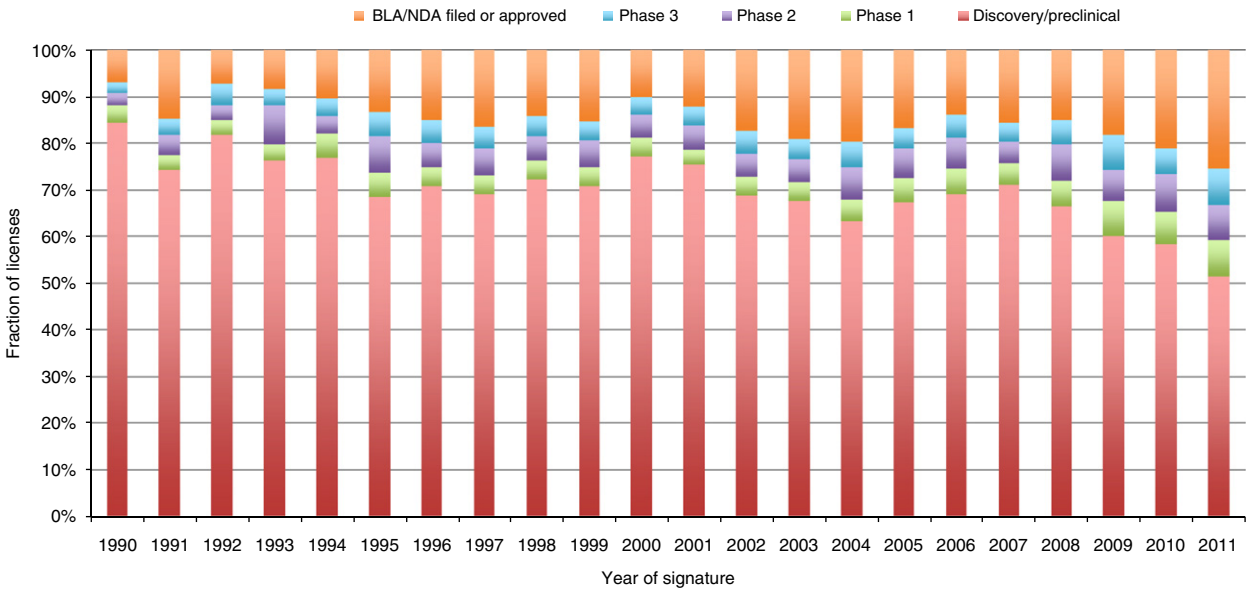

Figure 3 Licenses by stage of development.

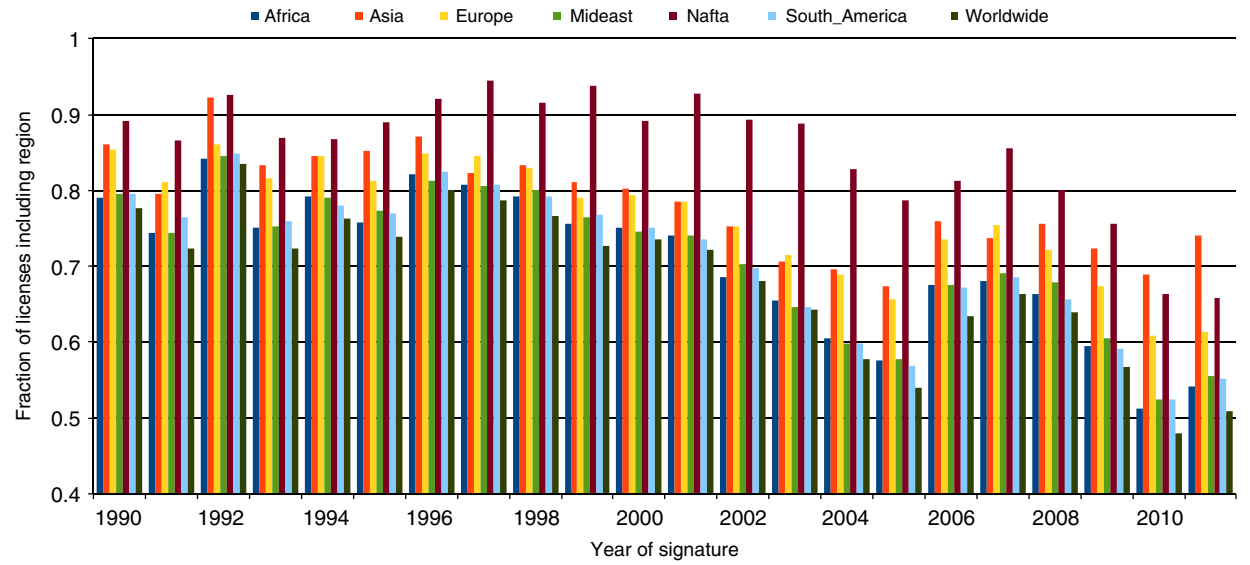

Figure 4 Regional coverage of licenses.

provides some concluding observations and interesting questions for future research.

Determinants of Mergers, Acquisitions, and Alliances

The motives for merger and acquisitions (M&As) activity can be broadly categorized into adaptive or defensive rationales versus proactive or offensive ones (Burns *et al.*, 2005). In this section, this classification is utilized to consider the economic drivers of M&As in the pharmaceutical industry. It is important to understand the rationales for mergers before attempting to evaluate studies that are focused on the effects of mergers. The role of alliances as a substitute or a complement to M&A activity is also considered.

Defensive Motives: Strategic Response to Environmental Change

The hypothesis that industry-wide shocks can precipitate merger waves appears to be a useful concept in understanding pharmaceutical mergers. The original hypothesis goes back to Gort (1969). Industry-wide shocks appear to explain merger waves in other industries like banking and telecommunications in the 1990s (Andrade *et al.*, 2001). In the case of

pharmaceuticals, the economic environment became more difficult and pipeline gaps emerged throughout the industry by the late 1980s. With stock prices under pressure, many affected drug firms were motivated to use their accumulated cash flows to acquire another firm's products and pipeline. The bidder often could pay the premium associated with these acquisitions by consolidating operations and cutting out the excessive infrastructure capacity. Various researchers have made the point that mergers and acquisitions facilitate disruptive organizational change that would otherwise meet with substantial internal inertia and resistance (Ravenscroft and Long, 2000). However, mergers are also associated with substantial integration costs that can affect the productivity of the firm in the postmerger period (Larson and Finkelstein, 1999).

Ravenscroft and Long (2000) performed one of the first analyses of pharmaceutical mergers. Their analysis covered mergers of significant value undertaken between 1985 and 1996. Using event study methodology, Ravenscraft and Long found that the large horizontal mergers and cross-border mergers created gains in overall stock market value. As in other industry studies, however, target firms captured most of the returns. Their findings are consistent with the response to the industry shocks, excessive capacity hypothesis. Their analysis of cost-cutting for large horizontal pharmaceutical mergers found a reduction in total headcount in the postmerger period ranging from 8% to 20% of the combined workforce in the premerger period. Although cost-cutting in manufacturing and marketing personnel were proportionately greater than for R&D employees, there also was a consolidation of R&D laboratories and the elimination of marginal R&D projects by several firms.

A subsequent analysis by Centerwatch of 11 large mergers (22 pharmaceutical companies) that occurred between 1989 and 1998 reported a 34% average reduction in development projects three years after the merger was consummated (Centerwatch, 2000). Neither the Centerwatch study nor Ravenscraft and Long's analysis, however, examined subsequent effects on the firms' R&D productivity or the probability of success. To the extent that these reductions in R&D activities eliminated duplicate efforts or projects with low probability of success, or facilitated more external alliances, the companies' R&D performance could have increased in the postmerger period compared with premerger one. This issue is considered further below.

Other researchers also find evidence that firms under economic stress are more likely to engage in mergers. An oft-cited firm-specific motivation for pharmaceutical M&As is to fill in gaps in a company's pipeline to maintain growth in the face of a major product's patent expirations. Patent expirations on major projects can produce rapid losses in unit sales to generic entrants and leave firms with substantial excess capacity in their marketing and sales forces. Pharmaceutical products exhibit a highly skewed distribution of revenues and returns (Grabowski *et al.*, 2002).

Two published studies have investigated this hypothesis and found that pipeline gaps and issues continue to be a key driver of merger activity. A study of 202 biotechnology and pharmaceutical mergers between 1998 and 2001 found that pharmaceutical firms that have a relatively old portfolio of marketed drugs exhibit a higher propensity to acquire another firm (Danzon *et al.*, 2007). A second study of 160 pharmaceutical mergers between 1994 and 2001 found that firms with lower scores in the strength of their R&D pipeline and fewer years of exclusivity on their marketed drugs had a greater probability of engaging in a merger (Higgins and Rodriguez, 2006).

The fact that firms in economic stress are more likely to engage in mergers creates methodological issues in evaluating pharmaceutical merger activity. In particular, one cannot simply compare merging entities to overall industry performance. Rather, it is important to construct control groups with similar firm characteristics in evaluating the effects of a merger. This issue is considered further below.

Economies of Scale and Scope

Proactive motives for mergers include increases in size to achieve critical mass and economies of scale in R&D and other firm activities. A series of papers by Cockburn and Henderson (1996, 2001) focuses on economies of scale and scope in drug R&D provides some insight on the effects of increased size on R&D productivity. They looked for the effect of scale and scope on productivity at a research program level, for 10 large firms. The advantage to these papers is that they use extremely detailed data (including program-level R&D spending) over a very long time period. They conclude that firms engaged in a broader scope of research activities are more productive than focused firms, but that scale does not matter much once the scope is controlled for. A more recent study by Danzon *et al.* (2005) finds benefits from a company's development experience as measured by the number of drugs in clinical trials, but these benefits are also subject to diminishing returns. In particular, this study finds the maximum performance measured in terms of success probabilities at different stages of the clinical development process occurs at 25 drugs in development. This is far below the number of drugs in development for the major firms listed in **Table 1**. This study is discussed further in terms of the effects of alliances on R&D productivity.

As a result of the consolidation that has occurred over the past few decades, some of the leading pharmaceutical firms now have annual R&D budgets of over several billion dollars to manage. At this size, companies may have entered a region of diminishing returns from the standpoint of managing and motivating creative individuals and coordinating their activities. It is notable that Pfizer, GlaxoSmithKline, and other firms with multibillion dollar R&D programs and several hundred R&D projects are instituting more flexible organizational structures, and delegating more decision-making authority to the heads of the various therapeutic areas (Dorey, 2001; Mathieu, 2007).

Mergers may also reflect management goals to maintain or increase firm size, even if this is not associated with economies of scale or improved long-term R&D productivity (Mueller, 1986). Although layoffs and consolidation typically occur in the aftermath of large-scale pharmaceutical M&A activities, the acquiring firm can also draw on an expanded portfolio of products and pipeline candidates to mitigate downsizing in the wake of imminent patent expirations on its major products. Managerial utility has been related to firm size in

several economic studies (Marris, 1998). This may help to explain the repeated serial use of large-scale mergers by many of the major ranked pharmaceutical firms in **Table 1**, mergers that appear to offer mainly short-run cost savings as discussed further below.

Access to New Technologies and Therapeutic Areas

Beyond economies of scale, biopharmaceutical firms may engage in mergers to gain a presence in an emerging therapeutic category that represents significant future growth opportunities. For example, the oncology class has been characterized by several new 'first-in-class' drugs in recent years (DiMasi and Grabowski, 2007). The oncology class is now the fastest growing therapeutic category among all major drug classes. The novel entities in this class have emerged primarily from the biotech sector, utilizing molecular biology techniques (e.g., new monoclonal antibody products and other targeted agents). Mergers provide a more expeditious way to enter such high opportunity fields relative to internal expansion. It can take several years or even decades to build the internal scientific capability to enter a new therapeutic area or implement a new research platform in an emerging scientific field. This appears to be an important motivation underlying both acquisitions and alliances of developing biotechnology firms by established pharmaceutical firms.

Alliances as Substitutes or Complements to Mergers

As discussed in Section 'Introduction,' larger firms are also increasingly looking to alliances and partnerships with smaller biotechnology firms as the source of new products. This suggests that scale requirements, at least in the discovery and early stages of the development process, remain modest. At these earlier stages, small research-oriented boutique firms may enjoy a number of advantages relative to their larger rivals. These include the fact that they are closer to cutting-edge technology emerging from universities and public supported basic research, are more willing to take risks on disruptive technologies, and are less bureaucratic in organizational structure (Scherer, 1999). By contrast, larger pharmaceutical and biotechnology firms may have advantages in the more advanced stages of development, where large-scale clinical trial design and regulatory coordination become important. This rationale for R&D specialization based on different comparative advantages in research versus development was advanced by Arrow (1983) in a more general model of the R&D process.

Although alliances and partnerships are an alternative to mergers as a means to acquire new technological platforms and R&D pipeline candidates, they also pose their own set of issues. Arora *et al.* (2001) find support for gains from a division of labor at alternative stages of the R&D process. There also are positive network effects associated with alliances and partnerships (Pammolli and Roccaboni, 2004; Powell *et al.*, 1996). However, partnership deals may be susceptible to a 'lemons' problem arising from agency and information problems (Akerlof, 1970; Pisano, 1997). Partnerships also raise challenging bargaining, management, and governance issues (Teece, 1998; Arora *et al.*, 2001).

Many M&As in the pharmaceutical area have occurred between firms that had first engaged in some type of alliance or partnership (Higgins and Rodriguez, 2006). This may help merging firms overcome pitfalls associated with agency problems and information asymmetries. In particular, the information gathered over time from an alliance may allow the acquiring firm to better assess the value of the acquired firm's intangible capital. It may also provide information on the resulting organization's ability to successfully integrate the strengths of the two companies. The difficulty of integrating firms with different cultures and organizational structures is an oft-cited reason for failures in mergers in the management literature (Larson and Finkelstein, 1999; Smith and Quella, 1995; Haspeslagh and Jemison, 1991).

Increasing Market Share

A traditional economic motive for mergers, of course, can be to increase market share and market power to gain competitive advantage. This has not been a major issue in the case of the large pharmaceutical mergers depicted in **Table 1**. In the USA and Europe, mergers are subject to scrutiny before their implementation by the antitrust authorities (Mueller, 1996). There are guidelines on what economic parameters can trigger challenges. In the case of pharmaceuticals, markets are defined in terms of therapeutic categories, because a drug product to alleviate pain, for example, does not compete with one that is approved for hypertension. Horizontal mergers of significant consequence, therefore, must go through a vetting process before implementation. These negotiations can result in a settlement where competitive products in the same therapeutic category are spun-off as a condition for allowing the merger.

Nevertheless, one of the distinctive areas of antitrust concerns for R&D-intensive pharmaceutical firms is in the area of innovation markets. In particular, this issue arises when two merging parties have potentially competing drug candidates in their R&D pipelines. The concern is that this merger could result in the combined firms suppressing one of the research paths in order to avoid cannibalizing the economic performance with the candidate that is carried forward. Since the 1990s, there have been several challenges of mergers in pharmaceuticals based on innovation markets. This issue is discussed in terms of policy issues considered in Section 'Summary and Concluding Comments.'

The Effects of Pharmaceutical Mergers and Alliances

Beyond the event studies discussed above, there have been a number of studies that have examined the specific effects of mergers or alliances on profits, R&D activity and other performance measures. The results are mixed in nature, and raise a number of issues and questions for further research.

Large Market Value Mergers and Acquisitions

Danzon *et al.* (2007) look directly at the effect of mergers in pharma/biotech on various measures of performance. They focus on mergers with $500 million or more of market value.

They find that these mergers are frequently a response to distress, so it is important to compare outcomes for merging firms to outcomes for other firms with similar characteristics, and they create propensity scores for this purpose. They conclude that mergers result in slower growth and a reduction in operating profit, though these effects are rather small. They also find smaller R&D growth for small merging firms. They look at performance in the first three years following a merger.

Ornaghi (2006) also looks at postmerger performance in the industry, and focuses on R&D productivity. He does not use the propensity score or economic distress index for developing a 'control group' with which to compare the performance of merging firms. He finds that in the three years following a merger, there is a decline in R&D spending as well as productivity, as measured by patents. Koenig and Mezick (2004) focus on a relatively small number of high-profile mergers consummated between 1989 and 1996 (a sample of seven large mergers). Comparing the performance of companies in the industry that undertook these mergers with a control group of firms that did not, they find that companies that merged were able to achieve more favorable postmerger productivity scores.

To summarize, although prior studies by Henderson and Cockburn (1996, 2001) and Danzon *et al.* (2005) generally find some advantage to R&D scale and scope, the studies analyzing merger effects find a weakly negative effect on R&D performance and related measures. This may be because there is no additional advantage to size at the level for most large market value mergers except perhaps for short-run cost savings reflected in the event studies discussed above. Alternatively, because many mergers are a response to distress, the counterfactual is hard to determine.

Existing studies leave open many questions for further research. First, none of them look at the long-run impact of mergers on a firm's productivity. Three years is unlikely to be enough time to pick up many changes in patenting activity, much less progression through the phases of development. Second, as Cockburn notes, patents and new chemical entities are not necessarily the best measure of output, though almost all the evidence on R&D productivity centers on these two measures. Third, the focus is on the larger mergers between public firms, and there is little attention paid to heterogeneity in outcomes. The management and finance literatures are concerned with what drives a successful merger, such as whether the R&D activities of merging firms are substitutes or complements, similarities in culture or corporate structure, the integration process, and other economic and organizational characteristics (Hitt *et al.*, 2001). These issues remain important questions for future research.

Studies of Mergers and Acquisitions Involving Development-Stage Firms and Partners

It is useful to distinguish the outcomes for M&As involving development-stage firms from those involving large-scale mergers between fully integrated pharmaceutical firms. Higgins and Rodriguez (2006) examined a sample of 160 research and development acquisitions over the period 1994–2004. Most of these deals involved an established pharmaceutical firm purchasing a development-stage company whose main assets involved new product candidates and R&D platforms. As discussed, Higgins and Rodriguez find support for the industry shocks motivation for these acquisitions of development-stage companies. In particular, they find that these acquisitions operate to effectively complement a firm's internal R&D efforts in the sense that acquirers either maintain or improve their product pipelines postacquisitions. They also find that acquirers also experience significant postannouncement, positive, abnormal returns in their market value.

Another significant finding by Higgins and Rodriguez is that firms that were engaged in an alliance before an acquisition exhibited greater success in terms of pipeline scores in the postacquisition period and abnormal market returns in the postannouncement period than did firms with no prior alliance history. This is preliminary evidence that alliances can help acquiring firms overcome agency problems (avoiding a 'lemons problem'). The information obtained over time can also improve the acquiring firm's ability to integrate the partner's assets in the postacquisition. As discussed, the difficulty of integrating firms with different cultures and organizational structures is a frequently reported reason for merger failures by business researchers.

An analysis of M&As that focuses on R&D outcomes is also undertaken (Grabowski and Kyle, 2007, 2012). In contrast to other merger studies, our analysis focuses on the effects at the R&D project level of observation. R&D outcomes are measured in terms of advancement through the various phases of drug research and market launch. It utilizes a large database of more than 4500 firms engaged in pharmaceutical R&D between 1990 and 2007. Our sample therefore includes a large proportion of development-stage companies.

Because most of the 4500 plus firms in this data set are not publicly traded in the USA, consistent time-series financial data such as R&D spending, total asset size, and other important control variables used in most other studies of mergers in this industry is lacking. Those studies focus on the performance of large firms. Our data has the advantage of including firms of varying size, at the cost of poorer information on financial data for nonpublic firms. To measure firm size, the count of active drug development projects each year is used, and four size categories are created: small (fewer than five projects underway in a year); medium (5–20 projects); large (20–50 projects); and very large (more than 50 projects).

It is found that a higher fraction of projects of firms that experienced a merger during the 1985–2006 period progress to the next phase. The differences in advancement rates are greater for the smaller merged firms at each research stage. However, the most substantial difference occurs in projects advancing from Phase III to market that originated in a firm with less than five research projects that was merged into or acquired by another company. Our general findings were confirmed in a logit regression analysis. The higher probability of market success for smaller merged firms compared with nonmerged ones is consistent with the comparative advantage of larger firms at later stages of the R&D process hypothesis (Arora *et al.*, 2001) or alternatively, with the hypothesis that large firms are better at weeding out unlikely successes earlier

in the process (Guedj and Scharfstein, 2004). Further research on this issue is warranted.

An important question for further research is the source of the observed benefits from development-stage company M&As. Our results leave open the question of whether high-performing firms are more likely to merge, or whether mergers lead to higher performance. If the latter do, mergers combine complementary skills of two firms, leading to better project selection and advancement? Are mergers necessary for the realization of these benefits, or could strategic alliances be used instead? Are firms that enter into alliances before mergers more likely to have higher probabilities of success in their R&D project as suggested by the work of Higgins and Rodriguez? These are among the open issues that are useful topics for further research.

Alliances

The most extensive published study evaluating the performance of alliances has been done by Danzon *et al.* (2005). They examine the productivity at each phase of drug development (i.e., success probabilities) for 900 firms over the period 1988–2000. They focus on experience, measured by the number of drugs a firm has in development, rather than sales in looking at economies of scale. They find that the effect of experience on productivity (advancing a drug through a phase) is positive with diminishing returns for Phases II and III, with the maximum occurring at 25 drugs in development. Products developed in an alliance tend to have a higher probability of success, at least for Phases II and III trials, and especially when the licensee is a large firm.

Arora *et al.* (2007) also examine the role of licensing and alliances in a working paper using data from 3000 R&D projects in preclinical and clinical trials in the USA in the 1980s and 1990s. After controlling for selection effects, they find licensing improves the probability of success when the licensee is a pharmaceutical firm. Their results are therefore generally consistent with the results of Danzon *et al.* (2005) on the positive benefits of alliances. Both studies are inconsistent with a 'lemons' hypothesis by Pisano (1997), at least for the typical development oriented licensing arrangement between biotech and advanced pharmaceutical firms.

Lerner and Merges (1998) use the Recombinant Capital database on licensing contracts to test the predictions of the theoretical literature on the allocation of property rights between licensor and licensee. Consistent with most theoretical predictions, they find that the R&D firm is less willing to cede control rights when it has greater financial resources. In contrast, they find little support for the theoretical prediction that the R&D firm will maintain control rights early in the development process, when its marginal contribution is higher. More recently, Lerner and Malmendier (2010) examine how contract terms are used to manage the risk that the R&D firm uses financing from the alliance to subsidize its other drug development projects. They find that in alliances where research is noncontractible, termination options that are expensive to exercise are more commonly used.

Allain *et al.* (2012) examine the relationship between market structure and the timing of pharmaceutical licensing. Alliances should result in efficiency gains if firms have comparative advantages and different stages of the R&D processes, but these efficiency gains depend on the transfer of technology occurring at the stage when the licensee has a comparative advantage. If biotechnology firms, or licensors, have private information about the quality of their drug candidates, this introduces a friction in the market for technology. Their theoretical model demonstrates that because of the potential for a lemons market, pharma firms offer prices for licenses based on the expected quality of an innovation, and these prices are too low for good innovations. Even though they are less efficient, biotech firms will elect to perform clinical trials themselves in order to prove their quality and command a higher price for a license later on. The effect of competition in this market is two-fold. Competition between potential licensees increases the bargaining power of the licensor, which increases the price the licensor expects to receive by conducting its own trials and waiting to license. But intense downstream competition between these potential licensees also erodes the profits that can be derived from the innovation and thus the price that licensees are willing to pay. In this case, the biotech firm gains less from waiting, and an increase in competition leads to more efficient licensing. Empirical analysis of data on the stage of development at which licenses were signed during 1990–2006 shows evidence of both effects of competition.

In contrast to the work on large-value mergers, the studies of alliances find positive effects on R&D performance. These studies indicate that development experience is generally associated with higher success probabilities, especially in later R&D stages. Hence, there appears to be a potentially important role for specialization across R&D stages. These findings are also consistent with the R&D productivity gains observed for development-stage firms merged into larger enterprises with more developmental experience.

These leading studies on the effects of alliances and innovation, however, also raise many issues for further research. The business alliance literature suggests a rich array of contractual terms and an evolving landscape of ventures. In this regard, Danzon *et al.* (2005) do not explicitly consider the contractual terms, the extent of integration of the R&D process, or the characteristics of the firms involved in the agreement beyond a few simple attributes relating to a firm's size and experience in performing clinical trials. Arora *et al.* (2007) adjust for product selection effects, but their analysis only considers a few characteristic variables. Both studies raise a number of issues about the underlying drivers of successful alliances for further research analysis.

Policy Issues

Innovation Markets and Antitrust Considerations

In evaluating mergers in research-intensive industries, antitrust agencies have been concerned that if two companies have potentially competing products in their R&D pipelines, a merger might increase the incentive to suppress at least one of the R&D paths. The idea that antitrust authorities should concentrate on the dynamic effects of mergers on R&D activities or innovation markets was first advanced in a paper in the

economics literature by Gilbert and Sunshine (1995). A number of merger challenges by the Federal Trade Commission (FTC) have been initiated around this innovation market concept, and the pharmaceutical industry has been a particular area of focus (Carrier, 2008).

Although the innovation market concept in antitrust enforcement has its supporters, its applications have been criticized by many economists and lawyers (Carlton, 1995; Rapp, 1995; Carrier, 2008). For pharmaceuticals, with their long and uncertain development process, critics argue that antitrust authorities should focus on drug candidates in the late-stage of development where potential competition is more easily assessed. Early-stage development activities involve relatively low costs and barriers to entry, and are also subject to high levels of uncertainty. Many firms take a portfolio approach to obtaining new product introductions at the early stages of R&D. There are also typically many parallel R&D efforts across firms searching for promising new therapeutic approaches (DiMasi and Pacquette, 2004). When a drug progresses to the final Phase III of clinical testing, however, the probability of success increases to approximately 70%, whereas costs of clinical trials also increase significantly. Antitrust concerns about potential anticompetitive effects then arguably become more relevant, particularly when there are a small number of late-stage competitors in a therapeutic class.

Carrier (2008) has analyzed nine challenges of pharmaceutical mergers brought by the FTC involving the issue of overlapping R&D activities. For example, in the first of these cases, involving the Roche–Genentech merger in 1990, Genentech had a CD4 drug candidate for HIV-AIDS in Phase I trials and Roche had a preclinical R&D program in the same class. To consummate the merger, Roche was required to offer a nonexclusive license to its CD4 drug candidate. However, none of the CD4 drugs were ever approved. Carrier (2008) finds that some of the challenges by the antitrust authorities are warranted, but others are more problematic, given the relevant characteristics of the market and an analysis of the potential costs and benefits. In the questionable cases, he argues that the FTC has attempted to protect innovation where future outcomes are uncertain and many years away from the market. By contrast, the EU has taken a less stringent approach to some of these innovation market cases (Morgan, 2001). This is clearly an evolving area of antitrust policy that warrants more research and attention by scholars.

Two former Directors of the Bureau of Economics of the FTC, William Comanor and F. M. Scherer, in a memorandum to the FTC, discuss some potential adverse consequences for alliance formation that antitrust officials should address when evaluating large-value mergers, even if there are no significant overlaps in the particular therapeutic areas of each merging firm (Comanor and Scherer, 2009). First, they point out that these large-scale mergers reduce the cohort of independent firms that are available to partner with or acquire earlier stage biopharmaceutical firms. This can lead to fewer projects originating in early-stage biopharmaceutical firms progressing to later stages of R&D process along parallel paths. Furthermore, the attendant reduction of R&D facilities and resources accompanying mergers is likely to reduce the number of internally originated projects compared with what would occur from two separate R&D-oriented firms. They are skeptical that these mergers will produce any offsetting benefits from economies of scale or scope in R&D, given the evidence from the available literature.

Although these issues and concerns did not prevent the FTC approval of large-scale mergers such as Pfizer–Wyeth or Merck–Schering Plough in 2009, they raise interesting questions for further research. In particular, even if mergers between large firms reduce overall R&D expenditures and the number of projects undertaken, it is important to understand the balance of impacts between internally generated projects and externally supported ones. Second, it is important to know the effects on early-stage versus later-stage development projects and firms. As discussed, at the present time, there appears to be a strong demand for late-stage product candidates with substantial market potential to fill pipeline gaps, so adverse effects, if any, may be primarily on deals for early-stage companies. A number of analysts have raised more general concerns about a funding gap in the technology transfer development process for start-ups with technologies that have proceeded beyond university-type basic research, but still are many years away from any commercial applications, as discussed below.

Biomedical Research Support and Technology Transfer Activities in the USA and Europe

Just as small, development-stage R&D firms now play a significant role in innovative research leading to commercialized biomedical products; in the past 25 years the university has assumed a far greater role. With the passage of the Bayh–Dole Act in 1980, and later the Stevenson–Wydler Act in the USA, universities were given increased new rights to patent federally funded research discoveries (Rai and Eisenberg, 2003). Bayh–Dole's policy goal was to increase the investment of private sector development funds for translating university research funded by federal monies into new products and processes. Before 1980, universities received fewer than 250 patents annually, compared with 3000 per year by 2002 (Association of University Technology Managers, 2003). This, in turn, has led to a large increase in university–industry licensing agreements as well as start-up companies originating from university R&D (National Academy of Sciences, 2004).

In Europe, public funding of biomedical research also has increased dramatically since the 1980s, even though total spending has remained significantly lower than in the USA. In this regard, Germany spends the most public funds on biotechnology, followed by the UK, and France (Pammolli *et al.*, 2002). In contrast to the USA (and to some extent also the UK), biomedical research in continental Europe tends to be concentrated in public research institutions and highly specialized university laboratories with little interaction with teaching, clinical practice, and industrial research (Gambardella *et al.*, 2000).

Europe has also been characterized by less mobility and interaction between university and public institution scientists on the one hand, and industry research activities and personnel on the other hand. Rather a more prevalent model is the establishment of specialized institutions, such as science and technology parks, to act as intermediaries between

publically supported biomedical research and industry (Gambardella *et al.*, 2000). To date, the US model appears more productive from the standpoint of creating new companies and fostering new technologies. However, the Bayh–Dole Act and its enhanced incentives toward licensing and commercialization have also been the subject of criticism in terms of potentially undermining the norms of open science (Dasgupta and David, 1994).

Policy Initiatives to Improve the Translation of Academic Science into New Therapies

One important issue that has emerged in recent years regarding technology transfer is a growing belief that there is a biomedical funding gap associated with early-stage preclinical R&D. These 'proof of concept' type activities (studies which provide early evidence a molecule may feasibly be developed for a particular use) are beyond the basic research questions typically investigated by university researchers. At the same time, many venture capital and private equity firms have pulled away from funding early-stage discovery companies and focused instead on companies with compounds in clinical trials. The excitement preceding and accompanying the announcement of the 'working draft' of the human genome sequence in 2000 created a surge of worldwide interest and private early-stage investment in genome-based projects. But assumptions about the time frames required to commercialize a gene-based product and the market acceptance of these new products were unrealistic, thus a period of overinvestment followed by negative returns, in effect, a bubble occurred (Klausner, 2005).

As noted in Section 'Introduction,' alliance activity has been more focused on clinical development activity in the past several years compared with early-stage research. The same appears to be the case for venture funding of start-up companies. The number of life science companies receiving first-time funding dropped from an average of over 250 companies in 2006–08 to less than 175 companies in 2007–11 (Leff, 2012). Average funding for early-stage projects have also been under pressure during this period (PWC, 2012).

The hypothesized early-stage funding gap, sometimes ominously referred to as the 'valley of death,' has been the subject of growing attention by policy makers. A number of recent initiatives to encourage public–private partnerships and other activities are focused at the precompetitive level. Their ultimate objective is to improve the low probability of success and address the R&D productivity problems of drug industry R&D discussed earlier. At the same time, there are skeptics who contend there is adequate funding by the private sector to pursue promising research leads emerging from academic science. They point to other explanations for the low probability of success, such as an increasing focus on therapeutic areas like Alzheimer's disease and oncology therapies that have low probabilities of success from a scientific perspective (Kahn, 2012; Pammolli *et al.*, 2011). Given the recent origin of the policy initiatives designed to improve the translation of academic research and increase success probabilities, it is likely to be several years before one can evaluate their effectiveness. Several of these different initiatives, many of which are at the pilot stage, are considered below.

A number of different models of nontraditional R&D collaborations have emerged to enhance biomedical innovative activity at the precompetitive level in recent years (Altshuler, *et al.*, 2010). One ambitious approach is the establishment of the National Institutes of Health (NIH) Center for Advancing Translational Sciences (NCATS) in fiscal year 2012 with a budget of more than $500 million and several new programs and initiatives. The mission of NCATS is to support research that will reduce costly and time-consuming bottlenecks in the development of new therapies (NIH, About NCATS, 2012). For example, NCATS is currently supporting efforts to identify drug targets faster and more efficiently and is collaborating with industry to develop a consortium to provide a repository and an analytical platform for target validation efforts. In addition, NCATS recently announced a collaborative pilot program with pharmaceutical firms to examine new therapeutic uses for existing molecules. In particular, eight pharmaceutical companies have contributed 58 compounds that have advanced to clinical trials, but were unsuccessful in its original therapeutic indication or not pursued for business reasons. The NIH-industry collaboration will match researchers to test these compounds for new therapeutic uses. These and several other related NCATS programs involve a multiprong approach to reengineer the precompetitive, preclinical process in order to bridge the gap between basic research and human medicines and increase the success rate of later-stage clinical compounds.

A second approach to precompetitive collaboration involves public–private consortia for process innovation or knowledge creation. Some existing examples include the Predicative Safety Testing Consortium (PSTC) established in conjunction with the FDA and the nonprofit Critical Path Institute. PSTC's 18 corporate members share information on safety testing methods and test methods developed by consortium members. The Critical Path Institute leads the collaborative process, and collects and summarizes the data. Another public–private collaborative organization, the Biomarker Consortium, addresses the development of good biomarkers for both safety and efficacy. Like the PSTC, the Biomarkers Consortium encourages scientists at competing firms to contribute their knowledge and expertise to the development of specific biomarkers. As with the PSTC, a public sector-related organization – the nonprofit foundation for the NIH – plays a key role in soliciting funding and selecting research projects (Rai *et al.*, 2008).

A third model involves so-called virtual pharma companies involving nonprofit foundations and patient advocacy organizations that provide funding and project selection oversight to bridge the gap between basic research and later-stage clinical development. Many of these groups are focused on relatively rare and neglected diseases (e.g., Cystic Fibrosis Foundation, the TB Alliance, Gates Foundation initiative on neglected diseases). These organizations have moved from sponsoring academic research proposals on an *ad hoc* basis to coordinating research agendas and activities with milestones and other contracting research approaches prevalent in downstream alliances and partnerships between pharmaceutical firms (Altshuler *et al.*, 2010).

At this point, all of the approaches to bridging the gap between basic biomedical research and therapeutic

development are somewhat experimental in character. They face significant challenges and barriers involving the alignment of incentives among participants with different expertise, resources, and objectives. Establishing a culture of mutual trust and cooperation between different stakeholders is also challenging. Because it can be difficult to delineate precompetitive from competitive activities, collaborations can give rise to free rider problems and conflicts of interest. At the same time, the potential opportunity to advance R&D productivity and facilitate innovative medicines through these precompetitive initiatives appear to warrant the continued experimentation with several forms of public–private entities. In effect, the current strategy of policy makers appears to be 'let a thousand flowers bloom' and see what approach, if any, yields positive outcomes.

Summary and Concluding Comments

As is the case in other industries, mergers in pharmaceuticals are driven by a variety of company motives and conditions. Given this is the case, it is important to take account of firm characteristics and motivations in evaluating merger performance rather than using a broad aggregate brushstroke. Research to date on pharmaceuticals suggests considerable variations in outcomes.

The empirical research on mergers is generally focused on the larger public companies. There is evidence that the large-scale mergers involving these pharmaceutical firms were driven in significant part by a series of industry-wide and firm-specific shocks. These shocks left many firms with R&D pipeline gaps associated with patent expirations (and the increased usage of generics in the USA and more stringent price controls in other countries). Although these mergers apparently have achieved cost reductions and addressed short-run pipeline problems, there is little evidence to date that they increased long-term R&D performance or outcomes. Many of the larger pharmaceutical firms listed in Table 1 continue to deal with a persistent R&D productivity problem.

By contrast, the empirical research on alliances between smaller biotech firms and larger pharmaceutical entities and on development-stage acquisitions is more encouraging in nature. There is evidence of a positive relation between a firm's experience in clinical development and the probability of successful outcomes. In particular, the 'R&D boutique' firms with a small number of research projects can apparently benefit from alliances with larger, more experienced firms, especially at the later stages of the R&D process. The work on alliances provides some support for this hypothesis, but also raises a number of issues for further research.

Our analysis of the effect of mergers on the success rates of drug development projects is generally consistent with these results from the alliance literature. In particular, using data on R&D projects from a large sample of public and private firms, it is found that a company's development experience is significantly related to the likelihood of success, especially for the large pivotal Phase III trials. Moreover, there is suggestive evidence that very small firms with only a few projects in their R&D portfolio can gain the most benefits from mergers with more experienced firms in developing new drug introductions.

Our results, and those of other studies, are subject to various qualifications and raise many questions for further research. The economics literature indicates, for example, that many acquisitions of smaller companies by larger firms are preceded in time by development-stage partnerships. This opens a fruitful line of research in terms of when alliances are a desirable alternative to mergers, and where they can be complementary in nature. More generally, there are a host of interesting research questions to be addressed relating to the various drivers of mergers and the conditions and firm characteristics that produce successful versus unsuccessful mergers. These are important issues from both a business strategy and economic efficiency standpoint.

From an antitrust policy standpoint, the larger horizontal mergers in pharmaceuticals have run into few challenges by the regulatory authorities in the USA and the European Union, given the option to spin-off competing therapeutic products to other drug firms. However, the issue of innovation markets, where firms have potentially competing development programs at various stages of the R&D process, remains a more controversial area of antitrust policy for industries like pharmaceuticals. This remains an important area for future research by law and economics scholars.

Another important area of policy review and debate concerns the apparent funding gap in transferring technology from publically supported basic biomedical research conducted largely in universities and nonprofit institutions to privately supported early-stage R&D activities primarily concentrated in start-up firms and development-stage entities. Both venture capital funding and development-stage alliances have focused more on later-stage clinical activities in recent years. A thriving market for downstream innovation activities depends on the public and private research support in upstream early-stage R&D activity. A number of initiatives and pilot projects are emerging at the NIH and elsewhere to enhance the scientific translational process from basic research to therapeutic medicines. It likely will be several years before one can assess the effectiveness of these collaborative activities.

Missing Data: Weighting and Imputation

PJ Rathouz, University of Wisconsin School of Medicine & Public Health, Madison, WI, USA
JS Preisser, University of North Carolina, Chapel Hill, NC, USA

Introduction and Goals

Missing Data and Their Consequences

Missing data are common occurrences in health economics and health outcomes research. The patterns of missing data can take many forms. Item missingness occurs when values are missing for selected variables (items) for a subset of subjects or cases; often the subset of cases missing one variable may not be identical to those missing another variable, thus compounding the problem. In contrast, case (record) missingness occurs when subjects selected for a study might have only minimal available data because they might be unreachable or even decline to participate. In panel (longitudinal) data, subjects might not be missing, but records for some waves might be. Dropouts are common, just as intermittent missing data arising when a subject misses a wave but participates in subsequent waves.

Missing data, even if relatively modest in scope, present a major problem when their frequency and structure call into question the validity of and conclusions from statistical analyses of a research study. The two main statistical issues are increased variability and bias. As a general rule, the loss of information resulting from the missingness increases the variability of statistical estimates, sometimes dramatically so, resulting in decreased power for hypothesis tests and wider confidence intervals. A more serious problem is bias, that is, systematic error that may result when the missing data occur disproportionately across subjects or records. Selection bias, which typically occurs when the individuals in the sample are not representative of the target population, may also be induced by nonresponse. The missing data may therefore result in reduced generalizability of study results, and may complicate statistical analyses through the need to mitigate bias.

Statistical Approaches to Missing Data: Overview

Analytic strategies for handling missing data have a long history and fall into several broad categories. The authors mention a few approaches here, and then in Sections 'Weighting' and 'Multiple Imputation' elaborate two of the most useful and popular ones for missing data.

Historically, methods were focussed on simple imputation of missing values with the aim of conducting analyses using statistical tools that required complete data. Simple imputation techniques such as unconditional mean imputation – replacing missing values with the sample mean of nonmissing values – or carrying the preceding nonmissing observation forward in a panel study were standard approaches. Conditional mean imputation improved slightly on these approaches as it replaces missing values with their sample mean on the basis of a regression model or a sample subset of the full data that is closer in some sense to the record with the missing data. In some settings, this method will yield reasonably unbiased estimators, but will often understate statistical uncertainty and inflate test statistics. Carrying the preceding nonmissing observation forward in panel studies is not recommended.

The most common strategy for handling missing data, complete-record analysis, is to simply delete the records for which data are missing, and base the analysis only on the observations without missing data. In univariate response problems, complete-record analysis ignores data on all subjects for whom some data are missing for a given analysis. In panel data, a subject may contribute data, but records for waves with missing data are ignored. This is referred to as available subject/complete-record analysis. (A subject without any missing items or waves is called a complete subject.) There is really no statistical principle guiding these decisions; rather it is mostly a matter of simplicity and convenience for software developers and analysts. Besides possible problems of bias and inefficiency, complete-record analyses suffer from the problem of different sets of records being included in different model fits, depending on the variables included in the model.

Modern methods for handling missing data frame the problem in terms of a pair of auxiliary statistical models: A model for the distribution of the missing values, and a model for the probability that a given value is missing, sometimes called the missingness mechanism. Sensitivity of inferences to these model specifications, and manipulation of them in order to obtain inferences, has been the topic of a vast missing data literature.

A minimal goal of any method is that it yields valid statistical inferences. For a method to be valid, it should produce consistent (i.e., unbiased in large samples) estimators of the parameters of interest, which are accompanied by consistent estimators of uncertainty (e.g., appropriate standard errors), thereby yielding correct test statistics and confidence intervals. Statistical efficiency (i.e., optimal use of the available data under acceptable modeling assumptions) is another important statistical desideratum.

With these three criteria in mind, one large body of approaches involves correcting bias and generating valid standard errors in complete-record analysis. Whereas other techniques are available, the most common of such approaches is the statistical weighting of complete records. In this approach, efficiency is more of a secondary concern. A key feature of weighting approaches is that a model for the distribution of the missing quantities is not needed. A model for the missingness mechanism is, however, needed in order to generate the weights.

At the opposite end of the spectrum from weighting lies full maximum likelihood estimation, which jointly estimates the model of interest and the model for the missing quantities. Maximum likelihood places the two issues of bias and

 doi:10.1016/B978-0-12-375678-7.00705-7

efficiency on equal footing. If the models are close to correctly specified, then bias will be eliminated, and the solution will be statistically efficient. However, bias and/or inefficiency can arise under misspecification. This approach is also limited because often the analysis of interest (i.e., the analysis one would do in case of no missing data) is not based on maximum likelihood.

For purposes of approximating maximum likelihood estimation, more advanced and flexible imputation techniques have been proposed. The simplest of these is conditional imputation, in which a probability model is specified and estimated for the missing quantities as a function of other nonmissing variables. A random draw from that model is then used to impute each missing value. This method improves on conditional mean imputation because it captures the variability in the data that would have been observed if they had not been missing. For small amounts of missing data, this method can work well. It is convenient and quick, not much more difficult than conditional mean imputation, and data preserving too. Its disadvantage is that the resulting measures of statistical uncertainty will be anticonservative because the approach does not account for the additional variability arising from having estimated the imputation model. Multiple imputation (MI) resolves this issue.

Goals for the Article

It is beyond the scope of this article to cover all missing data methods or to cover any one method in detail. Rather, the authors' main goal is to introduce key concepts and to provide some guidelines to help the analyst narrow down problems so that he/she may further research specific solutions. With this in mind, in the remaining sections, the authors will focus on the following three objectives. First, a discussion of missing data identifying assumptions, especially missing at random (MAR) and its variants, will be provided. Second, some leading case patterns of missing data with probably valid approaches in those settings will be discussed. Third, two model-driven approaches that are commonly used now, namely, complete-record analysis with weighting, and MI will be described in some more detail. Conditional single imputation, which is described above, is a special case of MI, so that approach will be implicitly covered as well. To focus the discussion, regression problems for univariate or for longitudinal (panel) data will be emphasized. Wherever needed, the settings of missing predictors and missing responses (e.g., attrition) will be differentiated. Also, the authors will emphasize statistical methods for MAR data. Such methods are generally easier to carry out than those for nonignorable missingness, and are more broadly applicable than those analyses that require the relatively severe assumption of missing completely at random (MCAR).

This article focuses on data that are missing by happenstance. There are many situations wherein data are missing by design, either at the item level or at the record or the unit level. Important examples include two-phase sampling designs, case-cohort designs, and outcome-dependent sampling designs for panel data. Some references for these designs are given under 'Further Reading'.

Foundational Issues

Preliminaries and Notation

To fix ideas, suppose that the analysis of interest involves the conditional distribution of response Y given predictors X, denoted as $[Y|X]$. Response Y may be univariate or, in the case of panel data or multivariate data, a vector. Predictors X are almost always row-vector valued or of higher dimension. For example, in panel data, X might be a matrix with number of rows equal to the length of Y. For clarity of exposition, an independent individual or sampling cluster is referred to as a sampling unit, and observations within that unit are considered as records. Units are considered to be stochastically independent, whereas observations within a unit may be correlated. For example, in a panel study, each participant would be a unit, and repeated waves of measurement would generate a separate record each. In a study of twins, the pair would constitute a unit, whereas each of the twins would yield his/her own record.

It is assumed that without missing data, the target of inference would be restricted to $[Y|X]$; the marginal distribution $[X]$ would be ignored. Therefore, in structural equations models wherein predictors are latent and are measured imperfectly by a set of manifest indicators, those indicators become part of Y because the measurement model is part of the analysis that takes place in the absence of missing data. Where no further specificity is needed, and recognizing that it is difficult to create a notation that is broadly applicable, Y_o and X_o will denote components of Y and X that are always observed, while those components that are potentially missing (i.e., missing for some individuals) will be denoted by Y_u and X_u.

In any analysis, it is important to take account of the pattern of missing data. Item nonresponse arises when the missing quantities Y_u or X_u constitute a set of component variables available in Y and/or X. Missing items may be similar or may vary considerably across units. For example, it may be that due to the sensitive nature of the data, many individuals are missing reports of household income. Alternatively, in a questionnaire with many items, some respondents will skip a few items or sets of items here and there, with no consistent pattern from one respondent to another. Unit nonresponse leads to record missingness, a situation where all of Y is missing, as is most of X. Depending on the sampling frame, some minimal part of X might be available. For example, for a nonresponding household in a sample survey, the investigator would still know the address and some neighborhood characteristics according to census information.

Panel data yield special types of record missingness. Most commonly, some participants drop out of a study, leading to attrition that results in monotone missingness patterns. Alternatively, some participants may not come for a given visit or respond at a given wave, but then respond in later waves, leading to wave nonresponse and intermittent missingness patterns.

For purposes of both formal theory and computational development, it is useful to introduce a variable R encoding the missingness pattern for any given unit. The specific form of R will depend on the nature of the missingness. For example,

if the only thing ever missing is a single predictor X_u, then R will be a binary indicator equal to 1 if X_u is observed, and to 0 if X_u is missing. Alternatively, in a panel study with intermittent missingness, R may be a vector of indicators with elements of 1 for observed and 0 for missing waves. R may take other forms that are necessary to fully codify the range of missingness patterns.

Some missing data analyses include auxiliary data Z. These additional variables are observed on all units that are associated with, and hence provide information on, the missing data. Auxiliary data can be quite informative in missing data problems. For example, if a key predictor is clinic-measured body mass index and it is missing on some participants, a reasonable pair of auxiliary variables can be self-reported height and weight. It is assumed that auxiliary variables are not part of the target of inference, i.e., the analyst would ignore Z in studying $[Y|X]$ if there are no missing data. For auxiliary data to be of use, it must be predictive of the missing data Y_u or X_u.

A Taxonomy of Missing Data Assumptions

Rubin (1976) has proposed a taxonomy of missing data assumptions, which has proven to be enormously successful; almost all modern missing data methods refer to it for formal identifying assumptions. Although his taxonomy is rooted in formal likelihood theory, the main ideas are sketched here, downplaying technical details.

Missing data assumptions are framed in terms of the missing data mechanism. This term does not describe the actual machinery or physical processes that lead to data being missing, but rather the stochastic dependencies of those processes on other variables at play in the analysis. Specifically, missingness mechanism refers to the probability distribution of missingness being conditional on (Y, X), viz. $[R|Y, X]$. Of course, understanding the physical processes may help the investigator in determining what is reasonable to assume where dependencies in the missing data pattern are concerned. In general, acknowledging and accounting for this probabilistic selection mechanism is central to understanding, developing, and applying modern missing data methods.

Data are considered to be MCAR when the probability of missing data is independent of both missing and observed variables. That is, R is independent of either (Y, X) or, when auxiliary data are available (Y, X, Z). Intuitively, under MCAR, complete records arise as if by a random sample from the population, because whether they are complete or not is unrelated to their realized (observed or unobserved) values. In univariate problems, complete-record analysis is a valid, albeit statistically inefficient, approach under MCAR. In panel data, under MCAR, either available subject/complete record or complete subject analysis will lead to valid but inefficient inferences.

The most common missing data assumption is MAR. Under MAR, R is independent of (Y_u, X_u) given (Y_o, X_o) or, in the case of auxiliary data, given (Y_o, X_o, Z). Under MAR, the distribution of unobserved data (Y_u, X_u) when $R=0$ could deviate from that when $R=1$, but not when controlling or stratifying on (Y_o, X_o, Z). That is, for a fixed value of (Y_o, X_o, Z), the values (Y_u, X_u) for $R=1$ (or $R=0$) are a random draw from their conditional distribution $[Y_u, X_u|Y_o, X_o, Z]$. MAR is a weaker assumption than MCAR (MCAR is a special case of MAR), but still yields identifiable models. Intuitively, the implication is that it is possible to model this conditional distribution, thus enabling generation of imputed values for (Y_u, X_u) for those subjects where they are missing. This intuition for model identifiability holds even if imputation is not formally pursued as an analysis strategy. Note that auxiliary data Z can be an important factor in meeting the MAR assumption; intuitively if Z is predictive of Y_u or X_u, it can lead to valid imputations of the missing values, imputations that would not have been available in the absence of Z.

It is useful to consider two special cases of MAR. In the first, missingness of Y_u or X_u only depends on the other covariates X_o, but not on Y_o or any auxiliary data. Because interest lies in the conditional distribution $[Y|X]$, it is possible to treat this covariate-dependent missingness essentially as MCAR. Alternatively, if missingness depends on Y_o, the authors have a true MAR situation and must account for this more carefully in subsequent analyses. Two key examples of this situation are as follows. In the first, a covariate X_u is sometimes missing, and whether or not it is missing depends on the response Y. For example, X_u may be a clinical laboratory test and the ordering of the test may be related to response Y. The second arises in panel data with attrition, where Y_o represents the responses before dropout, and Y_u represents the responses realized but not observed after dropout. This situation is termed sequential MAR if the potential missingness of the responses Y_u (after dropout) depends only on the covariates X and the components Y_o of Y being observed before dropout.

When data are not MAR, they are missing not at random (MNAR) or informative. In this case, the fact R that X_u (or Y_u) is missing is associated with its value, even after controlling for always-observed data (Y_o, X_o, Z). When missingness is nonignorable, statistical analyses can be considerably complicated because they require a model for the missingness process, and this model is based on untestable assumptions regarding the relationship of Y_u or X_u to R. As such, sensitivity analyses are often conducted to assess how inferences change over a range of parameter values for the nonignorable missingness process.

MNAR data are often termed nonignorable. The implication is that under MAR, the missingness is 'ignorable' in some sense. This is a potentially misleading statement. MAR allows the model to be identified, but the analyst cannot ignore the problem, or does so at his own peril. Indeed, whereas inferences can be safely based on the likelihood for the complete data, MAR missingness is only truly ignorable if what is missing is part of Y when there are no auxiliary data, and also if full likelihood analyses are pursued. That is, inferences based on likelihood $[Y_o|X]$ instead of on likelihood $[Y|X]$ are valid. If, however, it is a component of X that is missing, then a probability model for X_u is required, something that would not have been part of an analysis with no missing data. If nonlikelihood or conditional likelihood methods are being used, a model for the missing data mechanism is required.

Approaches: When to use What?

Before approaching any analysis, an assessment of missing data should be undertaken. One should quantify how much each variable is missing, and also document patterns of missingness. Are there a few variables missing often, or many variables wherein each is missing very occasionally? What is the relationship among the missingness of different variables? Is it the response of one or more predictors that is missing? It is then important to assess reasons for missingness during the study as this would lead to realistic assumptions regarding the mechanisms of missingness that will aid in the choice of statistical analysis.

Harrell (2001) provides rough guidelines for handling missing predictor variables X_u in univariate regression models. For 5% missingness or less, unconditional mean imputation of X_u will generally work fine. If 15% or less of observations are missing X_u, he recommends imputing it with conditional mean imputation without the response Y in the imputation model. As the missingness approaches 15%, standard errors may begin to be underestimated. If the missingness R is associated with Y (something that can be examined with the data), this approach will also begin to break down. For analyses where more than 15% of observations have at least one missing predictor and/or where missingness is strongly associated with the response, incorrect modeling assumptions could begin to introduce bias, and standard errors need to account for missing data. Weighting or MI (Section 'Multiple Imputation') is recommended.

For the missing responses Y_u in univariate models, if MAR can be assumed without auxiliary data Z, then complete-record analysis will yield valid and efficient inferences. If there are auxiliary data Z, one should examine whether they predict Y_u and/or missingness of Y_u (i.e., R). If Z is strongly predictive of Y_u but not related to missingness R, then imputation will increase statistical efficiency. If Z is related to R but not very strongly to Y_u, then weighting as a function of (Z, X) will help to avoid bias. If Z is related to both R and Y_u, then imputation is recommended to avoid bias and maximize statistical efficiency. In any case, for 5% missingness or less, complete-record analysis should work fine.

For panel data with MAR responses Y_u, for example, due to attrition, if the missingness only depends on X, but not on observed responses Y_o, available subject/complete records analysis using either maximum likelihood or semiparametric moment-based methods will yield valid and efficient inferences. If the missingness of Y_u also depends on Y_o, the best approach depends on the type of analysis being pursued. If the model is a full probability model with no auxiliary data Z, which otherwise would be fitted with maximum likelihood in the absence of missing data, then one should pursue the same approach on available subjects/complete records. In settings where a moment-based analysis is desired or where auxiliary data Z are available, then other approaches are required. Imputation is a possibility but it can be difficult to implement with both variably spaced observations and dropout at different waves in the study. Weighting is an alternative approach that relies on a model for the missingness or the dropout probability (see Section 'Weighting'). As this is a binary data model, modeling strategies for the missingness are straightforward to implement with sufficient flexibility. Covariate missingness in panel data is a more complex situation and beyond the present scope.

Weighting

Univariate Data

The general practice of weighting observed data to account for missing data comes from weighting for nonresponse in sample surveys to correct for bias, which has been discussed elsewhere in this volume. Briefly, when nonresponders differ from responders according to their distribution of measured characteristics, the responders' data are weighted so that analysis restricting to the complete data sample would resemble the analysis of the combined data of responders and nonresponders in the case where it had been observed. Use of weights assumes knowledge of some variables such as demographic characteristics, to be available on the nonresponders so that they can be placed in groups or bins with responders. The bin-specific inverse probability of being a responder is then calculated and used as the weight for observations in that bin. The same principle can be applied in a prospective study where the outcome Y at the end of the follow-up period is missing for some subjects. The general idea is to weight records inversely to their probability of being observed such that observed data with a low likelihood of being observed receive relatively high weight. When incorporating continuous as well as categorical baseline variables, instead of bins, a logistic regression model can be used to estimate the probability of being observed at follow-up for each study participant. The resulting inverse probability is then the weight used in the complete-data analysis for the outcome. The same general method of constructing weights applies to missing covariates in regression settings. When more than one covariate is missing or when missing data patterns for repeated measures are nonmonotone, implementation of weighting strategies becomes less straightforward. The next section considers the special problem of weighting for missing data due to subject dropout in panel data.

Weighted Estimating Equations for Panel Data with Dropouts

A common problem in panel studies is subjects dropping out before study completion. Whereas subject-specific random effects models estimated with maximum likelihood are a popular approach to the analysis of longitudinal data, another approach is population-averaged modeling of marginal means. Such semiparametric estimation of marginal mean regression models is especially attractive for discrete outcomes because specification of their full joint distribution is not needed. In particular, a semiparametric estimation approach using record-specific weights derived from a model for dropout addresses potential bias due to sequential MAR dropout.

To define the problem, assume that there is a set of T planned measurement times being common to all individuals, and that interest lies in the mean μ_t of response Y_t across times $t=1,\ldots,T$. However, some subjects drop out of the study before T, thereby creating a monotone pattern of missingness. Letting t' be the final observation time before dropout (for a

given subject), $Y_o=(Y_1,\ldots,Y_{t'})$, $Y_u=(Y_{t'+1},\ldots,Y_T)$, and $Y=(Y_o, Y_u)$ is obtained. To indicate missing data, $R=(R_1,\ldots,R_T)$ is also obtained, where $R_t=1$ for $t\leq t'$ and 0 otherwise. Next let X_t be the covariate vector which is used to predict μ_t, so that μ_t is a function of $X_t'\beta$. Assume that all X_t's are known, as is the case, if all covariates are baseline characteristics (time-independent) or deterministic functions of known quantities such as the planned measurement times, or are external to the measurement process.

Generalized estimating equations (GEEs) provide a common approach to marginal mean regression modeling for panel data while accounting for correlation among an individual's repeated responses. With dropout, GEE estimates β by solving the equations

$$\sum D_o V_o^{-1}(Y_o-\mu_o)=0,$$

where the sum is over all subjects in the panel. Here, $\mu_o=(\mu_1,\ldots,\mu_{t'})$, and V_o^{-1} is the inverse of the working covariance matrix of Y_o (i.e., the observed part of Y). $D_o=\partial\mu_o/\partial\beta$ and is a generalization of X_t in the normal equations of a linear regression model. GEE yields a consistent estimate of β even if the covariance structure is misspecified, provided the missing data are MCAR or when missingness depends only on covariates X_t. However, under MAR, a GEE analysis generally gives biased estimates.

In contrast, weighted GEE (WGEE) is valid under MAR even if the covariance structure is misspecified, provided the model for the probability of dropout is correctly specified. WGEE modifies GEE by solving instead the equations

$$\sum DV^{-1}W(Y-\mu)=0,$$

where μ, V^{-1}, and D now correspond to the full data vector Y, both observed and unobserved components, and W is a diagonal weight matrix with components $R_t w_t$, $t=1,\ldots,T$. Note that, because W is diagonal, it multiplies, or weights, each element $(Y_t-\mu_t)$ of $(Y-\mu)$ by $R_t w_t$. As in univariate data, w_t is equal to the inverse probability of the tth record being observed, and R_t selects the observed components of Y. In the case of a working independence covariance assumption, V is diagonal, and WGEE reduces to GEE, where W_o is diagonal with elements $w_1,\ldots,w_{t'}$. Compared to WGEE with a nondiagonal working correlation matrix, independence WGEE is rather straightforward to implement as it utilizes the same data structure as the independent GEE, with little efficiency loss when the number of subjects is large.

The benefits of WGEE relative to GEE are twofold. First, just as with the univariate analysis already described, the inverse probability weights in W serve to correct the bias due to nonresponse at the record level. Second, through the working correlation structure posited in V, multiplying by V^{-1} serves to implicitly impute components of Y_u via the observed data in Y_o. There are three main steps in implementing WGEE:

Step 1: Determine observation-specific weights w_t, $t=1,\ldots,T$, through a model for the missingness.
Step 2: Apply the weights to W in the WGEE equations and solve to estimate the $\hat{\beta}$ parameters in the marginal mean model for μ_t.
Step 3: Calculate the empirical sandwich-type estimator of the variance–covariance of $\hat{\beta}$ with the estimation of weights taken into consideration.

In Step 1, under sequential MAR, let λ_t denote the conditional probability that Y_t is observed, given Y_{t-1} is observed. This probability is typically modeled with logistic regression of R_t on X, prior responses $Y_1,\ldots,Y_{t-1}$, and possibly auxiliary data Z. Weight w_t is the inverse of the unconditional probability of being observed at wave t, estimated as the inverse of the cumulative product of conditional probabilities, $\hat{w}_t^{-1}=\hat{\lambda}_1\times\cdots\times\hat{\lambda}_t$.

With weights fixed in Step 2, β estimation is similar to that in classical GEE, alternating between regression and covariance parameter estimation. Under correctly specified models for the marginal means and the dropout process, WGEE yields a consistent asymptotically normal estimator of β. In Step 3, a sandwich estimator is generally used. This estimator is biased for the true variance of $\hat{\beta}$, because it treats the weights w_t as fixed even though they are estimated. In contrast to sampling theory, where fixed weights are used, semiparametric theory provides that this version of the weighted sandwich estimator tends to overestimate the true variance so that options for specifying fixed weights in widely available software for GEE tend to provide conservative estimates of the standard errors for $\hat{\beta}$.

In summary, the WGEE procedure corrects for bias when the GEE assumption of MCAR is in doubt. A few caveats are in order. As in GEE, choice of the working correlation structure in WGEE may affect efficiency. A particular concern with the WGEE method is that misspecification of the missingness model may cause bias in $\hat{\beta}$, which can even exceed that of GEE. Accurate choice of the working correlation can mitigate this problem. As with sample survey weights, caution should be used in applying very large weights. Finally, more complex extensions of this procedure are needed to mitigate efficiency loss.

Multiple Imputation

Overview

For relatively small amounts of missing data, single imputation is an approach that has many advantages. It is valid under MAR and can easily incorporate auxiliary data in the imputation model. It fully exploits the available data. Because data can be imputed before analyses, a single set of imputations can support multipleanalyses. Indeed, the imputation can even be done by a different data analyst other than the final data analyst. Single imputation replaces missing values with those drawn from a fitted distribution, obtained via the nonmissing values. Being drawn from a distribution, the missing values retain the same variability that would be seen if the data had not been missing.

The main disadvantage to single imputation is that it does not account for the fact that the model for imputing the data is itself estimated from the data and not known *a priori*. Specifically, once data are imputed, the final analysis produces estimates and standard errors as if the data are complete. MI solves this problem, thereby providing a complete inferential framework for conducting any type of statistical analysis when there are missing data.

MI proceeds via a three-step process. For ease of exposition, the authors sketch that process for the problem of imputing possibly multivariate missing predictors X_u; the process is similar for other missing data patterns, for example, if the missing data are Y_u.

Step 1: Posit a Bayesian model for $[X_u|Y, X_o, Z; \phi]$, governed by parameter ϕ. Specify a prior for ϕ and use the data with Bayesian inference to generate a posterior distribution for ϕ.

Step 2: Randomly draw a value $\tilde{\phi}$ from the posterior distribution of ϕ.

Step 3: For each missing X_u, randomly impute from the distribution $[X_u|Y, X_o, Z; \tilde{\phi}]$. Steps 2 and 3 are repeated M times to produce M imputed 'complete' data sets. The M data sets can then be analyzed using any valid statistical procedure. Historically, M was set at 5 or 10; with experience, methodologists have learnt that $M = 20$ often provides more reliable statistical performance with insignificant increases in computing costs or analyst's time.

MI yields several important advantages over other methods for handling missing data. The M imputations can be generated independently of the analysis using whatever variables are available. The analyst neither needs to explicitly account for the exact specification of the imputation model $[X_u|Y, X_o, Z; \phi]$ nor for the auxiliary variables Z being used in the imputation. Rather, all necessary information to make inferences is contained in the M imputed data sets. In particular, because each imputation is based on a different draw $\tilde{\phi}$ from the posterior of ϕ, the MIs capture the additional uncertainty due to the estimation of the imputation model. One implication is that the imputations can be generated as part of preliminary data processing, before generating analysis data sets. For example, in a publicly available national survey, the organization performing the survey can generate the imputed data sets and make them available for download with the original non-imputed data. A final advantage is that MI, via modern Bayesian resampling methods, is capable of flexibly handle both monotone and nonmonotone missing data patterns.

Computational Details

It is beyond the scope of this article to cover the statistical theory underlying MI. Nevertheless, it is useful to present the few central formulae prevailing in all MI routines, partly because they emphasize the simplicity and portability of the method across various analysis settings and approaches, and partly because they provide a vehicle for explicating about how MI incorporates the uncertainty due to missing data into the final analysis.

Picking up from Step 3 above, analysis is completed in two additional steps. Assume that interest lies in parameter $\hat{\theta}$ governing $[Y|X; \theta]$. For ease of exposition, the authors assume that θ is unidimensional. The extension to multidimensional $\hat{\theta}$ is straightforward, but involves both vector and matrix arithmetic, and is therefore more challenging to present.

Step 4: For each j from $1,\ldots,M$, the jth imputed data set is analyzed as if the data are complete, obtaining estimates $\hat{\theta}^{(j)}$ with corresponding standard errors $\sqrt{V^{(j)}}$.

Step 4 is repeated M times. Note that any type of analysis can be pursued to obtain estimates $\hat{\theta}^{(j)}$ and standard errors $V^{(j)}$. This could, for example, be a maximum likelihood or a generalized method of moment-based analysis. The key assumption is that the sample size is large enough for the $\hat{\theta}^{(j)}$s to be approximately normally distributed. Of practical importance, the repeated analysis in Step 4 can in almost all cases be automated, and several modern statistical packages (e.g., SAS and Stata) have written MI wrappers that can be applied to any standard analysis being available in the package.

Step 5: Estimates $\hat{\theta}^{(j)}$ and $\sqrt{V^{(j)}}$ are combined to yield final estimates $\hat{\theta}$ and $\sqrt{V}$, using the formulae shown in **Table 1**. In particular, the overall (and final) estimate of θ is the average of the M estimates. The overall variance V is comprised of two parts, the average within-imputation variance and the (scaled) between-imputation variance. The overall standard error $\sqrt{V}$ can be used in the usual way to construct normal or t-based hypothesis tests and confidence intervals. Owing to the fact that M is usually not large, Rubin (1987) has recommended about using the t-distribution with v degrees of freedom (df) for critical values, where v is given in **Table 1**. Notably, v goes to ∞ as M becomes large, or, for fixed M, as the amount of missing data become small. Specifically, as the proportion of missing data shrinks, the imputation specific estimates $\hat{\theta}^{(j)}$ will become closer and closer to one another so that the between-imputation variance will naturally shrink to zero, causing v to go to ∞.

Multiple Imputation in Practice

To implement MI in practice, the imputer needs to specify a model for $[X_u|Y, X_o, Z; \phi]$ as well as a prior for ϕ. For continuous components of X_u, the model is often based on linear regression, whereas for categorical, it is often based on logistic regression as well as its extensions for categorical and ordinal data. There is considerable benefit in having this model be fairly flexible, so if the sample size supports it, one should include nonlinear terms for continuous predictors as well as key pairwise interactions between predictors. Vague priors are generally used in an attempt to reflect a state of relative ignorance regarding ϕ.

Monotone missingness patterns are more straightforward to model because the joint distribution of all components of

Table 1 Formulae for combining multiple imputation estimates

Description	*Formula*
The overall (and final) estimate of θ[a]	$\hat{\theta} = M^{-1}\sum_{j=1}^{M}\hat{\theta}^{(j)}$
The average within-imputation variance[b]	$\overline{V} = M^{-1}\sum_{j=1}^{M}V^{(j)}$
The between-imputation variance	$B = (M-1)^{-1}\sum_{j=1}^{M}(\hat{\theta}^{(j)}-\hat{\theta})^2$
The overall, or total, variance	$V = \overline{V} + (1+M^{-1})B$
Degrees of freedom for t-distribution[c]	$v = (M-1)\left[1+\frac{V}{(1+M^{-1})B}\right]^2$

[a] M is the number of imputations and $\hat{\theta}^{(j)}$ is the estimate in the jth imputed sample.

[b] $V^{(j)}$ is the variance of $\hat{\theta}^{(j)}$ in the jth imputed sample.

[c] v can be expressed as $v = (M-1)[1+(1/\tau)]^2$, where τ is the relative increase in variance in $\hat{\theta}$ due to missing data. Owing to this simple interpretation, the quantity τ can be useful in study design and sample size calculations when it is known that some missing data will be unavoidable.

X_u can be modeled via a series of conditional models. In more complex nonmonotone missing data patterns, full conditional resampling methods are often used, wherein one component of X_u is modeled and imputed on the basis of imputed values of all the other missing components of X_u. This process is iterated with new samples of ϕ and all components of X_u in order to generate M imputed data sets.

In modern statistical packages, much of the missing data modeling and imputation is handled in procedures that automatically determine the scale of each component of X_u, specify a default model, determine whether the pattern is monotone or not, specify a prior for ϕ, and ultimately generate the imputed data sets. Default specifications can be overridden, but with modest levels of missingness, the defaults are often perfectly adequate. Those same packages often contain tools for carrying out the postanalysis summaries and inferences as described in Step 5 above. MI for clustered or longitudinal data is less systematically implemented in standard software packages. These situations are more complicated, especially if the data are imbalanced.

Finally, a comment regarding robustness. Certainly, there is a need for model flexibility in order to capture the key relationships of X_u to (Y, X_o). And, with a fairly extensive modeling machinery needed for complex missing data patterns, there are plenty of opportunities for misspecification. Nevertheless, simulation work and empirical evidence have shown that final inferences for θ are often quite robust to specifications of the missing data model. It is believed that the underlying reason for this is that most data are not missing. In most cases, less than 30% of data are missing, often even less. Hence, there is much to be gained by doing imputations even if the imputation model is only correct to first order. The degree to which incorrect models can lead to bias is in some sense bounded by the fact that at most 30% of the data (or whatever percent are missing) are the result of such incorrect model specifications. There is only so much damage that modest model misspecifications can inflict, especially when contrasted with the potential bias in carrying out naive complete-record analyses.

Conclusion and Key Literature

Missing data occurs in many if not most applied data analysis settings and can introduce bias and inefficiency if not handled properly. Quantifying the extent and structure of missing data is key to choosing appropriate methods, and this should be done using the framework of MCAR, MAR, and MNAR missingness. Two popular, widely applicable, and flexible methods are weighting and MI. These are valid under MAR missingness. Not being discussed here, NMAR missingness is especially challenging but can be approached via sensitivity analyses in the model for the missingness mechanism.

Modeling Cost and Expenditure for Healthcare

WG Manning, University of Chicago, Chicago, IL, USA

Introduction

The distributions of both healthcare expenditures and utilization share a number of characteristics that make their analysis more complicated than conventional economics outcomes; see also Models for count data and Cameron and Trivedi (2013). This article will focus on the analogous issues for costs and expenditures on healthcare. The most salient of these characteristics for many health economics applications are as follows: (1) a substantial part of the population will have no costs or expenditures during the period of observation; (2) among those with any expenditure, the amount is typically dramatically skewed right; and (3) not all parts of the distribution respond the same way to covariates. Even in clinical populations based on being treated for a specific health condition, the last two characteristics are still important. It is not uncommon to find that the top 1% of the population consumes nearly a fifth to a fourth of total health resources, and the top 10% nearly half of the total. Some types of expenditures are even more skewed with the top tenth of the distribution accounting for half or more of all healthcare expenditures, such as inpatient or mental health. These upper centiles or deciles may respond differently, such as being less elastic in their response to out-of-pocket price or income. In the Health Insurance Experiment (HIE), the upper decile was composed mostly of inpatient users, who were less responsive to insurance coverage than outpatient-only users (Duan *et al.*, 1983; Manning *et al.*, 1987).

Analysts have often found that the use of the least squares estimator with such data often leads to analytical problems from highly influential outliers – catastrophic cases, or chronic care patients with many visits and substantial pharmacy costs unless the sample size is sufficiently large so that there are a substantial number of such cases. For example, see the works on risk adjustment using a large fraction of the US Medicare claims files for risk adjustment. As the sample size becomes very large, the same concern does not remain, that the results will be driven by a small number of observations with catastrophic expenditures having undue influence.

Without the luxury of enormous data files, there is often the temptation to remove these extreme cases; removing or trimming or winsorizing such cases will reduce the influence of the extreme cases but will also introduce bias because catastrophic cases do occur in health and do consume real resources. Because of these issues, analysts often find that results are not replicable across alternative samples drawn from the same population. Least squares estimation under these circumstances is inefficient and in some cases biased, especially if zeroes are prevalent. Even when the estimates are unbiased, the inferences are biased because the underlying heteroscedasticity implicit in a model with a strictly nonnegative dependent variable is ignored. The inefficiency in the estimates and bias in the inference statistics for ordinary least squares (OLS) results arise from the property that the variability in costs is often an increasing function of the mean or some other function of the covariates x.

Health economists and econometricians have adapted various methods to deal with different outcomes and issues. The largest division is between count estimators to address the integer nature of MD visits and hospital admissions, compared to estimation approaches designed for continuous positive outcomes such as expenditures; survival approaches have been used, but are less common than the major splits of counts versus continuous. A cross-cutting issue is how to address the mass of observations at zero in either type of outcome, but the specific solutions differ both by the type of data on the outcome and by the underlying research question. In the case of count data, the concerns may include the mean response or marginal and incremental effects, or the response probability that the specific values of the counts respond in a particular way – does a change in the dental insurance coverage for prophylaxis change the probability that a patient has two such visits per year?

In the case of the limited dependent variable for expenditures, the issues are often the likelihood of any use and the overall mean response or some function of these such as the marginal and incremental effect. In both cases, the skewed nature of the outcome variables may make the results sensitive to influential outliers unless suitable methods are employed.

This article will focus on the health costs and expenditure case for individuals.

With data from either a general population or a population of users, it is not uncommon for cases in the top 1% of the distribution to have values that are nine times the sample mean, have studentized residuals that are beyond the $+4\sigma$ range, and maybe in double digits for the far right tail of the distribution, especially for expenditures. If such values are coupled with deviant values for the covariates, then they may have tremendous influence on the estimates. Because cost and expenditure data are so skewed right, there are no countervailing large residuals in the left tail. The consequence is that in small and moderate-sized samples, a single case can have tremendous influence on the estimates; as the sample size N increases, this issue of influence is diminished, especially with very large data sets, such as those used in estimating risk adjusters for the US Medicare program. The one notable exception occurs when one of the rate cells is relatively rare; see comments in Mihaylova *et al.* (2011). In the HIE, one single observation accounted for approximately 17% of the mean for that insurance plan.

The issues are different for very large data sets. As the sample size N increases, this issue of influence to skewness diminishes. The major modeling issue is getting the functional form to reflect the nonlinear nature of the response, an issue that applies to data sets of all sizes.

In what follows, first, a brief introduction to alternative approaches is provided for these types of healthcare or medical-care expenditures (or continuous positive outcomes).

Then questions about the treatment of the zero mass and skewness are addressed. There are some comments on methods for assessing differential responses in different parts of the distribution. Except where noted, the discussion applies to observations for fixed-size intervals of observations, rather than unequal-sized intervals; the latter can be addressed with formal offsets in some models.

Healthcare Expenditures

In what follows, a summary is provided of a number of issues that are of econometric and statistical concern in the modeling of healthcare expenditures. Jones (2011), Mihaylova *et al.* (2011), and Mullahy (2009) provided reviews of the modeling of healthcare expenditures and continuous outcomes with a more detailed discussion related to much of what is presented here.

Addressing the Zeroes Issue

Healthcare expenditures are nonnegative, often with many zeroes for the period of observation. One of the first issues is how to address the zeroes in the econometric modeling of the mean conditional on the covariates or of marginal effects when the focus of the analysis is on a general population rather than a clinical population of healthcare users. One approach has been to break down the distribution into two or more parts using the following rule:

$$E(y_i|x_i') = \text{Prob}(y_i > 0|x_i') \cdot E(\$_i|x_i', y_i > 0) \quad i = 1,\ldots,N \qquad [1]$$

The classes of two-part estimators provide different approaches to each part, with the two terms on the right side typically modeled separately because of the conditional independence of the second part (Cragg, 1967; Duan *et al.*, 1983). This type of estimators have been extended to include multipart models as well to address additional complication, such as differential response in the right tail, largely associated with inpatient care in the HIE (Duan *et al.*, 1983; Manning *et al.*, 1987). The analytical issues for both two-part and multipart models involve choices of the estimation approach for any expenditure and for the level of expenditure that are appropriate for the data at hand.

There is an alternative approach for the case where the concern is the mean response (conditional on a set of characteristics). That alternative involves a one-part part or single-equation, nonlinear model to obtain consistent estimates of $E(y|x)$, where the underlying explanatory variables are the same as those in the two-part models in equation 1 above. There is no necessity that the functional form of the response is the same as that for the second part of eqn [1]. For two-part models, see Duan *et al.* (1983), Blough *et al.* (1999), and various papers by X. H. Zhou. For single or one-part model, see Mullahy (1998) and Buntin and Zaslavksy (2004). There appear to be two unresolved issues in the debate over one- versus two-part models. The first is how large a fraction of the observations should be zeroes to make a difference, if any, in terms of bias or efficiency. The second is to what extent is this debate about the choice of the number of parts, rather than about how complicated the covariate specification should be to fit the actual distribution across the range of predictions in one- versus two-part models? Would a one-part model with additional covariates be able to capture curvature in the data to be equivalent to a two-part model?

There is a third, less common approach that builds on bivariate normal methods for two-part models, rather than the conditioning argument behind eqn [1], that are sometimes referred to as adjusted or generalized Tobit models or Heckit models. There is mixed evidence on how well these alternative estimators behave if there are no identifying restrictions across equations, which is the most common situation in health, unlike in labor economics. There are two common misconceptions in this debate. The first is that two-part models are nested within the bivariate normal alternatives; they are not. The second is that two-part models assume no correlation between any use and level of use; there are counterexamples in the literature.

All of the models considered here may be sensitive to influential outliers. The sensitivity to extreme cases is a natural byproduct of the skewness in the data. If expenditures were to be analyzed by a standard OLS model of the form $y_i = x_i'\beta + \varepsilon_i$ where y_i is the cost or expenditure on the raw scale (dollars, Euros, or pounds) for observation i, x_i' is a row vector of observed characteristics, and β is a column vector of coefficients to be estimated. Then the effect of an individual observation i on the estimate of β can be characterized by Cook's distance or the DFITS measure. Both measures depend on how extreme the observation is in terms of both the covariate values and the residual squared. These two diagnostics can be extended to nonlinear models as well as for least squares, as well as other tests of model checking such as Pregibon's Link Test or can be extended to include more complicated nonlinearity (as in Ramsey's RESET test), or less parametrically using a modified version of the Hosmer–Lemeshow test.

Addressing Skewed Positive or Overall Expenditures or Overall Nonnegative Expenditures

There are several approaches to dealing with such data: do nothing beyond OLS, use a Box–Cox transformation of the dependent variable, use one of the generalized linear models (GLMs) appropriate for continuous outcomes, use one of the three- and four-parameter distributions, or use a flexible and robust approximations to the underlying distribution. The consequence of the all-too-common alternative of ignoring the skewed data with a least squares approach is that the results are (1) sensitive to the skewness in the dependent variable, especially if the data set is of small or moderate size (such as the Medical Expenditure Panel Survey), and some of the characteristics are rare, and (2) the inference statistics are biased given the inherent heteroscedasticity in the data has not been captured in the estimation.

Box–Cox models

One alternative is to transform the dependent variable by the natural logarithm or a power transformation to eliminate the skewness in the error; transformations may also be used to achieve a model that is linear in the parameters (as in the

Cobb–Douglas production function) or to stabilize the variance of the equation estimated (as in the square root transformation for count data or the inverse sine root transform for proportions). Some of these transformations are special cases of the Box–Cox transformation, but some are less reliant on parametric distributional assumptions. Specifically, the Box–Cox models consider transformed equations $f(y)$ if y is positive of the form

$$f(y) = (y^{\lambda} - 1)/\lambda = x\beta + \varepsilon \quad \text{if } \lambda \neq 0 \qquad [1a]$$

$$f(y) = \log(y) = x\beta + \varepsilon \quad \text{if } \lambda = 0 \qquad [1b]$$

It is often assumed that ε is either symmetric or normally distributed. The model can be estimated either by maximum likelihood estimation (MLE) or by the use of least squares for suitable values of λ. There are also two-parameter versions of the Box–Cox model that allow explicitly for the mass of observations at zeroes, but these do not always provide consistent estimates of the mean outcome, conditional on the covariates.

The advantage of the power transformation if $\lambda < 1$ for data that are skewed to the right is that it pulls in the right tail of the distribution faster than it does in the middle or the left tail. As λ decreases toward zero, the error term in the estimated equation should become more symmetric, reducing the influence of the extreme cases in the right tail of the distribution. However, too low a values of λ (such as the log, when $0 < \lambda < 1$ would be more suitable) may lead to overcorrection in the sense that it would convert a right-skewed distribution into a left-skewed one after the transformation. The log transformation is not always the optimal choice for right-skewed data.

The problem with the log and Box–Cox approaches is that one is often not interested in the transformed scale *per se* – the government does not spend log dollars or log Euros. Rather, one is actually interested in the raw scale of expenditures y and predictions or marginal effects in dollars or Euros (in $E(y|x)$ more generally). This leads to concerns about the retransformation of the results from the scale of estimation (e.g., the log or the λth power) to the scale of interest (e.g., raw or actual dollars or Euros). Because of the nonlinear nature of the log and Box–Cox transformations, the transformation cannot be simply inverted to obtain unbiased estimates of the $E(y|x)$ because $E(f(y|x)) \neq f(E(y|x))$, where $f(y)$ is the transformation. This is the retransformation problem discussed by Duan (1983), Duan *et al.* (1983), Manning (1998), Mullahy (1998), and Blough *et al.* (1999).

The difference between the two is easy to see in the case of OLS on $\ln(y)$ if the error term is log normally distributed. OLS generates unbiased estimates of $E(\ln(y_i|x_i)) = x_i'\beta$ if $E(X'\varepsilon) = 0$. However, the term $E(\exp(x_{i_i}'\beta))$ yields an estimate of the geometric mean, not the arithmetic mean of the response function. The arithmetic mean is $E(y_i|x_i) = \exp(x_i'\beta + 0.5\sigma_{\varepsilon}^2)$ if ε is i.i.d. and normally distributed, and $E(y_i|x_i) = \exp(x_i'\beta + 0.5\sigma^2(x))$ if normally distributed and heteroscedastic in x (Manning, 1998). If the error is not normally distributed, then the estimates $x_i'\hat{\beta}$ may be consistent, but one can apply Duan's (1983) multiplicative smearing factor in the homoscedastic case to provide a consistent estimate of $E(\exp(\varepsilon_i))$, or its analog in the heteroscedastic case to obtain the mean response.

The goal of most analyses is some statement about how the mean or some function of the mean of y, such as the marginal effect on the raw scale, changes with x. In general, the expectation of y depends on the variance and heteroscedasticity on the log scale and on how higher order terms depend on the covariates. If the variable of interest x_j is not discrete, then the slope of the expected value with respect to the jth covariate is given by

$$\begin{aligned} \frac{\partial E(y_i|x_i)}{\partial x_{ij}} &= \left(E(y_i|x_i)\right) \cdot \left(\beta_j + 0.5\frac{\partial \sigma_{\varepsilon}^2}{\partial x_{ij}}\right) \\ \frac{\partial E(y_i|x_i)}{\partial x_{ij}} &\neq \left(E(y_i|x_i)\right) \cdot \beta_j \\ \frac{\partial E(y_i|x_i)}{\partial x_{ij}} &\neq \left(e^{x_i'\beta}\right) \cdot \beta_j \end{aligned} \qquad [2]$$

It is the first derivative in eqn [2] that should be used in the calculation of the elasticity of the mean response or the average marginal effect, rather than either of the other two in the case of log scale heteroscedasticity if the log-scale error is normally distributed. The last one applies only if $R^2 = 100\%$ on the log scale.

In the nonnormal case or for values of λ other than zero, the derivative will depend on the power transform λ, the nature of the distribution in the absence of the additional complication of heteroscedasticity:

$$\frac{\partial E(y_i|x_i)}{\partial x_{ij}} = \beta_j \int (\lambda(x_i'\beta + \varepsilon_i) + 1)^{(1-\lambda)/\lambda} dF(\varepsilon_i) \qquad [3]$$

where $F(\varepsilon)$ is the cdf for the error term.

In the square root case where $\sqrt{y_i} = x_i'\beta + \varepsilon$ with possible heteroscedasticity, the scale of interest relationship is $E(y_i|x_i) = (x_i'\beta)^2 + \sigma_{\varepsilon}^2(x_i)$. Here the retransformation factor is additive. The retransformation factor will be multiplicative only in the case of $\lambda = 0$ and will be moot if $\lambda = 1$.

There are a number of technical issues that arise with Box–Cox models. One of these is how to deal with observations where $y = 0$. Second, the estimates of the power transform are sensitive to extreme outliers in ε. In practice, it may be difficult to tell the effect of an influential outlier from skewness in the dependent measure that is not associated with the covariates. Third, if λ is not known *a priori*, then all of the inferences should reflect that β's, λ, and σ are estimated in calculating inference statistics for eqns [2] and [3], not just the β's.

Generalized linear models

A second alternative to a least squares linear model using some $f(y)$ directly is to model the $f(E(y)$ directly and deal with the skewed expenditure data (with or without the zeroes) by addressing the property that the variance function is often an increasing function of the mean. This can be done by using some iteratively reweighted least squares alternative or the GLMs for continuous outcomes (such as gamma regression) estimated with quasi-maximum likelihood methods. In the GLM case, the analyst specifies a link function between the linear model $x'\beta$ and the mean, so that $g(E(y|x)) = x'\beta$, and a variance function $v(y|x)$ that characterizes the nature of the relationship between the mean and the variance on the raw

scale. The $v(y|x)$ function is assumed to be a function of the mean, not of individual covariates in x directly. The correct specification of the variance function results in more efficient estimators and may correspond to an underlying distribution of the outcome measure. If the distribution is from the exponential family, then the estimation can be done by quasi-maximum likelihood methods. Although one can perform an MLE using the specific distributions, the conventional GLM is more robust in the sense it does not assume the distribution beyond the first and second moments. So, for the gamma GLM, only the gamma variance (the variance function increases as the square of the mean function) is assumed and not the full gamma distribution.

If the link function is misspecified, then the estimates will provide a biased estimate of the response. Much of the work to date on healthcare expenditures has used a log link: $\ln\left(E\left(y_i|x_i\right)\right) = x_i'\delta$; I use δ has been used for the index function in the log link GLM to avoid possible confusion with β from the $\ln(y)$ model. If the $\ln(y)$ error is homoscedastic, they have the same expectation, except for the intercept where δ_0 corresponds in expectation to $\beta_0 + \ln[E(\exp(\varepsilon_i))]$. However, some papers have also used power transformations, such as the square root. Just because the log transformation is often used in transformed y models, there is no reason to assume the same for the GLM or to use $\lambda = 0$ for all cases that are skewed right. In the transformed y models, the log (or any other Box–Cox transformation) is designed to achieve symmetry in the error. In the GLM case, the goal is to find a function of a linear index (say $x'\delta$, which provides a consistent estimate of $E(y|x)$ over the range of $x_i'\delta$ and the major covariates in $x_i'\delta$. This difference between least squares on transformed y and GLMs with power or log links is very important to understand, and has been a common source of confusion between log/Box–Cox methods and GLM alternatives.

Since the late 1990s, the most commonly used distribution for GLM applied to positive healthcare cost or expenditure data has been the gamma. This is appealing working assumption for the distribution function because the standard deviation under the gamma is proportional to the mean, a property often but not always exhibited by healthcare cost data. However, this is only one of several cases where the standard deviation or the variance is a power of the mean function. If the variance is not a function of the mean, then a Gaussian assumption may be used (Mullahy, 1998; Wooldridge, 1992). If the variance is proportional to the mean, then the Poisson may be more appropriate. If the standard deviation is proportional to the cube of the mean, then the inverse Gaussian is an alternative. Other applications could employ powers of the variance as in Blough *et al.* (1999) and Basu and Rathouz (2005) approach (see below).

As long as the link function and the index function of the covariates $x_i'\delta$ are correctly specified, the GLM provides consistent estimates. The wrong mean–variance relationship or the wrong distribution function can potentially lead to substantial efficiency losses. For Box–Cox models, there may be bias if there is heteroscedasticity and efficiency loss if the underlying error is not normal. Manning and Mullahy (2001) provide a fuller discussion and simulation results that illustrate the trade-offs involved among $\log(y)$ and GLM with log links. One implication of their work is that there is no one estimation approach that is ideal or even a close second best approach for all examples. The best estimation approach depends on the application at hand and its underlying data-generating process.

Extended GLM methods

There is a hybrid of the Box–Cox type of model and the GLM. Basu and Rathouz (2005) describe an extended estimating equation (EEE) algorithm that allows one to use the data to estimate both the link function from the power family via the Box–Cox link for the mean function and the power family relationship between the mean and the variance functions.

$$\begin{aligned} E(y|x) &= \mu = g^{-1}(x\beta) \\ g(\mu_i) &= (\mu_i^{\lambda} - 1)/\lambda \\ V(y_i) &= \theta_1(\mu)^{\theta_2} \end{aligned} \qquad [4]$$

This approach is more general than the two preceding alternatives and avoids the issues that arise in the common practice of using only a discrete set of GLM alternatives for the link and mean–variance relationship. In both the Box–Cox model and the GLM, the choice of the wrong transform of y or link for $E(y|x)$ can lead to biased estimates. In the GLM, only using integer powers for the mean–variance relationship can lead to a substantial loss of efficiency. Further, the results for inference statistics will reflect the uncertainty in the estimates of λ and θ_2, thus avoiding the corresponding issue and debate in statistics over the Box–Cox transformation of y.

Other parametric approaches

Manning *et al.* (2005) propose using an exponential conditional mean regression based on the three-parameter generalized gamma distribution that could be estimated by maximum likelihood. The generalized gamma model includes the gamma, Weibull, and exponential distributions with log link, as well as models for $\ln(y)$ with normal errors. This approach also provides a robust alternative to either the GLM with log link or the OLS on $\ln(y)$ when those two alternatives do not apply, assuming that the mean is truly an exponential function of $x'\beta$. The generalized gamma is a more precise alternative than the GLM when the distribution is more skewed than is implicit in the GLM case. However, the generalized gamma is susceptible to bias in the presence of certain forms of heteroscedasticity on the log scale. Manning *et al.* (2005) propose a modification of the model that corrects for this by allowing for two index functions, one for the $\ln(\sigma)$ term and the other for the log-scale mean.

There is some preliminary interest in four-parameter distributions, such as the generalized betas of the second kind because they allow for better fit to the actual distribution of positive expenditures, as well as have several of the other alternatives as special cases if the link is log or there is a proportional response. There is related work by the distribution of income. The five-parameter distribution has not been employed to the best of the author's knowledge. Nevertheless, the generalized gamma and the four- and five-parameter versions of the generalized beta permit an explicit allowance for skewness that is not always fully captured in simpler two-parameter distributions such as the Box–Cox/log normal or the GLM with its focus on the first two moments. Jones (2011)

reports results from a parametric model in the generalized beta of the second class. Although that model allows only one of the parameters to be a function of covariates, Jones has work allowing two or more parameters being a function of covariates. This work would be more general and flexible than either the GLM (with log link) or the generalized gamma, because these are limiting cases or more restrictive variants of the generalized beta of the second kind (GB2). That statistical distribution has a richer parameterization that allows the parameters to depend on patient or other characteristics.

Differential responsiveness

In their common formulations, the previous methods do not allow for heterogeneity in the healthcare responses to covariates over the population, by service, over the distribution of expenditures, or by allowing for latent groups. Quantile methods could be used to allow for differential responses, if allowances are made for ties in the zero spenders. The multipart models, especially the four-part model used in the HIE (Duan *et al.*, 1983) allow for inpatient users to have a different response to covariates; the four-part model is also a mixture model with known or observable separation among subgroups and differs from the latent class models more often used for count data. Finite mixture models with unobserved or unknown separation can be used to approximate an arbitrary distribution and to allow for some heterogeneity in response, given the number of latent classes included.

Less-parametric approaches

Gilleskie and Mroz (2004) have suggested that one can use a series of conditional models to address the skewed nature of healthcare expenditures and the zeroes problems together. They suggest a conditional density estimator (CDE) that breaks the dependent variable (healthcare expenditures) into J different segments, modeling the probability p of being in a specific segment j as a function of the covariates x's as a polynomial function f of the covariates x, and then using subsample means of y within each of those J segments. The basic approach takes advantage of the way conditional distributions work, namely, that $E(y) = E(y|z) \cdot E(z)$. In this case, the expected value of y, given the observed characteristics of the population is

$$E(y|x) = \sum_j p_j(y \text{ in range } j) \cdot (E(y|y \text{ in range } j)) \qquad [5]$$

The overall response $E(y|x)$ for person i over the j ranges is given by

$$E(y_i|x_i) = \sum_j \left((p_j(x_i'\alpha_j)) \cdot (\mu_j) \right) \qquad [6]$$

where j is an index for segments and x's are polynomials in the underlying independent variables. Gilleskie and Mroz propose a very specific form for the probability functions $p_j(x_i'\alpha_j)$, but one can use a more general approach than they used. By breaking the dependent variables into bounded values (except for the last segment), they avoid some of the issues of robustness to skewness in y because the values of y in a specified range are not as long tailed as the whole distribution of y. By using a polynomial in the underlying covariates, they allow for a nonlinear response to the individual characteristics.

Given the complexity of the model in eqns [4] and [5], the effects of covariates are assessed using a marginal or incremental effects approach just as in the multipart models.

They find that the model performs well in a range of simulated conditions. Also, they are able to obtain well-behaved results with data drawn from the HIE. One of two remaining issues is how big the intervals should be, especially given the substantial part of the overall expenditures that are in the last (open) interval. The other is how to model means of intervals if the mean conditional on being in an interval depends on covariates.

Assessing Model Fit

The literature provides a number of tests that can be applied to most of these models to assess the quality of the fit whether the model is based on single-equation methods (with or without the zeroes), two-part or multipart models, or GLM and extended GLM. Some of the omnibus fits of test are primarily done on the scale of estimation; they include Pregibon's Link Test and Ramsey's RESET test. The Pearson correlation test between the raw-scale residual and the raw-scale prediction, and the modified Hosmer–Lemeshow test, can be performed on the raw scale, which is often the scale of interest. Buntin and Zaslavsky (2004) provide discussions of a number of these, plus others that are often used in the risk adjustment literature.

Generally, the two-part and multipart models are more difficult to assess the overall fit because there is no established analog of Pregibon's Link or Ramsey's RESET test for multipart models. For this and the CDE class of models, model assessment is limited to Pearson and modified Hosmer–Lemeshow for in-sample assessment, and the usual cross-sample validation approaches including simple split sample or k-fold methods. There are other extensions of split sample cross-validation approaches that can be used on the scale of estimation, including the type of two-parameter more parsimonious work by Copas (1997). In health services research, there is also a set of cross-validation tests that have been called Copas tests but differ in that the estimates from the first split sample are predicted to the test or validation sample on the raw scale, sometimes called the scale of interest. There the test is whether the regression of the raw scale version of the dependent variable to the test but on the raw scale is a straight line through the origin with slope 1; see Veazie *et al.* (2003) and Basu *et al.* (2006).

Quantile Approaches

With the exception of the Gilleskie and Mroz (2004) approach discussed earlier, the approaches have been largely parametric. Often these approaches have assumed that there is limited heterogeneity in response over the distribution of expenditures (inpatient vs. outpatient, or across a small number of latent classes). Another approach is to employ quantile regression methods that allow the responses to differ across the distribution of expenditures, conditional on a set of covariates based on the quantile methods reviewed in Koenker (2005).

Note that these provide a more flexible approach to modeling the response because the responses are not forced to be parallel on the scale of estimation. For example, if the inpatient and outpatient responses are different, then that can be addressed with separate models for different services or by a multipart model. But if the catastrophic inpatient cases had a different response to income and price, then the simpler models could fail to be parallel in the right tail, where so much of the total resource cost and expenditure are.

This article will not address those quantile approaches in detail.

Strengths and Weaknesses

There have been a substantial number of papers of econometric and statistical models for modeling healthcare costs and expenditures as a function of patient characteristics of interest. Many of these deal with the whole distribution, especially the substantial fraction of the cases that have zero expenditure. Many of these papers involve comparisons for alternative models with the evaluation largely limited to how well specific models do for a specific data set. One of the concerns about such studies is their generalizability to other populations or to other types of healthcare expenditures. A second concern is that the performance in a specific application may reflect overfitting of badly skewed data, because many of the papers use within-estimation sample methods to evaluate the relative performance of the alternatives.

Manning and Mullahy (2001) report simulated comparisons of several exponential conditional mean models under a range of different data-generating mechanisms. These include the use of OLS on $\ln(y)$, various types of GLMs with log links (Gaussian, Poisson, and gamma). In each case, the true response was exponential conditional mean $E(y|x) = \exp(x\beta)$. They examined a number of data-generating mechanisms that lead to varying degrees of skewness, heteroscedasticity on the log scale, and even heavy-tailed distributions for $\ln(y)$. In the absence of heteroscedasticity on the log scale, they found that both the OLS on $\ln(y)$ and GLM with log link models provided consistent estimates of $E(y|x)$. But if the true model was linear on the log scale with an additive error term that was heteroscedastic in x, the log OLS provided biased estimates of $E(y|x)$ without suitable retransformation.

Although the GLM were always consistent, the choice of variance function assumption had substantial impact on the efficiency of the estimation, especially when compared with the results based on OLS on $\ln(y)$. Further, the loss of efficiency relative to OLS on $\ln(y)$ increased as the data became more skewed or became heavy tailed on the log scale.

Because of the potential for bias from OLS on $\ln(y)$ and of efficiency losses from the GLM with log link models when the log-scale error variances are large or the log-scale error is heavy tailed, they propose an approach for determining which estimation approach is better for a specific data set.

Basu and Rathouz (2005) also simulate the behavior of various GLM versus their proposed EEE extension of the GLM. They find evidence of bias and inefficiency when the incorrect power transformations are used for either or both of the link and the variance functions. But they do not examine the traditional Box–Cox estimator.

Except for Basu and Rathouz (2005) and subsequently Basu *et al.* (2006), there is little in the literature outside the exponential conditional mean that is not specific to a particular data set or health condition. But there is no reason why other link or Box–Cox style transformations of the dependent variable could not be used or seriously considered. More flexible alternatives could be used and then the results reported as incremental or marginal effects.

With data as skewed or with as many zeroes as healthcare data have, there is always a concern about overfitting. Traditional split-sample or cross-validation tests, or the more parsimonious Copas's (1997) tests on the scale of estimation can be employed to assess overfitting in the narrower sense of the term. But there is also a concern about how well the model fits on the scale of ultimate interest, especially if payment/risk adjustment issues are involved. Some of these have extended to split-sample, out-of-sample tests, and to test/validation sample methods on the scale of interest by Veazie *et al.* (2003) and Basu *et al.* (2006). These provide more confidence in the results than ones conducted on the statistical scale-of-estimation, as Copas and others have done; see Hill and Miller (2010) for a recent example of a scale-of-interest comparison.

Conclusions

Because of the very skewed nature of healthcare costs and expenditures, analysis based on simple regressions of costs or expenditures are not robust in data sets with the number of observations encountered by most analysts. The focus in most applications is on finding more robust estimates of the mean response than simple OLS, conditional on the covariates, or the marginal and incremental effects of particular policies or treatments. The literature offers a number of alternative estimation strategies for expenditures. These include both single and multipart models using a range of options to deal with skewness in general or in the positive cases: Box–Cox transformations (especially the log) of the dependent variable, and GLMs, and a less restrictive version of the GLM-type approach (the extended GLM or EEE), a broader class of distributional assumptions (the generalized gamma and the generalized beta), a discrete and less parametric approximation, have been suggested as alternative estimators.

At this point, it does not appear that any specific approach dominates the modeling of the data with continuous outcomes beyond the nonuser subset. Instead, it appears that econometric model needs to be able to address the research question and to match the characteristics of the data if the estimate is to be relatively efficient, with little bias, and to pass the Cox test. To paraphrase Cox and Draper, all models are wrong, but some are useful. That is, some econometric methods provide better approximations than others.

Models for Count Data

PK Trivedi, Indiana University, Bloomington, IN, USA

Introduction

Count data regression is now a well-established tool in econometrics. If the outcome variable is measured as a nonnegative count, y, $y \in N_0 = 0, 1, 2, \ldots$ and the object of interest is the marginal impact of a change in the variable x on the regression function $E[y|x]$, then a count regression is a relevant tool of analysis. Fully parametric formulations of count models accommodate this discreteness property of the distribution, with probability mass at nonnegative integer values only. By contrast, some semiparametric regression models accommodate only nonnegativity but not discreteness. For such data, a linear regression is generally not efficient, and hence the standard count model is a nonlinear regression. A fully parametric formulation is more attractive if the researcher's interest is in the full distribution of the data, whereas a semiparametric model like nonlinear least squares is often used when the focus is on the conditional mean only.

Cross-section and panel data on event counts, for example, doctor visits, hospital admissions, and many measures of health-care utilization, are very common in empirical health economics. This has contributed to the use of count data regressions. This entry covers the case where all regressors are exogenous or predetermined. The empirically important case in which some regressors are endogenous is treated in other articles. The focus here is on classical inference, but all models considered here are amenable to Bayesian analysis.

Poisson Regression

The starting point of many count data analyses is the Poisson regression, derived from the Poisson distribution, for the number of occurrences of the event, with probability mass function

$$\Pr[Y = y] = f(y|\mu) = \frac{e^{-\mu}\mu^y}{y!}, \quad y = 0, 1, 2, \ldots, \qquad [1]$$

where μ is the intensity or rate parameter. The first two moments of this distribution, denoted $P[\mu]$, are $E[Y] = \mu$, and $V[Y] = \mu$, which is the well-known equidispersion property of the Poisson distribution. The Poisson regression results from the parameterization $\mu = \mu(x)$, where x is a K-dimensional vector of exogenous regressors. The usual specification of the conditional mean is

$$E[y|x] = \exp(x'\beta) \qquad [2]$$

Standard estimation methods are fully parametric Poisson maximum likelihood (PML), 'semiparametric' methods such as nonlinear least squares, or (weighted) moment-based estimation, based on the moment condition $E[y - \exp(x'\beta)|x] = 0$ possibly further augmented by the equidispersion restriction used to generate a weighted moment function.

According to standard maximum likelihood theory, if the Poisson model is parametrically correctly specified, the maximum likelihood estimator (MLE) $\hat{\beta}_p$ is consistent for β, with covariance matrix estimated by

$$\hat{V}[\hat{\beta}_P] = \left(\sum_{i=1}^{N} \hat{\mu}_i x_i x_i'\right)^{-1} \qquad [3]$$

where $\hat{\mu}_i = \exp(x_i'\hat{\beta}_P)$. The use of this formula can be misleading if the equidispersion assumption is incorrect.

The Poisson regression is founded in the Poisson point process for the occurrence of the event of interest. This process is a characterization of complete randomness, which excludes any form of dependence between events, either cross sectionally or over time, and any form of nonstationarity. In the Poisson regression, these assumptions are conditional on the covariates x_i, which reduces the restrictiveness of the model. Even when analysis is restricted to cross-section data with strictly exogenous regressors, the basic Poisson regression is restrictive for most empirical work. First, the mean-variance equality restriction will be violated if there is significant unobserved heterogeneity in cross-section data – in which case (conditional) variance will exceed (conditional) mean. This feature, referred to as overdispersion (relative to the Poisson), manifests itself in a variety of data features, most noteworthy being the excess zeros problem.

Overdispersion

Overdispersion results from many different sources and is consistent with a variety of different deficiencies of the Poisson regression, including serial dependence, spatial dependence, or contemporaneous dependence of events. This motivates replacing the Poisson distribution with more flexible functional forms that can accommodate overdispersion as well as its other specific limitations.Thus, many functional forms are generated as Poisson mixtures. Replace the parameter μ_i in (1) by $\mu_i\nu_i$, where ν_i represents individual-specific, independently and continuously distributed, separable unobserved heterogeneity. Next make an assumption about the distribution of ν_i Finally, derive a new functional form by integrating out ν (subscript omitted) – a mathematical operation equivalent to averaging with respect to the assumed distribution of ν. A shortcut is to start with the more flexible functional form (i.e., the mixture distribution) without going through the intermediate mathematical step.

Provided the conditional mean is correctly specified, the PML estimator (PMLE) is consistent but not efficient in the presence of overdispersion. Considering overdispersion, one can use the pseudo-ML or quasi-ML approach, again using the PMLE for point estimates but computing the (Eicker–White) robust estimate of the variance–covariance matrix using an expression of the form $\hat{V}_{Rob}[\hat{\beta}_P] = A^{-1}BA^{-1}$, where $A = \sum_{i=1}^{N} \hat{\mu}_i x_i x_i'$ and $B = \sum_{i=1}^{N} (y_i - \hat{\mu}_i)^2 x_i x_i'$ and

 doi:10.1016/B978-0-12-375678-7.00716-1

$\hat{\mu}_i = \exp(x_i'\hat{\beta}_P)$, that is, the point estimates of β are as in pseudo-ML theory, but its sample variance is obtained robustly.

Efficient estimation of overdispersed model is possible if more specific parametric assumptions are invoked. The negative binomial (NB) regression is an example of a mixture model. It can be derived as a Poisson–Gamma mixture. Given the Poisson distribution $f(y|x,v) = \exp(-\mu v)(\mu v)^y/y!$ with the mean $E[y|x,v] = \mu(x)v$, $v > 0$, where the random variable v represents multiplicative unobserved heterogeneity, a latent variable assumed to be independent and separable has Gamma density $g(v) = v^{\alpha-1}\exp(-v)/\Gamma(\alpha)$, with $E[v] = 1$ and variance α ($\alpha > 0$). The resulting mixture distribution is the NB2 (negative binomial with quadratic variance), which has mean $E[y|x] = \mu(x)]$ and variance $V[y|x] = [1 + \alpha\mu(x)]\mu(x) > E[y|x]$, thus accommodating overdispersion. Relative to the Poisson, the overdispersed distributions have more probability mass at zero and high values of y. The same approach can be used with other mixing distributions.The NB1 variant of the NB, which has variance linear in $\mu(x)$, and the Poisson–lognormal mixture are two popular alternatives to the Poisson. The formulae for the probability mass function of NB1 and NB2 distributions are shown in Table 1.

Test of overdispersion

The null hypothesis of equidispersion can be tested by postulating an alternative overdispersed model. A formal test of the $V[y|x] = E[y|x]$ property can be based on the equation

$$V[y|x] = E[y|x] + \alpha E[y|x]^2$$

which is the variance function for the NB1 model. Equivalently, $H_0{:}\alpha = 0$ against $H_1{:}\alpha > 0$ is tested.

The test can be implemented by auxiliary regression of the generated dependent variable $((y - \hat{\mu})^2 - y)/\hat{\mu}$ on $\hat{\mu}$, without an intercept term, and performing a t test of whether the coefficient of $\hat{\mu}$ is 0. However, the rejection of the null does not automatically indicate a suitable alternative model because that outcome is consistent with failure of the null model in many different ways.

Alternatives to the Poisson

The NB regression has been found to fit well many types of data, including those with 'excess zeros.' It has an analytical closed form. Functional forms resulting from other mixing assumptions, for example, the lognormal, often do not have a closed form, although estimation using either simulation-based methods or quadrature methods for numerical integration is straightforward to implement.

The classic gamma heterogeneity assumption underlying NB2 is somewhat special. Modern approaches, however, can handle more flexible models where the latent variables are nonseparable, which means that in principle unobserved heterogeneity impacts the entire distribution of the outcome of interest. Quantile regression and finite mixtures are two examples of such nonseparable models.

The literature on new functional forms to handle overdispersion is large and still growing. Despite the availability of many functional forms, a relatively small class of models has attained much popularity in health econometrics. This includes especially the NB regression (NBR) presented above, the two-part model (TPM) or the hurdle model, and the zero-inflated Poisson (ZIP) and zero-inflated NB (ZINB), which collectively dominate the applied literature and form the set of basic parametric count regression models. These models are all mixtures of Poisson-type models. Discussion of these models provided as follows.

Hurdle Model

The hurdle model or TPM relaxes the assumption that the zeros and the positives come from the same data generating process. The zeros are determined by the density $f_1(\cdot)$, so that $\Pr[y=0] = f_1(0)$ and $\Pr[y>0] = 1 - f_1(0)$. The positive counts come from the truncated density $f_2(y|y>0) = f_2(y)/(1 - f_2(0))$, that is multiplied by $\Pr[y>0]$ to ensure that probabilities sum to 1. Thus, suppressing regressors for notational simplicity,

$$f(y) = \begin{cases} f_1(0) & \text{if } y = 0 \\ \dfrac{1 - f_1(0)}{1 - f_2(0)} f_2(y) & \text{if } y \geq 1 \end{cases} \qquad [4]$$

Table 1 Selected mixture models

	Distribution	$f(y) = Pr[Y = y]$	*Mean; Variance*
1	Poisson	$e^{-\mu}\mu^y/y!$	$\mu(x)$; $\mu(x)$
2	NB1	As in NB2 below with α^{-1} replaced by $\alpha^{-1}\mu$	$\mu(x)$; $(1+\alpha)\,\mu(x)$
3	NB2	$\dfrac{\Gamma(\alpha^{-1}+y)}{\Gamma(\alpha^{-1})\Gamma(y+1)}\left(\dfrac{\alpha^{-1}}{\alpha^{-1}+\mu}\right)^{\frac{1}{\alpha}}\left(\dfrac{\mu}{\mu+\alpha^{-1}}\right)^{y}$	$\mu(x)$; $(1+\alpha\,\mu(x))\,\mu(x)$
4	Hurdle	$\begin{cases} f_1(0) & \text{if } y = 0, \\ \dfrac{1-f_1(0)}{1-f_2(0)} f_2(y) & \text{if } y \geq 1 \end{cases}$	$\Pr[y>0\|x]E_{y>0}[y\|y>0,x]$
5			$\Pr[y>0\|x]V_{y>0}[y\|y>0,x]$ $+\Pr[y=0\|x]E_{y>0}[y\|y>0\|x]$
6	Zero inflated	$\begin{cases} f_1(0)+(1-f_1(0))f_2(0) & \text{if } y = 0, \\ (1-f_1(0))f_2(y) & \text{if } y \geq 1 \end{cases}$	$(1-f_1(0))(\mu(x)+f_1(0)\mu^2(x))$
7	Finite mixture	$\sum_{j=1}^{2}\pi_j f_j(y\|\theta_j)$	$\Sigma_{i=1}^{2}\pi_i\mu_i(x)$; $\Sigma_{i=1}^{2}\pi_i[\mu_i(x)+\mu_i^2(x)]$

This specializes to the standard model only if $f_1(\cdot)=f_2(\cdot)$. This model can handle both excess zeros and too few zeros.

A hurdle model has the interpretation that it reflects a two-stage decision-making process, each part being a model of one decision. The two parts of the model are functionally independent. Therefore, ML estimation of the hurdle model can be achieved by separately maximizing the two terms in the likelihood: one corresponding to the zeros and the other to the positives. A binary outcome model is used to model the positive outcome and a truncated Poisson or NB for the second part. The first part uses the full sample, but the second part uses only the positive-count observations.

For certain types of activities, such a specification is easy to rationalize. For example, in a model that explains the number of packs of cigarettes smoked per day, the survey may include both smokers and nonsmokers. The first part of the hurdle model determines whether or not one smokes and the second part determines the intensity, i.e., the number of packs smoked, given that at least one pack is smoked.

Models for Zero-Inflated Data

The zero-inflated model was originally proposed in manufacturing quality control settings to handle data with excess zeros relative to the Poisson. Like the hurdle model, it supplements a count density $f_2(\cdot)$ with a binary process with density $f_1(\cdot)$. If the binary process takes value 0, with probability $f_1(0)$ then $y=0$. If the binary process takes value 1, with probability $f_1(1)$, then y takes count values $0,1,2,\ldots$ from the count density $f_2(\cdot)$. This lets zero counts occur in two ways: as a realization of the binary process and as a realization of the count process when the binary random variable takes value 1.

Suppressing regressors for notational simplicity, the zero-inflated model has density

$$f(y)=\begin{cases} f_1(0)+(1-f_1(0))f_2(0) & \text{if } y=0 \\ (1-f_1(0))f_2(y) & \text{if } y\geq 1 \end{cases} \quad [5]$$

As in the case of the hurdle model, the probability $f_1(0)$ may be a constant or may be parametrized through a binomial model like the logit or probit to capture dependence on observable factors. Once again, the set of variables in the $f_1(\cdot)$ density need not be the same as those in the $f_2(\cdot)$ density. However, identifying the separate roles of factors that affect $f_1(0)$ and $f_2(y)$ is generally challenging.

Finite Mixture Models

The NB model is an example of a continuous mixture model. An alternative approach uses a discrete representation of unobserved heterogeneity to generate a class of models called finite mixture models (FMM) – a particular subclass of latent class models.

An FMM specifies that the density of y is a linear combination of m different densities, not necessarily from the same parametric class, where the *jth* density is $f_j(y|\beta_j)$, $j=1, 2, \ldots, m$. Thus an m-component finite mixture is

$$f(y|\beta,\pi)=\sum_{j=1}^{m}\pi_j f_j(y|\beta_j), \quad 0\leq\pi_j\leq 1, \quad \sum_{j=1}^{m}\pi_j=1 \quad [6]$$

For example, a two-component ($m=2$) mixture of $f_1(y|x,\beta_1)$ and $f_1(y|x,\beta_2)$ may reflect the possibility that the sampled population contains two 'types' of cases, whose y outcomes are characterized by distributions with different moments. The mixing fraction π_1 is, in general, an unknown parameter which could, for additional flexibility, be parameterized in terms of observed variable(s) z.

The FMM specification is attractive for empirical work in cross-section analysis because its functional form is flexible. Mixture components may come from different parametric families, although commonly they are specified to come from the same family. The mixture components permit differences in conditional moments of the component distributions, and hence in the marginal effects. In an actual empirical setting, the latent classes often have a convenient interpretation in terms of the differences between the underlying subpopulations. However, the number of latent classes is generally unknown and has to be treated as an additional parameter. This is a nontrivial complication that has often been handled as a model selection problem that is solved using penalized likelihood criteria. Bayesian analyses using Dirichlet process mixtures potentially allow for additional flexibility.

The main features of some popular models are summarized in Table 1.

Quantile Regression for Counts

Quantile conditional regression (QCR) is a robust semiparametric methodology for continuous response data. The conditional quantile function is a more general object of interest than the traditional conditional mean because it allows us to study potentially different responses in different quantiles of the outcome variable, and thus the entire distribution. It is consistent under weak stochastic assumptions and is equivariant to monotone transformations of the outcome variable. It is attractive because it potentially allows for response heterogeneity at different conditional quantiles of the variables of interest. By extending it to count data regression, one can overcome the standard and restrictive models of unobserved heterogeneity based on strong distributional assumptions. Further, QCR permits the study of the impact of regressors on both the location and scale parameters of the model and thus supports a richer interpretation under weaker distributional assumptions. A difficulty arises because the quantiles of discrete variables are not unique as the cumulative distribution function is discontinuous with discrete jumps between flat sections. By convention, the lower boundary of the interval defines the quantile in such a case. However, recent theoretical advances have extended QCR to a special case of count regression.

The key step in the extension of QCR to counts involves replacing the discrete count outcome y with a continuous variable $z=h(y)$, where $h(\cdot)$ is a smooth continuous transformation. The standard linear QCR methods are then applied to z. The particular continuation transformation used is $z=y+u$, where $u\sim U[0,1]$ is a pseudorandom draw from the uniform distribution on $(0,1)$. This step is called 'jittering' the count. Point and interval estimates are then retransformed to the original y-scale, using functions that preserve the quantile properties.

Panel Data

Count data panel models, like their linear counterparts, use three main frameworks: population-averaged (PA) models, random-effect (RE) models, and fixed-effect (FE) models. All are widely used in health econometrics. Maximum likelihood as well as moment-based estimation is common.

Given the scalar dependent variable y_{it} with vector of regressors x_{it} where i, $i=1,\ldots,N$, denotes the individual and t ($t=1,\ldots,T$) denotes time, the case of 'short panel' (small T) is empirically in health applications.

Many complications of count data panel models stem from discreteness of y and nonlinearity of the conditional mean. Assume multiplicative individual-specific scale effect α_i applied to exponential function,

$$E[y_{it}|\alpha, x_{it}] = \alpha_i \exp(x_{it}'\beta) \quad [7]$$

As x_{it} includes an intercept, α_i may be interpreted as a deviation from 1 because $E(\alpha_i|x)=1$.

Pooled or Population-Averaged Models

Operationally speaking, pooling involves 'stacking' cross-section observations and applying cross-section methods. Pooling multiple cross-section involves a strong assumption. The observations $y_{it}|\alpha_i, x_{it}$ are treated as independent, after assuming $\alpha_i=\alpha$, which implies absence of unobserved heterogeneity. The pooled model is also called the PA model. For parametric models, it is assumed that the marginal density for a single (i, t) pair,

$$f(y_{it}|x_{it}) = f(\alpha + x_{it}'\beta, \gamma) \quad [8]$$

is correctly specified, regardless of the (unspecified) form of the joint density $f(y_{it},\ldots,y_{iT}|x_{il},\ldots,x_{iT},\beta,\gamma)$. The PA specification accommodates some assumption about conditional dependence between y_{it}, over both i and t. Serial correlation of y_{it} suggests conditional dependence. Hence, after estimating the pooled model (by ML or moment-based estimator such as nonlinear least squares), 'residuals' may be dependent; hence a panel-robust or cluster-robust (with clustering on i) estimator of the covariance matrix can then be applied to adjust standard errors for such dependence.

The pooled model for the exponential conditional mean specifies $E[y_{it}|x_{it}] = \exp(\alpha + x_{it}'\beta)$. The model can be estimated by the efficient generalized method of moments (GMM) estimator, which embeds the generalized estimating equations (GEE) estimator in the statistics literature, which is based on the conditional moment restrictions, stacked over all T observations,

$$E[y_i - g_i(\beta)|X_i] = 0 \quad [9]$$

where $g_i(\beta) = [g(x_{i1},\beta), \ldots, g(x_{iT},\beta)]'$ and $X_i = [x_{i1}, \ldots, x_{iT}]'$.

Although the foregoing analysis is for additive errors, there are multiplicative versions of moment conditions that will lead to different estimators. Because of the greater potential for having omitted factors in panel models of observational data, fixed and random-effect panel count models are more flexible and plausible alternatives to the PA model.

Random Effects Models

A REs model treats the individual-specific effect α_i as an unobserved random variable, uncorrelated with the regressors $x_{i1}, \ldots, x_{iT_i}$, with specified mixing distribution $g(\alpha_i|\gamma)$, analogous to the cross-section case. Then α_i is eliminated by averaging over its distribution – an operation which is mathematically equivalent to integrating out α_i from the conditional distribution $f(y_{it}|x_{it},\alpha_i,\beta,\gamma)$. The resulting unconditional density for the *ith* observation is $f(y_{it}, \ldots, y_{iT_i}|x_{i1}, \ldots, \beta, \gamma, \eta)$ may have an analytical closed form for some combinations of $\{f(\cdot), g(\cdot)\}$, but in general it is handled numerically. Randomness restricted only to the intercept is easier to handle numerically than when it applies to both intercept and slope parameters, which means that the RE is not separable, as in an FMM.

As in the cross-section case, the NB panel model can be derived under two assumptions: first, y_{ij} has Poisson distribution conditional on μ_i and second, μ_i are independent, identically distributed (i.i.d.)-γ distributed with mean μ and variance $\alpha\mu^2$. Then, unconditionally $y_{ij} \sim \text{NB}(\mu_i, \mu_i + \alpha\mu_i^2)$. Although this model is easy to estimate using standard software packages, it has the obvious limitation that it requires a strong distributional assumption for the random intercept and it is only useful in the special case when the regressors in the mean function $\mu_i = \exp(x_i'\beta)$ are time invariant.

A potential limitation of the foregoing RE panel models is that they may not generate sufficient flexibility in the specification of the conditional mean function. Such flexibility can be obtained using a finite mixture or latent class specification of RE.

Fixed Effects Models

Given the conditional mean specification

$$E[y_{it}|\alpha_i, x_{it}] = \alpha_i \exp(x_{it}'\beta) = \alpha_i \mu_{it} \quad [10]$$

a FEs model treats α_i as an unobserved random variable that may be correlated with the regressors x_{it}. Such dependence may be present if one or more regressors are endogenous. In this sense the FE model deals with a limited form of endogeneity. It is known that ML or moment-based estimation of both the PA Poisson model and the RE Poisson model will not identify β if the FE specification is correct. The main difficulty in handling the otherwise more attractive FE model is that,in general in nonlinear panel models, the nuisance parameters α_i cannot be easily eliminated from the model, which is the incidental parameters problem.

However, under the assumption of strict exogeneity of x_{it}, the basic result that there is no incidental parameter problem for the Poisson panel regression is now established and well understood. The conditional likelihood principle can be used to eliminate α and to condense the log-likelihood in terms of β only.

Table 2 below displays the first-order condition for FE PMLE of β, which can be compared with the pooled Poisson first-order condition to see how the FEs change the estimator. The difference is that μ_{it} in the pooled model is replaced by $\mu_{it}\bar{y}_i/\bar{\mu}_i$ in the FE PMLE, where $\bar{\mu}_i = T^{-1}\sum_t \exp(x_{it}'\beta)$ and $\bar{y}_i = T^{-1}\sum_t y_{it}$ are time averages The multiplicative factor $\bar{y}_i/\bar{\mu}_i$

Table 2 Selected moment conditions for panel count models

Model	*Moment or model specification*	*Estimating equations or moment condition*
Pooled Poisson	$E[y_{it}\|\mathbf{x}_{it}] = \exp(\mathbf{x}'_{it}\beta)$,	$\sum_{i=1}^{N}\sum_{t=1}^{T}\mathbf{x}_{it}(y_{it}-\mu_{it})=0$ where $\mu_{it}=\exp(\mathbf{x}'_{it}\beta)$
Population averaged Poisson random effect (RE)	$E[y_{it}\|\alpha_i,\mathbf{x}_{it}] = \alpha_i\exp(\mathbf{x}'_{it}\beta)$,	$\rho_{ts}=\mathrm{cor}[(y_{it}-\exp(\mathbf{x}'_{it}\beta))(y_{is}-\exp(\mathbf{x}'_{is}\beta))]$ $\sum_{i=1}^{N}\sum_{t=1}^{T}\mathbf{x}_{it}\left(y_{it}-\mu_{it}\frac{\overline{y}_i+\eta/T}{\overline{\mu}_i+\eta/T}\right)=0$ $\overline{\mu}_i=\mathrm{T}^{-1}\sum_t\exp(\mathbf{x}'_{it}\beta);\ \eta=\mathrm{var}(\alpha_i)$
Poisson fixed effect (FE)	$E[y_{it}\|\alpha_i,\mathbf{x}_{it}] = \alpha_i\exp(\mathbf{x}'_{it}\beta)$	$\sum_{i=1}^{N}\sum_{t=1}^{T}\mathbf{x}_{it}\left(y_{it}-\mu_{it}\frac{\overline{y}_i}{\overline{\mu}_i}\right)=0$,

is simply the ML estimator of α_I; this means that the first-order condition is based on the likelihood concentrated with respect to α_i.

The result about the incidental parameter problem for the PMLE model does not extend to the FEs NB1 model (whose variance function is quadratic in the conditional mean) if the FEs parameters enter multiplicatively through the conditional mean specification. This fact is confusing for many practitioners who observe the availability of the FEs NB option in computer packages.

Moment Function Estimation

Modern literature considers and sometimes favors the use of moment-based estimators that may be potentially more robust than the MLE. The starting point here is a moment condition model which mimics the differencing transformations used to eliminate nuisance parameters in linear models, that is, moment condition models are based on quasi-differencing transformations that eliminate FEs. This step is then followed by application of one of the several available variants of the GMM estimation, such as two-step GMM or continuously updated GMM.

Two alternative formulations are

$$y_{it} = \exp(x_{it}'\beta + \alpha_i)u_{it} \qquad [11]$$

$$y_{it} = \exp(x_{it}'\beta + \alpha_i) + u_{it} \qquad [12]$$

where, in the first case $E(u_{it})=1$, the x_{it} are predetermined with respect to u_{it}, and u_{it} are serially uncorrelated and independent of α_i. A quasi-differencing transformation eliminates the FEs and generates moment conditions whose form depend on whether one starts with eqn [11] or eqn [12]. Several variants are shown in Table 2 and they can be used in GMM estimation. Certainly, these moment conditions only provide a starting point and important issues remain about the performance of alternative variants or the best variants to use. In essence these specifications lead to GMM estimation which differ in terms of the weights attached to the moment conditions.

Conditionally Correlated Random Effects

Given the difficulty of eliminating FEs for any flexible functional form, an extension of the RE model offers an attractive alternative. The standard RE panel model assumes that α_i and x_{it} are uncorrelated. Instead, suppose that they are conditionally correlated. This idea, originally developed in the context of a linear panel model, can be interpreted as a compromise between fixed and random effects, that is, if the correlation between α_i and the regressors can be controlled by adding some suitable regressors, then the remaining unobserved heterogeneity can be treated as random and uncorrelated with the regressors. Although in principle a subset of regressors may be introduced, in practice it is more parsimonious to introduce time-averaged values of time-varying regressors. This is the conditionally correlated random effects (CCRE) model. This formulation allows for correlation by assuming a relationship of the form

$$\alpha_i = \overline{x}_i'\lambda + \varepsilon_i \qquad [13]$$

where $\overline{x}$ denotes the time average of the time-varying exogenous variables and ε_i may be interpreted as unobserved heterogeneity uncorrelated with the regressors. Substituting this into the above formulation essentially introduces no additional problems. To use the standard RE framework, however, it is needed to make an assumption about the distribution of ε_t and this will usually lead to an integral that would need evaluating. Estimation and inference in the pooled Poisson or NLS model can proceed as before. This formulation can also be used when dynamics are present in the model.

Dynamic Panels

As for linear models, inclusion of lagged values is appropriate in some empirical models. An example is the use of past research and development expenditure when modeling the number of patents. When lagged exogenous variables are used, no new modeling issues arise from their presence. When lagged dependent variables are introduced, for example, $y_{it} = \exp(\gamma y_{it-1} + x_{it}'\beta + \alpha_i)$, additional complications arise. First, in short panels, initial condition y_{i0} will have a persistent influence. Second, the presence of zero outcomes or large lagged outcomes can induce instability. The literature offers a number of solutions whose suitability should be determined on a case by case basis. However, a relatively simple and appealing solution of the initial condition problem is to embed the dynamics in a CCRE model by assuming that

$$\alpha_i = \gamma_0 y_{i0} + \overline{x}_i'\lambda + \varepsilon_i \qquad [14]$$

where the individual-specific effect absorbs the initial condition. Finally, the i.i.d. component ε_i can be dealt with using the RE framework for the panel data. Estimation of such a model may entail numerical integration to deal with the i.i.d. error and/or the initial condition.

Models for Discrete/Ordered Outcomes and Choice Models

WH Greene, New York University, New York, NY, USA

Introduction

This paper will survey the application of discrete choice models in health economics. The application of econometrics to understanding the health system takes place at several levels:

- *Aggregate*: modeling the behavior over time of aggregates such as health care spending and demographics.
- *Market*: modeling the behavior of specific markets such as hospital services markets and market structures and labor markets such as the market for nurses.
- *Individual*: modeling the behavior of individuals making decisions such as whether to have insurance, visit a physician, or how intensively to use the health care system.

It would be overly ambitious to attempt to cover the field in a single essay. This survey will focus on the third topic. The analysis of individual behavior in health economics generally involves a particular style and tradition of econometric model building. At the individual level, behavior often takes the form of discrete choices over particular sets of alternatives. To focus ideas, we consider the examples of whether individuals purchase insurance or not, or how they report their health status or satisfaction, or which type of products to purchase, or how many times they visit the physician or engage in a particular behavior such as smoking or consuming narcotics. Each of these is a discrete choice, in most cases, a binary choice between two distinct alternatives. Understanding these individual choices helps the analyst to understand aggregate behavior and, for example, the impact of policy changes on behavior.

Choice Modeling: Theory and Econometrics

There are two fundamental building blocks that underlie the methodology of discrete choice modeling, the model of random utility and the basic econometric binary choice model for choice between two alternatives. (The theory of random utility began in the 1920s. It gained great momentum with the econometric research by McFadden, 1974.) The econometric approach to analyze discrete choices departs from the assumption that an individual's behavior reflects an underlying preference structure that is consistent with the familiar constructs of microeconomic theory. That is, the individual's preferences are continuous, complete, and transitive. The implication is that choices are made in the setting of a particular process, or calculus. The nature of the choice mechanism, if not the choice itself, follows from some familiar axioms of economic theory: choices are continuous, meaning that small variations in circumstances generally lead to small or no changes in decisions; choices are complete, meaning that decision makers are able to rank any pair of alternatives presented; and choices are transitive, meaning that, in broad terms, choices are logically consistent. The model builder moves forward from this underlying preference structure to a model of the value or utility of a specific alternative, which it is convenient to label U_{ij}, with U meaning utility and j indicating the alternative. Thus, U_{ij} is the utility, or value to individual i of making choice j. The centerpiece of the econometric model is the random utility model (RUM), which states that from the point of the model builder, U_{ij} is a random variable with a particular form that will be described. It is noted at this convenient juncture, that the idea of random utility is from the point of the observer. It does not imply that individuals make decisions randomly, for example, by using a coin toss to decide whether or not to visit a physician or to consume a narcotic. The random utility model is used as a platform for the analysis on which aspects of behavior are 'observable' (or nonrandom), whereas others are 'unobservable' (so, from the observer's standpoint, random). Thus, for example, it can be confidently said that price is a determinant of whether an individual chooses to smoke. But, there are also other intrinsic and inherently unobservable features of the individual's psyche that motivate a decision to smoke; price alone is not the full story. The observed outcome appears random because observable information is not sufficient to provide a complete explanation of the observed choice.

Random Utility

For convenience, it will help to write the RUM in a particular additive form,

$$U_{ij} = V_{ij} + \varepsilon_{ij}$$

The model of random utility is stated from the point of view of the analyst – it embodies their understanding of individual behavior. It states that the utility of the observed individual is composed of a deterministic part that is amenable to model building and responds predictably to observable stimuli, and a random part that embodies the unobservable aspects of individual preferences. It is crucial to the understanding of behavior that it is assumed that under the same circumstances, the individual will always behave the same way. The randomness of random utility describes the analyst's understanding of the differences across different people.

It should also be noted that RUM is a model – a description of behavior. A common mistake is to attack the RUM as if it was an immutable statement of the precise nature of underlying utility, which would then be characterized as hopelessly naïve. The RUM is a broad characterization of the process that lies behind observations of choices that individuals make. To make it convenient to discuss ideas, a particular form for the utility function is assumed,

$$U_{ij} = \boldsymbol{\beta}'_j \mathbf{x}_{ij} + \varepsilon_{ij}$$

For the less mathematically inclined reader, it is noted, the vector symbol $\boldsymbol{\beta}'\mathbf{x}$ is used here as a shorthand for the equivalent linear equation, $U_{ij} = \beta_0 + \beta_1 x_{ij1} + \beta_2 x_{ij2} + \ldots \beta_K x_{ijK} + \varepsilon_{ij}$.

 doi:10.1016/B978-0-12-375678-7.00715-X

The variables x_{ijk} represent either attributes of the choices, such as the price of a particular kind of insurance policy, or characteristics of the individual, such as age, gender, or income. The definition of a utility function in this form embodies the assumption that these features influence the choice made because they influence utility. For example, an increase in the price of an insurance plan (it is assumed) will make that plan less desirable – the choice of that plan, all else equal, will afford the individual lower utility (because the plan's greater price will divert income from other activities that would provide utility). The lower utility, working a step backward, makes it less likely that an individual would choose that plan instead of others available.

Binary Choice

The second fundamental building block of a paradigm of modeling discrete choices is a mechanism that translates unobserved utility into an observed counterpart. The departure point is the choice between two alternatives. The random utilities for two alternatives, for example, 'being a smoker,' or 'being a nonsmoker,' would be represented by

$$U_{iN} = \boldsymbol{\beta}'_N \mathbf{x}_{iN} + \varepsilon_{iN}$$
$$U_{iS} = \boldsymbol{\beta}'_S \mathbf{x}_{iS} + \varepsilon_{iS}$$

These two utility functions are implied by the RUM. The assumption that observed behavior is consistent with an underlying preference structure of utility maximization implies that the (now hypothetical) individual i will make choice S if $U_{iS} > U_{iN}$ and will make choice N if $U_{iN} > U_{iS}$. Thus, the decision actually made is termed the revealed preference – the decision to be a nonsmoker reveals that the individual prefers being a nonsmoker to being a smoker. (There is a slightly inconvenient ambiguity in how to break a tie. It is assumed that if the individual is indifferent between the two alternatives, they will choose alternative N (or, the first alternative). In more formal mathematical terms, since the random variables involved are continuous, the probability of a tie is zero and one need not worry about it in developing the theory. It might be tempting to think the individual mentally tosses a coin when faced with indifference between two choices. However, this would violate the continuity assumption made earlier, and seems unrealistic as well.)

The utility maximization assumption implies an econometric model: Specifically, it can be reasoned backwards from the observed choice to the underlying outcome. In our example,

$$\text{Choice } N \rightarrow U_{iN} \geq U_{iS} \quad \text{or} \quad \boldsymbol{\beta}'_N \mathbf{x}_{iN} + \varepsilon_{iN} \geq \boldsymbol{\beta}'_S \mathbf{x}_{iS} + \varepsilon_{iS}$$

Collecting terms, this implies that if choice N is made, then it follows that $(\boldsymbol{\beta}'_N \mathbf{x}_{iN} - \boldsymbol{\beta}'_S \mathbf{x}_{iS}) + (\varepsilon_{iN} - \varepsilon_{iS}) \geq 0$. Combining and renaming terms, it is determined that choice N will be made if $\boldsymbol{\gamma}' \mathbf{x}_i + \varepsilon_i \geq 0$. This provides the underpinning of an econometric model that will help in understanding individual choices and the differences across individuals. In particular, if two individuals who make different choices are observed, two underlying sources for the difference can be asserted. The first arises from the deterministic parts of the utility functions. The second comes from the random parts. Suppose, for example, that income is the only observable difference between individuals in the analysis, income appears in the deterministic part of the utility functions. Then, according to the model, if income is higher, it makes one of the two choices more likely and the other less so. Of course, this does not imply that it can be deduced which choice the individual makes. The presence of the random term in the model implies that the information in hand suggests the impact of changes in income will be exerted only on the probabilities. Therefore, implications of the model can only be drawn in probabilistic terms. The model is completed with a specification of the probability distribution of the random term. Traditionally, the analysis has been based on one of two frameworks. The most appropriate choice for the behavior of ε would seem to be motivated by the central limit theorem, which describes the behavior of aggregates of small influences. Assuming a normal distribution produces the probit model. Although less natural from a behavioral standpoint, because of its convenient mathematical properties, the logistic distribution has often been specified instead. This gives rise to the logit model of binary choice. (Foundational work on this specific type of model appears in the bioassay literature. The modern, social science paradigm can be traced back to work on information theory by Walker and Duncan (1967). An introduction to the use of binary choice models is contained in Greene and Hensher (2010).)

Before turning to a survey of extensions, an application that should help to focus ideas is noted. Riphahn, Wambach and Million (RWM, 2003 – Riphahn *et al.*, 2003) studied the use of the health care system by a large sample of German households. Among the interesting variables in their data set is a question about health satisfaction (HSAT), a scale variable coded 0 to 10. For purposes of the application, this variable is recoded to be HEALTHY = 0 if HSAT < 6 and HEALTHY = 1 if HSAT > 6. The average of HSAT in the sample is 6.8. (This sample is a panel. There are 27 326 household years in the data, but the sample is 7293 households.) The RWM data is used to construct a probit RUM of the binary choice of whether the individual reported feeling healthier than average or not. Note that it is not appropriate to assume that the individual reports that they feel healthier than the average person in the sample – they would obviously not know that. An ongoing theme in this area of research is an understanding of how the model should accommodate the idea that different individuals would view the term 'healthy' differently. If there were an objective construct, 'health,' different individuals at the same location on the scale might still report different answers. The estimated equation shown in the first row of **Table 1** is

$$\begin{aligned}\text{Estimated}[U_{it,\text{Health}}] = &-0.414 + 0.301\,\text{INCOME} \\ &+ 0.071\,\text{MARRIED} \\ &+ 0.069\,\text{EDUC} - 0.153\,\text{PUBLIC}\end{aligned}$$

MARRIED and PUBLIC are dummy variables for marital status and whether the individual purchased public health insurance (roughly 88% of people did). (How coefficients in a probit model are computed, what they mean, and how they are used for estimation and inference in an analysis is discussed in Greene (2011, chapter 17) and in Greene and Hensher (2010).) Based on the description so far, one would infer from these results that increases in income, and education, and if

Table 1 Estimates of discrete choice models

	Constant	*Income*	*Married*	*Education*	*Public*	*Age*	*Kids*	*Health*
1. Healthy	−0.414	0.301	0.071	0.069	−0.153			
2. Healthy[a]	−0.577	0.144	−0.118	0.107	−0.171			
3. Healthy	−0.602	0.179	−0.118	0.108	−0.168			
	$\sigma=1.084$	$\sigma=0.589$						
4(a). Addon	−2.436	0.857	0.029				0.013	
4(b). Public[b]	3.921	−0.929		−0.172		−0.000 5		−0.041
5. Health[c]	1.463	0.194	0.037	0.034		−0.019 8	0.048	

[a]Estimated correlation = 0.559.
[b]Estimated correlation = 0.522.
[c]Estimated threshold parameter between outcomes 1 and 2 = 1.872.

one is married, all act to make it more likely that an individual will report feeling healthy, whereas if they purchased public insurance, they are more likely to report feeling unhealthy. An important point to note – will be returned to it below – is the possibility that the purchase of insurance included in this equation is, itself, motivated by the individual's health satisfaction. This ambiguous directionality of the causal effect in this equation is a fundamental aspect of the model building effort. (The opportunity to discuss elements of the econometric/statistical framework related to the estimation machinery – parametric vs. nonparametric, Bayesian vs. Classical, etc. – is not used. Although they are important questions, they are only secondary to the focus on the paradigm itself. See Greene (2011) for further discussion.)

Issues in Binary Choice Modeling

The binary choice model can be used to understand individual behavior or to try to forecast it. For example, in the preceding model, it is found that INCOME seems to be an important variable – its coefficient is very large compared to the others. Translating the coefficients in the model into meaningful quantities is one of the burdens of the model builder (see Greene (2011)). There are also some fundamental issues that are relevant here and in other modeling contexts described later. Several of them are noted, in particular: endogeneity, heterogeneity (and panel data) and selectivity. It will be convenient to pivot this discussion off the small model given above in the section on Extended Choice Models.

- The model for HEALTHY includes INCOME. It might be supposed that a self-report of healthy is a revelation of an underlying, objective measure of health outcome – an individual who reports that they feel healthy really is healthier than one who does not. It may well be that one's health is a determinant of their ability to earn their income, so that if a causal effect can be considered between healthy and income in the equation, it runs in both directions. That would require some special treatment in estimation of the model. Likewise, the model seems to suggest that those who purchase public health insurance feel less healthy. It is possible that individuals who feel less healthy (because they are less healthy) are more likely to purchase the insurance. Once again, the direction of the causality is uncertain. This problem of endogeneity (of the explanatory variable) is common in the analysis of health-related outcomes.
- It is difficult to argue that the model builder should ignore the heterogeneity issue. With panel data such as available here, there are a variety of strategies that can be used. The general result is that if there are features of the individual, albeit unobservable by the analyst, that can be reasonably assumed to be constant through the time period for which the data are observed, then, with some defensible assumptions, the model can be enhanced to accommodate individual heterogeneity. The 'random effects' (RE) model is an example. In this framework, the random component of the random utility model is assumed to include two parts, the overall random term, ε_{ijt} that contains the effects that vary from period to period, and a time constant term, u_{ij} that is a fixed (albeit unobserved) characteristic of the individual. The RE model assumes that this effect can be modelled as a random variable that varies across individuals. Row 2 of Table 1 shows estimates of the same model shown earlier, but with a common random effect included in the equation. The estimate of ρ of 0.559 is a measure of the variation of the time invariant part of the random part of the utility function. To assess how important this term is, the variance of this term is computed, which is $\rho/(1-\rho)=1.267$. The model assumes that the variance of ε is 1.000, so it would appear that there is greater variation in the invariant unobserved effect than in the time variant part.
- The model contains a coefficient of 0.301 on income. However, this value is translated into a meaningful measure of causal influence of income on health satisfaction, and will be translated into the same measure for every individual in the sample. This seems naïve – the impact of income on the probability of reporting good health will surely differ from one individual to the next. Although it has already been acknowledged that the model is meant to be succinct and descriptive, this still seems like a degree of realism that would prove important to consider. How one should accommodate heterogeneity in a choice model that is an econometric issue which many authors have considered (see, e.g., Train, 2003). An extension of the RE model is a similar model that allows the marginal utilities to vary over individuals as well. The random parameters model (RPM) allows coefficients to have a distribution across individuals. Row 3 of Table 1 shows the estimates of

a model with random coefficients. It requires a bit more work to translate the estimates of the structural parameters of an RPM into a meaningful set of numerical results. It can be seen in Table 1 that in the distribution of income coefficients across the sample individuals, it appears that the standard deviation is much greater than the mean.

- Data on health outcomes are often self reported. When the sample, itself, is self selected, then the generality of the econometric model is called into question. In particular, when individuals select themselves into the sample, and the motivation for participation is connected to the health outcome being analyzed, a problem of sample selection arises. Studies of drug efficacy based on data gathered from physician visits would present an example. Jones (2007) describes some methods of analyzing models with sample selection. Some general commentary on application of the models in health economics is given in Madden (2008).

Extended Choice Models

The binary choice model based on a random utility platform with a linear index function is the workhorse of discrete choice modeling in health econometrics. There are a wide range of variations on the binary choice model that accommodate different sampling frameworks and decision situations. Madden (2008), for example, discusses the choice of sample selection versus two part models. Broadly, two part models examine consumer decisions as a pair of sequential decisions. For example, in Harris and Zhao (2007), the authors examined smoking behavior. A two part model of the intensity of smoking behavior (e.g., number of packs of cigarettes per week) might involve a decision of whether or not to be a smoker, then, for smokers, a second decision, how much to smoke. The core of the model is its allowance of the determinants of the two decisions to differ – for example, price might motivate the intensity variable, but might be tangential to the base decision whether to be a smoker or not. For another example, another interesting variable in the RWM study is ADDON, which is an indicator of whether the observed individual purchased an enhanced type of health insurance. To purchase the addon insurance, one must purchase the public insurance, so a model that purports to describe ADDON must account for the condition that the individual purchases the public insurance. Not all individuals did; approximately 88% of the individuals purchased the public insurance. The model then describes these two simultaneous decisions. Row 4 of Table 1 contains estimates of such a model. The fairly high value of the correlation coefficient is interpreted to suggest that the unobserved factors that determine purchase of the public insurance also help to explain purchase of the addon insurance.

The list of similar extensions of the basic binary choice model is extensive. Two major directions of research in discrete choice modeling are examined, ordered choice and unordered choice.

Ordered Choices

The example of modeling in health economics includes a variable HSAT, which is self-reported health satisfaction. In the original data, this variable is coded 0,1, …, 10. That is, it is a 'scale' variable coded on an 11-point scale. Many surveys, such as the British Household Panel Survey (BHPS – see Contoyannis *et al.*, 2004) and the German Socioeconomic Panel (GSOEP – see RWM (2003)) that have been used above, include attitude variables such as health satisfaction (HSAT) or subjective well being (SWB). Pudney and Shields (2000) examine the promotion process in the UK nursing market. Conventional regression methods are inappropriate for modeling such variables. A natural extension of the random utility model provides an appropriate framework for the analysis. The model supposes that the observed scale variable reflects an underlying continuous preference scale. Thus, in the RUM framework, it begins with an assumption that $U_{i,\text{health}} = \boldsymbol{\beta}'\mathbf{x} + \varepsilon$ as usual. The observed outcome is not utility, or the continuous counterpart to 'health.' Rather, the respondent is given an opportunity to place themselves in their choice on a scale, indicated '0', '1', etc. The outcomes are thus indicators of the strength feeling on the utility scale. For the 0–10 scale, for an individual in particular, a choice of 8 rather than 7 indicates an increase in perceived health, but the difference of one unit is not meaningful. Thus, the difference between 8 and 7 of 1 is not necessarily the same as the difference between 6 and 5. The observed outcome only suggests that a response of 8 represents a greater value on the preference scale than a 7 would. This observation mechanism gives rise to an ordered choice model. The ordered choice model has proved useful for many applications in health economics (and many other fields). See Greene and Hensher (2010) for an extensive survey. See Boes and Winkelmann (2004, 2006), and Contoyannis *et al.* (2004) for applications.

Like the binary choice model, the ordered choice model has been extended in many directions. For example, Harris and Zhao (2007) examined data on tobacco use behavior in which there is reason to suspect willful misreporting. The accommodation in the ordered choice model is to 'inflate' the zero outcome. An interesting problem in understanding ordered choices is that the model assumes that all individuals interpret the scaling in the same way. This is likely to be particularly problematic when models are used to compare health outcomes across cultures and countries. In the simple example above in the section on Binary Choice, the model is likely to produce different predictions if it is used to compare two countries in which one is populated by inherently optimistic individuals whereas the other is less so. The meaning of 'middling health' might be very different in the two cases, being a very negative statement in the first case noted and a positive one in the second. King *et al.* (2004) and a succession of authors have designed models that involve anchoring vignettes. Vignettes are designed to solicit attitudes on scales that (arguably) all respondents should agree on. The scale built into the ordered choice model is calibrated to accommodate these differences in the arrangement of the outcomes on the preference scale. King *et al.*'s. study used the approach to compare survey data on political efficacy in Mexico and China.

Unordered Choices

Models of discrete choice are also extended to analyze situations in which individuals select among unordered alternatives. For example, modeling a choice among different

health insurance plans is considered. To construct an application, it supposes that plans are differentiated by features such the amount of the copayment, ceiling, and coverage of specific situations and by the price of the insurance plan. An RUM of the choice of which plan to choose would assign a utility to each plan:

$$U_{i,\text{plan}} = \cdots + \beta_D \,\text{DentalLimit}_{i,\text{Plan}} + \beta_P \,\text{Price}_{i,\text{Plan}} + \gamma \,\text{Income}_i + \varepsilon_{i,\text{plan}}$$

Maintaining the assumption of utility maximization, it is assumed that the individual makes the choice that provides the greatest utility. Because it is a RUM, as in the previous cases, the model is completed by specification of the random terms. The counterpart to the binary probit model in this setting is the multinomial logit model (MNL). Since the work of McFadden (1974), the MNL has been used by generations of researchers to model unordered choices among multiple alternatives. An example is Gertler *et al.* (1987) who analyzed a Peruvian household survey of the choice of health care provider, public clinic, public hospital, or private doctor. The focus of extensive recent research has been on formulating more realistic formulations of the choice model that accommodate heterogeneity in preference structures. A leading example is Fiebig *et al.*'s (2010) development of a generalized mixed logit model, which is an elaborate form of random parameters model.

Multinomial logit models and variants such as the mixed logit model provide information on the preference structure and on effects of interest such as how price influences the choice among the alternatives. Another useful quantity revealed through the estimated preference structure is willingness to pay. It can be recalled, the model does not predict utilities – there is an inherent scaling and translation problem. But, the model does provide information about marginal utilities. The standard measure of willingness to pay for an attribute of a choice in a multinomial choice context is

$$\text{WTP} = \frac{\text{Marginal utility of feature}}{\text{Marginal utility of income}}$$

In this example, the marginal willingness to pay measure for an increase in the limit of the dental coverage of our (hypothetical) policy would be $\text{WTP}_{\text{dental}} = \beta_D/\gamma$. This would provide an empirical estimate of the amount that an individual would value (i.e., be willing to pay) for an increase in the desirable attribute of the choice, such as an increase in the amount of dental coverage in our example.

Conclusions

The econometric models examined in this essay form the platform for a large share of the empirical analysis of individual behavior in health economics. The random utility model and its corollary, the fundamental model of binary choice, are the pillars of econometric analysis throughout the social sciences. Because the choice variables in health economics often involve Likert-like scales and choices among sets of alternatives, the ordered choice and unordered choice models are natural settings in which to examine health economics outcomes.

Models for Durations: A Guide to Empirical Applications in Health Economics

M Lindeboom and B van der Klaauw, VU University, Amsterdam, The Netherlands

Introduction

Often one is interested in the time spent in a specific state and the effect of variables influencing the length of stay; for example, how long does a patient stay in a hospital and what is the effect of a medical intervention. The state can also be employment, and one may be interested in the effect of (changes in) health status on the probability that a worker leaves employment. Such processes are often described in the context of a duration model. In the duration models literature, the probability of leaving a specific state is referred to as the exit probability (in discrete time), or the exit rate or hazard rate (in continuous time). High exit rates are associated with short durations in the state and low exit rates with long durations.

Regression methods may not be useful in such applications. In practice, individuals are often observed for a limited time period, and, therefore, some individuals are not observed to have left the state of interest. Dealing with such censored observations is not straightforward in a regression model. It requires specifying a censored regression model, which often makes strong distributional assumptions. Furthermore, the value of some regressors may change over time. The health status of an individual can change during the course of an employment spell. It is unclear how one can include time-varying covariates in a regression model. Finally, a regression model considers only the mean duration. In applications one may be directly interested in the effect of a variable on the exit rate, or in the evolution of the exit rate over time. Example of the former is the effect of a drug on the recovery rate of a sick patient, or the effect of a health shock on the exit rate out of employment. These effects may be different early in the spell than later on.

This article reviews the literature with attention to empirical applications of such methods and the use of standard software such as STATA. The article will not fully cover all aspects of duration analysis. The remaining of this article is organized as follows. In the next section some formal concepts are introduced and simple nonparametric methods to describe duration data are provided. Section 'Parametric and Semiparametric Models' discusses different models used in applied duration analyses. Section 'Unobserved Heterogeneity in Duration Models: The Mixed Proportional Hazard' discusses the issue of unobserved heterogeneity in duration models. Section 'Other Relevant Issues in Applied Duration Analysis' provides a brief introduction to other relevant issues in the context of duration models, such as multiple spells, competing risks, and dynamic treatment evaluation. The article also includes an appendix with some relevant STATA commands, a description of a data set on sickness absence durations, and a link to this data set.

Concepts and Nonparametric Estimates

Concepts

Let T be a nonnegative random variable representing the time spent in a specific state. This can, for example, be the length of an employment spell or the duration for which a person is sick. In practice, when there are individual data on durations, outcomes of this random variable are observed. The distribution function of this random variable is given by $F(t)=\Pr(T<t)$, which denotes the probability that the individual leaves the state within t time periods. The distribution function is uniquely characterized by the so-called hazard rate, which describes the exit rate out of the state at a point in time given that the individual is still in the state. The hazard rate is in continuous time the instantaneous exit rate at time t and is denoted by $\theta(t)$. In discrete time, $\theta(t)dt$ is the probability that an individual who did not leave before time period t leaves the state within a short time interval dt after time period t.

If the hazard rate is decreasing in t, then exiting the state becomes less likely the longer the individual is in the state. In case of sickness, one might expect to see such a decreasing pattern; individuals who have been sick for only a short period are more likely to recover than individuals who have been sick for a longer period. A decreasing pattern in the hazard rate is often referred to as persistence or state dependence. The complement of the distribution function $1-F(t)$ is referred to as the survivor function $S(t)$. The survivor function describes the fraction of individuals who are still in the state after t time periods. This is thus the cumulative of not having left the state in all short time intervals before t. With high hazard rates, generally fewer people remain in the state when one proceeds over time; with low hazard rates, more people remain in the state. This illustrates the one-to-one relation between the hazard rate and the survivor function $S(t)$ (and its complement $F(t)$).

Nonparametric Estimates of the Hazard Rate: Bringing the Concepts to the Data

The appendix includes a link to a data set on individual sickness absence spells of teachers working in primary schools in the Netherlands. The data set includes individual sickness spells (t_i), an indicator whether or not the spell is right censored ($d_i=1$ for a completed spell and $d_i=0$ for a censored spell), and observed individual characteristics X_i. Censoring implies that recovery from sickness is not observed in the data. This may be the case because individuals are still sick at the end of the observation period, either because the observation window has ended or because the respondent leaves the sample (for instance, because she/he leaves the school). For

now it is assumed that the censoring mechanism is independent of the outcome variable of interest (the issue of independent censoring will be elaborated in Section 'Other Relevant Issues in Applied Duration Analysis,' where competing risks models is discussed). To define in STATA that one is using duration data, the command stset spell-length, failure(failed) should be used. Some elements of X_i may change over time, but for now it is assumed that these are fixed as of the start of the spell. The sickness spells in the data are all observed to start during the observation window. In the literature this kind of sampling scheme is referred to as a flow sample.

With data as described above, one can obtain a nonparametric estimate of the hazard rate. Recall that the intuition of the hazard rate is that it describes exit probabilities in short time intervals, given that the individual has not left the state before the start of the interval. Therefore, as a simple and direct estimate of the hazard rate after t time periods, one can take the ratio of the number of observed exits in the next short time period as a fraction of the number of individuals who are still in the sample at the start of the interval. Or in more technical terms,

$$\hat{\theta}(t)dt = \frac{\sum_{i=1}^{N} d_i I(t \le t_i < t + dt)}{\sum_{i=1}^{N} I(t \le t_i)}$$

The denominator is referred to as the risk set, i.e., those individuals who are still in the state at time period t and who are 'at risk' of leaving the state.

Often not only the hazard rate is of interest, but also the survivor function is estimated. Given the one-to-one relation between the hazard rate and the survivor function, the latter can be estimated using the estimated hazard rates. If it is imposed that the unit of time dt is 1, then the fraction surviving after the first period $S(1)$ is the fraction of people who have not left the state in the first period: $1 - \hat{\theta}(1)$. The fraction surviving after two periods $S(2)$ equals $(1 - \hat{\theta}(1)) * (1 - \hat{\theta}(2))$, and so on. There are alternative formulations for the nonparametric estimation of the survivor function. Most statistical software packages report the popular Kaplan–Meier estimator.

In STATA sts list should be used to get estimates of the hazard rate and the survivor function. With sts graph the Kaplan–Meier estimate for the survivor function is plotted. And sts graph, hazard plots the smoothed empirical hazard rate. Figure 1 shows the smoothed hazard rate for the data on sickness absence of teachers for the first 60 days. The figure shows a high recovery rate quickly after the start of sickness absence and declining hazard rates with occasional jumps thereafter. The declining hazard rate suggests state dependence. It may be that for each individual, recovery becomes more unlikely as time proceeds. Alternatively, there could be dynamic selection: those with less serious illnesses leave the state first, so that in the end the most serious cases remain. This illustrates that the nonparametric methods are useful for summarizing the data, but that it is important to control for heterogeneity within a sample of individuals. This is discussed further in the next section. Figure 2 shows the Kaplan–Meier estimate of the survivor function. At the start all individuals are present (at $t=0$, $S(t)=1$), and as time proceeds, more and more people leave the state. Note that, as

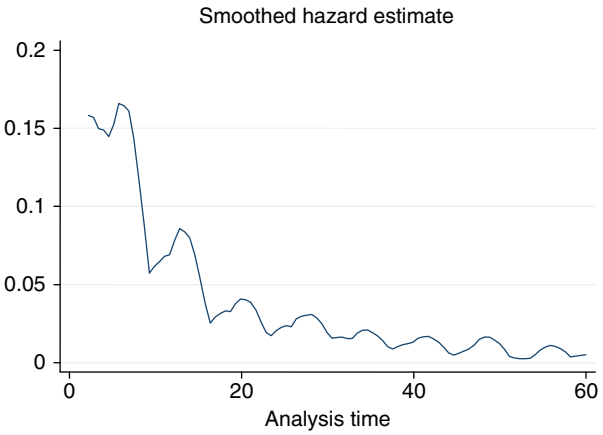

Figure 1 The smoothed hazard rate for the sickness absence example.

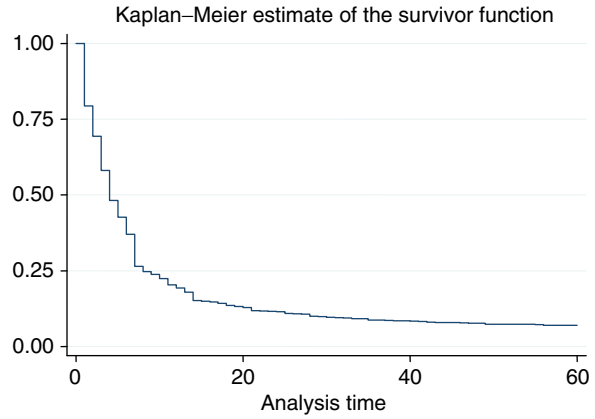

Figure 2 The survivor function for the sickness absence example.

expected, the high hazard rates in the beginning lead to a steep decline in the survivor function and the lower hazard rates later in time lead to slower decline in the survivor function.

Often, data describe different groups. For example, the data may contain sickness durations of individuals who received some treatment and of individuals who did not receive this treatment, or sickness absenteeism spells of teachers in different schools. One might be interested in whether or not hazard rates differ between groups. This can formally be tested using Logrank tests, which are nonparametric tests for the null hypothesis that the survival functions describing the durations in the different groups are identical. The underlying idea of the Logrank tests is that the order in which individuals exit the state is random in case the different groups have the same survival function. If after t time periods an exit is observed in one of the two samples, under the null hypothesis, the probability that the exit occurred in the first sample is simply the number of survivors in the first sample after t time periods as a fraction of the total number of survivors in both samples at this moment. The Logrank test is based on evaluating these probabilities for all observed exits in the data. It can also be used in case the data contain more than two groups. In STATA the comment sts test strata is used to perform Logrank tests,

where the variable strata denotes the different groups. Finally, if the data do not contain any censored observations, the ranksum test can also be used.

Parametric and Semiparametric Models

Parametric Models

The previous section mentioned that state dependence implies that the hazard rate is decreasing in the time spent in the state. There can be two reasons for observing state dependence. First, individual hazard rates are decreasing over time, which implies that for each individual, exit becomes less likely the longer the individual has already been in the state. So in case of sickness this implies that for each individual it is the case that she/he is more likely to recover in the next period if the sickness spell is still short than when the sickness spell is further progressed. The second reason for observing state dependence is dynamic selection, which means that individuals with good characteristics (i.e., with high exit rates) leave the state early. So the longer is the duration, the more the sample of survivors will move toward individuals with bad characteristics and consequently low exit rates. Also dynamic selection implies that (overall) hazard rates decrease in the elapsed duration.

In many settings, both causes for state dependence have different implications for public policy. To analyze how important both mechanisms are, often more structure is imposed on the hazard rates. A popular specification is the so-called proportional hazard (PH) specification:

$$\theta(t|X) = \lambda(t)\exp(X\beta)$$

The function $\lambda(t)$ is the baseline hazard. This describes duration dependence common to all individuals, which does not vary with individual characteristics. So a declining baseline hazard is the first explanation for observing state dependence. The role for regressors X is in the regression function $\exp(X\beta)$, which is specified such that it is nonnegative. The latter is required because hazard rates cannot be negative. The PH assumption implies that the ratio of the hazard rates of two individuals is constant over time. At any moment in time, individuals with good characteristics are more likely to leave. So when the elapsed duration is progressing, the composition of survivors moves more toward individuals with bad characteristics. The presence of heterogeneity, therefore, always causes aggregated hazard rates to decline.

The most straightforward way to estimate duration models is by using maximum likelihood. However, in the case of the PH model, this also requires parameterizing the baseline hazard. A simple parametric function is provided by the Weibull distribution, $\lambda(t) = \alpha t^{\alpha-1}$. This specification imposes a monotonic relationship for the effect of time on the hazard rate. For $\alpha > 1$ the hazard rate increases with time (positive duration dependence), for $\alpha < 1$ the hazard rate decreases over time (negative duration dependence), and for $\alpha = 1$ the hazard rate is constant over time (exponential distribution). This is illustrated in Figure 3.

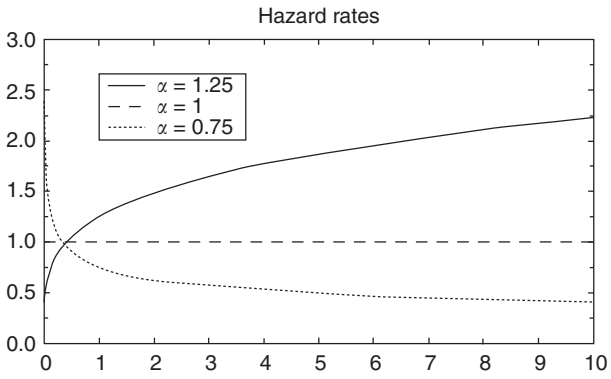

Figure 3 Hazard rates with Weibull duration dependence, for different values of α.

In STATA, PH models can be estimated using the command streg varlist, distribution (Weibull) nohr. Varlist is the set of observed characteristics included in X. The baseline hazard follows a Weibull distribution, but also other specifications can be used. For example, a log-normal specification allows for a nonmonotonic pattern of duration dependence. Finally, nohr ensures that in the output, the parameter estimates for β are reported rather than hazard ratios.

Semiparametric Models: Piecewise Constant Specification of the Baseline Hazard

Maximum likelihood estimation provides only consistent estimators if the model is specified correctly. Most choices for the baseline hazard involve specific functional forms and these may be too restrictive. For example, the Weibull distribution assumes that the hazard rate is constant, monotonically increasing or monotonically decreasing. This assumed duration dependence pattern may be violated in practice and will then lead to inconsistent estimates of the regression parameters β. Heckman and Singer (1984) provide a piecewise constant specification for the baseline hazard, which minimizes the distributional assumptions. The idea is that the baseline hazard takes different values on prespecified time intervals:

$$\lambda(t) = \exp(\lambda_k) \quad \text{if} \quad c_{k-1} < t \leq c_k$$

For $k = 1,2,\ldots,K$, with c_0, the lower bound, set to zero and c_K, the upper bound, set to infinity. The λ_ks are parameters to be estimated along with the regression parameters β. The cutpoints c_k are chosen in advance by the researcher. The piecewise constant specification requires a normalization. Either one can exclude an intercept from the regression function $\exp(X_i\beta)$, or a restriction should be imposed on the λ_ks. Most straightforward is to fix $\lambda_1 = 0$.

The key advantage of the piecewise constant specification is that by making the intervals very small, the specification can approximate any function arbitrarily close. In practice, when estimating a PH rate model with piecewise constant duration dependence, in each interval at least some exits should be observed. If there are no exits in an interval, the parameter λ_k cannot be estimated. Furthermore, without making strong extrapolation assumptions, the duration dependence pattern cannot be estimated beyond the latest observed exit in the

data. This implies that after estimating the model, it is, for example, difficult to estimate the expected duration. Consequently, it may be preferable to present estimates of the median or other quantiles of the distribution. In practice when estimating hazard rate models with piecewise constant duration dependence, it is advised to start with a very small number of broad intervals, and subsequently split intervals until no substantial improvement in the model is found. A complication is that most statistical software packages, such as STATA, do not directly allow for the option of piecewise constant duration dependence. However, in case one divides the data in discrete time intervals (such as weeks or months), the piecewise constant duration dependence translates into different intercepts for each time interval. STATA can handle time-varying regressors. The next section elaborates on the issue of time-varying regressors.

Semiparametric Models: Cox's Partial Likelihood

Even though one can try to minimize the distributional assumptions by choosing, for example, piecewise constant duration dependence, the maximum likelihood estimation requires the full specification of the hazard rates. The risk of misspecification, therefore, always remains present. An alternative estimator can be based on the rank order in which individuals exit the state. If $t_{(1)}$ describes the shortest observed duration in the sample, then the probability that individual i leaves the state at $t_{(1)}$ conditional that someone leaves at $t_{(1)}$ equals

$$\Pr\left(\text{individual } i \text{ leaves} \middle| \text{someone leaves at } t_{(1)}\right) = \frac{\theta(t_{(1)}|X_i)}{\sum_{j=1}^{N}\theta(t_{(1)}|X_j)}$$

$$= \frac{\exp(X_i\beta)}{\sum_{j=1}^{N}\exp(X_j\beta)} \qquad [1]$$

This probability is thus the ratio of hazard rates of individual i and the sum of all individuals in the risk set. Owing to the proportionality of the hazard rate, this probability does not depend on the baseline hazard $\lambda(t)$. This holds not only for the shortest duration in the spell. For all observed completed durations, the probability that a specific individual exits is the ratio of the regression function for this individual over the sum of regression functions of all survivors at that duration. Cox partial likelihood estimation only evaluates points where exits are observed in the data, and uses the probabilities provided in eqn [1] above. So without making any functional form assumptions on the baseline hazard, the parameters β can be estimated. In STATA the command stcox varlist, nohr is used for partial likelihood estimation.

Because partial likelihood estimates only β, the estimation results cannot be used for making predictions on durations, such as computing median durations (for individuals with specific characteristics). If one wants to make such predictions or is interested in the duration dependence pattern, the baseline hazard should be estimated. The Breslow method gives a procedure to retrieve the baseline hazards after partial likelihood estimation. To obtain the estimate for the baseline hazard in case of partial likelihood estimation in STATA, the options basehc (hazard) and basesurv (survivor) can be used.

Additional Complications in Estimating Duration Models

So far this article made the implicit assumptions that each spell is followed from the inflow in the state, that one observes the exact duration of the spell, that censoring is exogenous, and that individual characteristics remain constant during the spell. Next, the article briefly discusses the consequences if the data do not fit these assumptions.

Duration data may not be registered in continuous time, but describe in which time interval a spell ends. For example, the NFHS India describes for child mortality, the exact day of death if a child died within the first months after birth, the months of death if the child died between 1 month and the first birthday, and the year of death if the child died after the first birthday. In such cases the appropriate likelihood contribution should be based on the probability statements associated with such observations. Unfortunately, statistical software packages such as STATA do not handle this in their standard commands.

More problematic is the case in which spells are not followed from the inflow in the state. When, for example, looking at mortality rates of older individuals, often the data describe individuals who were at some calendar time older than a particular age. Or when looking at transitions out of employment into retirement, the data may contain a sample of older persons who are still working. These kinds of samples are referred to as stock samples, because they describe at a specific calendar time the stock of individuals who are in a state. Inference using stock samples is more complicated than using inflow samples. In stock samples individuals with bad characteristics (for leaving the state) are overrepresented. Individuals with bad characteristics experience, on average, longer time periods in the state. Therefore, they are more likely to be in the state at the calendar time of sampling and thus to be included in the stock sample. For example, when considering individuals on sickness absenteeism at a specific calendar time, this will include a relatively large share of long-term sick people, so people with more serious conditions.

In the most general set-up, a stock sample includes retrospective information (the elapsed duration e that an individual already has been in the state) and prospective information (residual duration r beyond the time of sampling). Inference can be based on the retrospective information, the prospective information, or both retrospective and prospective information. The expressions for the likelihood function become cumbersome and cannot be estimated with standard software in all but one case: the case in which one looks at the distribution of the duration r conditional on the elapsed duration e. This can be implemented in STATA by using the subcommand origin of the stset command.

So far it was assumed that censoring ($d_i=0$) is independent of the duration of interest (T). This may not always be the case. For instance in a clinical trial, terminally ill patients may be removed from the trial before the trial has ended. In this case the censoring is informative on the hazard rate. In case censoring is not exogenous, competing risks models should be used. Section 'Other Relevant Issues in Applied Duration Analysis' briefly discusses this.

Finally, until now it was implicitly assumed that the vector X includes only variables that are constant from the start of the spell, but some characteristics may change over time. For

instance, time spent in employment may depend on the health and the health status may change over time, or individuals may move to another region. The hazard rate can easily be modified to allow for time-varying characteristics. For example, one can write the PH rate as $\theta(t|X_i(t)) = \lambda(t)\exp(X_i(t)\beta)$ and the discussion above still applies. However, exogeneity of the regressors becomes an issue. The process $X(t)$ must be (weakly) exogenous, implying that values of $X(t)$ are only influenced by events that have occurred up to t and these events are actually observed. In the example of healthy lifetime, this excludes the situation where the individual knows that future health will fall (e.g., because of a chronic illness) and in anticipation reduces hours worked ($X(t)$). The article returns to this in Section 'Other Relevant Issues in Applied Duration Analysis' when discussing dynamic treatment evaluation. In case the exogeneity condition holds, STATA can be used for estimating. See the **stsplit** command in STATA to reorganize the duration data so that one can deal with time-varying covariates.

Unobserved Heterogeneity in Duration Models: The Mixed Proportional Hazard

Often the vector of observed characteristics X does not contain all variables relevant for leaving the state. For instance, in the context of individual lifetime, genetic factors may be relevant but unobserved, and the same may hold for factors like time preference or risk attitude driving health investment behavior. Ignoring unobserved heterogeneity causes the models to fail to control for dynamic selection, and thus the estimator for the baseline hazard $\lambda(t)$ will be inconsistent. Incorrectly ignoring the presence of unobserved heterogeneity not only generates spurious duration dependence, but also the estimates of β are biased toward zero. The latter holds even if the unobserved heterogeneity is orthogonal to the variables included in X. Therefore, one would like to allow for the presence of unobserved heterogeneity within the hazard rate.

Let V describe the unobserved characteristics in the hazard rate, and it is assumed that unobserved characteristics V are independent of observed characteristics X, i.e., $V \perp X$. The unobserved factors are random effects and follow at inflow ($t=0$) in the state a distribution $G(v)$. The individual exit rate is often specified using a mixed proportional hazard (MPH) specification:

$$\theta(t|X,V) = \lambda(t)\exp(X\beta)V$$

As time proceeds, individuals with good characteristics (high values of V) are more likely to leave the sample. This implies that among the survivors at time t, individuals with bad unobserved characteristics will be overrepresented. And the longer the time period t, the more the sample of survivors will move toward individuals with bad characteristics. This will lead to a discrepancy between the inflow distribution $G(V)$ of V and the distribution of V among the survivors in the sample ($G(V|X,\ T \geq t)$). As time proceeds, the observed hazard $\theta(t|X)$ declines faster than the baseline hazard $\lambda(t)$.

In the presence of unobserved heterogeneity, the observed hazard rate $\theta(t|X)$ does not factorize into t and X anymore. Therefore, it is not possible to use Cox's approach to eliminate the baseline hazard from the partial likelihood function. This implies that maximum likelihood estimation should be used. In STATA the command streg varlist, duration (Weibull) frailty(gamma) nohr can be used to optimize this loglikelihood function. It is, however, necessary to specify the unobserved heterogeneity distribution $G(v)$, for example, a gamma distribution. Furthermore, two normalizations are necessary on the duration dependence $\lambda(t)$, the regression part $\exp(X_i\beta)$ and the mean of the unobserved heterogeneity $\mathbf{E}[V]$ in the inflow.

Misspecification of $G(V)$ leads to biases in the estimators for $\lambda(t)$ and β if there is substantial censoring in the data. Furthermore, misspecification of $\lambda(t)$ usually causes significant biases in the regression parameters. It is therefore advisable to use flexible functional forms for the mixing distribution and for the baseline hazard. The previous section already introduced the piecewise constant specification as very flexible for the baseline hazard. Usually a mass-point distribution is considered to be the most flexible distribution for the unobserved heterogeneity. The idea is that V can take M different values, each acting as constants on the hazard rate:

$$\Pr(V = v_m) = p_m \qquad \text{with } p_m \geq 0 \quad \text{and} \quad \sum_{m=1}^{M} P_m = 1$$

In theory any distribution can be approximately arbitrarily close if M is chosen to be sufficiently large. However, in most applications M does not exceed 3. STATA does not have a command for a mixing distribution with discrete mass points. When optimizing the loglikelihood function, it is advised to start with a small M and then to add new points until the loglikelihood function does not improve anymore. The latter often implies either that new points have a very small probability mass or that the location of two mass points converge toward each other.

Other Relevant Issues in Applied Duration Analysis

Multiple Spells

So far it was implicitly assumed that for each individual only one spell is observed. However, it may be that the data contain multiple spells sharing the same unobserved component. For example, because within the observation period many workers experience multiple spells of sickness absenteeism, or because children born in the same family have the same unobserved component when modeling child mortality.

To formalize multiple spells, consider a cluster $c = 1,\ldots,C$ containing I_c observed spells. The hazard rate of observation $i = 1,\ldots,I_c$ in cluster c equals

$$\theta_{ic}(t|x_{ic}) = \lambda_c(t)\exp(X_{ic}\beta)$$

Each cluster is allowed to have a separate baseline hazard $\lambda_c(t)$ including duration dependence, cluster fixed effects, and possible interactions between both. To estimate the regression parameters β, stratified partial likelihood estimation can be used. The idea is similar to partial likelihood, but the risk set is

defined within clusters. The cluster-specific baseline hazards $\lambda_c(t)$ are eliminated and not estimated. This also implies that covariates that do not vary between observations in the same cluster are eliminated from X_{ic} and the corresponding covariate effects cannot be estimated. Obviously, clusters without observed exits do not contribute to the stratified partial likelihood function. So when modeling child mortality, only families in which multiple children are born and in which at least one child died contribute to the stratified partial likelihood function.

Finally, one cannot include all covariates in X_{ic}. The variables in X_{ic} should be (weakly) exogenous and may not be related to the observed exit of any individual in the cluster other than via the hazard rate. A violation of the weak exogeneity assumption may be if mothers make the decision to breastfeed a newborn child based on expected survival. Also if birth spacing might depend on the death of earlier born children, there may be a problem (in particular, if the observation period is limited and some spells are right censored). So breastfeeding and birth spacing should in those cases not be included in X_{ic}. However, if such variables are not included in X_{ic}, then there might be unobserved differences between observations in the same cluster that are not captured by the cluster specific effects, which again would violate the specification of the hazard rate above.

When baseline hazards are the same for all clusters, stratified partial likelihood estimation and partial likelihood estimation should give similar estimation results for the regression parameters β. Comparing the estimates from both procedures yields a test for similarity of the baseline hazards. Under the null hypothesis that all clusters have the same baseline hazard, both stratified partial likelihood estimation and partial likelihood estimation are consistent, but partial likelihood estimation is more efficient. Under the alternative hypothesis, only stratified partial likelihood estimation is consistent. This implies that a Hausman test can be used.

In STATA the command stcox varlist, strata(cluster) nohr provides estimation results where each cluster is allowed to have a separate baseline hazard. After estimating the coefficients these can be stored using est store sple. The same can be done for partial likelihood estimation of the regression coefficients (hereafter ple). When the results from both regressions are stored, the Hausman test can be done using the STATA command Hausman sple ple.

Competing Risks Models

It is mentioned above that duration models deal with censoring relatively easy, but it also stressed that this is only the case when censoring is exogenous. Exogenous censoring occurs, for example, when an individual is still in the state at the end of the observation period. There may, however, also be other reasons for censoring. For example, when considering sickness absenteeism of teachers, recovery may not be observed when a sick teacher quits working at a school. In such a case the censoring may be related to the process of recovery, because those individuals with more serious health conditions may decide earlier to quit working. In the case that censoring is not exogenous, a competing risks model should be used, which implies jointly modeling the process until recovery and the process until censoring.

There are also cases in which a researcher might be interested not only in the duration until leaving a specific state but also in the exit destination. For example, when modeling the age of death, the cause of death might be relevant. In these cases competing risks models are useful. Usually, data only describe the first exit, so except for the shortest duration, all other durations are latent. In the context of mortality, where individuals can die due to different causes (risks), death due to, for instance, a heart attack means that the individual did not die of cancer. Stated differently, the duration of dying of cancer is censored at the point where the individual dies of other diseases.

If the hazard rate of one cause is independent of death via other causes, then censoring due to these other diseases can be treated as exogenous and the parameters of the different hazard rates can be estimated by using successive analyses with the standard command of STATA (or other statistical software). Often it is likely that the different competing risks are not independent of each other. For example, healthy people are less likely to die both from cancer and from cardiovascular diseases. Erroneously assuming independence leads to incorrect inference.

Dynamic Treatment Evaluation

Often researchers are interested in the causal effects of (policy) interventions. A researcher might, for example, be interested in how a medical intervention affects the length of sickness. The effect of the medical intervention might depend on the moment in the sickness spell at which the treatment starts or the elapsed duration since the start of treatment. Estimating dynamic treatment effects is complicated, not only because there can be the usual endogeneity in assigning treatment to individuals, but also because there can be dynamic selection. If the treatment starts during the spell, individuals exposed to the treatment must have survived until the start of the treatment and may, therefore, have worse unobserved characteristics.

Usually one distinguishes between static and dynamic treatment evaluation. The difference is that in the static case, treatment starts at the beginning of the spell, whereas in the dynamic case treatment starts later during the spell. The key complication of static treatment evaluation compared to usual treatment evaluation is that the observation period is often limited and some spells are right censored. The methods discussed in the previous sections can be used to analyze static treatment effects, in particular when conditional on the observed individual characteristics X treatment assignment is independent of unobserved characteristics V. However, if conditional on X at the start of the spell treatment assignment is independent of V, this is not the case later during the spell. The intuition is that if treatment is successful in reducing the duration of spells, after some elapsed duration those who are still in the sample and who have been treated have, on average, worse characteristics than those who have not been treated.

Dynamic treatment evaluation is more complicated. In a dynamic setting, exclusion restrictions are often difficult to

justify. In particular, when individuals know at the start of a spell the value of an instrument describing whether or not they are likely to be treated early or later in the spell, they might already change behavior before the actual start of the treatment. For example, an individual who is on a long waiting list might search for alternative treatments, whereas an individual with a higher priority might just wait for the medical intervention. Even if the order on the waiting list is randomized, the realized order might have an effect on recovery already before the actual intervention. This implies that once an individual knows the instrument and understands the consequences, the instrument might affect the outcomes already before the actual intervention starts.

Most empirical studies focus on the *ex-post* effects of an intervention, which are the changes in hazard rates after an individual has been exposed to treatment. Empirical studies often ignore *ex-ante* effects, which describe differences in hazard rates from the beginning of the spell because at some moment in the spell, treatment may start. Exclusions restriction may be informative on the presence of the *ex-ante* effects. To identify the *ex-post* effects of treatment, a so-called *no-anticipation* assumption is required. This no-anticipation assumption imposes that individuals do not change behavior before the intervention after learning the actual moment of the intervention. So conditional on observed characteristics X and unobserved characteristics V, the intervention does not have any effect of hazard rates before the start of the intervention. This does not imply that the start of treatment is assigned randomly (conditional on observed characteristics X).

If the no-anticipation assumption holds, the *ex-post* effect of treatment δ can be specified within the MPH rate model for exits from the state

$$\theta_e(t|X,s,V_e) = \lambda_e(t)\exp(X\beta_e + \delta \cdot I(t>s) + V_e)$$

In this specification s describes the start of treatment and the indicator function $I(t>s)$ denotes if after t units of time the individual is exposed to the treatment. The key problem in the estimation is that the timing of the start of treatment s is often not independent of unobserved characteristics V. Therefore, the treatment effects model is extended by a PH rate model for the start of treatment

$$\theta_p(s|X,V_p) = \lambda_p(t)\exp(X\beta_p + V_p)$$

By allowing the unobserved terms in both hazard rates to be dependent, the model allows for endogeneity of the start of treatment. This model is often referred to as *timing-of-events* model.

To estimate the timing-of-events model, maximum likelihood estimation should be used. This requires the specification of the baseline hazards $\lambda_e(t)$ and $\lambda_p(t)$, as well as the joint distribution of the unobserved heterogeneity terms V_e and V_p. The model can allow for heterogeneous treatment effects. In particular, the treatment effect δ can be made dependent on observed characteristics X, unobserved characteristics V, the elapsed duration in the state t, the moment of starting treatment s, and thus also on the elapsed duration since the start of the treatment $t-s$.

This timing-of-events approach has in dynamic settings a number of advantages over other methods for treatment evaluation. Most important is that if treatment starts at some moment during a spell, it is difficult to define control groups for those individuals who receive treatment. In many cases, all individuals will receive treatment at some point when staying sufficiently long in the state. Therefore, individuals who are observed to be untreated are often so because they left the state relatively fast. Next, the timing-of-events model allows for selection on unobservables. Furthermore, most alternative methods require discretizing time, which has the disadvantage that results might be sensitive to the choice of the unit of time. Finally, the timing-of-events model explicitly models dynamic selection and the entry into treatment, which might be of interest in itself.

Monopsony in Health Labor Markets

JD Matsudaira, Cornell University, Ithaca, NY, USA

In recent years there has been a surge in interest in models of imperfect competition in the labor market, and monopsony in particular (Boal and Ransom, 1997; Bhaskar *et al.*, 2002; Manning, 2003; Ashenfelter *et al.*, 2010; Manning, 2011). The term 'monopsony' was introduced by Joan Robinson in her 1933 book *The Economics of Imperfect Competition*. Taken literally, monopsony means a situation with only one buyer in a labor market and textbook discussions of Robinson's theory have accordingly been largely confined to 'company town' examples such as a coal mine in a rural town that is the only local employer. But Robinson's discussion makes it clear that monopsony power allowing employers to set wages may exist whenever frictions in the labor market give rise to an upward sloping labor supply (LS) curve at the individual firm level. (In this light, recent allusions to a 'new monopsony' framework represent a new shift of attention amongst sources of monopsony enumerated in Robinson's original discussion rather than new conceptual insights. Of course theoretical developments in the interim, particularly in the area of search theory, have helped make information related frictions more salient as a potential source of monopsony.) Such frictions might arise because "there may be a certain number of workers in the immediate neighborhood and to attract those from further afield it may be necessary to pay a wage equal to what they can earn near home plus their fares to and fro; or there may be workers attached to the firm by preference or custom and to attract others it may be necessary to pay a higher wage. Or ignorance may prevent workers from moving from one firm to another in response to differences in the wages offered by the different firms" (Robinson, 1933, p. 296).

Writing in 1946, Lloyd Reynolds predicted "The view that labor-market imperfections result in a forward-rising supply curve of labor to the firm... first elaborated by Mrs. Robinson... seems well on the way to being generally accepted as a substitute for the horizontal supply curve of earlier" (Reynolds, 1946, p. 390). But despite this early enthusiasm, monopsony models have rarely been invoked to characterize important segments of the US labor market, as the 'company town' metaphor led many economists to dismiss their broader relevance. One important exception is the labor market for registered nurses (RNs), where Yett (1970) suggested that monopsony was the most likely explanation for the consistent nurse 'shortages' reported by hospitals at least since World War II. To Yett, and many economists since, oligopsony seemed a natural model for the nurse labor market since many hospitals operate in counties with few other hospital competitors for workers, and there are reasons to believe that the geographic and occupational mobility of nurses is low. Indeed, the lion's share of empirical papers directly investigating the predictions of monopsony models cited in three recent reviews of the literature involve the nursing labor market (Boal and Ransom, 1997; Manning, 2003, 2011). (The only other occupation frequently featured in the monopsony literature is teachers (Landon and Baird, 1971; Boal, 2009; Falch, 2010).

In this brief research synthesis, it is attempted to illustrate why health labor markets so often evoke monopsony models to economists and review the empirical evidence on their relevance. Nearly all the relevant empirical literature concerns nurses, so it will largely be confined to the discussion of the same. It is started by providing a sketch of different models that imply an upward sloping LS curve, and thus some market power, for individual employers. It will be seen that these models provide an alternative, and arguably more persuasive explanation for several empirical facts that neoclassical models have struggled to rationalize. For example Manning (2003) argues that vacancies, wage dispersion across firms for similar workers, and employer provision of general skills training are all suggestive of monopsony. The second Section Suggestive Evidence therefore presents some facts about the nurse labor market with an eye toward assessing such a *prima facie* case for the plausibility of monopsony. Since many of these facts can be explained in a neoclassical framework, their existence does not constitute a 'severe test' (Mayo, 1996) of whether the labor market is monopsonistic. The third section reviews how economists have attempted to test for monopsony and assess the overall body of evidence. It is ended by discussing some areas that might be fruitful avenues for future research.

Why might we care whether monoposony is a better model of labor markets in health care? One reason is simply that monopsony models may provide a more accurate explanation for why many labor market phenomena, such as wage dispersion, vacancies, or large employers paying higher wages are observed (Manning, 2011, 2003). But the extent of monopsony power in the market also has important consequences for public policy. The implication of most monopsony models is that wages will be set lower in equilibrium than would be the case under perfect competition. If so, then labor will be inefficiently allocated across nursing and nonnursing sectors with too few nurses, obviously a concern in the context of the nursing shortages that have continued well past Yett's study and into the present. Some researchers in this area have suggested that the government should therefore be more active in monitoring nurse compensation, or perhaps promote unionization or a mandated wage to provide countervailing power to nurses in wage setting. Another public policy area where the extent of monopsony is important is the large public investment in nurse education. If employers are able to capture a substantial portion of the returns to nurses' human capital investments due to their ability to set wages below marginal products, then government subsidies may be less attractive relative to relying on private employers to pay for (part of) nurse training.

Models and Predictions

Since by now there are many excellent survey treatments of the various models implying monopsony power, here only a short

sketch of some of these models and their empirical predictions is provided (Boal and Ransom, 1997; Bhaskar *et al.*, 2002; Manning, 2003, 2011). In a perfectly competitive labor market workers are fully informed about the wage offerings of alternate employers, other jobs that are perfect substitutes for their own are readily available, and job mobility is costless. Under these assumptions, the LS curve facing a firm is infinitely elastic because a firm reducing their wage even slightly will see all its workers leave to work for other firms. At the same time, employers have no reason to offer anything above the market wage, since they can get all the workers they need at that wage. The monopsony models discussed in this section are all concerned with explaining why these assumptions might not be satisfied.

Employer Concentration or Collusion

The most straightforward case of monopsony arises when a single firm constitutes the only buyer of labor in a particular market. The classic work of Bunting (1962) showed that high employer concentrations were rare for the US labor market as a whole, leading many economists to dismiss the relevance of this type of model. In health care, however, this isolated firm model may apply more frequently as many hospitals operate in counties with few other competitors for nurse labor. (Of course, even in rural areas significant alternate employment opportunities may exist for nurses in doctors' offices, schools, etc.)

With a single employer for an occupation, the LS curve to the firm is the supply curve for the whole market. The market supply curve is typically assumed upward sloping, reflecting the idea that higher wages should induce more workers of that occupation to enter the labor market of the area, or workers already in the area to switch to the occupation in question. As described in Section Nurse Labor Supply, economists have presumed this elasticity to be low for nurses, making it more likely they might be vulnerable to being 'exploited' – in a sense defined below – by a monopsonistic employer.

Assuming a firm produces its output using only labor (L) its profit maximization problem can be written as

$$\max_{L} \pi(L) = pF(L) - w(L)L$$

where $\pi(\cdot)$ is firm profit, $F(\cdot)$ is the firm production function or revenue normalizing output price to unity, and $w(L)$ is the wage required to attract L workers (i.e., the LS function). The first-order conditions of this problem imply the following wage-setting rule

$$\frac{MRP - w}{w} = \frac{\partial w}{\partial L}\frac{L}{w} = \varepsilon^{-1} \qquad [1]$$

where MRP is the firm's marginal revenue product, t is the elasticity of LS with respect to the wage. Unless the LS curve is perfectly elastic, eqn [1] suggests that the monopsonist will pay workers less than their marginal revenue product, and employment will be lower than in the perfectly competitive case. Since Pigou (1924), economists have sometimes called the ratio on the left of eqn [2], the 'rate of exploitation', referred to below as E. Note that a nearly identical result can be derived from a model with multiple firms in the same market that collude to maximize joint profits (Boal and Ransom, 1997, p. 91).

Robinson's classic graphical analysis of equilibrium in a monopsonistic labor market is depicted in Figure 1. With an upward sloping LS curve, the marginal cost of hiring labor (MCL) lies above the LS curve so long as the employer must pay workers the same wage (i.e., cannot perfectly wage-discriminate). Thus, the employer hires workers up until the marginal cost of doing so equals the value of the marginal revenue product at L^*. As described above, there will be a gap between wages (w^*) and workers' marginal revenue product (MRP^*). But note also that at the wage prevailing in equilibrium, labor demand exceeds LS. In other words, firms face a shortage of labor, or 'vacancies' (Archibald, 1954), equal to $L' - L^*$. This is still an equilibrium because in fact firms cannot hire additional workers at the wage w^* as workers demand higher wages to increase their supply – in other words, firms are '(labor) supply constrained'. In this model, minimum wage policies that raise wages above w^* and as high as MRP^* can increase both employment and wages.

With a few large employers in the market, the situation might best be thought of in terms of oligopsony where there may not be collusion but employers do consider other firms' actions in their hiring decisions. The Cournot model provides a tidy analytical result: if employers choose labor to maximize profits taking other firms' employment levels as given, the first order conditions of the model suggest an employer-specific E_i equal to

$$E_i = \frac{MRP_i - w}{w} = \frac{L_i}{L}\varepsilon^{-1}$$

and thus an average (employment-weighted) market level E of

$$E = \sum \frac{L_i}{L}E_i = \varepsilon^{-1}\sum \left(\frac{L_i}{L}\right)^2 = \varepsilon^{-1}H \qquad [2]$$

where H is the Herfindahl index of employment concentration. The latter condition suggests a relationship between the level of exploitation (and thus wages) at the market level and the concentration of employment so long as the inverse LS elasticity is nonzero (i.e., so long as the labor market is not perfectly competitive). Note, however, that correlations across markets between H and wages are only indicative of

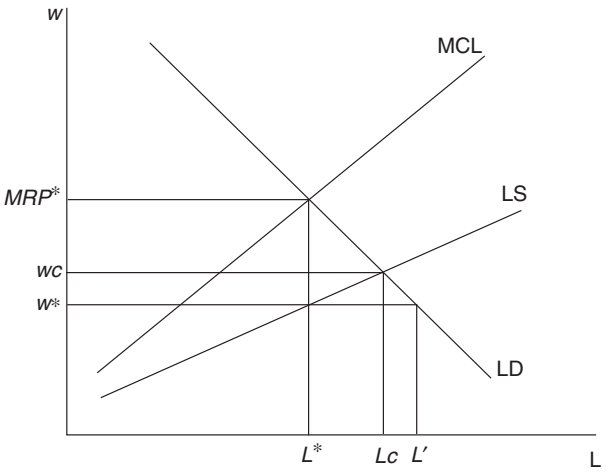

Figure 1 Equilibrium in a monopsonistic labor market.

monopsony power if total labor demand (i.e., the sum of firms' *MRP)* and LS are held constant.

What testable predictions arise from models of employer concentration or collusion? The most frequently explored prediction in the empirical literature is the idea that across markets, higher concentration should lead to greater 'exploitation' and lower wages. In part, such a prediction is generated by the assumption that collusion between employers is more likely to be enforceable with relatively few actors. Although intuitive, it's important to keep in mind that this assumption has little empirical evidence behind it – little is known about the prevalence of collusive agreements among employers across market structures. Short of collusion, models of oligopsony do generally predict a relationship between concentration and wage levels like eqn [2] above. It is important to remember that this prediction discriminates between competition and monopsony only if market level labor demand and supply are held constant. In general, markets that are more concentrated (e.g., rural areas) may differ along both of these lines leading to indeterminate biases – unaccounted for differences in demand would tend to amplify any negative correlation between concentration and wages, whereas differences in supply would tend to lead to a positive bias. (These presumptions about the direction of correlation are based on the assumption that areas with more concentrated employment probably have lower unobserved demand and supply shocks.)

Worker or Firm Heterogeneity

Another source of employer market power is that alternate firms may not be viewed as perfect substitutes in the eyes of job seekers due to differences in worker preferences or differentiation amongst firms. Bhaskar *et al.* (2002) present an intuitive model that illustrates the idea, and a similar idea is developed by Staiger *et al.* (2010) in their analysis of the market for RNs, discussed below. (Also see Bhaskar and To (1999) for a more detailed exposition of the model.) In their model, workers are uniformly distributed along a 1 km road with two firms (firm 0 and firm 1) located at either end. The cost of transportation to and from the work is t per kilometer, so a worker who lives x kilometers from firm 0 incurs a cost tx if he works for firm 0 and $t(1-x)$ if he works for firm 1. Thus, transportation costs differentiate the desirability of employment at the two firms for a given worker's location. If both firms paid identical wages, then all else equal workers would simply choose to work for the nearest employer. If firm 0 increased its wage by a small amount and firm 1 did not, it would attract more workers from firm 1 but clearly not all of them because a small wage increase would not be enough to compensate workers who live close to firm 1 for their cost of travel. Instead, LS would vary continuously and positively with the wage. The greater is t, the transportation cost parameter, the greater a wage increase will be necessary to increase LS for each firm and conversely with $t=0$ the supply curve will be perfectly elastic.

It should be clear here that transportation costs are simply a metaphor for some nonwage aspect of a job that affects the relative utility workers derive from employment at a particular employer. In nursing markets it is easy to imagine many such dimensions along which jobs might differ, including not only geography but also workload (patients per day), control over their work hours, the quality of facilities, etc. Perhaps less information is available regarding how much these other job aspects affect LS decisions – in other words, what is the magnitude of t for these aspects?

Equilibrium Search

Another strand of the literature on monopsony invokes search frictions as the cause of firm-level upward sloping LS curves. Search models provide an alternative, dynamic way of viewing firm-level LS. A firm's level of employment L_t can be written in terms of its previous level of employment, the separation rate of employees from the firm $s(wt)$, and the number new recruits $R(wt)$:

$$L_t = [1 - s(w_t)]L_{t-1} + R(w_t)$$

In this context, wages influence the size of the firm through the flows of workers to and from the firm. In steady state, the dynamic LS equation can be written

$$L(w) = \frac{R(w)}{s(w)}$$

or in elasticity terms,

$$\varepsilon_{Lw} = \varepsilon_{Rw} - \varepsilon_{sw} \qquad [3]$$

In other words, the LS elasticity to the firm can be estimated as the difference between the elasticity of new recruits and the elasticity of the quit rate with respect to the firm's wage (Card and Krueger, 1995). Manning (2003) suggests the simplification of assuming the elasticities on the right-hand side of eqn [3] are equal in magnitude, so the elasticity of LS is just twice the elasticity of separations with respect to the wage. In this light, a firm has market power whenever the elasticities of recruits or separations are less than infinite.

The model of Burdett and Mortensen (1998) is commonly invoked in this literature, and is striking in that it shows that a lack of perfect information (i.e., a finite job offer arrival rate) can generate monopsony power for firms even with identical workers and infinitely many small firms. (See Manning 2003) for a simplified presentation of this model and discussion.) One key result of the model is that the ratio of the job arrival rate to the separation rate indexes the degree of market power firms possess in a market. Manning (2003, p. 44) shows that this parameter is monotonically (negatively) related to the fraction of new hires (recruits) who come from nonemployment, and so the latter is positively related to the extent of monopsony in the market. The intuition is that the higher the fraction of new recruits coming from nonemployment, the less is the direct competition among employers for workers as fewer workers are leaving one firm for another.

Suggestive Evidence

The models of monopsony outlined in the Section Equilibrium Search all suggest a variety of symptoms that might

suggest their presence in the labor market. Before turning to a review of the literature formally testing the implications of such models, it is perhaps useful to review some features of the nurse labor market that hint at either the motivations or the predictions of these models. This evidence is suggestive, and meant only to encourage the reader to view the nursing market through a monopsonistic lens, as it has led many economists to do already. The literature that more formally tests the monopsony hypothesis is reviewed in the following section.

A preliminary note is that since nearly all of the empirical studies of monopsony in health labor markets use data from the US, international comparison is not provided. Although the basic forces at play in other developed countries are likely to be the same as those identified in the theoretical discussion in the Section Equilibrium Search, there are reasons to believe the degree of monopsony power for employers in other countries may differ from that found for firms in the US. For example, Acemoglu and Pischke (1999) argue that lower labor mobility in Germany gives firms there more monopsony power than in the US and helps explain the higher prevalence of employer sponsored training in Germany. It seems likely that differences in labor markets in the US and other developed countries like this exist in health care as well, so the discussion in this section should be viewed in this light.

Vacancies

More than any other feature, the presence of nurse-shortages evidenced by high vacancy rates has motivated the *prima facie* case that nurse labor markets are monopsonistic. Since the 1950s, hospitals have reported RN vacancy rates ranging as high as 10–20% (Yett, 1970; Buerhaus *et al.*, 2009). Amongst economists, early explanations for such shortages suggested that they reflected a state of dynamic disequilibrium whereby increases in the demand for nurses were constantly outpacing increases in supply, and wages were adjusting only slowly. Thus, at the (lagging) wage prevailing in the market, demand for nurses frequently exceeded supply (Blank and Stigler, 1957; Arrow and Capron, 1959). Invoking the work of Archibald (1954) who wrote "we will find oligopsony in the labour market whenever there are few employers of a given type of labour in an area and the cost of mobility is positive," Yett (1970) argued instead that hospitals were oligopsonists and so vacancies could exist even in equilibrium whatever dynamic (out of equilibrium) shortages may or may not be occurring in addition.

Although comprehensive national data are not available, more recent statistics suggest that relatively high vacancy rates persist for several types of nurses across a range of employment settings. A 2010 survey of 572 community hospital CEOs by the American Hospital Survey found RN, licensed practical nurse (LPN), and nurse aide vacancy rates of 4%, 4%, and 5%, respectively, which is low by historical standards due to the recession causing more nurses to join the labor force (Association, 2010). (One should be cautious about comparing reports of vacancy rates across different information sources, as the definitions used appear to vary significantly.) Among nursing homes, a 2007 survey found vacancy rates of 16.3%, 11.1%, and 9.5% for RNs, licensed practitioner nurses, and certified nurse assistants, respectively. (This is based on information from 3828 responding nursing homes from a 2007 survey of all 15 558 nursing homes in the US conducted by the American Health Care Association (Table 1, http://www.ahcancal.org/research_data/staffing/Documents/Vacancy_Turnover_Survey2007.pdf%20accessed%20May%2030,%202011).)

Concentration and Collusion

Another aspect of the nurse labor market that has evoked monopsony models is the relatively high employment concentration ratios. Yett (1970) suggested that the emergence of nursing shortages coincided with consolidation of RN employment in hospitals around World War II, and it remains true that the plurality of RNs work for hospitals. Many hospitals, in turn, operate in labor markets with few other employers: Yett (1970, p. 378) cites the figure that 60% of hospitals are in a health service area with fewer than six hospitals. More recent statistics suggest approximately 60% of US counties are served by only one hospital and approximately 25% of all hospitals are the only hospital in their county. (Author's tabulations of 2004 Area Resource File data. Of course hospitals are not the only employer of nurses but, especially in less populous counties, they account for the lion's share of employment.) That said, there are other employers of nurses such as nursing homes, doctors offices, schools, etc. and their presence in even the most rural markets may provide enough competition to prevent nurse exploitation in the sense of eqn [1].

Arguably the most direct evidence on monopsony would be the discovery of explicit agreements amongst employers to lower wages. Although economists tend to be skeptical of the sustainability of such arrangements among any substantial number of employers (For an early example, see Rosen (1970). He was also skeptical that hospitals, as nonprofit organizations, would engage in such rent appropriating behavior – a concern echoed by Pauly (1969). A classic reference is Stigler (1964).), there is scattered evidence that such arrangements have existed amongst hospitals. For example, in a survey of metropolitan hospital associations by Yett (1970), 14 of the 15 respondents reported having established successful 'wage-standardization' programs and the 15th asked for information about establishing one. Devine (1969) provides similar evidence on hospital collusion over wages in Los Angeles in the 1960s.

More recently, in 2006 nursing groups filed class action lawsuits against hospital chains in several large cities across the US (Greenhouse, 2006). These lawsuits alleged that the hospitals shared information about the wages of competitors for the purpose of keeping RN wages low (Miles, 2007), in violation of antitrust laws. An interesting feature of all of this evidence is that the collusion apparently took place in large metropolitan areas with many employers. In this light, the notion that the opportunity to collude is limited to those areas with high employer concentrations seems dubious. Indeed, the opportunity to share information on wages with competitors through consulting companies that conduct compensation surveys may enable a substantial degree of 'arm's-length' or tacit collusion.

Nurse Labor Supply

A common part of *a priori* arguments for monopsony in the nurse labor market is the notion that the market-level elasticity of LS for nurses is low due to high mobility costs. With few other hospital employers in an area, any job switching, particularly for RNs, would likely entail either relocating to a different area or switching to a different occupation. Yett argued both costs were substantial since (1) many nurses were married and their location decisions were likely constrained by their husbands' careers and (2) "few other occupations for which nurse training provides any advantage pay competitive salaries" (Yett, 1970, p. 381), so it would be costly for a nurse to switch to another occupation. To support this claim, Yett cited the results of a survey of nurses that reported low mobility rates overall, and suggested only 4–8% of nurses reported changing jobs because they were dissatisfied with their pay. More recently, Shields (2004) reviews a range of studies of nurse LS conducted over the past four decades, and reports the overall conclusion that nurse (market level) LS is indeed quite unresponsive to wages.

An implication of monopsony first highlighted by Robinson (1933, p. 302) is that employers may be able to discriminate between different types of workers. In particular, if there are two groups of workers with different LS elasticities to the firm, the profit-maximizing employer will offer a lower wage to the group with less elastic supply. Robinson provided a theoretical example where a wage differential emerged between male and female workers assumed equally productive, but men were organized into a trade union and thus had perfectly elastic supply at the union negotiated wage rate. In the nurse labor market, this phenomenon is a potential explanation for the wage premium paid to temporary contract, or registry, nurses.

In general, however, it is not clear that nurses stand out from other workers in the sense of having markedly different LS elasticity. For example, motivated by the intuition of the Burdett and Mortensen (1998) search model outlined above, Hirsch and Schumacher (2005) calculate the fraction of new RN hires from nonemployment using Current Population Survey data for the years 1994 to 2002, and find that 41.8% of recruits come from nonemployment on average each year. Surprisingly, however, they find that the ratio is actually higher (51.2%) for a nonnursing control group (women with a college degree). Although this does not imply that the RN market is not monopsonistic, it does cast some doubt on whether the nursing market is distinctively so.

Other Features

The features of the nurse labor market described in Section Nurse Labor Supply help to explain why health labor markets are singled out disproportionately in discussions of monopsony. There are other empirical 'puzzles' that have been documented more broadly in the economy, however, that some have argued are more naturally explained by monopsony models than by a model with a perfectly competitive labor market (Bhaskar *et al.*, 2002; Manning, 2003). Without going into much detail, it is noted in passing that many of these 'puzzles' are characteristic of the nurse labor market as well.

One hallmark of the competitive model is the 'law of one wage' (Bhaskar *et al.*, 2002, p. 156), or the prediction that similarly productive workers should all receive the same wage at jobs that are similar in their nonwage attributes. In nursing labor markets, wage differentials across employers are quite common. For example, in 2005 among 363 nursing homes in Los Angeles county, the average hourly wage level of RNs was US$28.2 (2005 dollars). But the firm at the 10th percentile of the firm-average wage distribution paid US$23.4 and the firm at the 90th percentile paid US$32.9, or 40% more. Such differentials are more pronounced for more skilled nurses, but are present for nurse aides as well. Among the same set of nursing homes, nurse aides made US$9.7 on average but the firm at the 90th percentile paid US$10.9 on average, or 25% more than the firm at the 10th percentile (US$8.7). (These data are taken from Matsudaira (2010), and are described in more detail there. Note that a limitation is that they represent average wages paid to a particular occupation by a firm. It is likely that this understates the degree of wage dispersion, though part of the differentials will reflect differences in composition among workers across firms, e.g. in experience. Also see Machin and Manning (2004) for an interesting and more detailed study of wage dispersion among nursing home workers in the UK.)

Some economists have argued that wage dispersion might reflect differences in worker productivity or compensating differentials for nonwage aspects of the jobs at different firms. But another piece of evidence argues against such explanations: turnover is negatively related to wage levels. Using data on the same set of Los Angeles nursing homes from 1981 to 2004, a regression of turnover rates for nurse aides on their average wage levels and a set of facility and year fixed effects suggests that raising hourly wages by $1 reduces turnover by approximately 7.4 percentage points (approximately 10%). If wage differences reflect unobserved productivity differences, there should be no reason for low wage workers to leave their jobs at higher frequency since they would not expect to be able to get the higher wage jobs. Similarly, differences driven by compensating differentials are inconsistent with the turnover result as switching from a low to a high wage job would not yield an expected utility gain.

Another interesting feature of labor markets that has challenged competitive theory is the fact that many employers seem to provide and pay for general human capital training to their workers. With perfect labor mobility, one might be skeptical that firms have an incentive to do this since they would be unlikely to recoup any investment in their workers' human capital that is not firm-specific Becker (1993). Despite this, it appears common for hospitals to pay for general skills training for their nurses, consistent with the view that imperfections in the labor market allow firms to recoup part of their investment in their employees general skills (Acemoglu, 1997). For example, May *et al.* (2006) document that many hospitals in their survey offer in-house nurse training programs, or subsidize their staff's training at nearby nursing schools. Benson (2011) provides a test of monopsony of sorts based on this reasoning, showing that hospitals with higher concentration ratios in their metropolitan area are more likely to subsidize training to RNs.

Empirical Studies of Monopsony

What direct evidence is there about whether nurse labor markets are actually monopsonistic? Previous studies on this question can be grouped into two broad categories: (1) an early literature that attempts to determine whether there is a link between employment concentration and the level of nurse wages, and (2) a more recent and smaller set of papers attempting to directly estimate the facility level elasticity of LS for nurse employers. Each of these literatures are discussed in turn.

Concentration and Wages

The first serious empirical test of the hypothesis that nursing markets are monopsonistic was Hurd (1973). Using data from the 1960 Census, Hurd estimates the relationship between hospital employment concentration and median nurse earnings across the 100 largest Standard Metropolitan Service Areas (SMSAs). The regression model includes control variables for the cost of living, the percentage of nurse employment accounted for by hospitals, the percentage of hospital employment accounted for by federal hospitals and the percentage accounted for by state and local hospitals, and the percentage of nurses receiving earnings who worked for less than 50 weeks. Hurd finds that holding these other factors constant, there was a significant negative relationship between concentration, measured by the share of employment of the eight largest hospitals, and median nurse earnings. In auxiliary analyses using wage data from the Bureau of Labor Statistics for a subset of cities he finds a similar relationship, and interpreted his findings as supportive of the monopsony hypothesis.

Subsequent studies by Link and Landon (1975), Feldman and Scheffler (1982), and Robinson (1988) (Robinson (1988) tests the prediction that the employment of nurses will be relatively low in areas with higher hospital employment concentrations.) confirm Hurd's findings, using hospital-level data and slightly different measures of firm concentration (e.g., a Herfindahl index based on hospitals' share of total beds in a city). As emphasized above, however, a correlation between concentration and wages is only evidence of monopsony if other factors related to LS and demand are held constant across markets.

More recent studies, such as Adamache and Sloan (1982) and Hirsch and Schumacher (1995), suggest that the relationship between concentration and wages may not be robust to better controls for such factors, such as population density and the wages of alternative occupations. The best study in this literature is probably Hirsch and Schumacher (1995), who pursue a two-step strategy for testing the prediction that hospital concentration depresses wages. Using data from the 1985 to 1993 Current Population Survey Outgoing Rotation Group (CPS-ORG) files, they first identify a control group of workers for each type of three nurse occupations (RNs, LPNs, and nurse aides) based on similarities in educational requirements. Then, for each occupation they estimate the relative wage gap between nurses and their respective control group separately for each of 252 geographic areas – including 202 metropolitan areas and 50 nonmetropolitan area state groups – controlling for worker characteristics and time effects. In a second-step regression, they then test whether hospital concentration and market size are correlated with the nursing wage differential and find no evidence that supports such a claim for any of the nurse occupations considered. (In a follow-up study, Hirsch and Schumacher (2005) use a similar design to see whether an alternative measure of monopsony power – the fraction of RN recruits from nonemployment – is correlated with wages across geographic areas. They find again no evidence for monopsony power for hospitals.)

The research design in Hirsch and Schumacher (1995) is clearly better than earlier studies in that measuring nursing wage differentials relative to a control group more effectively controls for market specific differences in demand and supply conditions that apparently confound earlier estimates. That said, the design relies heavily on the premise that nonnursing occupations are not subject to monopsony, or more accurately that variations in monopsony power in nonnursing labor markets is uncorrelated with variations in hospital concentration and market size. If monopsony is a more pervasive feature of labor markets for other occupations, then the approach may understate the wage-setting market power of hospitals.

Labor Supply to the Firm

As discussed in Section Models and Predictions, the key distinguishing feature of monopsony models relative to perfect competition is an upward sloping LS curve to individual firms. Despite its importance, only a handful of studies have attempted to credibly estimate this elasticity parameter. The reasons for this are readily apparent: the observed changes in wage and employment levels across firms are in general the result of changes to both supply and demand. So long as the supply curve is shifting, the observed equilibria cannot reliably be used to identify its slope. This is a well-known problem in economics dating back at least to Haavelmo (1943), but the solution of finding a 'demand shifter' to use as an instrumental variable for the observed quantities, tricky in the best of settings, is particularly difficult in this case. Since firm-level LS is of interest, any instrument must act differentially only on the labor demand of the specific firm in question so market wide phenomena are off the table.

Sullivan (1989) was the first to make a serious attempt at estimating the firm-level elasticity of LS to individual hospitals using data from 1979 to 1985. He derived LS equations based on different assumptions about the nature of competition among firms in an oligopsonistic setting, and controls for hospital and region specific fixed-effects to estimate the (inverse) elasticity of supply. For example, assuming Nash equilibrium in employment levels his estimating equation is

$$w_{rit} = \alpha i + \delta_r t + \theta n_{rit} + \gamma on_{rit} + \varepsilon_{rit}$$

where w_{rit} represents log wages for hospital i in region r at time t; n_{rit} is the log number of nurses employed; and on_{rit} the log of the sum of nurses employed at other hospitals. θ represents the inverse elasticity of supply. The simultaneity problem is addressed by using the number of caseloads and average length of stay as instrumental variables for the number of

nurses at hospitals, the notion being that these variables affect output demand and thus the derived demand for nurses but not necessarily nurse supply for a given hospital. Sullivan finds that the inverse elasticity of supply is approximately 0.79 (with standard error of 0.13) over a 1-year period and 0.26 (0.07) over a 3-year period and asserts this represents a significant amount of market power for hospitals. In a static model these elasticities can be used to compute the 'markup' of marginal product over wages using eqn [1], in this case implying wages are between 43% (for 1-year changes) and 21% (for 3-year changes) below marginal product. In a dynamic setting, however, this 'rate of exploitation' is a weighted average of short and long run elasticities where the weights are a function of a firm's discount rate. Assuming a long run elasticity of zero, Boal and Ransom (1997, p. 105) suggest Sullivan's estimates imply that wages might be set between 87% and 96% of marginal product. Using this logic, they characterize Sullivan's results as being suggestive of only slight market power for hospitals but of course such a conclusion rests on the accuracy of its assumptions.

The validity of this instrumental variable has been questioned. Staiger *et al*. (2010) point out that Sullivan's sample brackets a period when Medicare's Prospective Payment System is introduced, and suggests that much of the variation in hospital days over the period was therefore endogenous as the transition presumably may have led to independent (downward) pressure on nurse wages. Manning (2003) suggests, alternatively, that caseloads might be related to population shocks, and thus might fail the exclusion restriction.

An instrumental variable strategy is also employed by Staiger *et al*. (2010) who use legislated wage changes in Veteran's Affairs (VA) hospitals to identify the firm-level LS elasticity of RNs. Similar to the analysis in Sullivan (1989), Staiger and his coauthors adopt an explicit model of oligopsony (based on Salop (1979)) where hospitals compete most intensively with hospitals in close proximity, leading to an estimating equation where employment depends on a hospital's own offered wage but also the average wage at nearby hospitals. They demonstrate that VA wage changes affect the wage levels of RNs at nearby hospitals (up to 30 kms away), suggesting that hospitals do have the ability to set wages. Using gaps between the newly legislated wage and wages at the time of the legislation as instruments for wage changes, the estimated LS elasticity over a 2-year period ranges from approximately 0 to 0.2 with standard errors approximately 0.13 (or an inverse elasticity ranging from approximately 5 to infinity). Even using the upper bound of the 95% confidence interval from Staiger *et al*.'s estimates implies that the inverse elasticity of LS is at least 2, far from the 0 assumed by the theory of perfectly competitive labor markets.

Matsudaira (2010) attempts to estimate the degree of monopsony power for nursing home employers using a different strategy. In 2000, the state of California adopted minimum staffing regulations for nursing homes requiring them to employ a minimum number of nursing hours for each patient in residence. Depending on the gap between a home's initial staffing level and the legislated threshold, this law created more or less pressure to hire additional nurses to comply. Thus, Matsudaira uses this measure of the staffing gap as an instrument for subsequent changes in nurse employment.

Despite finding that homes initially out of compliance with the staffing law did hire significantly more nurse aides than those already in compliance, there were no differences in wage changes of aides across these groups of firms suggesting a highly elastic firm-level LS curve (i.e., an inverse elasticity close to 0). Since homes complied with the law almost exclusively by hiring nurse aides, the LS elasticity estimates for more skilled nurses (RNs and LPNs) were not estimated.

The estimates in Matsudaira (2010) differ markedly from those in Sullivan (1989) and especially Staiger *et al*. (2010). This may reflect differences in the supply elasticities of different kinds of nurses – nurse aides do not have near as much occupation-specific human capital, and so may have a broader set of alternative employers and thus more elastic LS. Or, if factors such as ignorance about alternative wage offers are the primary source of labor market frictions and this ignorance affects all occupations similarly, then the results may well be in conflict. A third possibility raised by Manning (2011) is that none of the studies are accurately measuring the firm-level LS elasticity, and that the models of firm-level LS used in the literature reviewed here are overly simplistic. This point is returned to below.

Discussion

Overall, the evidence above presents a very mixed case on the empirical relevance of monopsony models for understanding the nurse labor market. On the one hand, as in other markets there seems to be strong *prima facie* arguments that the market is monopsonistic ranging from 'smoking gun' evidence of wage-fixing, to reports of vacancies, to wage dispersion and provision of training. On the other hand, formal tests of the implications of monopsony theory have yielded varied results. The best studies on the relationship between employment concentration and wage levels suggest there is no relationship, and direct estimates of firm-level LS elasticity have produced some estimates consistent with extremely inelastic LS, and some estimates consistent with perfectly elastic LS.

It would be suggested that part of the reason for these ambivalent results is the reliance on overly simplistic theoretical models to guide empirical work. As noted above, although some models predict that collusion is more likely in more concentrated industries, there seem to be many cases where employers have colluded to keep wages low even in large, fairly unconcentrated markets. (Relatedly, Levenstein and Suslow (2006) report that although most cartels that have been studied in the product market have few members (with a median number of companies approximately 6 to 9), about one-third have more than 10 members with some having hundreds of members. They report that with cartels of many companies, industry associations often play a key role in coordination.) More work on the prevalence of collusive agreements on wages and competition for employees, and the effects of industry associations and wage-information sharing through compensation surveys would be useful, particularly given the recent legal actions taken by RNs alleging wage-fixing by hospital chains in many large MS as in the US. It may well be that traditional measures of concentration are a poor proxy for the prevalence of collusion among employers to

keep wage levels low in the nursing labor market. (Another interesting direction for future research is exploring the ways in which regulations restrict competition in the labor market. In a recent study, Kleiner and Park (2010) show evidence that state licensing rules restricting the work that can be done by dental hygienists have important effects on the earnings of hygienists and dentists. Licensing is obviously a pervasive feature of the health labor market, as are noncompete clauses among physicians. Exploring the consequences of such regulations for health care workers would be an interesting addition to the literature.)

Manning (2011) makes the point that if the firm-level LS function is not one-to-one with respect to wages, then the elasticities estimated in the literature may be incorrect. For example, if LS to the firm depends both on wages and recruitment expenditures (e.g., on advertising vacancies), then faced with a mandatory increase in employment it may be optimal for the firm to respond by increasing recruitment expenditures rather than by increasing wages. If such a model applied, the results of Matsudaira (2010) might overstate the LS elasticity to the firm, and conversely a design estimating the impact of a legislated wage increase on employment like Staiger *et al.* (2010) might understate the degree of elasticity. Other models with heterogeneity in worker quality or nonwage aspects of jobs can have similar implications. For instance, Matsudaira (2010) cautions that firms may respond to the mandate to hire more nurses by reducing their hiring standards with respect to worker quality at a given wage. If so, then the LS curve to the firm for nurses of a given quality may well be upward sloping even given his result that wages remain constant in firms that hire more nurse aides. Currie *et al.* (2005) test the predictions of a monopsony model in the context of examining the effects of hospital mergers on RN wages, and suggest that nurse effort (proxied in their context by nurse–patient staffing ratios) may be an important nonwage dimension that hospitals use to affect LS. They suggest that rather than suppressing wages, hospital mergers may lead to increased nurse effort for a given wage, a result consistent with the predictions of monopsony in their model. (The result is also consistent with a contracting model that they develop.)

The empirical literature on the importance of monopsony in the nurse labor market has yet to provide a conclusive answer. As suggested above, however, this is in part because our theoretical understanding of frictions in the labor market has evolved. Unfortunately it is difficult to formulate tests that would allow one to definitively reject monopsony or perfect competition under all theoretical formulations, and the tests that suggest themselves are hard to capture in the 'real world.' To wit, the thought experiment "what would happen if one employer was randomly forced in a market to increase its wage holding the wages of all competitors constant?" is easy to posit but near impossible to observe in the wild. Moreover, formulating direct tests of more general models of monopsony (Manning, 2006) present a challenge since many other determinants of LS are hard to observe at the firm level. In general, there are little data on worker quality, nonwage attributes of jobs, recruitment expenditures, and the other margins along which employers might adjust in response to (firm-specific) labor demand shocks. However, there may be relatively greater opportunities to advance a research agenda along these lines in the nurse labor market due to a long history of health management studies focused on understanding the determinants of nurse turnover and job satisfaction.

Moral Hazard

T Rice, University of California, Los Angeles, Los Angeles, CA, USA

Introduction

The term 'moral hazard' is surely one of the most controversial in the field of health economics. Although it would seem that the connotation must be pejorative – immorality is certainly implied if one is prey to the hazard (Dembe and Boden, 2000) – it is commonly used to describe a much more benign situation in which a person with health insurance will use more services. Indeed, as Pauly (1968) pointed out long ago, "the response of seeking more medical care with insurance than in its absence is a result not of moral perfidy, but of rational economic behavior" (p. 535).

In reality, though, health economists have not viewed the concept agnostically. Moral hazard has been linked inextricably to another concept: the welfare loss from excessive health insurance. This, too, is value-laden, as it implies that social welfare would be higher if people did not have so much insurance. Some estimates put the cost of this welfare loss as high as 30% of all spending on health care in the US (Manning *et al.*, 1987; Feldman and Dowd, 1991). Evidence on the existence of moral hazard has led to increasing patient cost-sharing for health care services (Manning *et al.*, 1987; Newhouse, 1993).

How one views the concept and evidence has a profound impact on the public policies espoused – and even carried out. Because raising cost sharing requirements can be shown to reduce welfare loss under the traditional theory, this has been a policy advocated by many health economists. Others, particularly those from outside of the US, have been less sanguine about such policies as they can lead to less use of necessary care, as well as more inequity. Many countries instead rely more on quelling unnecessary utilization by providing incentives to providers rather than demanders of care.

This article is organized as follows. It begins with an explication of the traditional economic theory of moral hazard. Next, it provides some challenges to this theory. After that, empirical evidence is provided, first, from the RAND Health Insurance Experiment (HIE) and a critique of it, as well as some more recent studies. It then raises a topic of some currency: the advisability of evidence-based cost sharing based on the value that services convey. Finally, alternative ways of controlling the use of unnecessary care are presented that focus on the supply rather than demand side of the health care market. The article concludes with a call for less value-laden terminology.

Traditional Economic Theory

Before addressing moral hazard, it is useful to consider the traditional concept of consumer demand more broadly. If some key assumptions – for example, consumers are rational and well-informed – are deemed to be true (or are ignored), then what people demand (that is, what they are willing to pay for goods at different prices) is a barometer of social welfare. This is because in asserting these demands, they 'reveal themselves' to prefer one set of goods over another. It is a short leap to conclude that for society as a whole, whatever people choose will make society best off.

Not everyone, of course, agrees that demand curves can be used in such a way. American economists Ellis and McGuire (1993) take a much less value-laden approach, asserting that, "[W]e are skeptical that the observed demand can be interpreted as reflecting 'socially efficient' consumption, [so] we interpret the demand curve in a more limited way, as an empirical relationship between the degree of cost sharing and quantity of use demanded by the patient" (p. 142). Nevertheless, not only is that the first interpretation by far the most common one, but it underlies the entire notion of welfare loss discussed below.

To understand that theory it is useful to begin with the concept of 'consumer surplus.' This is defined as "[t]he difference between what a consumer pays for a good or service and the maximum they would pay rather than go without it" (Culyer, 2010). The former is set by the marketplace, the latter by the consumer's own preferences. To illustrate, suppose a pound of apples costs US$2 and a consumer is willing to buy 4 lb at that price. This fourth pound, however, is probably of less value to him or her than are the previous pounds (unless a pie is being baked requiring that much). This is because of another economics concept, 'diminishing marginal utility.' In fact the consumer might be willing to pay US$5 for the first pound, US$4 for the second, and US$3 for the third. Fortuitously, they do not have to, as the market price is only US$2. As a result, in this example they have generated US$6 worth of consumer surplus: for each pound of apples, the difference between how much they are willing to pay and how much they actually have to pay. The term, incidentally, was first used in the mid-nineteenth century by a French engineer named Jules Dupuit as a way of calculating the value of railroad bridges (Ng, 1979) (A history of Dupuit's contribution – and notably, the lack of contribution by John Marshall, who popularized the concept to the English-speaking world, can be found in Houghton (1958)).

Public policymakers are not very interested in the individual consumer as they are in the aggregation of all consumers. By summing up the consumer surplus, we can derive the value to society of a particular commodity or investment over and above its costs. This is useful to know in and of itself, but also can help policymakers choose among alternative projects in which to invest.

Pauly (1968) focused on the concept of moral hazard in critiquing a famous article by Kenneth Arrow (1963). Although Arrow raised the issue, he nevertheless argued, "The welfare case for insurance policies of all sorts is overwhelming. It follows that the government should under-take insurance in

 doi:10.1016/B978-0-12-375678-7.00916-0

those cases where this market, for whatever reason, has failed to emerge'' (p. 961).

Pauly showed that this is not necessarily the case because it fails to take into account moral hazard, which can chip away at consumer surplus. In essence, with full insurance, people would demand more services, even ones that had only marginal value. Because these services would cost (perhaps) as much to produce as others, society would suffer a welfare loss from this excessive amount of health insurance coverage. The welfare loss would equal the difference between how much it cost to produce the services and how much people were willing to pay for them. Suppose that a medical service cost $10, and a person would be willing to pay that much for up to three doctor visits per year. If, however, they had full insurance and had to pay nothing, they might demand six visits. Suppose for the fourth visit they would be willing to pay US$7, the fifth US$4, and the sixth US$1 (each still cost US$10 to produce). The sum of the welfare loss would be US$3 + 6 + 9 = US$18.

Because people use more services when they have full insurance, it costs more to provide medical care than it would otherwise. Pauly's point with regard to Arrow's comment is critical. Arrow said that government should provide insurance if it is not available. Pauly shows that this is not necessarily true: people will have to pay (in taxes) for the insurance program, but much of the spending will go toward services that they would not have chosen to purchase in lieu of insurance – services, he argued, are of less value by definition. Stated more bluntly, the individual, and therefore society as a whole, could very well be better off with no insurance than with government-provided insurance, due to the concept of moral hazard. Or as Robert Evans (1984) states disparagingly of this line of reasoning, ''The welfare burden is minimized when here is no insurance at all'' (p. 49).

The word 'could' in the previous paragraph is there advisedly. Although Pauly argues that there is a welfare loss to health insurance, there is also a gain: people obtain utility from being protected against large medical expenses. The issue, then, is determining which is larger: the welfare gain from this security, or the welfare loss described above. Feldman and Dowd (1991) took both elements into account, and concluded that the loss was far greater than the gain.

The policy implication that is generally taken away from this analysis is that consumers should share in the cost of services, or, put more graphically, 'have some skin in the game.' Patient cost sharing will reduce service usage; it is assumed that the services that are forgone will be those that bring the lowest utility (a concept returned in the section The RAND Health Insurance Experiment). Although the RAND HIE has not been discussed yet, its authors touted the societal savings that they argue were generated by the uptick in cost-sharing requirements in the US that followed publication of the study results. The study cost US$285 million in 2010 dollars; they argue that this cost was made up in only a week from savings that resulted from the lower costs associated with the increased cost sharing (Manning *et al.*, 1987).

Before going on, it needs to be pointed out that the discussion in this article focuses on 'ex post moral hazard.' This is the phenomenon that occurs when the out-of-pocket price of medical care is reduced through the possession of insurance, such that the quantity of services demanded subsequently increases. There is another type of moral hazard, known as *ex ante*. According to Culyer, this ''refers to the effect that being insured has on behavior, generally increasing the probability of the event insured against occurring'' (p. 331). For example, if you are insured you may be less likely to engage in preventive behaviors – or may take up skydiving – because of the financial protection afforded by insurance. Because *ex ante* moral hazard has received much less consideration in the health care literature, it is not discussed further here. It is more salient in other types of insurance, such as for fires. By possessing such insurance, business and homeowners may take less care in taking care of electrical wiring, installing fireproofing, etc.

Challenges to the Traditional Theory

Although it is probably fair to say that most health economists are largely comfortable with the traditional theory moral hazard, there have been both direct objections as well as indirect ones. The former concern the issue of whether there is substantial welfare loss from health insurance, and the latter relate to the notion that substantial patient cost sharing is an advisable policy.

One objection raised by the present author (Rice, 1992; Rice and Unruh, 2009) relates to the notion that one can derive accurate estimates of social welfare from traditional methods. The way in which welfare losses are calculated assumes that individuals can accurately predict (at least on average) the benefits they will derive from using a medical service. They then compare this to the cost that they have to pay, and make a decision about whether such a service is worth purchasing. If they cannot predict these benefits accurately, then the method of ascribing welfare loss to excessive health insurance is invalid.

Why is this the case? Recall from above that welfare loss is defined as the difference between how much it costs to produce the services and how much people were willing to pay for them. How much people are willing to pay is defined by the demand curve, which shows, at all hypothetical prices, how many of an item a consumer will purchase. The traditional theory assumes that what people are willing to pay is an accurate measure of how much something is worth to them, or, which can call 'utility' or 'welfare.' It assumes that people know the benefit they will derive from a service – before purchasing it – and therefore can compare it to the cost to make a purchase decision that is in their best interest.

Consider the following. A person has a number of health ailments that include an ear infection and throat pain. Treating each will involve visiting a physician, so the out-of-pocket costs are the same. Researchers, however, probably unbeknownst to the person, have found that medical care has been shown to be highly effective in treating the ear infection, but rarely effective in treating throat pain (Lohr *et al.*, 1986). It is logical to assume that a person would get more utility from the ear treatment and therefore would be willing to pay more for it – perhaps even the full price even in the absence of having insurance (This assumption is, admittedly, somewhat controversial. It may be that consumers are not interested in

the conclusions of medical researchers but instead trust their own judgments in these matters. Here a different view is taken – that consumers would generally prefer to pay more for services that are judged to be more effective by medical research). In contrast, they would perhaps be willing to pay only the cost sharing amount – which is far less than the total cost of the service – to be treated for the cough. If the person actually behaved this way, then the welfare loss calculations would appear to be valid.

In reality, however, consumers are often unaware of which service will be more useful to them. If so, then examining what services they demand when they have to pay the full price, versus what they demand when they are insured, does not provide an indication of the utility or welfare derived. In the parlance of economists, the author is positing here that the demand curve does not necessarily reflect utility or welfare when consumers do not have good information about the benefits and costs of alternative services. Empirical evidence will be examined on this issue below. To give a preview, there is some evidence to suggest that when facing cost-sharing requirements, patients cut back on service usage somewhat indiscriminately, equally reducing use of services that are deemed by experts to be most and least useful. Moreover, there is growing evidence that cost sharing result in forgoing needed services.

A second objection to the welfare loss theory has been propounded by John Nyman (1999, 2002, 2007). The traditional model of welfare loss assumes that the only benefit of insurance is that (a risk-averse) people will receive utility from the financial protection afforded by insurance. Nyman, however, asserts that there is a yet more important aspect of insurance to purchasers: it allows them to be able to afford very expensive medical procedures that, in lieu of having insurance, they would not be able to obtain. If this is the reason why people use more services when they are insured, then, he argues, there is a welfare gain rather than a welfare loss to the additional utilization that occurs when a person is insured.

Nyman provides a hypothetical example. Assume that a mastectomy costs US$20 000 and breast reconstructive surgery, another US$20 000; the total cost of care for this episode of illness is therefore US$40 000. Further assume that an uninsured woman who has breast cancer can afford the US$20 000 surgery, but does not have the resources to pay for the reconstruction. Compare that to a second hypothetical situation, where the woman is insured and therefore can afford the mastectomy and the reconstruction. Under the conventional theory there would be a welfare loss associated with the reconstruction, because the woman only demanded it when having insurance made it cheaper.

According to Nyman, it is not the reduction in price brought about by insurance, but rather the increase in effective income that generates the demand for reconstructive surgery. In effect, having insurance has increased the woman's income by making a heretofore unaffordable service, affordable. The woman, in turn, chooses to spend this new wealth on the reconstruction. When the insurance company wrote her a US$40 000 check, and the woman chose to use the money toward not only the mastectomy but also the reconstruction instead of spending it on something else, then the purchasing behavior is evidence of a welfare gain (Nyman 2007).

A third objection to the welfare loss theory is also ethical in nature but more general. As noted, the major policy implication of the welfare loss is that cost sharing (compared to free care) will increase social welfare. Two concerns rise from this. The first relates to the distribution of income; cost sharing is highly regressive, falling most heavily on those with low incomes. Moreover, the poor tend to be sicker and, if they avoid care due to its costs, are more likely to suffer the consequences of unchecked illness. This is well summarized by Evans *et al.* (1993), who wrote:

> [P]eople pay taxes in rough proportion to their incomes, and use health care in rough proportion to their health status or need for care. The relationships are not exact, but in general sicker people use more health care, and richer people pay more taxes. It follows that when health care is paid for from taxes, people with higher incomes pay a larger share of the total cost; when it is paid for by the users, sick people pay a larger share.... Whether one is a gainer or loser, then, depends upon where one is located in the distribution of both income... and health.... In general, a shift to more user fee financing redistributes net income... from lower to higher income people, and from sicker to healthier people. The wealthy and healthy gain, the poor and sick lose (p. 4).

There is a final objection to relying on patient cost sharing, as implied by the welfare loss theory. If patient cost sharing defines efficiency by reducing welfare loss, this implies that the US has the most efficient health care system in the world (or is second to Switzerland, which also has substantial cost sharing). Although this is not the place to review the evidence, the assertion that the US health care system is among the most efficient in the world is hard to justify given the far higher costs, but mediocre at best process and outcome indicators that are available from international comparative research (Rice and Unruh, 2009, ch. 10).

Evidence

The RAND Health Insurance Experiment

The RAND HIE was the most important empirical study done on the demand for medical care. It also provided evidence of the impact of cost sharing not only on use of services but also on patient health status. Researchers have used the results on moral hazard to estimate the welfare loss from excess health insurance.

Conducted between 1974 and 1982, approximately 5800 individuals in six sites (in a total of four US states) were randomized into groups that faced different cost sharing requirements. Although the actual experimental design was somewhat more complicated, the main intervention tested concerned cost sharing. Participants were assigned to pay 0%, 25%, 50%, or 95% of their medical care expenses. There were also maximums associated with how much they would have to pay each year.

The study's findings with regard to use of services and costs showed that cost sharing indeed had a substantial impact. Those who received free care spent, on average, US$750 annually, compared to US$617 for those paying 25% of costs,

US$573 for responsible for 50%, and US$540 for those paying 95% (in 1984 dollars) (Manning *et al.*, 1987). Most income groups behaved similarly, as did those who were healthy versus sick. The reductions were similar for children and adults for outpatient services. However, cost sharing did not deter inpatient utilization for children. Of note is that nearly all of the impact of cost sharing was on seeking care in the first place. Once a person entered the medical care system for an episode of illness, it did not have a marked effect on usage.

With one or two exceptions, these results were not surprising. What was surprising was that for the most part, those who paid more and used less did not experience a reduction in health status. This was measured in numerous ways, including self-assessed health status, physical functioning, role functioning, health perceptions, and mental health (Brook *et al.*, 1983). There were few exceptions to this for the sample as a whole (mainly slightly higher blood pressure and lower corrected vision). Those already at elevated risk of dying were also adversely affected, mainly due to the impact of cost sharing on blood pressure (Brook *et al.*, 1983). If there was one group that did benefit from free care, it was those with low incomes. Their risk of dying was lower and they experienced fewer serious symptoms (Shapiro *et al.*, 1986). Free care also led poorer individuals to obtain more medical examinations (Lohr *et al.*, 1986).

Interestingly, another finding by the RAND researchers was that those facing higher copayments were rather indiscriminant in their reduction of services (Lohr *et al.*, 1986). They categorized services into four groups: highly effective, quite effective, less effective, and rarely effective. The authors concluded that "cost sharing was generally just as likely to lower use when care is thought to be highly effective as when it is thought to be only rarely effective" (p. S32) and that "cost sharing did not lead to rates of care seeking that were more 'appropriate' from a clinical perspective. That is, cost sharing did not seem to have a selective effect in prompting people to forego care only or mainly in circumstances when such care probably would be of relatively little value" (p. S36). This was essentially the finding of another aspect of the experiment, which looked at the effect of coinsurance on the appropriateness of hospitalization (Siu *et al.*, 1986).

Although generally viewed as the seminal study in the area of demand, there are a number of caveats that need to be kept in mind:

- The study's results are from 30 years ago. Much has changed since then, including a dramatic drop in hospital usage in the US. Moreover, there has been a shift from fee-for-service to managed care. Managed care implies that not only the patient and their cost sharing requirements, but the health plan itself, is involved in determining which services are used.
- The study did not examine the impact of uninsurance. Everyone who participated in the study was assigned an insurance plan, so such comparisons were not possible.
- Seniors were also excluded so the results do not apply directly to them.

Some more controversial concerns have also been raised. The first concerns the internal validity of the experiment. Nyman (2007) points out that those individuals who were assigned to cost sharing were much more likely to drop out of the experiment than those assigned to free care, presumably because they did not like the prospect of facing higher expenditures.(The experiment was designed so that no one could be made worse off financially by participating, but this might not have been clear to participants who noted that they were paying 50% or 95% of their medical costs.) Just half a percent of those who were assigned to free care dropped out compared to seven percent of others. He contends that this could not only bias the results on service usage but also the health status results. If those who dropped out had stayed in, their health would have been more likely to have been adversely affected because, facing higher coinsurance, they would likely have forgone needed medical care. These criticisms were not taken lightly by the researchers who conducted the experiment, who contended that it was not in people's best interest to leave the experiment and that other factors provide more likely explanations for the differential drop-out rate. They also contend that those dropping out would have to have had remarkably different hospitalization rates than those who stayed in the study (Newhouse *et al.*, 2008). At the time of writing there does not appear to be a consensus in the literature on these issues.

A second criticism relates to external validity. Although cost sharing may reduce patients' demand, it is possible that the impact on overall utilization will be less. Consider that the experiment included, at most, 2% of the people in a geographic area – and those with considerable cost sharing, perhaps half that. This means that the experiment would have had almost no impact on the behavior of physicians and hospitals. In reality, though, if cost sharing were increased dramatically, suppliers would likely respond to reduced demand by trying to generate some more, to compensate. This implies that one cannot take the results from individuals and apply them to the population as a whole (Rice and Unruh, 2009). This criticism was raised at the outset of the experiment (Hester and Leveson, 1974), although the researchers conducting the experiment contended that the study was not "designed to replicate what would happen if various health insurance proposals were enacted into law" and that they "deliberately selected sites that vary considerably with respect to the amount of stress on the delivery system" (Newhouse, 1974, pp. 236–237).

More Recent Evidence

What is striking about the most recent evidence from the US is that it does tend to show that higher cost sharing reduces health status. It is important to note, however, that unlike the HIE, these studies are not based on true experimental designs. A few such studies are noted below:

- Trivedi *et al.* (2008), focusing on the appropriate use of mammograms, examined Medicare beneficiaries aged 65–69 years in managed care plans, a group excluded from the HIE sample. In the period from 2001 to 2004, many more plans required modest copayments (US$10 or a coinsurance of 10%). The authors found that not only cost sharing reduced screening rates by 8.3 percentage points compared to those with full insurance coverage, but that

the effect "was magnified among women residing in areas of lower income or educational levels. Screening rates decreased by 5.5% points in plans that instituted cost sharing and increased by 3.4% points in matched control plans that retained full coverage" (p. 375).

- Much research has been conducted on the appropriate use of prescription drugs. Looking again at Medicare beneficiaries, Rice and Matsuoka (2004) report on five studies where it was possible to directly assess the impact of cost sharing on mortality, and 15 others where health status effects could be inferred by examining the appropriate use of medications. In two of the five studies examining mortality, cost sharing led to higher incidence of death; in three there were no effects. Of the other 15 studies, 12 found evidence that cost sharing led to less usage of appropriate medications, and three found no effects.
- Studies have also been conducted on younger populations. For example, a study of more than half a million employees from 30 employers found that doubling of copayments reduces use of nonsteroidal antiinflammatory drugs (NSAIDS) by 45% and antihistamines by 44%. The authors conclude that, "significant increases in copayments raise concern about adverse health consequences because of the large price effects, especially among diabetic patients" (Goldman *et al.*, 2004, p. 2344). Indeed, among the diabetics, a doubling of copayments reduced their use of medications by 23%.
- In a similar vein, a study from a single large employer found that enrollees in a high-deductible plan reduced substantially their filling of prescriptions for blood pressure and cholesterol medication (Greene *et al.*, 2008). Furthermore, a study of examining an increase in copayments from US$2 to US$7 in the Veterans Administration found large reductions in drug adherence for cholesterol medication, even among those at high coronary risk (Doshi *et al.*, 2009).

In sum, these studies further impugn the notion that charging patients more increase social welfare. The author concludes this article by considering two alternatives: tailoring cost-sharing to medical effectiveness, and focusing on the supply rather than demand side of the health care marketplace.

Tailoring Cost-Sharing to Medical Effectiveness

Although the traditional economic model calls for patient cost sharing as a way of reducing moral hazard and the concomitant reduction in societal welfare, it has been suggested that there are a variety of reasons – both conceptual and empirical – that cast doubt on this interpretation. In the last section the author will address larger policy alternatives that rely on controlling service use by relying on suppliers. Here, examination is made of one other demand-side policy that is now receiving much attention: tailoring cost-sharing to the medical effectiveness of services.

This is commonly called value-based insurance design (VBID). According to Chernew and colleagues (2007), under VDIB, "cost sharing is still put to use, but a clinically sensitive approach is explicitly adopted to mitigate the adverse health consequences of high out-of-pocket spending" (Chernew *et al.*, 2007, p. W196). Fendrick *et al.* (2010) write, "[t]he basic premise … is to align out-of-pocket spending with the value of medical services" (p. 2017). Cost sharing requirements can, in theory, be the same for everyone, or tailored to the individual. The latter, although probably more effective in matching reduced cost-sharing to medical need, is much more administratively cumbersome as well as difficult for the individual patient to understand. As Robinson (2010) notes, "[t]ailoring benefit design to differences among patients will depend on the development of reliable diagnostic tests that can identify ex ante which products will be effective for which patients" (p. 2012). He suggests that VBID move away from low-cost preventive services and chronic medications to surgery, specialty drugs, implantable medical devices, and imaging services, which "constitute the new frontier for insurance design and require that value principles…" (p. 2015).

Thus far, VBID programs have focused more on reducing cost sharing for high-value and preventive services rather than raising them for low-value services. Although this does encourage more appropriate utilization, it may not be cost-saving and therefore could be unsustainable (Fendrick *et al.*, 2010). To illustrate, one US company, Pitney Bowes, eliminated cost sharing requirements for cholesterol drugs and for a blood clot inhibitor; the policy did indeed improve drug adherence (Choudhry *et al.*, 2010). On a larger scale, a large insurer, Blue Cross Blue Shield of North Carolina, showed similar results when it eliminated copayments on generic drugs and reduced them on selected brand-name drugs (Maciejewski *et al.*, 2010).

Supply-Side Policies

An alternative to focusing on moral hazard on the patient is to instead focus on the suppliers of care. This has several potential advantages, including a greater potential to control costs, the ability of experts to target which services should be encouraged, and less distributional impact than demand-side policies, which focus on ability to pay.

Just as there can be cost sharing on the demand side of the market, Ellis and McGuire (1993) argue that there is an analogous concept, supply-side cost sharing, "which seeks to alter the incentives of health care providers to provide certain services" (p. 135). Examples they list include the use of a fixed payment per hospital stay (e.g., diagnosis-related groups or DRGs) and even more broadly, the use of Health Maintenance Organizations (HMOs) rather than fee-for-service medicine. Both DRGs and HMOs focus on influencing the behavior of the provider rather than the patient.

Supply-side policies have the potential of improving social welfare by focusing not on supposed overinsurance, but rather on encouraging the use of appropriate services and discouraging inappropriate ones – that is, removing some of the waste in the medical care system, which has been estimated to be up to 30% of services used (Leape 1989; Schuster *et al.*, 1998). Much effort is being expended on this, through comparative effective research and the dissemination of practice guidelines.

Although demand-side policies are certainly in vogue now, it is still true that most policies worldwide – including in the US – focus on suppliers. Common supply-side policies such as the movement away from fee-for-service payment of physicians, incentivizing providers to provide high-quality care and avoid wasteful procedures, utilization management, and global budgets, are aimed directly at providers, not patients. It is not that they eschew patient input but the focus is clearly elsewhere. If, as is argued here, these strategies are designed to reduce waste, then it can be argued that nearly all nations act as though the waste in medical care is more through the provision of unnecessary services, and not much through excess demand stemming from overinsurance.

Conclusion

At the beginning, the author noted Pauly's comment that it is rational economic behavior rather than 'moral perfidy' that drives people to seek more care when they are insured. Despite this, there is undoubtedly a lingering effect to term 'moral hazard' that influences economists' views on the subject, and perhaps therefore, their policy prescription. In his Dictionary of Health Economics, Culyer (2010) argues, "before rushing to the conclusion that moral hazard must be controlled through coinsurance, copayments and other forms of rationing, it needs to be borne in mind that there may be reasons for wanting individuals to consume more care. Even more fundamentally, there may be reasons for entirely eschewing the idea that the demand curve reveals anything worth knowing about the value placed on health care. In that case, even if the behavioral account given of moral hazard may still stand, the ethical accusation of 'waste' fails entirely" (pp. 331–332).

Thus, one thing that might be helpful is coming up with a more neutral term for the concept. The phenomenon one wants to capture in the health insurance context is similar to what Ellis and McGuire (1993) were attempting to do when redefining the demand curve to reflect nothing about social efficiency but rather simply "an empirical relationship between the degree of cost sharing and quantity of use demanded by the patient" (p. 142). The concept to be captured here is the additional use of service as a result of possession of insurance. As such, one value-neutral term could be 'insurance-driven utilization.'

Indeed, analyzing the history of moral hazard in the context of the workers compensation field, Dembe and Boden (2000) also call for the use of less value-laden terms, "[u]nless economics intend to pass judgment on the moral conduct of system participants…" (p. 273). They further state that, "Attention is focused on the costs of increasing benefits and not on the adequacy of those benefits. Insurance is characterized as leading to more time lost from work, not as providing a valuable buffer against the economics stresses resulting from workplace injuries and illnesses. Recipients of workers' compensation benefits are characterized as engaging in malingering or fraudulent behavior and are thus classified as undeserving of those benefits. They are not characterized as hard-working individuals who have suffered an injury and who may nevertheless receive inadequate benefits from their insurance carrier" (p. 274).

The same argument can be made in the field of health economics. Charactering additional utilization that comes about from possessing health insurance in nonvalue-laden terms can widen the scope of policy options beyond simply charging people more, and provide a more positive view of the benefits that people derived from health insurance.

Multiattribute Utility Instruments and Their Use

J Richardson, J McKie, and E Bariola, Monash University, Clayton, VIC, Australia

Introduction

A multiattribute utility (MAU) instrument consists of two parts: (1) a health questionnaire, and (2) a scoring formula which converts answers into an overall score. Each set of answers to the health questionnaire defines a 'health state.' The overall score reflects the strength of people's preferences for the state, and, consequently, it is a measure of the utility of the state as understood in economics.

Box 1 illustrates this. The EQ-5D MAU instrument consists of five single 'items', i.e. questions and response levels (see Box 2 on terminology). Each relates to a separate dimension of health (mobility, self care, usual activities, pain, and depression), which collectively constitute the 'descriptive system' or classification. The instrument combines these using the formula shown below the questionnaire. An individual answering level 1 for each item (1, 1, 1, 1, and 1) would obtain a utility score of 1.00; a person answering (3, 3, 3, 3, and 3) – the 'all worst' health state – would obtain a utility score of −0.594. As health states change (because of a health program), answers change, and the MAU instrument predicts a change in a person's utility. Someone answering (1, 1, 2, 2, and 3) before health care and (1, 1, 1, 2, and 2) afterwards would score 0.225 before and 0.725 after care, an improvement of 0.5.

Utility scores calculated this way may be used for economic evaluation, and, in particular, cost–utility analyses (CUA), which compare health program costs with the number of quality-adjusted life-years (QALYs) obtained. QALYs are calculated by multiplying an index of utility by years of life. The index must be measured on a scale on which 1.00 is 'best health' (as defined by the instrument) and 0.00 is the 'utility' of death. Consequently, in best health, the number of QALYs equals life years times 1.00 and therefore equals the number

Box 1 EQ-5D descriptive system

EQ-5D descriptive system

1. Mobility (MOB)
   - MOB 1: No problems walking about
   - MOB 2: Some problems walking about
   - MOB 3: Confined to bed
2. Self-Care (CARE)
   - CARE 1: No problems with self-care
   - CARE 2: Some problems washing or dressing
   - CARE 3: Unable to wash or dress self
3. Usual Activities (ACT)
   - ACT 1: No problem with performing usual activities (e.g., work, study, housework, family, or leisure activities)
   - ACT 2: Some problems with performing usual activities
   - ACT 3: Unable to perform usual activities
4. Pain/discomfort (PAIN)
   - PAIN 1: No pain or discomfort
   - PAIN 2: Moderate pain or discomfort
   - PAIN 3: Extreme pain or discomfort
5. Anxiety/Depression (DEP)
   - DEP 1: Not anxious or depressed
   - DEP 2: Moderately anxious or depressed
   - DEP 3: Extremely anxious or depressed

Combinations of answers ('Health states') $= 3 \times 3 \times 3 \times 3 \times 3 = 243$

EQ-5D Scoring formula

$$\begin{aligned}\text{Utility} = 1 - [&(0.069\ \text{MOB2} + 0.314\ \text{MOB3}) + (0.104\ \text{CARE2} + 0.214\ \text{CARE3}) \\ &+ (0.036\ \text{ACT2} + .094\ \text{ACT3}) + (0.123\ \text{PAIN2} + 0.386\ \text{PAIN3}) \\ &+ (0.071\ \text{DEP2} + 0.236\ \text{DEP3}) + (0.081\ \text{ANY(A)} + 0.269\ \text{ANY(B)})]\end{aligned}$$

where

[MOB2,... PAIN3] = 1 (or 0.00) if the respondent did (did not) tick the corresponding response level of the item ANY(A) = 1 if any level ≠ 1; ANY(B) = 1 if any level = 3

Note: The derivation of the formula and parameters (0.69, 0.314, etc) are explained in the text.

Box 2 MAU instrument-related terminology

Algorithm	(or formula) The rule for converting answers to a questionnaire into a number. It is constructed by 'scaling' a 'model'
Attribute	A characteristic or property, which an instrument seeks to describe, for example, vitality, depression, and mobility
Construct	An attribute, which is constructed or conceptualized as part of a theoretical explanation
Content	The scope and detail of the instrument's descriptive system: the behaviors, outcomes, or states, which determine an instrument's score
Descriptive system	(or descriptive 'classification'; or descriptive 'instrument'). The collection of items and dimensions, which describe the health state
Dimension	A collection of attributes with a common theme (a 'super construct'), for example, physical, mental, or social health. It usually consists of more than 1 item
Element	A single idea or attribute embodied in an item or dimension, for example, contentment or exhilaration but not contentment and exhilaration
Instrument	A questionnaire with an associated method for attaching a numerical value to the answers
Item	A linguistic statement generally consisting of a stem (e.g., 'in the last 7 days I was: …) plus a number of ordered response levels (e.g., 'always happy' … 'never happy')
Model	A conceptual or mathematical framework, which defines how values will be combined (e.g., simple or weighted averaging of the level of the item responses)
Reliability	See **Box 5**
Scaling	(or calibrating) The process of creating the algorithm for attaching numbers to health state descriptions. It requires a scaling instrument (e.g., TTO or SG) plus a model for combining the numbers produced by the scaling instrument
Sensitivity	The extent to which the instrument content allows the detection of changes in a health state
Validity	See **Box 5**

of life years. With death, life years times utility equals zero. In the example above, a health program which moves an individual from health state (1, 1, 2, 2, and 3) to (1, 1, 1, 2, and 2) for 10 years, would result in $0.5 \times 10 = 5$ QALYs, which would, in turn, be compared with the cost of the care, to obtain a cost per QALY.

Even when utility scores are not used, MAU instruments are useful for describing changes in health states over time and for comparing the health states of different individuals. In principle, the instrument can also be used to estimate the QALY-based burden of disease. However, this type of analysis has been dominated by the use of disability-adjusted life years, which combine the quality and length of life in a related but different way.

In principle, an MAU instrument can be generic, i.e., applicable to a wide range of health states, or it may be condition-specific and apply to only a specific disease. This article is about generic MAU instruments, and the term 'MAU instrument' is used here to refer to generic instruments.

Construction: The construction of an MAU instrument entails three steps. First, 'items' must be selected to create the questionnaire ('descriptive system' or 'classification'). Second, individuals are interviewed to obtain numerical data from which their utility – strength of preference – can be calculated for different health states. Third, a 'model' is used to attach values (utility scores) to all of the possible health states described by the instrument. The third step is necessary because the number of health states described by an MAU instrument is, generally, too large for the utility of each health state to be evaluated individually. Modeling is therefore used to extrapolate from measurements that are made to all possible health state values.

These steps have been approached differently by different research teams, and the scope and detail of the resulting descriptive systems varies considerably. The numerical data used for predicting utility have been obtained using different 'scaling' techniques including the time trade-off (TTO), standard gamble (SG), and the rating scale (RS). Models have employed different econometric techniques, sophisticated averaging, and a combination of these to derive a general formula for predicting utility scores from the numerical data (see section Instrument Use and Acceptance).

Box 3 Six multiattribute utility instruments and country of origin

QWB	Quality of Well-being Index	USA
15D	15 dimension instrument	Finland
EQ-5D	Originally EuroQol (RS and TTO versions)	Europe/UK
HUI	Health Utilities Index, 3 versions, HUI 1–3	Canada
SF-6D	Short form 6D (SF-6D (12) and SF-6D (36)	UK/USA
AQoL-8D	Assessment of Quality of Life (8D)	Australia

MAU instruments are flexible and easy to administer. However, they have their limitations. Their usefulness for evaluation is constrained by the content and sensitivity of the instrument's descriptive system and by the validity of the utility scores produced by the algorithm.

In the following section, six MAU instruments (see **Box 3**) are reviewed. Their chronology, characteristics, and construction are described and compared in the section History, Description and Construction of MAU Instruments. Section Instrument Use and Acceptance summarizes their use and recognition by health authorities. Different instruments produce different scores, as discussed in the section Comparison of Instruments. The reasons for this include differences in the theoretical traditions adopted in constructing the descriptive systems and scoring formula (section Theory and Evaluation) and differences in instrument content (section Construct and Content Validity). The implication of these differences for the validity of utility scores and therefore for policy is discussed in section Criterion Validity. Challenges to the field are outlined in the concluding section Conclusions. Additional

readings are suggested, which contain references supporting the present text.

History, Description and Construction of MAU Instruments

Chronology

Figure 1 summarizes the historical development of the six MAU instruments. Most writers in the area commence with a reference to the famous 1948 World Health Organization (WHO) definition of health as a 'state of complete mental and physical well-being and not merely as the absence of disease and infirmity.' This legitimized the concept of 'health' as a single construct. However, it did not provide a basis for measurement.

In the USA, the 'blueprint' for measurement was published in 1970 by Fanshel and Bush. This provided the theoretical basis for the earliest instruments, the health status index (1973), the Quality of Well-Being (QWB) (1976), and the Short Form 36 (SF-36) (1977). The latter was also the empirical basis for two later UK versions of the SF-6D developed by Brazier, one directly derived from the SF-36 (2002) and one from its reduced form, the SF-12 (2004).

The first UK instrument, the Rosser Index, was initially intended for hospital patients (1972) but was subsequently generalized to a generic 29 health state classification instrument, the 'Rosser-Kind Index' (1978). This was displaced by the EuroQol, which was created by a European consortium (The EuroQol Group) formed in 1987. The instrument was subsequently renamed as 'EQ-5D' and adopted for general use following creation of a scoring algorithm at the University of York in 1995. Earlier, Sintonen had created the 12D instrument in Finland, and the revised 15D was published immediately before publication of the EuroQol in 1989.

Three Canadian health utility instruments (HUI) were initiated by Torrance in 1982 for the evaluation of neonatal intensive care. These were modified for use in childhood cancer (HUI 2) in 1996 and further developed and scaled by Feeny for the adult population in the HUI 3 in 2002. The Assessment of Quality of Life (AQoL) instruments were developed in Australia by Richardson and Hawthorne. The AQoL-4D was published in 1997 and subsequently modified as the AQoL-6D in 2004. Additional dimensions were added to increase sensitivity for vision (AQoL-7D) in 2005 and for mental health (AQoL-8D) in 2009.

Description of Instruments

Tables 1–3 compare the six MAU instruments. Two broad conceptual approaches to description have been used (Table 1). Following the WHO typology, health problems result in impairment, disability and handicap; that is, body malfunction, limitations of body performance, and problems affecting life in a social context, respectively. Three MAU instruments (EQ-5D, SF-6D, and AQoL) have based their descriptions primarily on the last concept (i.e. health problems affecting life). By contrast, two MAU instruments (15D and HUI) have adopted a 'within-the-skin' approach (impairment/disability), although 15D was modified to include one handicap dimension. The QWB spans all concepts.

The resulting instruments have between 5 and 15 dimensions, with one item per dimension in the HUI 3, 15D, EQ-5D, and SF-6D and an average of four items per dimension in the AQoL-8D. QWB has three basic dimensions supplemented with 27 'symptom/problem' groups. Items have four to six response levels (e.g. the severity of pain or the level of mobility). Overall, items plus response levels define between 243 health states for the EQ-5D and 2.37×10^{23} for AQoL-8D. Larger instruments, particularly AQoL-8D, define numerous 'empty' states (e.g., 'bedridden' but 'no problems with self-care').

Different instruments include different dimensions (Table 1). Several are unique to a particular instrument and dimensions with similar titles include different items. Consequently, to appreciate the scope ('content') of an instrument an examination of the items is required. These are compared in Table 2, which indicates that the scope of instruments varies significantly, in part, because of the differing conceptual bases and, in part, from the level of descriptive detail contained in the items. In principle, instruments with fewer items may indirectly capture the same – or even more – information as the larger instruments by using items with broader descriptions. Alternatively, they may be omitting content to

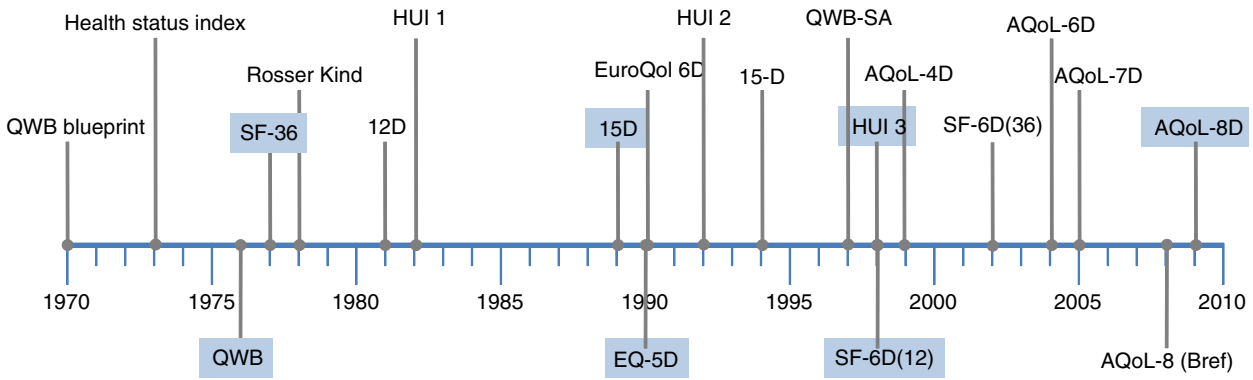

Figure 1 History of MAU instruments.

achieve some other goal such as brevity. The differences are potentially important for the validity of the instruments and are discussed further below.

In addition to differences in their descriptive systems, different scaling techniques have been used to measure utilities (in particular, the TTO, RS, and SG) and different models have been used to extrapolate utility scores over the full range of health states (Table 3). Three instruments have adopted models based on MAU theory. Two have used statistical analysis and one (AQoL-8D) uses both techniques (see section Theory and Evaluation). Best health states are described differently by each of the scales, but all assign 'best health'

Table 3 Properties of the combination model and the predicted utilities

[i](Intraclass) correlation between scores obtained after 1 month.

a numerical value of 1.00. This implies that 1.00 corresponds with different levels of real utility. The utility of the worst health state varies in the instruments from 0.32 (QWB) to −0.59 (EQ-5D), similarly implying differences in the numerical scale.

Instrument Construction

QWB Index: The QWB descriptive system was derived from the Health State Index Questionnaire. Items for this were selected from 343 'core descriptions' (items) derived from the literature and from existing health surveys.

The three multiresponse items of the QWB (mobility, social, and physical activity) define 47 health states. In combination with 27 symptom/problem groups, this rises to 945 states (**Table 1**). Although these contain no explicit mental health components, the instrument has been used for patients with psychiatric problems as the general items are sensitive to psychiatric problems. Items were scaled using RS responses from the general population of San Diego ($n=866$). An additive model was used in which the disutility from each dimension and from the worst symptom is subtracted from 1.00 (the utility of full health). The distribution of scores for the general population is approximately normal – bell-shaped – with responses distributed symmetrically around a central point. Perfect scores are rare and there are neither significant ceiling nor floor effects – that is, the instrument is sensitive at both ends of the value scale and can discriminate between states close to full health and between very poor health states.

QWB was the first MAU instrument. Originally administered by trained interviewers, a self-administered version (QWB^{SA}) was created in 1997. Translations exist into Spanish, German, Italian, Swedish, French-Canadian, and Dutch. Information and the user manual may be obtained at https://hoap.ucsd.edu/qwb-info/.

15D: The descriptive system of the 15D is based on a review of Finnish health policy documents. Scores were obtained from a sample of the Finnish population. The instrument has 15 items, 14 relating to disability (mobility, mental function, etc.) and one to handicap ('usual activities'). The 1981 version was revised following feedback from the medical profession in 1986 and again in 1992 following further user feedback and factor analysis. Utilities were obtained using a RS. Each level of each dimension is given a value and each dimension given an importance weight. Utility is calculated by adding the weighted dimension scores together.

Five separate models were subsequently used to re-estimate utilities. These used published econometric formulae to convert RS values into 'utility' scores ($n=2500$). Results demonstrated convergent validity of 15D values (i.e., the different models produced similar results).

Few people have perfect scores on the 15D, but few obtain scores below 0.4; that is, there are no serious ceiling effects, but the instrument does not identify health states with very low utility scores, at least, as measured by other scales.

The 15D has been modified for children (16D) and has been translated into 25 languages with 4 in preparation. The 15D website is: http://www.15d-instrument.net/15d

HUI 3: The HUI 3 descriptive system is an adaptation of HUI 2 and reflects the importance ranking assigned to a list of 15 symptoms in a Canadian survey of hospital patients. It consists of eight items with either five or six response levels. The 'within-the-skin' – i.e. disability based – descriptive system has no explicit social or handicap-based dimensions. An RS was used with 504 residents of Ontario, Canada, and the scores were converted to a SG (utility) equivalent score using an equation (a power function), which was calibrated to predict three SG scores from their corresponding score on a RS.

The HUI 3 model for combining items was based on the assumption of 'structural independence' – that is, the assumption that a single attribute is not measured in more than one way (as this will result in 'redundancy' or 'double counting' of disutility). According to one study, the correlation

between items varies between 0.02 and 0.35, which is consistent with the conventional psychometric definition of 'independence.' (When item correlation is low, it is assumed in psychometrics that items are picking up different aspects of a construct.) Instead of combining dimensions with an additive model, the HUI 3 employs the multiplicative formula recommended by Decision Analytic (Multiattribute Utility) theory.

The actual formula is deceptively complex and constructed from disutilities. As an example, with a three-dimensional instrument the formula might take the form:

$$\mathrm{DU} = 1.06\,[1 - (1 - 0.7\mathrm{DU}_1)(1 - 0.6\mathrm{DU}_2)(1 - 0.5\mathrm{DU}_3)]$$

where 1/1.06 is the scaling constant, and 0.7, 0.6, and 0.5 are dimension importance weights times the scaling constant, $U = 1 - \mathrm{DU}$. The scaling constant constrains the scale to the range of 0.00–1.00. When the dimension disutility scores for the three dimensions DU_1, DU_2, and DU_3 are all 0.00 (or 1.00), the utility score will be 1.00 (or 0.00).

The utilities predicted by HUI 3 fall below zero (worse than death), indicating the absence of floor effects. However, approximately 30% of scores from the general population exceed 0.95 indicating the likelihood of ceiling effects.

HUI 3 questionnaires are available in English, Chinese, Japanese, Russian, Dutch, French, German, Italian, Portuguese, Spanish, Czech, Polish, Finnish, Norwegian, and Danish. There are sixteen English versions, which differ in their mode of administration, the assessment viewpoint, and duration of assessment period. The website is http://fhs.mcmaster.ca/hug/

EQ-5D: The five item, three level EQ-5D defines 243 health states. It was originally designed as a brief 'linkage tool' to be used alongside more comprehensive MAU instruments and to facilitate comparison between studies that had used different instruments. Following the development of preference weights at the University of York, it became widely accepted as a standalone generic MAU instrument and eventually became the preferred instrument of the UK National Institute of Health and Clinical Excellence (NICE).

The UK weights, which are the most widely used, employ TTO data from a survey of 2997 adult members of the general UK population. TTO values were obtained for a number of holistic health states, which were created by combining different response levels from the EQ-5D descriptive system. These were regressed on item levels, and the best fitting regression equation was used to generate a score for all the health states defined by the descriptive system. Linear regression was used, so the final model, as with the QWB and 15D, is additive. Models were created for different sociodemographic groups with eight algorithms estimated using both TTO and RS. However, only the general population TTO formula is normally used (the formula was reported earlier in **Box 1**). The utilities for the 243 health states can be obtained directly from a table.

The correlation between EQ-5D dimensions varies, typically, from approximately 0.20 to 0.60 indicating structural dependence – that is, some aspects of HR-QoL are picked up by more than one item. However, econometric scaling may, potentially, overcome this problem (see section Theory and Evaluation) ensuring that predicted values and actual values are equal at the mean.

Negative scores are predicted for some of the general population indicating the absence of floor effects. However, approximately 35% of the general population obtain a score above 0.95 indicating the presence of ceiling effects.

The EQ-5D has been translated into 150 languages. A version for children aged 7–12 has been translated into 12 languages. A scoring algorithm has been estimated in the USA and 9 other countries (Belgium, Denmark, Finland, Germany, Japan, the Netherlands, Slovenia, Spain, and Zimbabwe). In 2009, the EQ-5 L, a 5-response level instrument (with the same items) was published and the EuroQol Group executive approved the use of 'bolt-ons' to increase instrument sensitivity for particular health states. The website is http://www.euroqol.org/.

SF-6D: Two versions of the SF-6D instrument are available – one derived from the SF-36, the most widely used generic (nonutility) HR-QoL instrument, and the other from its derivative, the SF-12. Consequently, utility scores may be derived from any study reporting values from these instruments. 'SF-6D (12)' and 'SF-6D (36)' are similar except for a reduction in the response categories for two items in SF-6D (12), which reduces the number of possible health states from 18 000 to 7500.

The items of the descriptive system of the SF-6D were derived from the factor analysis undertaken in developing the SF-36 and other psychometric evidence.

Utility scores for 249 health states were obtained from 611 respondents using the SG. These were regressed on item levels and the resulting linear equation used to predict utility scores for other health states. The resulting (0.5) formula took the form:

$$\mathrm{Utility} = 1 - 0.009\ \mathrm{PF2} + 0.008\ \mathrm{PF3} + \ldots - 0.007\ \mathrm{VIT5}$$

where PF2 and PF3 are the second and third response categories on the physical functioning dimension scale, and VIT5 is the fifth response category on the vitality dimension scale.

Several different models were used to estimate utilities (based on random effects linear regression, rank estimation data, and a nonparametric Baysian approach). The best fitting model predicted a minimum utility score of 0.203. Approximately 5% of the general population obtain scores below 0.5, indicating possible floor effects. In contrast only approximately 8% scored above 0.95, indicating the absence of ceiling effects.

Versions of the instrument have been developed in Australia, Brazil, Hong Kong, Japan, Portugal, and Singapore. More information about SF-6D can be accessed at: http://www.shef.ac.uk/scharr/sections/heds/mvh/sf-6d.

AQoL: AQoL descriptive systems were constructed from reviews of existing instruments, the HR-QoL literature, from focus groups and 'construction surveys'. The latter involved administering large numbers of items to selected patients and the public. Factor analyses and structural equation modeling (SEM) were used to obtain a multilevel model. AQoL-8D has 35 items, which combine to form eight dimensions, which, in turn, combine into the two 'super dimensions' of physical and psychosocial ('mental') health.

Utility (TTO) scores are estimated from a multistage procedure, which employed both the multiplicative model described earlier for the HUI 3 and econometric modeling,

similar to the SF-6D (except that exponential net linear models were used).

The estimation procedure has four steps: (1) estimation of dimension from item scores with multiplicative models; (2) econometric correction of these dimension estimates; (3) combination of corrected dimensions into a (single) multiplicative model; and (4) econometric correction of the final multiplicative model.

AQoL-8D used a sample of 712 people aged 18–70 years to construct the descriptive system and a second sample of 628 to obtain TTO scale values (322 patients and 306 public). The scaling survey obtained values for 174 'within dimension,' multiitem health states and 375 multidimensional health states. Transformations have been created between AQoL-4D, 6D, and 8D. AQoL-4D (the original AQoL instrument without the original dimension for symptoms) has been reduced to an 8-item AQoL-Bref or AQoL-8 (which should not be confused with the AQoL-8D).

In a general population, few people score below 0.25, approximately 1.5% have perfect scores, and approximately 14% score above 0.95. Floor effects are therefore closer to 15D and SF-6D than to HUI 3 and EQ-5D, but there are no significant ceiling effects. The AQoL instruments have been translated into traditional and simplified Chinese, Spanish, German, Arabic, Norwegian, and Danish. The AQoL website is: http://www.aqol.com.au/.

Instrument Use and Acceptance

Instrument Use

Information on the use of each of the MAU instruments was obtained from the Web of Science database for the period 2005–10 and supplemented by references provided to the authors or from the instrument websites. The search identified 1682 studies, which employed at least one of the MAU instruments. These were used to construct Tables 4–6.

Table 4 indicates that EQ-5D was the most popular instrument by a significant margin, with 63.2% of the 1682 studies using it. This was followed by HUI 3 (9.8%) and SF-6D (8.8%). At the other end of the scale, 15D and AQoL were included in 6.9% and 4.3% of studies, respectively, and the QWB, the earliest widely used instrument, accounted for only 2.4% of total use.

The EQ-5D also dominated use in most countries and was only exceeded in Canada by the HUI 3 and in Finland by the 15D. Table 4 reveals significant 'local loyalty' with the use of all instruments peaking in their country of origin. Apart from EQ-5D, only HUI 3 and SF-6D achieved significant use in other countries.

Use of the instruments was also very concentrated. European studies accounted for 55% of the total, and the addition of USA and Canadian studies raises this to 80.5%. Within Europe, use was also concentrated, with Finland and Netherlands each accounting for more than 8% of the total, or double the usage by Germany, despite its much larger population and more than 65% of the usage by all other European

countries combined. The extent to which this is attributable to language and publication bias is unknown.

Only 15% of the studies included in Table 4 were primarily concerned with economic evaluation (which need utility scores) as distinct from their use as generic tools for the measurement of HR-QoL (which does not require scores to be 'utilities'). The disease categories in which they were used are reported in Table 5. This reflects a broad acceptance

of MAU instruments across the spectrum of disease categories, possibly reflecting the widespread use of self-reported disease-specific instruments in medicine. Given the scope of the literature search, however, the number of studies published in most of the disease areas is relatively small.

Acceptance by Government Health Authorities

The different instruments enjoy varying degrees of acceptability by health authorities and in national pharmaceutical guidelines. Examples of this are given in Box 4. Each of the instruments has been used in government health surveys. The 15D and AQoL instruments have only been adapted in this capacity in Finland and Australia, respectively.

Comparison of Instruments

Table 6 reports the number of studies which compare instruments and the head-to-head comparisons between MAU instruments between 2005 and 2010. From the first three columns, the majority of comparative studies involved a disease-specific instrument (238) or a generic nonutility instrument (84). There were 310 comparative studies of MAU instruments. Because these included multi-instrument comparisons, the number of head-to-head comparisons was greater than the number of studies (392). The largest number of these comparisons involved the EQ-5D (120) closely followed by the SF-6D (95) and HUI 3 (71). Comparisons primarily consisted of a Pearson correlation. Intraclass correlation, the preferred statistic even in simple comparisons, was relatively

[b]Kaplan, R. M., Tally, S., Hays, R. D. *et al.* (2010). Five preference based indexes in cataract and heart failure patients were not equally responsive to change. *Journal of Clinical Epidemiology*, doi:10.1016/j.jclinepi.2010.04.010.

uncommon and psychometric analyses were rare. This is discussed further below.

Despite the large number of comparisons between MAU instruments reported in **Table 6,** only two large and two smaller studies have included five instruments. In an early Australian comparison (Hawthorne *et al.*, 2001), 956 hospital patients and general population respondents were administered the EQ-5D, SF-6D, 15D, HUI 3, and AQoL-4D. The proportion of instrument variation explained by other instruments varied from 41% to 59% leaving an average of 44% unexplained. The highest explanatory power was achieved by 15D, followed by AQoL-4D (**Table 7**). In a recent US study (Fryback *et al.*, 2010), 3844 adults were surveyed to compare the EQ-5D, QWB, HUI 2, HUI 3, and SF-6D. A weaker association was found than in Australia (reflecting the inclusion of only general population respondents). Overall 53% of instrument variance was not explained (**Table 7**). Recent work indicates that the strength of the association between instruments varies across the health spectrum.

Frequency distributions from the US study are reproduced in **Figure 2**. As the individuals included in each distribution are the same, the distributions would be identical (subject to respondent or transcription errors) if the instruments were measuring the same construct on the same scale. However, the figures indicate significant differences. A more recent and smaller Australian study (Khan and Richardson, 2011) reinforces this conclusion by creating the pair-wise comparisons of instrument frequencies shown in **Figure 3**. If the different instruments predicted identical utilities, the points in **Figure 3** would lie on the 45° line, i.e., Instrument A = 0.00 + 1.00 Instrument B. This does not occur indicating significant discrepancies in the predicted utilities.

Generally, researchers conducting multi-instrument comparisons have concluded that the utilities derived from the instruments are 'not equivalent,' that translation between them will result in 'low precision,' and that comparisons between them 'warrant caution.'

Theoretical reasons for these differences are discussed in section Theory and Evaluation and section Construct and Content Validity. However, one proximate cause is the difference in upper and lower end sensitivity, i.e., in 'ceiling' and 'floor' effects. For example, in the five-instrument US study cited earlier, the percentages of scores above 0.95 were 37.0 for EQ-5D, 36.9 for HUI 2, 36.2 for HUI 3, 1.7 for SF-6D, and 2.3 for QWB. **Figure 3** also reflects the strong ceiling effect of the EQ-5D (the horizontal scale in the three left hand diagrams) and the HUI 3. The SF-6D and EQ-5D have the strongest floor effect(s) with no values below 0.6. The AQoL-8D and HUI 3 had minimum values of 0.42 and −0.04, respectively. Additionally, for each value on one instrument there is significant variation in the value of other instruments (for the same person). For example, when SF-6D = 0.6, HUI 3, and AQoL-8D values varied from 0.25 to 1.00 and 0.55 to 0.95, respectively; when AQoL-8D = 0.8, HUI 3, and SF-6D varied from 0.25 to 1.00 and 0.10 to 1.00, respectively. Some of these variation will be undoubtedly random. Some may be attributable to the choice of scaling instrument as TTO, SG, and RS give slightly different values. The remainder must be attributable to the instrument descriptive systems and models.

The variation in instrument scores raises the question of which instruments yield the most appropriate utilities for use in economic evaluation and the appropriate contexts in which they might be used. There is no agreement about this. The theoretical foundations of the instruments are discussed in the next section. Instrument performance and validity is discussed in sections Construct and Content Validity, and Criterion Validity.

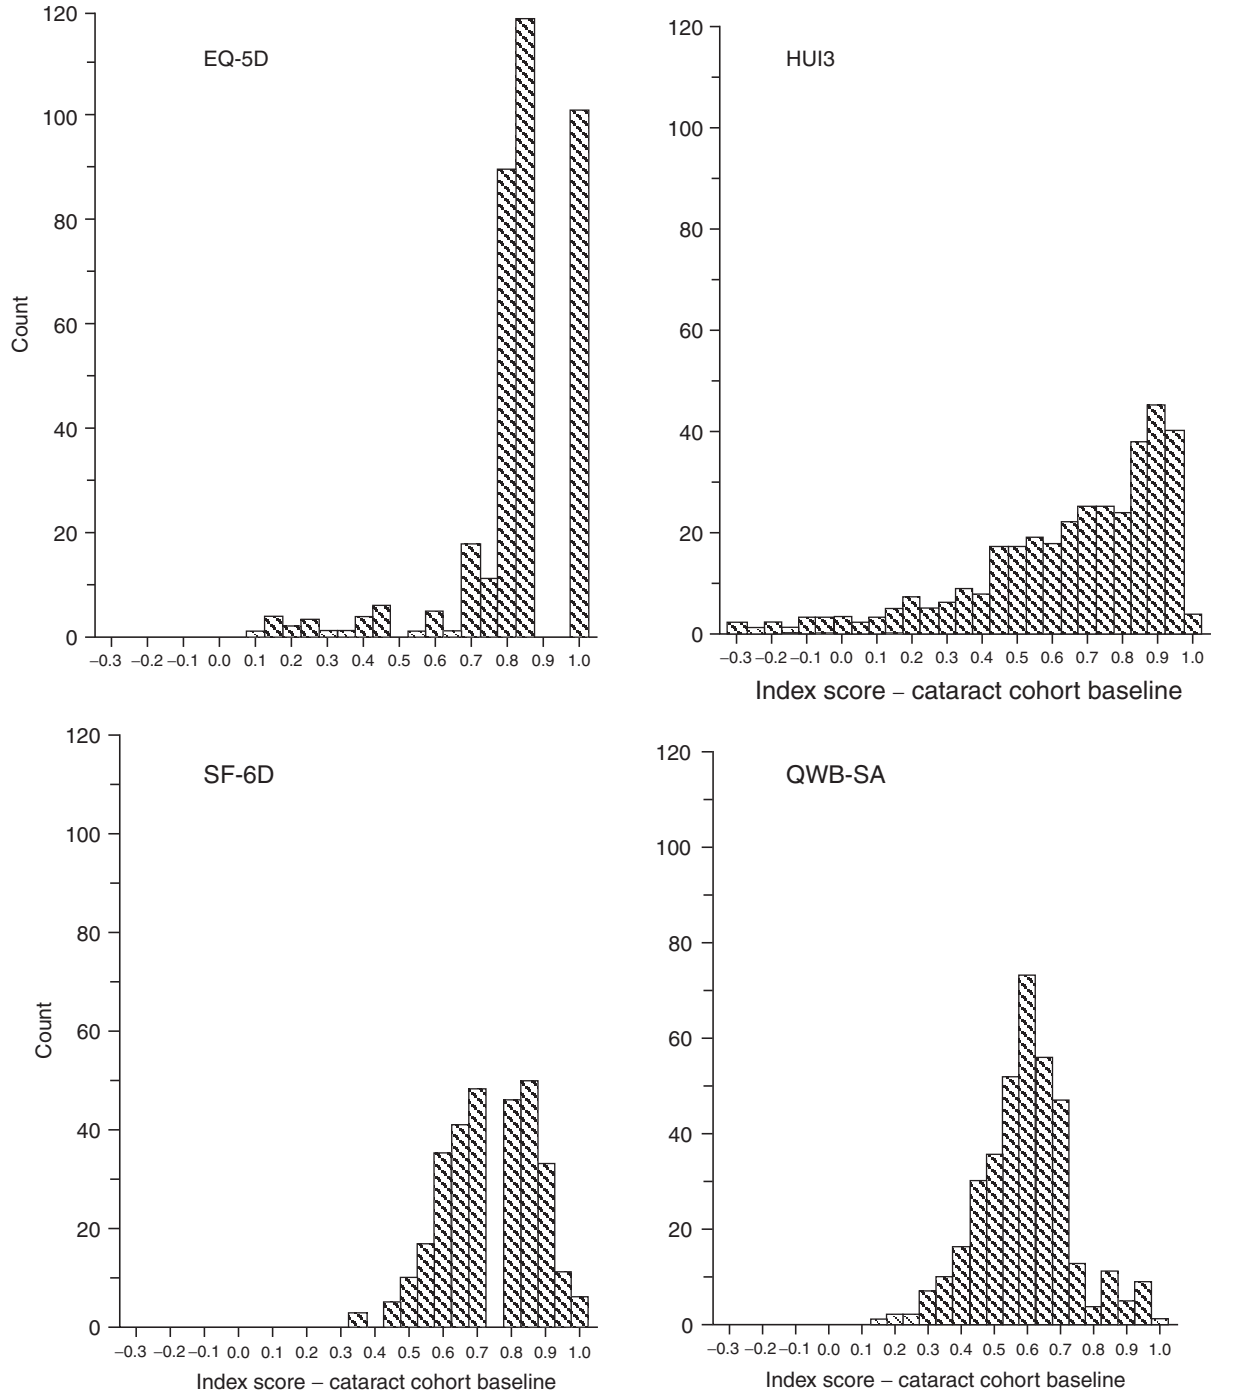

Figure 2 Distributions of baseline scores on 5 indexes at baseline for cataract. Reproduced from Kaplan, R. M., Tally, S., Hays, R. D., *et al.* (2010). Five preference based indexes in cataract and heart failure patients were not equally responsive to change. *Journal of Clinical Epidemiology*, doi:10.1016/j.jclinepi.2010.04.010.

Theory and Evaluation

Theoretical Foundations

Present MAU instruments draw on theory from three relatively distinct disciplines: decision analysis (DA), psychometrics, and economics/econometrics. The traditions in these areas are not always consistent, reflecting the context from which they arose. This has received relatively little explicit discussion, possibly because decision analysis and psychometrics have played only a limited role in mainstream economics. Nevertheless, they are of fundamental importance for the methods adopted in the construction of MAU instruments and their validity.

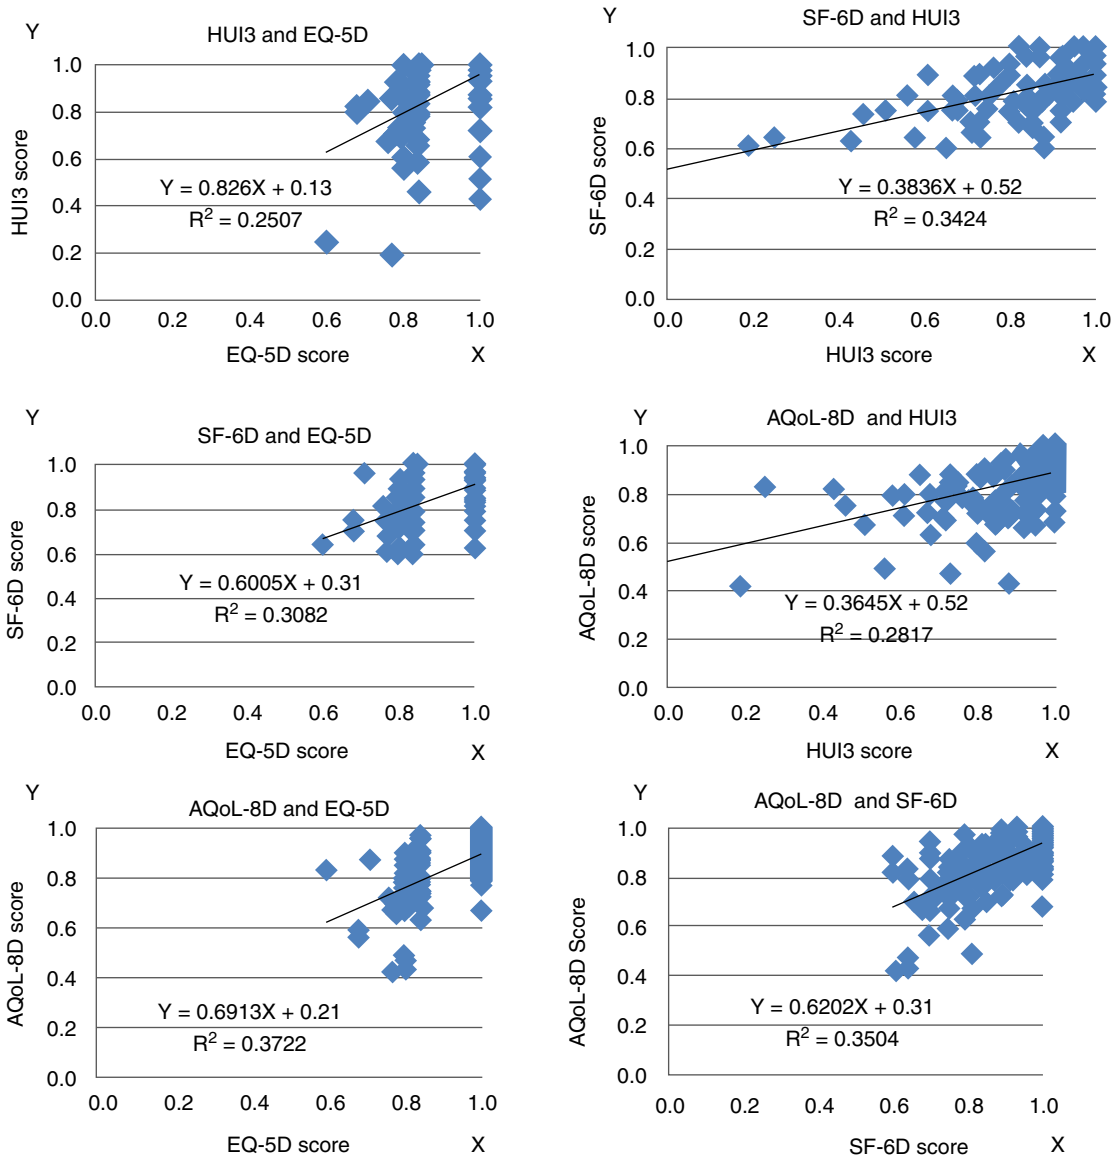

Figure 3 Pair-wise comparison of 4 MAU instruments. Reproduced from Khan, M. A. and Richardson, J. (2011). A comparison of 7 instruments in a small, general population, Research Paper 60. Melbourne: Centre for Health Economics, Monash University.

DA: The 15D, HUI 3, and AQoL-8D all seek theoretical justification, at least in part, from MAU theory, a subset of DA theory. This recommends that complex outcomes (in the present case, 'health states') should be decomposed into attributes (dimensions) such as pain and vision. Utility scores should be assigned to each of the attributes and a model used to combine attribute utilities into a total utility score.

Importantly, the theory requires that descriptive attributes should be structurally independent. For example, a business model optimizing output as a function of total revenue, total cost, and profit would result in 'double counting' as the first attribute is the sum of the other two. Depending on the nature of preferences (for the attributes) DA models may be additive, multiplicative, or multilinear. The QWB and 15D assume additive independence. Empirical results for the HUI 3 and AQoL-8D implied the need for multiplicative models.

Psychometric theory: Psychometrics is the basis of measurement theory in education and psychology, which quantifies unobserved 'constructs' (such as educational attainment, IQ, and personality). Its potential contribution in the present context is threefold. First, it prescribes methods for constructing instruments; second, it describes criteria for their evaluation; and third, it describes numerous forms of bias and other sources of measurement error.

A tension exists between the decision analytic and psychometric approaches. The former requires independence between items and between dimensions to avoid double counting of disutilities. The latter approach assumes that items will correlate to some extent and that the scale for a satisfactory construct requires a minimum of 3 and

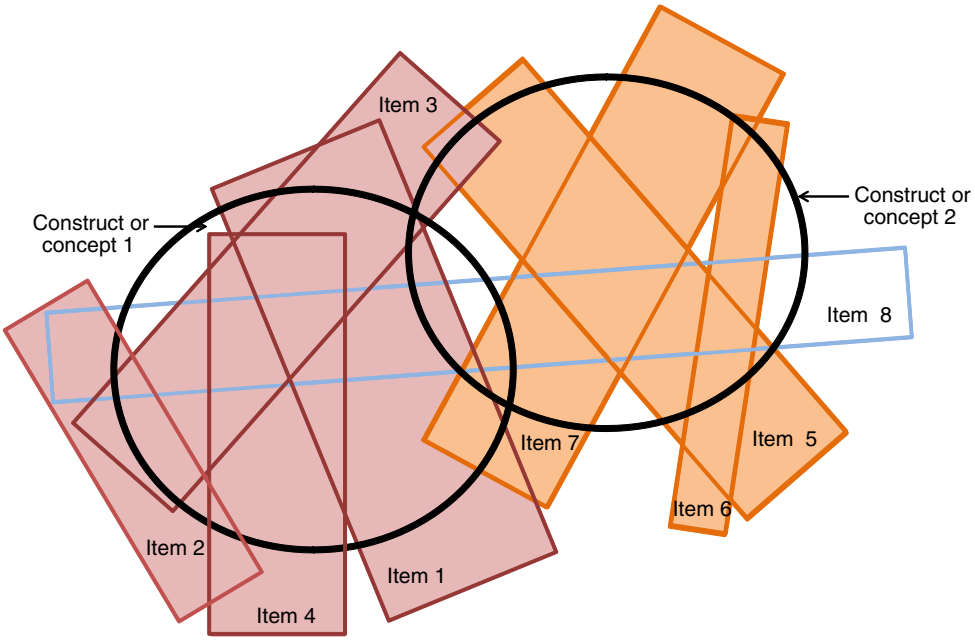

Figure 4 Item: Question with a series of possible response levels (e.g., how often do you feel sad? (a) never, (b) rarely, (c) some of the time, (d) usually, and (e) nearly all the time). Concept 1: An abstract idea concerning some hypothesized attribute or characteristic, mental health. Concept 2: A mini theory or created construct to explain observed behavior.

preferably 4 items for content validity. The reason for this is illustrated in Figure 4. Two constructs are represented by bolded circles and a number of items – linguistic statements – are represented by rectangles. Reflecting the imprecision of language, no one item exactly corresponds with a construct. Items 1–4 are required to measure construct 1 and items 5–7 to measure construct 2. Factor analyses may be used to obtain the efficient set of items and to omit items that 'cross load' (item 8). Confirmatory factor analysis or SEM may be used to achieve this goal while forcing the retention of theoretically desired constructs. However, the resulting instrument structure achieves content validity by violating the DA requirement of structural independence, which is needed to avoid the double counting of disutilities. This issue, however, has received little attention.

With the exception of the AQoL instruments, full psychometric analysis has played little or no role in MAU instrument construction. The SF-6D employed psychometric evidence from the SF36 in the selection of items, and the 15D was revised following psychometric analysis. Other instruments selected items by other means (see section History, Description and Construction of MAU Instruments). One explanation offered for this is the belief that it is preferences that are important for MAU instruments, not description. However, valid preference measurement requires valid description of what is to be evaluated. If a descriptive element is unimportant, then the preference weight will be lower or zero. Use of the best preference methods and modeling cannot compensate for the absence of a nontrivial descriptive element. Content validity is discussed further in the section Construct and Content Validity.

Economics and econometrics: The gold standard for evaluating an MAU instrument is whether or not it measures 'utility' as envisaged in economic evaluation studies (see section Criterion Validity). This implies that a preference-based instrument should be used for scaling, and this is generally interpreted as implying the use of the SG or TTO. However, the subject is controversial, and some argue that there are insufficient reasons for excluding the RS. Recently, weights have been assigned using ranking techniques and item response theory, and the use of 'best–worst scaling' has been foreshadowed.

As noted above, the decision-theoretic requirement of item or dimension independence is difficult to achieve, and the resolution of this problem in the EQ-5D, SF-6D, and AQoL-8D has been to use statistical methods to determine the importance of items. Multiattribute health states are evaluated with the SG or TTO and regressed on item scores or on dummy variables for the response levels. The regression assigns the most efficient weights to the items, i.e. the regression coefficients – which best explain variation in the health state values. The predicted values 'fit the data' as a regression line passes through the mean value of observations. Consequently, at least at the mean, the effect of 'double counting' is mitigated. The choice of regression model, however, is contentious. From MAU theory, linear (additive) models may be inappropriate, and utilities predicted from linear models may therefore incorporate systematic bias as they move away from the mean. However, these models are employed by the QWB, SF-6D, and EQ-5D.

Competing claims have been made about the use of decision analytic and econometric techniques, but the evidence is limited. Both approaches are based on a set of assumptions and constraints that are violated to a greater or lesser extent depending on the population group and

Box 5 Validity reliability-related definitions

Validity: Measurement of what is intended
Validation: A process of determining (the appropriate level of) confidence in the inferences drawn from instrument values
Construct: A concept created to explain observed relationships
Construct validity: The construct measures what is intended
  a. Convergent validity: Correlation with other measures expected to correlate with the construct
  b. Discriminant validity: Non-correlation with measures of different constructs (e.g., MAU instruments and blood pressure
  c. Discriminative (extreme group) validity: Discrimination between different groups (patients and public)
Content validity: There is a representative sample of target elements in the descriptive system (i.e., outcomes, behaviors, symptoms, etc.) or elements, which vary directly with the elements of interest
Face validity: The content appears adequate on inspection
Criterion validity: Constructs behaviors expected as judged by external criteria
  a. Gold standard validity: The instrument correlates with the gold standard measure
  b. Concurrent validity: The instrument correlates with the criterion
  c. Predictive validity: The instrument predicts other (criterion) variables as expected
Reliability: A measure of consistency. It is the proportion of the total variability in scores, which is accounted for by the differences in the average values across observations. It applies to the interval consistency of the items of an instrument and to the test-retest consistency of the instrument over time.

disease. This suggests that validation requires context-specific evidence.

Evaluation Criteria

Evaluation criteria for assessing MAU instruments include practicality and reliability (measurement error should be a small fraction of total variability as judged, for example, by test–retest and by Cronbach's α). The MAU instruments reviewed here have evidence of these properties, which is short in terms of most questionnaire-based research. The largest instrument – AQoL-8D – takes an average of 5.4 min to complete in its online version. Test–retest and Cronbach's α coefficients are satisfactory according to accepted norms.

The most contentious criterion is validity, whether or not an instrument measures what it purports to measure. The lack of agreement between instruments noted earlier implies that some or all of the MAU instruments are not universally valid or that they seem to measure differing concepts, although this possibility has not been suggested in the literature.

Different types of 'validity' are defined in Box 5. The common element is that each is a test that justifies greater or lesser confidence in the instrument's predictions. This means that in practice an instrument is never (fully) 'validated' in the sense that it has been 'proven universally correct' and the statement that 'an instrument has been validated' is misleading in implying this. Rather, instruments are more or less supported both empirically and theoretically (an interplay sometimes described as a 'nomological net'). Importantly, the strength of the evidence depends on the stringency as well as the outcome of the test.

Construct and Content Validity

The validity of an MAU instrument depends on the validity of its three components: the descriptive system (items and dimensions), the scaling method (TTO, SG, etc.), and the model used to combine items (additive, multiplicative, etc.). There is no consensus concerning the scaling method (TTO, SG, etc.). However, there is a relatively high level of agreement between scores from the chief scaling methods, and differences in between these could not explain the observed variation between instrument scores.

Combination models also differ and the evidence for the assumptions behind them is incomplete. Validity could be tested by comparing estimates of health state utilities from different models with independent holistic estimates of the same health states. Few such studies have been undertaken. Descriptive systems also differ very significantly in size, item content and syntax (Tables 1–3). The effect of this on MAU instrument scores and validity is an unresolved, although critical, issue. Some of the evidence is outlined in section Criterion Validity below.

The great majority of the validation studies in Table 6 are concerned with 'construct validity' and primarily 'convergent validity'. These correlation-based studies are relatively weak tests, which are necessary but not sufficient for confidence that an instrument measures the utilities needed for economic evaluation. Correlation will occur as long as an instrument can, minimally, detect extreme values. It does not indicate that values have the properties needed for economic evaluation or even that both instruments use the same scale. In the linear relationship, $U = a + bI$, where I is an instrument's estimate of true utility U, instrument validity would imply that $a = 0$; $b = 1.0$. For this reason, a better measure of association than correlation is the intraclass correlation (ICC), which tests the equivalence of absolute values. However, only a minority of the studies use this technique. The difference is potentially important. In the early five-instrument Australian study, the 15D had the highest average correlation with other instruments (construct validity). However, incremental changes in 15D were about half the magnitude of corresponding changes in other instruments indicating a low ICC. Similarly, the ability to discriminate between extreme groups is a weak test of the validity of the numerical values produced by an instrument.

Differences between instrument descriptive systems, summarized in Tables 1 and 2, indicate the potential for different levels of content validity. The early five-instrument Australian study anecdotally illustrated the importance of these differences when the same respondent scored 0.14 and 0.8 for the HUI 3 and EQ-5D, respectively. When the HUI 3 items for sense perception were altered from their reported scores to the highest HUI 3 item score (effectively removing them from the instrument), the predicted HUI 3 utility score rose to 0.74; that is, 91% of the original difference was attributable to items in HUI 3 which are not included in the EQ-5D. If the items in the EQ-5D had the same descriptive power – 'content' – in the context of sense perception, this would not have occurred.

Evidence for content validity is commonly obtained from the psychometric analyses, which led to the selection of the instrument's item structure and, in particular, evidence of whether or not additional items were redundant or added new content. However, except for AQoL, generic MAU instruments have not been developed in this way.

Few other tests of content validity have been reported. The most common have been comparisons of ceiling and floor effects (i.e. 'insensitivity' close to 'best' and 'worst' health). The test is limited as it applies only to extremities of the scale and results will vary with either the item structure or the weights attached to a given set of items. As noted in the section History, Description and Construction of MAU Instruments, ceiling effects vary significantly between instruments.

In one recent test, scores for each attribute of the EQ-5D, HUI 2, and SF-36 were individually predicted from the scores obtained by the other two instruments using data from 264 German patients. Adjusted R^2 values were between 0.01 and 0.57. The SF-6D attribute 'role limitation' and HUI 2 'sensation' were 'virtually unrelated to the other instruments.' The authors concluded that the instrument content differs 'so much that... (they) would produce different valuations even if other components of the instruments were the same' (Konerding *et al.*, 2009).

Rather than demonstrate differences, the authors of the Australian study reported in **Figure 3** (Khan and Richardson, 2011) attempted to identify missing content. Instruments on the vertical axis in **Figure 3,** which are relatively sensitive to a particular dimension, will, on average, have lower scores than predicted. Points will be below the line. The ratio of dimension scores of individuals from above to below the line therefore indicates the relative sensitivity of the instrument to a dimension. Results suggest that, at least in the relatively healthy population surveyed, HUI 3 has less content than other MAU instruments in the domains of mental health and relationships, and that AQoL-8D has greater content for all of the mental and social dimensions. EQ-5D is relatively sensitive to pain. Unexpectedly, HUI 3 was not significantly more sensitive with respect to senses, but this is probably because the sample was small ($n=158$) and there were few respondents with impaired senses.

Table 8 Predictive validity: prediction from utility scores

Instrument	*Permanent problem cured (health states of similar severity chosen for each instrument)*	*Increase in utility*[a]	*Equivalent*		
	= return to good health for 20 years	*Value per annum*	*Cures = 1 life saved*[b]	*Life extension with original QoL*[c]	
				Rate of time preference = 0%	*Rate of time preference = 2%*
QWB	Headache, dizziness, ringing in ears, and spells of feeling hot, nervous, or shaky	0.244	4	6.5 years	9.6 years
15D	Mild physical discomfort...pain, ache, nausea, itching, etc.	0.023	43	5.6 months	8.3 months
EQ-5D	Moderate pain or discomfort and some problem walking	0.273	4	7.5 years	11.1 years
HUI 3	Moderate pain that prevents a few activities	0.137	7	3.2 years	4.7 years
SF-6D	Pain, which interferes with normal work...a little bit	0.07	14	1.5 years	2.2 years
AQoL-8D[d]	Moderate pain...which sometimes interferes with usual activities	0.02	50	4.9 months	7.3 months

[a]Increase in utility if an individual is cured from the permanent problem and returned to best health on the scale or in the case of AQoL-8D to normal health as this corresponds approximately to best health on other scales. The seven items set at 'normal' levels are jobs around house, getting around the house, mobility, toileting, coping, relationships, content with life, and enthusiasm.

[b]The number of cures, *n*, equivalent to saving one life is calculated as $n=1/(\text{increase in utility})$. Therefore, cures times value of cure $= n \times$ increase in utility $= 1.00$.

[c]The number of years of life extension, *n*, is calculated from QALY gain $= 20(\text{utility gain}) = n(\text{original utility})$.

[d]AQoL-8D is at 'normal' (not best) levels for seven items, viz, jobs around the house, getting around the house, mobility, toileting, coping, relationships, content with life, and enthusiasm.

Criterion Validity

Comparisons of an instrument with external criteria are usually classified as tests of concurrent or predictive validity. They raise the question of what represents an acceptable external criterion. The theoretical questions include the choice between (*inter alia*) 'decision' and 'experience' utilities (i.e. evaluation before and after experiencing a state); the selection of the appropriate judge of utility – the public or patients – and the measurement perspective – individual or social. These issues are unresolved in the literature. However, instruments (of necessity) incorporate judgments with respect to each of these questions.

All of the instruments in the present review incorporated an individual perspective. TTO or SG values were obtained from people imagining they were, personally, in a health state. They were not asked to be representatives of the society. Most instruments embody answers from members of the public, not from patients (AQoL-7D and AQoL-8D obtained answers from both). Perhaps the most important neglected question is the scope of the construct 'health-related quality of life' to be incorporated in the instrument: should it include social dimensions, be restricted to a 'within the skin' concept or be defined by what individuals have in mind when asked about 'health?'

Subject to these caveats, a limited number of tests of criterion validity have been reported. One approach has been to ask respondents to directly value their own health state using a scaling instrument (TTO, SG, etc.) and to compare the result with the value predicted from an MAU instrument. Testing individual instruments this way has provided supporting evidence for the validity of the HUI and 15D.

The early Australian study (Hawthorne *et al.*, 2001) tested the validity of 15D, SF-5D, AQoL-4D, HUI 3, and EQ-5D using the 'self TTO' – i.e. the reduction people would accept in their own life expectancy in exchange for perfect quality of life. The aim of the test was two-fold: to determine (1) which instrument explained most variation in self TTO and (2) which instrument best explained what other instruments failed to explain, i.e. the residual from the first stage analysis. The results of both tests were similar: 15D demonstrated the greatest explanatory power followed, respectively, by SF-6D, AQoL-4D, HUI 3, and EQ-5D.

The results of this study are similar to those of a recent five instrument Finnish study (Honkalampi and Sintonen, 2010). However, the properties of self-referential measures have not been discussed in the economics literature and interpreting these results is difficult. A further suggested test is the use of willingness to pay as a criterion for evaluating MAU instruments. However, the technique is controversial in the context of QALYs, and no one has adopted the suggestion empirically.

A weak test of preferences is to determine whether most people agree that improvement has occurred when MAU instrument scores increase. Applying this test, Roberts and Dolan (2004) found that a 0.20 increase in the EQ-5D score was necessary before 70% of respondents agreed that any improvement had occurred.

The logic of this test of predictive validity was to use MAU instrument scores to predict what people would choose. Similar logic was used earlier in a study by Nord *et al.* (1993) drawing on the idea that QALYs are the product of utility, life years, and the number of people affected. From this, MAU instrument scores were used to predict the number of people moving from a health state to full health, which would be equivalent to saving one life. Results from the QWB and HUI 1 were so implausible that they suggested a lack of predictive validity.

An objection to this latter approach is that the test alters the distribution of utility and introduces a consideration of equity, which may (or may not) invalidate the conclusion. However, the method could have been applied with respect to individuals' personal trade-offs between quality of life and length of life, the right hand columns of **Table 8**. According to this, the life extension that is equivalent to a moderate improvement in the quality of life (described in somewhat different ways across instruments) is 38 times greater for the EQ-5D (11.1 years) than for AQoL-8D (3.5 months) and 14 times greater for the QWB (9.6 years) than for the 15D (8.3 months). As with the Roberts and Dolan (2004) study, (dis)agreement with the predictions from each instrument could be obtained independently from the population. Because the test is simple, it is a potentially powerful and rigorous test of criterion validity in the context of economic evaluation.

Conclusions

Numerous questions have not been considered here. Foremost is disagreement about what is to be measured. 'Health' like 'beauty' is a vague concept and has been operationalized very differently. In effect, each MAU instrument has provided its own unique definition, which has generally been unchallenged. The chief decision concerns the breadth and content of the definition. If an MAU instrument is intended strictly for use within a Government Health Service, the definition may remain narrow and exclude items extraneous to government funding, for example, social or dental-specific dimensions. The values embodied in the WHO definition of health and in orthodox economics would suggest a broader, more encompassing approach. That is, anything affecting preferences should be included.

Other omitted issues include perspective and the concept of utility. Present MAU instruments seek to measure personal, not social, preferences. These are generally measured on the basis of descriptions given to the public or to individuals who have experienced the health state and without any consideration given to the distribution of benefits. Challenges include a proper demonstration that MAU instruments have construct validity in different disease areas and, more fundamentally, predictive validity using criteria relevant for economic evaluation.

The article has focused on the construction and validity of MAU instruments. It indicates that the scores obtained from different MAU instruments differ significantly and, consequently, QALY values, CUA ratios, and the likelihood of health service funding are all significantly affected by the choice of instrument. The numerical values obtained from the instruments depend on the validity of the descriptive system, model combining the items, and scaling instrument.

Of these, the evidence suggests greatest agreement about the scaling instruments. TTO, SG, and even RS values correspond fairly well. Despite this, the focus in the economics literature has been on this choice, with overall instrument validity often judged primarily on the basis of the scaling instrument.

There has been little empirical evidence published with respect to the choice of the MAU model. Authors of the HUI 3 and AQoL-8D both found evidence that additive models were less satisfactory than multiplicative models. However, these models permit double counting of the disutility. Econometric linear models are flexible and ensure that predicted values 'pass through' the observed utilities, at least at the mean. But extrapolation with an additive model is problematical. Apart from AQoL-8D, there has been little experimentation with nonlinear models. Least agreement exists between the items of the MAU instrument's descriptive system, but this is where there has been least discussion. Instruments have been created using different approaches and generally with little explicit regard for content validity. It is therefore, at this level that differences between instrument scores will most probably be found.

None of the studies evaluating MAU instruments (which have been published) appears to have concluded that a scale is invalid. This poses a problem for decision makers as the outcome of an evaluation may presently depend on the choice of instrument. The approach to this problem by the UK NICE has been to nominate a preferred instrument for use in all evaluations. This does not overcome the underlying problem because, as recognized by NICE, a single instrument may not be an appropriate measure of health-related utility in all circumstances and, at present, there are no evidence-based guidelines concerning which instrument to use or how to interpret results from instruments which conflict.

Instruments are neither right nor wrong. The evidence suggests that they are more or less sensitive in different contexts. Use of a single instrument will favor interventions affecting health states where the instrument is sensitive (and the intervention efficacious) and disadvantage interventions where sensitivity is low. Researchers presently have little choice but to select from available instruments and to evaluate their ability to measure the health states which are of relevance to them. In the longer term, there is a need for a significant research program to determine which instruments should be used in which contexts and how to compare their values.

Multiattribute Utility Instruments: Condition-Specific Versions

D Rowen and J Brazier, School of Health and Related Research, University of Sheffield, Sheffield, UK

Introduction

A multiattribute utility (MAU) instrument consists of (1) a health questionnaire that establishes a health profile and (2) a scoring system that converts the multiattribute profile into an overall utility score. A generic MAU instrument can be used for all patients, whereas a condition-specific MAU instrument is intended only for patients with the condition of interest. Overall utility scores are used in economic evaluation of health care in terms of cost-utility analyses, where benefits are measured using quality-adjusted life-years (QALYs). They can also be used in monitoring of population health in terms of quality-adjusted life expectancy (QALE).

Some reimbursement agencies prefer the use of generic MAU instruments to generate QALYs. However, the generic measures may not always be available or appropriate. There is published evidence indicating that existing generic MAU instruments are valid, responsive, and reliable for many conditions. However, generic MAU instruments have been shown to perform poorly in terms of validity or responsiveness to change in some conditions. For example, the generic EQ-5D has been found to perform poorly in visual impairment in macular degeneration, hearing loss, leg ulcers, and schizophrenia. For these conditions the descriptive system of the generic MAU instruments either does not capture the impact of the change for that condition within its dimensions, or is not sufficiently able to capture small changes within a dimension. This means that the generic MAU instruments will not capture potentially important changes in utility across interventions because of the inadequacy of the descriptive system for that patient group. Condition-specific MAU instruments by contrast are designed to focus on functionings and symptoms that are affected both by the condition and treatments for the condition. This enables them to capture potentially important changes better across interventions for that condition.

In the following greater details on the construction and use of condition-specific MAU instruments are provided. Section 'Construction' summarizes their construction. Section 'Validity' examines their performance both in comparison to condition-specific instruments that are not preference-based and generic MAU instruments and addresses some further issues regarding validity. Section 'Future developments' outlines future developments. Additional readings are provided which contain information and references supporting the text in this article.

Construction

Background

Condition-specific measures vary in composition but typically have multiple domains, at least some of which may be highly correlated and not independent, and each of which has multiple items. The number of domains and items is often large (e.g., 30 items). The scoring process is often not based on preferences (i.e., non-preference-based), as item scores are typically summed to obtain a domain score and an overall score across all items. This simple summative scoring unrealistically assumes that all items, and the difference between all response choices, are equally important. Changes in scores do not necessarily reflect changes in quality of life that are valued by either patients or the general population. In the following these non-preference-based condition-specific measures are referred to as 'NPCS measures.'

Clinical studies often use NPCS measures (e.g., the cancer-specific EORTC QLQ-C30) and do not include generic MAU instruments. This is in part because of concerns about the appropriateness of generic measures in some conditions, but is also because of concerns surrounding patient burden and costs. Many trials are designed to provide information for multiple analyses (e.g., licensing and labeling claims) rather than economic evaluation alone, and often NPCS measures are used in these analyses rather than generic MAU instruments. This means that NPCS measures will continue to be an important source of evidence for economic evaluation. However, these measures cannot be used directly to generate QALYs. As shown by John Brazier and colleagues, they can be used indirectly to generate QALYs using mapping, which uses the statistical relationship between the NPCS measure and a MAU instrument to estimate utility scores using data from the NPCS measure alone. However, NPCS measures can be used directly if a condition-specific MAU instrument is derived from them. Section 'Development from existing non-preference-based condition-specific measure' describes this process.

Development from Existing Non-Preference-Based Condition-Specific Measure

For the majority of condition-specific MAU instruments the scoring system generates a score using responses to only a subset of the items included in the questionnaire. This is because the original questionnaire was often not designed as a MAU instrument and typically contains a large number of items across many domains. To derive utility scores from the questionnaire a subset of items is selected to form a descriptive system, which contains a small number of dimensions and severity levels for each dimension. The descriptive system is used to describe all possible health states with its associated utility score. What this means in practice is that for condition-specific MAU instruments the utility scores are usually generated by converting data for an existing questionnaire in the same way that SF-36 or SF-12 data are used to generate the SF-6D. For example, the cancer-specific EORTC QLQ-C30 data are used to generate the EORTC-8D cancer-specific utility score. This has the advantage that many condition-specific utility scores can be generated using existing data sets. Furthermore these data sets will contain both domain scores for

 doi:10.1016/B978-0-12-375678-7.00512-5

the original instrument and a utility score to provide detailed information for a range of analyses.

Figure 1 reports a six-stage process for deriving a condition-specific MAU instrument from an existing non-preference-based condition-specific measure that was first used to derive an overactive bladder-specific MAU instrument (AQL-5D) from the overactive bladder questionnaire (OABq). Stages 1 to 4 produce the descriptive system and stages 5 and 6 generate utility scores for all states defined by the descriptive system.

Stages 1 to 3 produce the descriptive system using existing data for the NPCS measure, and stage 4 validates the descriptive system using other data. Stages 1 to 3 provide the structure of the descriptive system by selecting dimensions and a minimum number of items per dimension to fully represent that dimension. This involves the use of psychometric techniques such as factor analysis, Rasch analysis, and Item Response Theory alongside classical psychometric techniques such as standardized response means and effect sizes. This process is undertaken to ensure that the selected descriptive system accurately represents the dimensionality and maintains the desirable psychometric properties of the original instrument. For example, the overactive bladder questionnaire has 33 items each with 6 severity levels covering 5 domains: symptom bother; sleep; coping; concern; and social interaction. The descriptive system of the OAB-5D MAU instrument derived from the questionnaire has 5 dimensions: urge to urinate; urine loss; sleep; coping; and concern each with 5 severity levels (Young *et al.*, 2009).

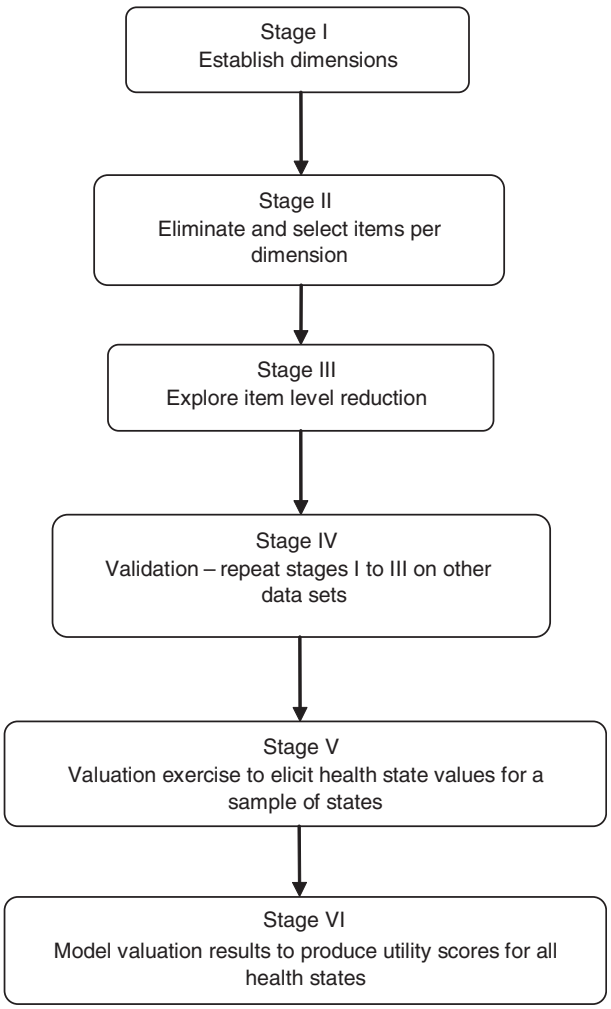

Figure 1 Six stages for deriving a condition-specific MAU instrument from an existing condition-specific non-preference-based measure. Reproduced with permission from Brazier, J., Rowen, D., Mavranezouli, I., et al. (2012). Developing and testing methods for deriving preference-based measures of health from condition specific measures (and other patient based measures of outcome). *Health Technology Assessment* **16**(32), 1–114.

Stage 5 elicits health state utility scores for a sample of health states. Even health state descriptive systems like OAB-5D define thousands of health states meaning it is impractical and infeasible to value all states. A sample of health states are selected for valuation using a variety of techniques such as an orthogonal array or balanced design. The selection process differs by whether multiattribute utility theory (MAUT) or statistical inference is the proposed modeling strategy for stage 6 and the valuation technique used, but states are selected in order to enable utility scores for all states to be estimated from the elicited data for the sampled states. A variety of elicitation techniques is used, such as time trade-off (TTO), standard gamble (SG), visual analogue scale (VAS), and discrete choice experiment (DCE). Preferences can be elicited from a variety of sources including general population, patients, and carers. However, it should be noted that when patients value health states in such experiments they value hypothetical health states, not their own health state, to enable these values to be used to estimate scores for all health states described by the descriptive system. Currently, general population preferences are typically recommended by health economists if the measure will be used in economic evaluation submitted to policy decision makers. However, as noted by Mike Drummond and colleagues, this is being debated. Stage 6 models the utility data to produce utilities for every health state defined by the descriptive system. The modeling follows either a MAUT or statistical inference approach and will differ depending on the process used to select states and the elicitation technique. As noted by John Brazier and colleagues, the process will also differ if the instrument is not multiattribute with multiple independent attributes, but instead has one main attribute, such as flushing or mental health.

New Developments

The descriptive systems for some condition-specific MAU instruments are developed 'de novo' rather than derived from existing non-preference-based condition-specific measures, requiring a modified approach for stages 1 to 4 outlined above. The most rigorous method of development of a new descriptive system involves qualitative research to identify dimensions and items and validation of the generated descriptive system using psychometric analyses before valuation. Other approaches in the literature include the use of psychometric analyses on a battery of existing measures or a literature review. Recent US Food and Drug Administration (FDA) guidance for industry (U.S. Department of Health and Human

Services Food and Drug Administration (FDA), 2009) outlines guidelines for the development of dimensions and items for non-preference-based measures and emphasize the role of patients with the condition in generating and validating the content. Valuation follows the process as outlined in stages 5 and 6 above.

Description of Existing Instruments

Table 1 outlines the descriptive systems for existing condition-specific MAU instruments. Instruments were identified by John Brazier and colleagues in a recent review of published studies. Unpublished instruments that the authors were aware of were added to the list (see http://www.sheffield.ac.uk/scharr/sections/heds/mvh). There are 28 instruments covering 27 different conditions ranging from exact diagnoses, such as glaucoma and lung cancer, to more general conditions, such as visual impairment and cancer. The size of the descriptive system varies greatly by measure, with a range of possible health states for a system ranging from 10 to 390 625. The focus of the dimensions differs across instruments: (1) symptoms or health-related quality of life (HRQL) and (2) condition-specific dimensions alone or dimensions able to capture side effects and comorbidities. Indeed, dimensions vary for instruments within a condition or International Classification of Diseases.

Table 2 outlines the valuation processes used to produce utility scores for all states defined by the descriptive system of the various condition-specific instruments. Fourteen instruments use the statistical inference approach to select health states for valuation and model utilities, and eight instruments use a decomposed approach, which is either a pure MAUT approach or an approach combining statistical inference and MAUT. Three instruments value all health states defined by the descriptive system and thus require no modeling to produce utility scores for all health states. TTO, VAS, and SG and combinations of these were most commonly used to elicit utility scores. Twelve instruments have values elicited using TTO, six used VAS and SG, four used VAS alone, two used SG alone. Although VAS was used in 13 instruments and is the most commonly used technique, its usage differs across studies varying from valuing health states to valuing severity levels within a dimension or valuing different dimensions. Eight instruments cannot be used to estimate QALYs as they are not anchored onto the full health-dead 1–0 scale required to estimate QALYs. Half of the measures are valued using only a general population sample, with 10 measures valued by patients and one by patients and carers (using hypothetical states not own state). Valuation studies across all instruments have only been conducted in the UK, the US, Netherlands, and Canada with the majority of instruments valued only in the UK.

Validity

Comparison of Performance to Original Measure

There is little published analysis examining the extent of information loss arising from moving from the original non-preference-based condition-specific measure to a smaller condition-specific MAU instrument. However, evidence reviewed recently by John Brazier and colleagues suggests that there is either no information loss or a minimal degree of information loss when examining patient data sets for instruments produced for asthma, cancer, common mental health problems, and overactive bladder in terms of discrimination across severity group and responsiveness to change over time. This is reassuring given the rationale for deriving a MAU instrument from an existing measure is to benefit from its relevance and sensitivity, and means that this informational advantage is retained in the process of deriving a MAU instrument from the original measure.

Comparison of Performance to Generic MAU Instruments

Overall there is limited evidence comparing the performance of condition-specific and generic MAU instruments and it is mainly concerned with psychometric tests such as known group differences and responsiveness. However, analyses comparing generic EQ-5D to instruments produced for asthma, cancer, and common mental health problems found that the condition-specific MAU instruments performed better than EQ-5D regarding discriminative validity across severity groups. Figure 2 plots pair-wise comparisons of EQ-5D and these condition-specific MAU instruments, demonstrating that the condition-specific MAU instruments have a narrower range of utility scores than EQ-5D but there is a large dispersion of condition-specific MAU scores for each EQ-5D score (and vice versa). Unlike EQ-5D the condition-specific MAU instruments did not suffer from ceiling effects (where a large proportion of respondents report themselves as in full health and are clustered at the top end of the scale), suggesting they are more responsive for patients at the upper end of HRQL. It is also clear that there are differences between the condition-specific MAU instruments and EQ-5D at the observational level, and the condition-specific utility scores are typically higher with the exception of observations in full health on EQ-5D. Although research found that the condition-specific MAU instruments were better at discriminating between groups with different severity, they were comparable to EQ-5D regarding responsiveness to change following treatment (although for responsiveness this is based on little data owing to limited data availability). Typically, mean change over time and differences between severity groups were smaller for the condition-specific MAU instruments but with smaller standard deviation that improved precision in comparison to EQ-5D. This reduced uncertainty in utility scores for different time periods and severity groups is important for trials. However, the smaller mean change over time or across groups found using these condition-specific MAU instruments may potentially indicate that interventions are less cost–effective. Further research is needed to determine whether these findings are generalizable to all condition-specific MAU instruments. It should be noted that as a MAU instrument contains a subset of items from the original measure it will only offer an improvement on a generic MAU instrument if the original non-preference-based condition-specific measure offers an improvement. Therefore, the development of condition-specific MAU instruments from existing measures should be limited to measures already shown to be more responsive and valid.

Table 1 Condition-specific MAU instrument descriptive systems

Condition: name of MAU instrument (where available)	*Non-preference-based measure*	*Number of dimensions*	*Severity levels*	*No. of states defined by system*	*Dimensions*
Amyotrophic lateral sclerosis (ALS): ALS utility index	Amyotrophic Lateral Sclerosis Functioning Rating Scale – Revised (ALSFRS-R)	4	5–6	750	Speech and swallowing; eating, dressing and bathing; leg function; respiratory function
Asthma: Asthma Symptom Utility Index (ASUI)	N/A	5	10	100 000	Cough; wheeze; shortness of breath; awakening at night; side effects of asthma treatment
Asthma: AQL-5D	Asthma Quality of Life Questionnaire (AQLQ)	5	5	3 125	Concern about asthma; shortness of breath; weather and pollution stimuli; sleep problems; activity limitation
Cancer: EORTC-8D	EORTC QLQ-C30	8	4–5	81 920	Physical functioning; role functioning; pain; emotional functioning; social functioning; fatigue and sleep disturbance; nausea; constipation and diarrhea
Common mental health problems: CORE-6D	Clinical outcomes in routine evaluation – outcome measure (CORE-OM)	6	3	729	Functioning – close relationships; functioning – social relationships; functioning – general; symptoms – anxiety; risk/harm to self; physical health
Dementia: DEMQOL-U	DEMQOL (self-report)	5	4	1 024	Positive emotion; memory; relationships; negative emotion; loneliness
DEMQOL-Proxy-U	DEMQOL-Proxy (carer proxy-report)	4	4	256	Positive emotion; memory; appearance; negative emotion; loneliness
Diabetes: Diabetes Utility Index	Audit of diabetes-dependent quality of life (ADDQoL) plus additional items	5	3–4	768	Physical ability and energy level; relationships; mood and feelings; enjoyment of diet; satisfaction with managing diabetes
Epilepsy: NEWQOL-6D	Quality of life in newly diagnosed epilepsy measure (NEWQOL)	6	4	4 096	Worry about attacks; depression; memory; cognition; stigma; control
Erectile (dys)functioning	IIEF Index of erectile function	2	5	25	Ability to attain an erection sufficient for satisfactory sexual performance; ability to maintain an erection sufficient for satisfactory sexual performance
Flushing	Flushing symptoms questionnaire (FSQ)	5	4–5	2 500	Redness of skin; warmth of skin; tingling of skin; itching of skin; difficulty sleeping
Glaucoma: Glaucoma Utility Index (GUI)	Glaucoma profile instrument	6	4	4 096	Central and near vision; lighting and glare; mobility; activities of daily living; eye discomfort; other effects
Handicap: London Handicap Scale	International classification of impairments, disabilities, and handicaps (ICIDH)	6	6	46 656	Handicap mobility; occupation; physical independence; social integration; orientation; economic self-sufficiency
Head and neck cancer	N/A	8	5	390 625	Social function; pain; physical appearance; eating problems; speech problems; nausea; donor site problems; shoulder function

(*Continued*)

Table 1 Continued

Condition: name of MAU instrument (where available)	*Non-preference-based measure*	*Number of dimensions*	*Severity levels*	*No. of states defined by system*	*Dimensions*
Lung cancer	FACT-L	6	2	64	Physical; social/family; emotional; functional; symptoms – general: symptoms – specific
Menopause	Menopause-specific quality of life questionnaire	7	3–5	6 075	Hot flushes; aching joints/muscles; anxious/frightened feelings; breast tenderness; bleeding; vaginal dryness; undesirable androgenic signs
Menorrhagia	N/A	6	4	4 096	Practical difficulties; social life; psychological health; physical health; working life; family life
Minor oral surgery	N/A	5	4	1 024	General health and well being; health and comfort of mouth, teeth, and gums; impact on home/social life; impact on job/studies; appearance
Overactive bladder: OAB-5D	OABq overactive bladder questionnaire	5	5	3 125	Urge to urinate; urine loss; sleep; coping; concern
Pediatric asthma: Pediatric Asthma Health Outcome Measure (PAHOM)	N/A	3	2–3	12 – but only 10 are valid	Symptoms; emotion; activity
Pediatric atopic dermatitis	Unnamed questionnaire on atopic dermatitis	4	2	16	Activities; mood; settled; sleep
Parkinson's disease	N/A	2	2–5	10	Disease severity; proportion of the day with 'off-time' (impact on QOL due to condition covering domains: social function, ability to carry out daily activities, psychological function)
Pulmonary hypertension	Cambridge pulmonary hypertension outcome review (CAMPHOR)	4	2–3	36	Social activities; traveling; dependence; communication
Rhinitis: Rhinitis Symptom Utility Index (RSUI)	N/A	5	10	100 000	Stuffy or blocked nose; runny nose; sneezing; itchy watery eyes; itchy nose or throat
Sexual quality of life: SQOL-3D	Sexual quality of life questionnaire (SQOL)	3	4	64	Sexual performance, sexual relationship, sexual anxiety
Stroke	N/A	10	3	59 049	Walking; climbing stairs; physical activities/sports; recreational activities; work; driving; speech; memory; coping; self-esteem
Urinary incontinence	The King's health questionnaire (used for urinary incontinence and lower urinary tract symptoms)	5	4	1 024	Role limitations; physical limitations; social limitations/family life; emotions; sleep/energy
Venous ulceration	N/A	5	3–5	720	Pain; mobility; mood; smell; social activities
Vision/visual impairment: VisQoL/AQoL-7D	N/A	6	5–7	45 360	Physical well being; independence; social well being; emotional well being; self-actualization; planning and organization

Table 2 Condition-specific MAU instrument valuation

Condition: name of MAU instrument (where available)	*Theory and model type*	*Preference elicitation technique*	*Anchored on 1–0 full health-dead scale*	*Population*	*Country*
Amyotrophic lateral sclerosis (ALS): ALS Utility Index	Decomposed – multiplicative	VAS both for each level of each dimension alone and health states, and SG	Yes	General population	US
Asthma: Asthma Symptom Utility Index (ASUI)	Decomposed – multiplicative	VAS and SG both for states and for the levels per dimension	No	Patients	US
Asthma: AQL-5D	Statistical – additive	TTO	Yes	General population	UK
Cancer: EORTC-8D	Statistical – additive	TTO	Yes	General population	UK
Common mental health problems: CORE-6D	Statistical – additive	TTO	Yes	General population	UK
Dementia: DEMQOL-U DEMQOL-Proxy-U	Statistical – additive	TTO	Yes	General population	UK
Diabetes: Diabetes Utility Index	Decomposed – multiplicative	VAS and SG	Yes	Patients	US
Epilepsy: NEWQOL-6D	Statistical – additive	TTO	Yes	General population	UK
Erectile (dys)functioning	All states valued	TTO	Yes	General population and students	Netherlands
Flushing	Maps Rasch logit scores onto mean utilities – additive	TTO	Yes	General population	UK
Glaucoma: Glaucoma Utility Index (GUI)	Statistical – additive	DCE	No	Patients	UK
Handicap: London Handicap Scale	Statistical – additive	VAS	No	Patients	UK
Head and neck cancer	Decomposed – additive	VAS both for dimensions relative to each other and for the levels per dimension	No	Surgeons	UK
Lung cancer	Statistical – additive	VAS	Yes	General population	UK, Netherlands
Menopause	Statistical – additive	TTO	Yes	Patients	UK
Menorrhagia	Decomposed – additive	2 tasks: distribute 21 counters across the dimensions in proportion to their importance; VAS of the levels per dimension	No	Patients	UK
Minor oral surgery	Decomposed – additive	2 tasks: distribute 100 counters across the dimensions in proportion to their importance; VAS of the levels per dimension	No	Patients	UK
Overactive bladder: OAB-5D	Statistical – additive	TTO	Yes	General population	UK
Pediatric asthma: Pediatric Asthma Health Outcome Measure (PAHOM)	Power function used to convert VAS to SG, all states valued using VAS	VAS and SG	Yes	General population	US
Pediatric atopic dermatitis	All states valued	SG	Yes	General population	UK
Parkinson's disease	All states valued	VAS and SG	Yes	Patients	US
Pulmonary hypertension	Statistical – additive	TTO	Yes	General population	UK
Rhinitis: Rhinitis Symptom Utility Index (RSUI)	Decomposed – multiplicative	VAS and SG both for states and for the levels per dimension	No	Patients	US
Sexual quality of life: SQOL-3D	Statistical – additive	TTO	Yes	General population	UK
Stroke	Unclear	VAS	No	Patients and caregivers	Canada
Urinary incontinence	Statistical – additive	SG	Yes	Patients	UK
Venous ulceration	Statistical – additive	TTO	Yes	General population	UK
Vision/visual impairment: VisQoL/AQoL-7D	Decomposed – multiplicative	TTO, VAS for the levels per dimension	Yes	Unclear	Unclear

Notes: Statistical, statistical inference; decomposed, MAUT or combination of MAUT and statistical inference. Preference elicitation technique is reported only if it was used to produce the recommended utility scores for all health states.

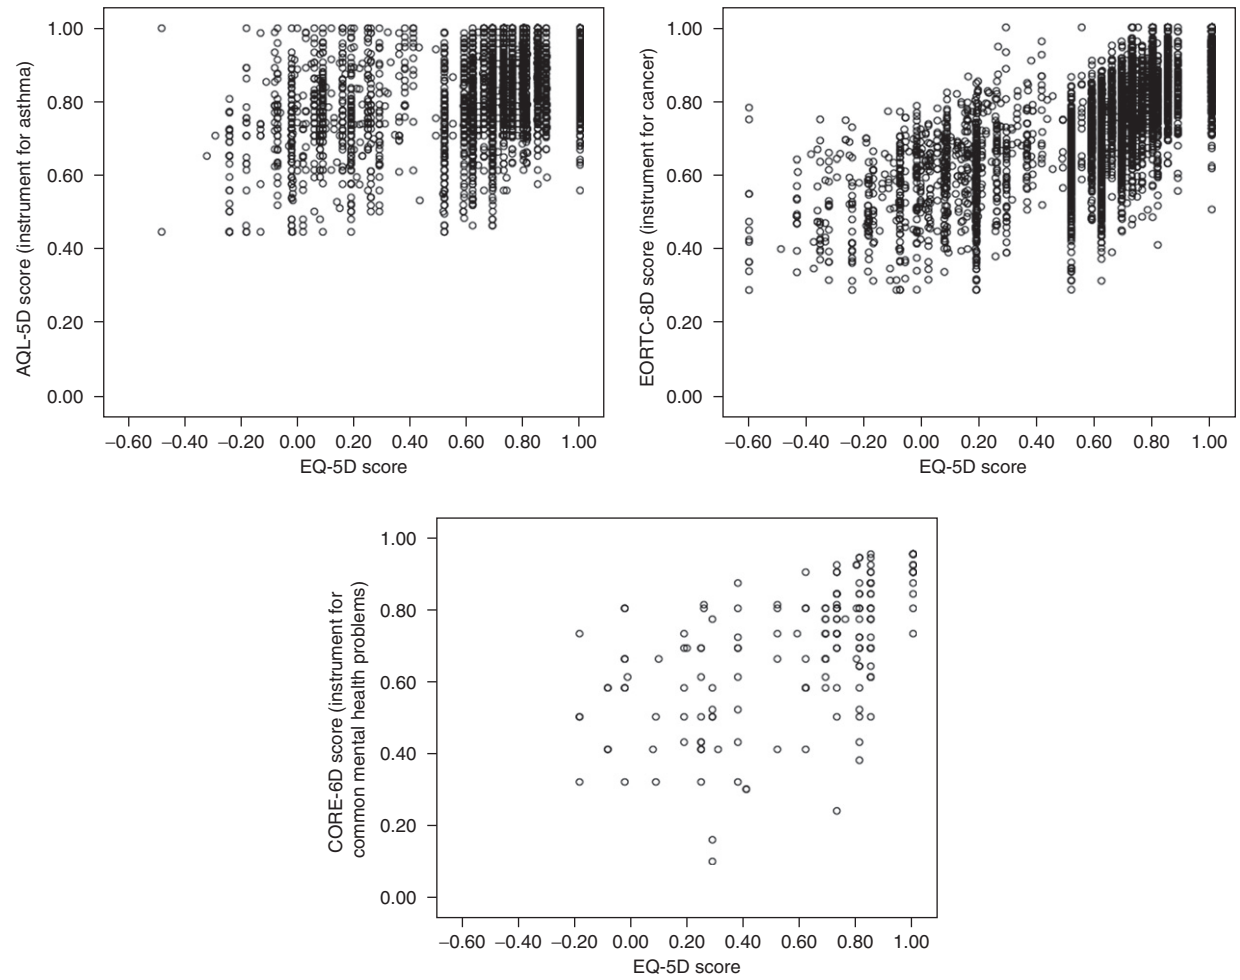

Figure 2 Pair-wise comparisons of 3 condition-specific MAU instruments and generic EQ-5D.

Other Issues

Condition-specific MAU instruments have been criticized on the grounds of focusing effects. It has been argued that respondents may provide lower utility scores for health states with only condition-specific dimensions as they are focusing on the problems presented rather than judging these relative to other generic dimensions of health that are not impaired, such as mobility or self-care. But this is not supported by evidence of the kind shown in Figure 2.

Some evidence suggests that the inclusion of the condition label in the health state descriptions used to elicit utility scores can itself affect results (e.g., a 'cancer' label was found to lower values). The inclusion of these condition labels is often unavoidable as the condition is embedded into the descriptive system (e.g., take the dimension 'concern about asthma') and is an important factor that may affect health state utility scores for condition-specific MAU instruments and question comparability to values produced by generic MAU instruments.

It has been argued that condition-specific MAU instruments are unable to capture comorbidities or side effects because of their focus on the condition. Table 1 indicates that whereas this may be a concern for some instruments with a descriptive system largely focused on symptoms related to the condition, this is unlikely to be an important concern for many instruments that cover a broad range of functionings (e.g., the EORTC-8D for cancer).

In relation to focusing effects and the inability to capture side effects and comorbidities, there is a concern that elicited utility scores may be affected if the descriptive system does not contain all important dimensions. There is some evidence supporting this concern, where it was found that adding a generic dimension to an existing condition-specific MAU instrument affected the utility scores for the condition-specific dimensions. This suggests that condition-specific MAU instruments should contain all important dimensions for that condition.

Future Developments

Ongoing research will identify where generic MAU instruments are insufficient or inappropriate and condition-specific MAU instruments are appropriate. Further research examining the impact of using either generic or condition-specific MAU instruments in economic evaluation is encouraged. Future

research should also examine the role of the descriptive system in valuation studies as this has largely been ignored to date. This research would determine the importance of focusing effects, condition labeling, and missing dimensions. These findings would indicate the comparability of valuation studies undertaken for generic and condition-specific MAU instruments and the accuracy of health state utility scores for condition-specific MAU instruments.

Mental Health

Mental health problems are among the most complicated and challenging of all illnesses, with considerable economic implications. It is conventional to distinguish between common mental disorders (including depression, generalized anxiety disorder, panic disorder, obsessive–compulsive disorder and post-traumatic stress, with an overall prevalence of 15–20%) and severe mental disorders (particularly schizophrenia and bipolar disorder, with a combined prevalence of approximately 2–3%). Alcohol and drug abuse are usually included under the mental health heading, as is suicide or suicidal ideation. The World Health Organization (WHO) also classifies epilepsy as a mental disorder, although many countries' national health systems do not (and it is not included in this article; intellectual disabilities and neurological disorders are also excluded). It is estimated that approximately 6% of children and young people aged under 18 years have behavioral problems serious enough to be classified as psychiatric disorders, and 4% have emotional disorders. Alzheimer's disease and other dementias become increasingly prevalent with age: 5% for people aged 65 years or over but 20% for those aged 85 years or over.

According to the WHO, mental, substance use, and neurological disorders as a group account for approximately 14% of the global burden of disease (measured in disability-adjusted life years), which is roughly 30% of the total global burden of noncommunicable disease. Both proportions are expected to grow over time, particularly in low- and middle-income countries (LAMICs).

The large disease burden follows from the high prevalence and chronic course of most mental disorders and is associated with high costs (see Economic Impacts). Few mental disorders can be cured, although symptom alleviation through evidence-based treatment is a realistic goal for many people. Primary prevention of illness is achievable for some common mental disorders and some people, although illness etiology remains only partially understood. What distinguishes mental from other illnesses is a particularly troublesome combination of at least four interconnected features: links to suicide and self-harm; associations with dangerous behavior; widespread public fear, stigma and discrimination; and restrictions to individual choice and liberty because of assumed or ascribed inability or danger.

There are wide gaps between underlying and treated prevalence, particularly in LAMICs where WHO estimate that 76–85% of serious cases have received no treatment in the previous 12 months; the figure in high-income countries is said to be 35–50%. This is why the WHO launched the Mental Health Gap Action Program (mhGAP) to support and encourage strategic planners and policy makers – as well as international donors – to tackle the 'burden' of untreated disorders.

Poor access to evidence-based care and treatment is a key factor in the overall disease burden. One reason is simply that policy makers fail to allocate sufficient funds to mental health programs, or that voluntary insurance coverage excludes some or all mental disorders. But there are other 'resource barriers' such as the unequal distribution of services and available treatments across regions, socioeconomic groups, genders, and age bands. Another is the inappropriateness of certain types of investment (e.g., the large, usually decrepit, dehumanizing institutions that still dominate mental health systems in some countries) and the consequent inflexibility of available resources to meet needs most cost-effectively. A further problem is a basic lack of information about what works in terms of symptom alleviation and quality-of-life enhancement or on the resource implications. In countries where health systems are primarily reliant on voluntary insurance or out-of-pocket payments, poverty is a major barrier.

Economic Impacts

Mental disorders are defined by their clinical symptoms and so impact heavily on health systems. But they have consequences across many life domains, leading to potentially wide-ranging needs for support from social care, housing, employment, criminal justice, income support, or other systems. The direct costs of treatment and care are high, but the indirect costs of mental disorders can be higher. For example, calculations for Europe in 2010 suggest that indirect costs (mainly from unemployment, absenteeism, and presenteeism) account for 38% of the total cost of anxiety disorders, 63% for mood disorders, and 69% for psychotic disorders.

There can be high opportunity costs for families because the need for unpaid care and support interferes with employment and leisure, as well as out-of-pocket payments if families subsidize treatment expenses. Estimates published by Alzheimer's Disease International in 2010 indicate that unpaid care from family members and other unpaid carers accounts for 58% of the total costs of dementia in low-income countries, 65% in lower middle-income countries, and 40% in high-income countries. These indirect costs are largely hidden but crucial inputs. They are often overlooked in policy frameworks; this is a dangerous strategy given rapidly ageing populations, the resulting rapidly growing prevalence of dementia, and the dwindling number of family carers (because of trends toward smaller families and higher female labor force participation rates).

 doi:10.1016/B978-0-12-375678-7.00613-1

For the wider society, economic impacts can include the victim, fear, and criminal justice system costs of acquisitive crime by people with serious substance misuse disorders, violent crime by people experiencing florid psychotic episodes, and suicide and self-harm by people experiencing severe depression. Although in some societies there is exaggerated attribution or fear of these criminal activities, it is nevertheless the case that, for instance, 5–15% of homicides in high-income countries are committed by people with psychosis. Responses can be both appropriate and inappropriate: a high proportion of people in prison have untreated mental disorders, in many cases before their incarceration, whereas most countries have legal structures in place to compulsorily detain and treat individuals at times of crisis. These powers can too easily be abused, as in the Soviet Union and Nazi Germany, but in less dramatic ways the basic human rights of people with mental disorders are still denied – often trampled – in many societies in the present day.

Because of the enduring nature of most mental disorders, economic impacts can be seen across much of the life course, including poor employment outcomes, low incomes, continuing high use of mental health services, continuing antisocial and criminal activity, and difficulties with personal relationships. Behavioral and emotional disorders in childhood have impacts well into middle adulthood and possibly beyond.

An immediate corollary of this multiplicity and durability of economic impacts – following from the multiplicity and chronicity of needs associated with some mental disorders – is for coordinated action across budgets and systems to avoid gaps and wasteful overlaps and particularly to ensure that resources work together effectively and efficiently. Silo budgets are almost clichéd but remain a substantial challenge, sometimes exacerbated by professional rivalry, narrowly framed performance assessment, and the slow churn of bureaucratic processes.

Mental Health, Employment, and Productivity

There are multiple, complex, two-way links between mental disorders and employment difficulties. People with mental disorders are at greater risk of unemployment, job insecurity, early retirement, absenteeism, presenteeism, and low salaries. However, stress, bullying, and other difficulties in the workplace are known risk factors for onset or exacerbation of common mental disorders. Psychoses, particularly schizophrenia, are most likely to emerge when people are in their late teenage years or early 20s, which is precisely when most people would make key investments in their human capital, and so these disorders have lifelong economic consequences. As it has been seen, lost productivity is the biggest contributor to the immediate costs of mental disorders but with wider consequences for household income, community prosperity, and national economic growth.

People with mental disorders – like most people – put great emphasis on employment, not only partly and obviously because it generates earnings, but also because it brings social status and social role, fosters social participation and networking, and is a major source of self-concept. Barriers to the employment of people with mental disorders will obviously include reduced abilities because of their symptoms, but endemic social stigma and widespread discrimination by employers are major challenges.

Given the close links between employment, income, personal debt, and poverty (see Mental Health, Poverty, and Debt), the complex downward spiraling relationship between mental disorders and work difficulties can be hard to break into. One set of responses, coming from strategic policy makers, is to create conditions so that employment opportunities are better, even if they are unlikely to match those available to the 'mentally well' population. There is also growing support for approaches that provide intensive support for employees with mental disorders and their employers in 'open employment' settings rather than traditional 'sheltered workshop' environments. The Individual Placement and Support approach, for example, has proved effective and cost-effective across many high-income countries, helping people with quite severe mental disorders to enter, remain, and sometimes thrive in the workforce, albeit with ongoing support in many cases.

Some countries have introduced legislation so that mental disorders are viewed in the same way as physical disability in terms of rights to employment and other opportunities. Some of these initiatives go hand in hand with attempts to address moral hazard concerns about criteria for income support eligibility and to counter what can easily become a dependency culture in groups with long-term conditions. Most people with mental disorders want to work are perfectly capable of working in appropriate settings, and derive therapeutic and other benefits from it. The alternatives are not only disabling, disempowering, and disadvantaging for those individuals but also costly for societies.

Employers face high productivity losses if key employees have mental disorders because losing skilled staff for short or long periods is both disruptive and expensive. Consequently, private businesses (and public and NGO sector employers, of course) have gains to make if there is appropriate preventive or ameliorative action. Employers in many countries have become more aware in recent years of the impacts on their profit margins of disrupted employment as a result of employees' poor health, particularly poor mental health. Perhaps more gradually, employers have also become more aware of the benefits of tackling some of the associated risk factors through workplace initiatives. Some risk factors for mental disorders are within their control, such as demands made on employees, opportunities for them to participate in decision-making, promotion prospects, harassment, and bullying. Workplace well-being programs and screening initiatives for stress and other approaches have a good evidence base in support. Although attention to the bottom line – the profit margin – should be enough of a motivation to introduce such programs in some companies (provided the risks and consequences are fully appreciated), small- and medium-sized enterprises may need support through tax incentives or health insurance deals.

Mental Health, Poverty, and Debt

Mental illness and poverty interact in vicious circles. Evidence from high- and low-income countries shows the close relationship between mental disorders and various measures of

individual economic disadvantage. Two hypotheses have been propounded. According to the social causation hypothesis, economic disadvantage such as poverty increases the risk of mental illness through augmented risk factors (e.g., financial stress, stigma, social exclusion, and malnutrition) and decreased protective factors (e.g., social capital, education). However, the social selection or 'drift' hypothesis argues that people with mental disorders have an increased risk of remaining or falling into poverty because of the costs of their treatment, lost or disrupted employment, and hence reduced earnings. The social causation explanation is more relevant for common mental disorders such as depression and anxiety, and the drift explanation more relevant for severe mental disorders such as schizophrenia, but the pathways are complex and evidence suggests causation in both directions for many people.

Poverty

The World Bank defines poverty as marked deprivation in well-being that includes monetary (e.g., income and consumption) and nonmonetary aspects (e.g., health, education, and housing), as captured by indices measuring one dimension (e.g., absolute and relative poverty) or many (e.g., the Multidimensional Poverty Index).

In high-income countries, poverty and unemployment are known to be associated with the maintenance of common mental disorders but apparently not their onset, whereas financial strain (personal debt) is associated with both. Several epidemiological studies have found positive associations between low socioeconomic status, on the one hand, and alcohol and substance misuse, and rates of schizophrenia and major depression, on the other hand. Suicide and parasuicide are strongly associated with socioeconomic deprivation. Children in the poorest households are much more likely to suffer from conduct disorders (severe antisocial behavior) and attention-deficit hyperactivity disorders than children from more affluent households. In LAMICs, common mental disorders have been found to be positively associated with low socioeconomic status, financial stress, low social class, low educational attainment, food insecurity, and bad housing conditions. More ambiguous associations have been found with low income, unemployment, underemployment, and low consumption.

Debt and Financial Instability

Following the recent global economic downturn, the relationships between mental disorders, personal debt, and financial instability have attracted considerable interest. Personal or household debt has a two-way association with mental health. In high-income countries, the impact of financial difficulties on depression depends in part on the type of debt and whether it is 'manageable', but there is apparently no direct association with anxiety disorders or nonspecific mental disorders. For example, a positive association has been found between the onset of mortgage indebtedness and rent arrears and poor mental health, with men more likely to be affected in the short term and women in the long term. A negative association has been found between outstanding nonsecured debt and psychological well-being, but no association for secured debt (such as a mortgage on housing). In a LAMIC context, one study found higher rates of distress and suicide among farmers who went into debt as a result of the agricultural crisis in India, whereas another found a positive association between personal debt and suicide attempts in Pakistan.

Macroeconomic recession affects numerous determinants of mental health, such as employment and job security, productivity and earnings, socioeconomic status, and social cohesion. In high-income countries, slower economic growth and associated increases in unemployment are associated with higher suicide rates. A positive association has also been found between unemployment *duration* and suicide, with a noticeable increase in suicide risk shortly after mass layoffs. Macroeconomic fluctuations that lead to worsening market conditions appear to be associated with poorer mental health in those people least likely to be employed, in ethnic minority groups, and in men with lower educational attainment. A macroeconomic downturn affects not only the mental health of some adults but also of their children. The Asian economic crisis of 1997 was associated with an increase in suicide rates in the years that followed, as well as a widening of income-related mental health inequalities. Sociopolitical crises in Serbia and Belarus increased suicide rates, and socioeconomic upheavals in the Russian Federation were followed by increased rates of suicide and alcohol-related deaths. Agricultural crises are strong risk factors for depression and suicide attempts in South Asia.

Solutions

Acknowledging the bi-directional relationship between mental illness and poverty, interventions have targeted both the causes of mental disorders and the causes of poverty. Poverty-alleviation interventions, such as cash transfers and microcredit, have as a by-product the potential to address the social causation of mental illness. Mental health interventions, such as drug treatments, psychotherapy and community rehabilitation, might be primarily focused on symptom alleviation but in so doing can also address the drift into poverty. In LAMICs, the effect of mental health interventions on poverty and other economic outcomes has been found to be positive but not always significant, whereas evidence is inconclusive on the effect of financial poverty-alleviation interventions on mental illness. Asset promotion programs have mental health benefits, and the evaluation of the conditional cash transfer program *Oportunidades* in Mexico found a significant reduction in both depressive symptoms in mothers and behavioral problems in children. A microcredit intervention in South Africa *increased* perceived stress levels among recipients of small loans (both men and women) but decreased depressive symptoms in men. Debt advice and counseling services can decrease the risk of developing or exacerbating mental disorders.

Macroeconomics and Mental Health

Mental disorders have large economic impacts that are often spread well beyond health care systems as conventionally constructed. There are also persistent economic impacts across

long time periods. Employment and associated productivity difficulties are common, both for people with mental disorders and their families, while disorders in childhood and adolescence reduce levels of educational attainment. Hence, the macroeconomic consequences flowing from untreated or inadequately treated mental disorders can be considerable. There is also the strong likelihood that social and economic inequalities will widen.

From the other direction, there is also strong evidence that economic difficulties experienced by individuals increase the risk of mental disorder so that countries experiencing prolonged recession will likely see growth in the prevalence of common mental disorders. Becoming unemployed, remaining unemployed for long durations, experiencing a drop in earnings or other income, moving into personal debt in ways that cannot be managed, and experiencing housing problems can all lead to lower psychological well-being and resilience, more mental health needs and alcohol misuse, higher suicide rates, greater social isolation, and worsened physical health.

Efforts are already being made to break, weaken, or respond to the links between the state of the macroeconomy and mental health-related needs, although in most countries a lot more could and should be done. The available options are many and various. They include poverty-alleviation strategies, programs to help individuals with mental disorders to get jobs, early intervention to head-off the most damaging of personal and economic consequences of disorders, investments to build community and social capital, stronger social safety nets, antistigma campaigns, workplace initiatives, alcohol price increases, school-based schemes to tackle bullying and build resilience, and personal health budgets. And, of course, the options also include the more conventional pharmacological and psychosocial treatments, family psychoeducation, respite care, liaison services between medical specialties, and reorganization of care arrangements, each in turn requiring commitment of budgets to mental health systems from governments or other funders, followed by investment in suitably trained staff and other treatment inputs.

Nonparametric Matching and Propensity Scores

Potential Outcomes Framework

In problems studying the effects of a given intervention or treatment on health outcomes or health costs, it is often the case that researchers and analysts are faced with using observational study data to draw inferences. The use of such data gives rise to various concerns about biases that may influence treatment effect estimates. In the ideal world, one would be able to observe how an individual or agent would act under two scenarios – one where the agent had been treated and the other where the agent had not been treated. From here, estimating the effect of treatment on both the individual agent and population would be straightforward. Unfortunately, this is never a possibility in real-world settings.

To illustrate in more detail the difference between the ideal and real world, we can utilize the potential outcomes framework that has become popular in both statistics and econometrics in the past two decades. First, it is assumed that the study sample has N individuals. For each individual, we can define two potential outcomes, namely $Y_i(1)$ and $Y_i(0)$, which denote individual i's outcome under the treatment and control conditions, respectively, for $i=1,\ldots,N$. In the ideal world, we would be able to observe both $Y_i(1)$ and $Y_i(0)$ and we would directly know the effect of the treatment on individual i (namely, $Y_i(1)-Y_i(0)$). However, in the real world, it is usually observed that $Y_i=Y_i(Z_i)$, where Z_i denotes whether the ith individual actually received treatment ($Z_i=1$) or control ($Z_i=0$) in practice. The value of $Y_i(1-Z_i)$, commonly referring to as the counterfactual for the ith individual, is not observed. In most studies, researchers also observe (in addition to Y_i and Z_i) a set of pretreatment covariates or exogenous variables, X_i, which are assumed to be unaffected by treatment but that may predict the outcome Y_i as well as whether the ith individual received the treatment or control condition. The variables in X_i are also commonly referred to as confounding factors or confounders because excluding them from an analysis examining the effect of Z_i on Y_i may lead to results from observational data in which the differences in the values of X_i between groups with $Z_i=0$ and $Z_i=1$ are combined with or confound the true causal effects of Z_i on Y_i.

With the potential outcomes framework in hand, we can now introduce a number of different types of treatment effects that a researcher may be interested in estimating in addition to the effect of the treatment on the ith individual ($Y_i(1)-Y_i(0)$). First, it is often the case that researchers are interested in estimating the population average treatment effect (PATE), which is defined as $E[Y(1)-Y(0)]$, and tells us the impact of treatment on average over the entire population to which inferences are being drawn. Alternatively, it may be of interest to estimate the PATE for the treated (PATT), which is defined as $E[Y(1)-Y(0)|Z=1]$, and tells us the average effect of treatment on individuals like those who actually receive treatment.

To estimate the PATE, the primary quantity of interest would be the sample average treatment effect (SATE), which equals $\frac{1}{N}\sum_{i=1}^{N}(Y_i(1)-Y_i(0))$, and takes the average over the effect of treatment on all individuals in the sample. To estimate the PATT, the primary quantity of interest would be the SATE for the treated (SATT), which equals $\frac{1}{N_T}\sum_{i:Z_i=1}(Y_i(1)-Y_i(0))$, where N_T denotes the number of individuals who are observed to receive treatment. SATT takes the average of the effect of treatment on all individuals in the sample who were observed to receive treatment. Both SATE and SATT are consistent (unbiased) estimates of PATE and PATT, respectively. However, it is never the case that one would be able to compute the SATE and SATT as only one of the two potential outcomes for each individual in the sample is usually observed.

A natural next step in trying to estimate PATE and/or PATT in practice would be to simply take the mean of Y_i among those with $Z_i=1$ and compare it to the mean of Y_i among those with $Z_i=0$. Unfortunately, this will only work if one has treatment and control conditions that are well balanced with regard to the distribution of all pretreatment factors that are known to be associated with the outcome. Such balance is hard to find when researchers are faced with using data from observational studies that do not randomize individuals in the sample to the treatment and control conditions. Moreover, usually only a handful of the pretreatment factors known to be associated with Y are actually available (i.e., those in X). Thus before estimating PATE and PATT, additional statistical and econometric methods must be utilized to achieve balance on the available pretreatment covariates or confounding factors, X, and additional assumptions must be made to ensure there is no residual confounding from imbalances in pretreatment covariates which were not observed. The rest of this article focuses on describing these assumptions and methods.

Critical Assumptions: Unconfoundedness and Overlap

Before introducing various methods that are available to researchers to achieve balance between individuals in the treatment and control conditions on the observed pretreatment covariates, X, when trying to estimate PATE or PATT, it is important to understand two key assumptions that are required to obtain consistent treatment effect estimates when faced with observational data.

The first key assumption goes by various names in the literature. It requires in layman's terms that one has matched or balanced the individuals in the treatment and control conditions on values of X in such a way that there are no unobservable differences between the individuals in the two conditions after conditioning on X. In notational terms, we write this as $(Y(1), Y(0))\perp Z|X$. The implication of this assumption is that systematic differences in outcomes between

 doi:10.1016/B978-0-12-375678-7.00711-2

individuals with the same values of the pretreatment covariates are solely attributable to treatment. This assumption is commonly referred to as either the unconfoundedness assumption, selection of the observables, the conditional independence assumption, or ignorable treatment assignment. Throughout the remainder of this article, we will refer to it as the unconfoundedness assumption.

In principle, the unconfoundedness assumption is untestable. However, a number of approaches have been proposed that are useful for addressing its credibility, which revolve around the idea of doing sensitivity analyses to assess how sensitivity treatment effect estimates are to specific types of deviations from the unconfoundedness assumption.

The second key assumption required for consistent estimates of PATE or PATT using the methods discussed is the overlap assumption. The overlap assumption is formally written as $0 < \Pr(Z = 1|X) < 1$. The implication is that one needs sufficient overlap in the distributions of the observed pretreatment covariates between individuals who are in the treatment and control conditions to be able to identify consistent estimates of PATE or PATT. Checking overlap is usually done by comparing the distribution of the estimated probability of receiving treatment conditional on X (commonly called the propensity score) among those in the treatment and control conditions to see if there is sufficient overlap in the estimated values of the measure; however, some promising work has been published which describes more formal ways to check overlap in the covariate distributions of the two conditions. Checking overlap is a critical step when estimating PATE and PATT. It is important to note that all is not necessarily lost if overlap is lacking. Assuming it is meaningful to do so, one may limit inferences to the average effect of treatment for the subset of the pretreatment covariate space where there is overlap.

Nonparametric Matching Methods

With our two key assumptions in hand, we now turn our attention to understanding ways in which researchers can try to balance the treatment and control conditions on the distributions of pretreatment covariates, X, so that consistent estimates PATE or PATT can be obtained. One of the most commonly used approaches for estimating PATE and PATT is to match individuals in the treatment and control conditions on values of X so that one can compare outcomes across pairs of matched treatment and control individuals with similar distributions of pretreatment covariates. Methods for creating meaningful matchings are numerous in the literature. This section focuses on the use of nonparametric matching techniques as nonparametric matching provides a method by which there are no restrictions on the functional form of the relationship between the outcome (Y), the treatment indicator (Z), and the pretreatment covariates (X). We begin by describing common techniques for one-to-one or pair matching (i.e., matching one control individual to one treatment individual) and then focus on the more elaborate techniques available for matching more than one individual to a given treatment or control individual.

The simplest case of one-to-one matching is exact matching which selects one control individual and one treatment individual so that they match exactly on X. Exact matching is only really feasible when the pretreatment covariates are all discrete (i.e., binary or categorical) and/or when one has only a handful of pretreatment covariates that need to be controlled for. In most other cases of one-to-one matching, the idea is to match one control individual with one treatment individual such that they have pretreatment covariates X whose values are within the same small neighborhood of each other. This type of matching (to no surprise) is commonly referred to as neighborhood matching or nearest neighbor matching.

The first step for any type of matching scheme (exact or neighborhood) is coming up with a meaningful distance metric that summarizes how close one individual is to another in terms of their values of X. There are generally three core types of distance metrics: categorical, caliper, and quadratic (including Mahalanobis distance). In each type, one begins by defining the distance between individual a in the treatment condition and individual b in the control condition using a specific formula. Here, the distance between individual a and individual b is denoted by δ_{ab}. Categorical distance metrics are usually defined such that $\delta_{ab} = 1$ if the covariates are an exact match and $\delta_{ab} = \infty$ otherwise. Caliper distance metrics are defined such that $\delta_{ab} = 1$ if $|X_{aj} - X_{bj}| \leq c_j$ for all j where $j = 1, \ldots, J$ and J denotes the total number of pretreatment covariates and $\delta_{ab} = \infty$ otherwise. Quadratic distance metrics are defined such that $\delta_{ab} = (X_a - X_b)D(X_a - X_b)^T$ and thus can take on any real number; Mahalanobis distance which defines D to the inverse of the variance–covariance matrix of X is an example of a quadratic distance.

Once the distance metric is defined, it is then computed for all possible pairs (a,b) of individuals, one in the treatment group and the other in the control condition and then an optimization algorithm selects the pairs that minimize the sum of δ_{ab} across all pairs. From there, PATE and PATT follow directly by computing the treatment effect estimate for each pair and averaging across these estimates. The key difference in obtaining an estimate of PATE and PATT is in how the matching is done. For obtaining an estimate of PATT, one would aim to match each treatment case to a single control case and throw away all other controls which were not matched. For obtaining PATE, one would try to optimally match across both conditions without requiring that one condition is favored more than the other.

There is an extensive number of methods available for implementing one-to-one matching, including canned programs in most standard statistical software packages. However, there has also been extensive work done on matching algorithms which go beyond one-to-one matching, including matching one treatment individual with multiple controls (say two or three for each treatment individual) or matching each treatment individual to a variable number of controls in such a way that all control individuals are utilized. The ideas for these methods build off the theory described earlier in the article for one-to-one matching. However, it is important to note that matching methods that match a fixed number of controls to a single treatment individual tend to be criticized for being overly restrictive and for discarding data (namely, the unmatched control individuals). Various authors have shown

that the use of a more flexible method, often called full matching, which makes use of all individuals in the data by forming a series of matched sets in which each set has either one treatment individual and multiple control individuals or one control individual and multiple treatment individuals is particularly effective at reducing bias due to confounding from pretreatment variables.

The section is ended by touching on the issue of how best to choose which pretreatment covariates that one should use in the matching algorithms described earlier in the article. It is generally recommended that variables chosen be predictive of both the outcome, Y, and the likelihood that the individual receives treatment, $\Pr(Z=1)$. Inclusion of irrelevant pretreatment covariates has the potential to impact both consistency and precision of treatment effect estimates.

Propensity Score-Based Methods

There is a second class of methods that are commonly used by researchers to handle the differences in the observed pretreatment covariate distributions among the treatment and control conditions. The class of methods differs from the methods presented in the previous section on Nonparametric Matching Methods because instead of matching on X directly, one matches on the predicted probability of receiving treatment, given the observed pretreatment covariates, commonly referred to as the propensity score. Matching on the propensity score as opposed to X greatly reduces the dimensionality problem of the nonparametric matching methods described earlier in the article. The theory shows that consistent estimation of PATE and PATT is possible when the treatment and control conditions are balanced with respect to the propensity score because balancing the two conditions on the propensity score in theory also balances the two conditions with respect to X.

Formally, the propensity score is denoted by $e(x) = \Pr(Z=1|X=x) = E[Z|X=x]$ and let $\hat{e}(x)$ denote the estimated propensity score (see below in this section for estimation). Various matching techniques (similar to those described earlier in the article) have become available for the case of trying to match treatment and control conditions on the propensity score in order to obtain consistent estimates of PATE and PATT. Each one is fundamentally based on the same ideas as the techniques for nonparametric matching on X, which are described earlier in the article except that things are much simpler when one only has to match on the single quantity of the propensity score rather than the entire vector of pretreatment covariates in X.

The most common approach for matching on the propensity score continues to be the nearest neighbor matching where a fixed number of controls, say k, are matched to one treatment individual and an optimal matching algorithm (as opposed to a greedy matching algorithm) are utilized to estimate PATT (as matching is driven by treatment individuals). The popular use of the nearest neighbor matching is likely a consequence of these algorithms being readily available in statistical software packages. However, as stated earlier in the article, such matching is suboptimal to full matching where a variable number of control individuals can be matched to a single treatment individual and a variable number of treatment individuals can be matched to a single control individual. The idea is that full matching forms the matched sets in an optimal way on the basis of the propensity score so that individuals from either condition who do not have many similar matches will not be forced to have bad matches as may happen when forcing all individuals to have a fixed number of controls. Unfortunately, software is not readily available to implement full matching in most software packages; the optmatch package available in R appears to be the only canned software currently available for implementing full matching.

The class of propensity score methods used to estimate PATE and PATT are not limited to matching. Commonly, both weighting by and subclassification on the propensity score are also used to obtain consistent estimates of PATE and PATT. With regard to weighting, one can consistently estimate PATE using the following formula:

$$\text{EATE} = \sum_{i=1}^{N} Y_i Z_i w_i / \sum_{i=1}^{N} Z_i w_i - \sum_{i=1}^{N} Y_i (1-Z_i) w_i / \sum_{i=1}^{N} (1-Z_i) w_i$$

where $w_i = 1/\hat{e}(X_i)$ for those with $Z_i=1$ and $w_i = 1/(1-\hat{e}(X_i))$ for those with $Z_i=0$. This estimate of PATE takes the difference in weighted means between those in the treatment and control conditions where the weights are set equal to the reciprocal of the estimated probability that an individual received the condition that they actually received. Such weights serve to make the distribution of observed pretreatment covariates, X, in each condition (treatment and control) look similar to the population's distribution of X. The corresponding estimate of PATT is

$$\text{EATT} = \sum_{i=1}^{N} Y_i Z_i / \sum_{i=1}^{N} Z_i - \sum_{i=1}^{N} Y_i (1-Z_i) w_i / \sum_{i=1}^{N} (1-Z_i) w_i$$

where $w_i = \hat{e}(X_i)/(1-\hat{e}(X_i))$. This estimate for PATT takes the unweighted mean for the treatment condition and subtracts off the weighted mean for the control condition where the weights for the control condition equal the odds of an individual in the control condition being in the treatment condition. This weight serves to upweight control individuals who look more like individuals in the treatment condition and downweight those who do not in order to yield a consistent estimate of PATT.

With regard to subclassification techniques based on the propensity score, the idea is to estimate the treatment effect of interest within subclasses that are defined based on the values of $\hat{e}(x)$ and to then aggregate across subclasses in a meaningful way to obtain final estimates of PATE or PATT. For example, it is generally the case that separate regression models on the outcome or mean differences between the two conditions are computed within each subclass and then results are aggregated across the subclasses by weighting those estimates by the subclass sample sizes if one is interested in PATE or the proportion of treatment cases in the subclass if one is interested in PATT.

A key issue for matching on, weighting by, or subclassification on the propensity score, is how best to estimate the propensity score. In most applications, simple logistic regression (or parametric) models are utilized to estimate the

propensity score. The treatment indicator, Z, is regressed on the pretreatment covariates X, possibly with or without interactions between the pretreatment variables and with limited attention paid to model selection procedures. In spite of the apparent ease of using logistic regression to estimate the propensity score, it is not the recommended method in the statistical and econometrics literature. Instead, use of more sophisticated semiparametric and nonparametric techniques are recommended. For example, it has been well established that machine learning methods outperform the use of simple logistic regression models in the binary treatment case. Machine learning methods work in an iterative fashion to fit nonparametric models to the predicted probability of receiving treatment. Use of conventional methods for estimating propensity scores such as logistic regression are less flexible than the machine learning techniques and typically require ad hoc variable selection procedures to reduce the number of degrees of freedom required by the pretreatment covariates and their interaction terms in the model. Such variable selection procedures risk biasing estimates of treatment effects because they can incorrectly omit covariates that are important to treatment selection. Similarly, variable selection procedures and the typical assumptions common in conventional modeling approaches risk model misspecification of the functional form of the relationship between the covariates and the treatment indicator, which can lead to very large biases in treatment effect estimate.

One example of a flexible, nonparametric machine learning technique that has been frequently utilized in the literature is the Generalized Boosted Model (GBM). GBM estimates the propensity score model using a flexible estimation method that adjusts for a large number of pretreatment covariates and which adaptively captures the functional form of the relationship between the pretreatment covariates and treatment selection with less bias than traditional approaches.

Use of propensity score weights has been shown to have a number of advantages over matching or subclassification techniques based on the propensity score. In comparison to one-to-one or k-to-one matching techniques which throw away observations that do not match, weighting includes all observations in the outcomes analysis. In comparison with subclassification techniques that require fitting multiple regression models to the outcome (one within each class), weighting techniques only fit one (weighted) regression model to the outcome which greatly minimizes variable selection issues and the need to tinker with the functional form. The main disadvantage of weighting is that it can be less efficient than matching or subclassification, particular when good weights are difficult to obtain.

Doubly Robust Methods

We end this article by describing doubly robust methods that are commonly used to consistently estimate PATE and PATT. To put the goal of doubly robust methods in context, one must note that historically, the traditional approach for estimating PATE and PATT using observational study data was to utilize multivariable parametric regression models of the outcome (Y), which regress Y on the treatment condition indicator (Z), and the observed pretreatment covariates (X), which were concerned to be potential confounders of the relationship between Y and Z. However, the assumptions of linearity (additivity) for the effects of the pretreatment covariates on Y was considered too rigid of an assumption and drew into question whether such models can yield consistent estimates of PATE and PATT giving raise to the nonparametric and propensity score methods described earlier in the article for obtaining consistent estimates of PATE and PATT. Although the methods described do not do any direct modeling of the outcome, they do come with their own assumptions, namely that the modeling done between the pretreatment covariates and treatment indicator are well specified. Doubly robust methods apply both techniques simultaneously (parametric regression modeling which control for X and matching or weighting the treatment and control conditions with respect to X) to produce consistent estimates of PATE or PATT as long as one of the two modeling approaches has been correctly specified. Thus, for example, use of both propensity score weighting and regression on the outcome with a parametric model leads to a doubly robust estimate of PATE or PATT because the estimates are consistent as long as one of the models is correct. Similarly, both matching on observed pretreatment covariates and controlling for those covariates in the outcome regression model fit to the matched pairs represent a doubly robust estimate of PATE and PATT assuming one of the two models is correct. Although doubly robust techniques can be less efficient if the parametric outcome model is correct, it is the final recommendation of this article that researchers go doubly robust whenever feasible to minimize the potential biases that could arise from using only a single technique.

Nurses' Unions

SA Kleiner, Cornell University, Ithaca, NY, USA

Introduction

Nurses' unions are widespread in the developed world. In the European Union, 90% of Denmark's nurses are members of a union (Danish Nurses' Organization, 2009), and in the UK, nurses (along with teachers and other professional workers) have the highest union density of any occupation (Metcalf, 2005). Organized labor for the nursing profession is prominent in non-EU countries as well, with nearly one-quarter of Australian nurses belonging to a union (Daly *et al.*, 2004), and 87% of Canadian nurses are represented by organized labor (Informetrica Limited, 2011), though OMalley (2012) reports the figure as lower (62%).

In the USA, the health care sector has been the most active sector of the economy for union organizing in recent years (NLRB, 2004). The percentage of health care practitioners reporting union membership has increased from 12.9% in 2000 to 13.3% in 2010 (Bureau of Labor Statistics, 2011), versus a corresponding decrease in overall union membership rates during that time period from 13.5% to 11.9% (Hirsch and Macpherson, 2013a). In addition, the number of unionized health care practitioners has grown by 38% to nearly 960 000 during this same period, versus a 9.5% decrease in the number of unionized members in the overall economy. Union representation among nurses is particularly strong; 18.7% of registered nurses (RNs) were represented by unions as of 2010 (Hirsch and Macpherson, 2013b) and as **Figure 1** indicates, these rates are even higher in states such as Washington (61%), Hawaii (55%), California (53%), and New York (46%).

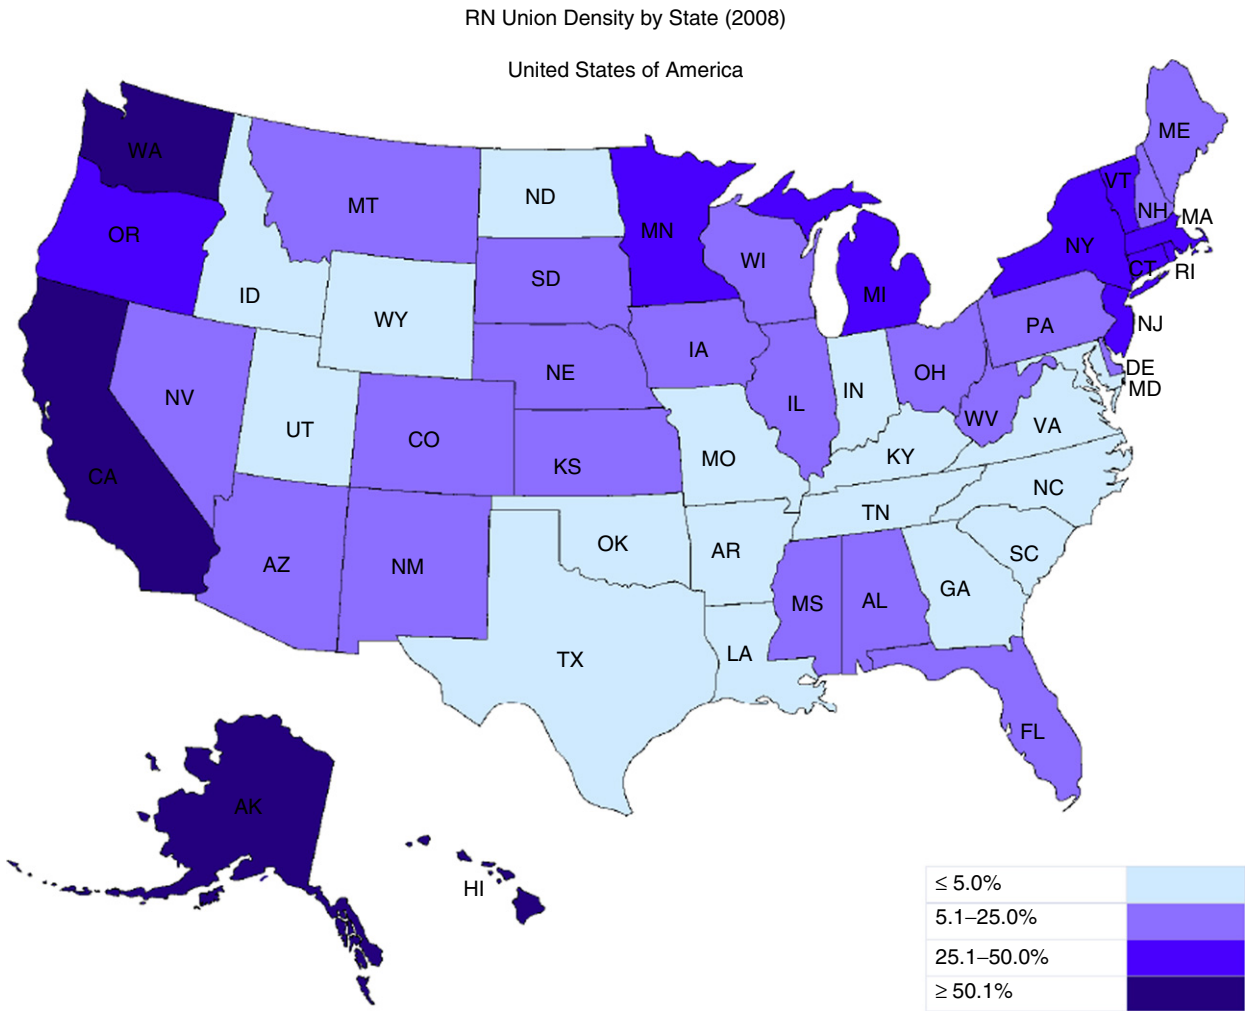

Figure 1 RN union density by state (2008). Calculated using the Current Population Survey Files for 2008. The author is grateful to Rebecca Givan for providing this figure.

Although a complete international comparison of trends in the union density rate for nurses is limited by data availability, the Amsterdam Institute for Advanced Labor Studies gathers data on the overall health care sector union density rate for a small group of countries, which is included in **Figure 2**. For each of the seven listed countries, the health care sector union density rate exceeds that of the overall trade union density rate. However, with the exception of New Zealand, the data show a slight downward trend in the union density rate for health care workers.

Nurses play a significant role in the delivery of health care. They are the most numerous health professionals in most Organization for Economic Cooperation and Development (OECD) countries, with particularly high numbers of nurses per capita in the Nordic countries, Belgium, and Ireland (OECD, 2011a). In the USA, the nursing profession comprises the largest group of health care employees, holding 2.6 million jobs in 2008. Employment in the nursing profession has grown substantially in the past three decades, and if current trends continue, nurse employment is expected to surpass 3 million by 2014 (Health Resources and Services Administration, 2010). In addition, health care production is particularly labor intensive; 60% of hospital costs are labor related (American Hospital Association, 2010) and nursing services constitute the single largest item in most hospital budgets (Public Policy Institute of California, 1996). Consequently, the presence of labor market institutions such as nurses' unions have the potential to substantially affect both the provision and cost of health care, an industry that accounted for an average of 9.6% of Gross Domestic Product in OECD nations (OECD, 2011b), and greater than 17% of spending in the US economy in 2009 (Martin *et al.*, 2011).

Central to the understanding of the effects of nurses' unions in the health care sector is the understanding of the two distinct 'faces' of unionism. The first, as characterized in Freeman and Medoff (1984), is to exercise market power when bargaining with employers in order to obtain more favorable working conditions for their members, including higher wages, and improved conditions of employment. The other, not necessarily incompatible role of unions is to facilitate a 'collective voice' that enables workers to channel their discontent into improved workplace conditions and productivity-enhancing industrial relations policies. Because these forces operate simultaneously within a unionized firm, the fundamental question for understanding the overall impact of unionism relates to the relative magnitude of each of these effects. Consequently, much of the economics literature on unions has focused on an empirical assessment of these two sides of unionism. Several research studies have established that unionized sector workers earn more and have better benefits than their nonunion counterparts (Mellow, 1979; Lewis, 1986; Freeman and Kleiner, 1990; Jakubson, 1991; Wunnava and Ewing, 1999; Hirsch and Schumacher, 2001), whereas evidence on the union productivity effect is less definitive (Fuchs *et al.*, 1998; Doucouliagos

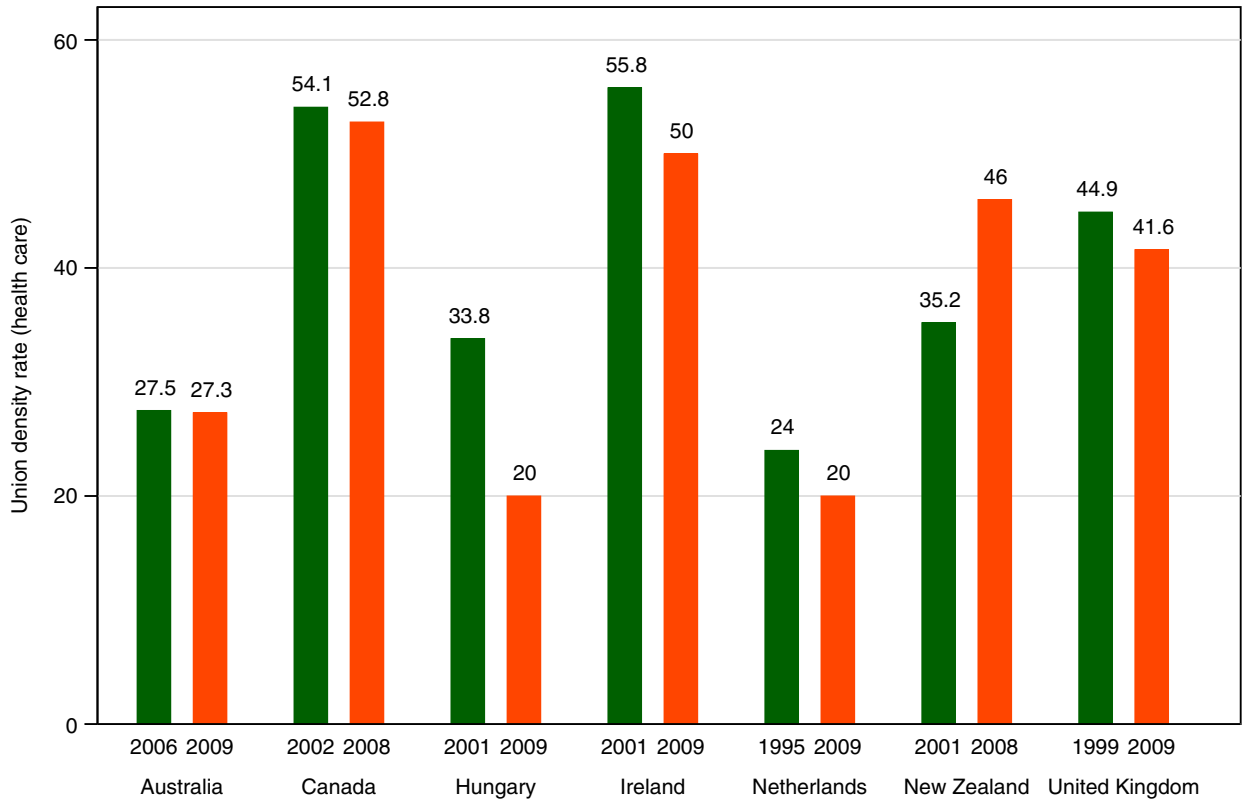

Figure 2 Health care union density rates for selected countries. Reproduced from Amsterdam Institute for Advanced Labor Studis, ICTWSS Database. Available at: http://www.uva-aias.net/208 (accessed 21.09.12). (Note: Overall trade union density rates for the listed countries in 2010 were as follows: Australia (18.0%), Canada (29.5%), Hungary (16.8% in 2008), Ireland (35.0%), the Netherlands (18.6%), New Zealand (20.8%), and the UK (26.5%). See http://stats.oecd.org/Index.aspxDatasetCode=UN_DEN (accessed 24.09.12).)

and Laroche, 2003; Hirsch, 2007, 2008). Furthermore, as Hirsch (2007) indicates, the importance of each side of unionism is very much dependent on the legal and economic environment in which unions and firms operate, as well as the skill level of the employees who are organized (Card, 1996).

This article critically reviews the literature on nurses' unions. Because most studies of nurses' unions rely on data from the USA, in what follows the focus is primarily on the role of these unions in the US economy (unless otherwise noted). The article proceeds in four steps. First, the section "Organized Labor in the US Health Care Industry" provides a brief overview of the legal and regulatory issues surrounding union organizing in the health care industry. The second section "Nurses' Unions and the Labor Market for Nurses," summarizes the evidence on the effects of nurses' unions on the labor market. In the section titled "Nurses' Unions and Firm Performance" I review evidence on the productivity effects of nurses' unions on the firms in which they are employed. I conclude by focusing on priorities for future research.

Organized Labor in the US Health Care Industry

The growth of organized labor in the US health care industry is a relatively recent phenomenon when compared with that of other traditionally unionized sectors of the economy. Although initially covered under the prounion Wagner Act of 1935, collective bargaining in health care institutions was limited by the National Labor Relations Act (NLRA) of 1947. This Act, which outlined unfair practices on the part of unions, also excluded both government and nonprofit hospitals from the right to unionize, asserting that unionization could disrupt the provision of necessary charitable services and open the way for "strikes, picketing and violence which could impede the delivery of health care" (Zacur, 1983, p. 10). Clark *et al.* (2002) note that although eight states enacted legislation granting some collective bargaining rights during this time, most employees in the sector did not have a right to unionization.

After intense lobbying efforts by hospital employee organizations, in 1974, President Nixon signed Public Law 93-360 (PL 93-360) reversing the 23-year exclusion. This law subjected all nongovernmental health care facilities to federal labor law, as governed by the NLRA, and in particular nurses, as 66% of nurses were employed by hospitals at the time (Aiken *et al.*, 1981). In the 4 years following this amendment, there were over 1000 hospital union certification elections (Scott and Simpson, 1989), and an increase in the percentage of hospitals with collective bargaining agreements to 23% in 1976 versus 3% in the early 1960s (Huszczo and Fried, 1988).

In the 15 years following the passage of PL 93-360, a protracted case-by-case bargaining unit determination process enabled hospitals to strategically challenge the bargaining unit determination in each union election, in order to reduce the resolve of employees voting to unionize (Keefe and Rakich, 2004). However, in a final rule published by the National Labor Relations Board in 1989 and affirmed by the US Supreme Court in 1991, eight separate bargaining units were clearly delineated, one of which included registered nurses. Tomey (2004) and Keefe and Rakich (2004) show that this ruling further opened the health care industry to unionization, and increased the number of union elections won in the years following this ruling.

Although these recent protections extended to health care workers have increased the ease with which workers are able to organize, despite these protections, the collective bargaining rights of nurses continue to be disputed. For example, recent cases have disputed the rights of nurses to organize on the grounds that they represent supervisory personnel and are thus exempt from the protections afforded by the NLRA (see *NLBR v. Kentucky River Community Care, Inc., 532 US 706, 2001* and *Oakwood Healthcare, Inc., 348 NLRB 686, 180 LRRM 1257, 2006*). Nonetheless, union representation among nurses remains strong, and is growing.

Nurses' Unions and the Labor Market for Nurses

One of the most important potential impacts of nurses' unions is their effect on the labor market for nurses. Unions have been shown to significantly raise wages in the overall economy (Fuchs *et al.*, 1998; Hirsch and Schumacher, 2004), and registered nurses have realized significant gains in wages in the three decades following the passage of PL 93-360. According to the 2010 National Sample Survey of Registered Nurses, real wages (in 1980 dollars) for registered nurses increased by 54% from 1980 to 2008, from US$17 400 in 1980 to nearly US$27 000 in 2008 (average nominal wages for RNs in 2008 were nearly US$67 000). Furthermore, nurses' unions have recently claimed credit for securing wage increases for their employees, as well as the implementation of employment-related regulation such as minimum nurse-to-patient ratios in California, and the introduction of federal minimum staffing legislation in Congress (California Nurses Association, 2009).

Effects on Employee Compensation

Despite the growing numbers of unionized nurses in the USA, most studies analyzing the effects of nurses' unions on wages are somewhat outdated. Before the passage of PL 93-360, evidence of only a small and sometimes statistically insignificant union wage effect was found in studies relying mostly on data from aggregate metropolitan areas or state-level data for their estimates (Feldman and Scheffler, 1982). Link and Landon's (1975) analysis of the interaction of union and monopsony effects was a notable exception during this period, in that it used a hand-collected data set from individual hospitals. Their results show a 5–10% gain in the wages for hospital nurses due to unionization, with particularly strong gains for lower skilled nurses.

Following the change in the NLRA in 1974, a number of studies attempted to quantify the effects of unions in hospitals, and most focused at least in part on the effects of union membership on nurses. Feldman and Scheffler (1982) use a national probability sample of hospitals drawn from the American Hospital Association (AHA) survey, and present results indicating that both hospitals and unions have market

power. Their findings indicate an overall effect of unions on nurses' wages of approximately 8%, with more substantial wage gains for unions established for at least 10 years at the time that their sample was collected. Adamache and Sloan (1982) in their study of a sample of hospitals in 1979 find a smaller union wage premium of 5% for hospital nurses, although they do not reject a union wage premium of up to 20%. Their study is also unique in that their estimates imply substantial union spillover effects, equating to a 10% wage premium at surrounding hospitals if 75% of hospitals in a market have formal collective bargaining agreements. Furthermore, their analysis of the effects of market structure on nurse wages finds no evidence that unions possess countervailing power that offsets the effects of monopsony. Groshen and Krueger (1990) also find evidence of a wage premium for nurses of approximately 4%, although their results suffer from similar limitations of earlier studies on union wage premiums in that their unit of analysis is a metropolitan area rather than a hospital.

Two more recent studies by Schumacher and Hirsch (1997) and Hirsch and Schumacher (1998) adopt a distinctly different approach to identifying the union wage premium for nurses, arguing that measurement of the union wage premium using firm-level data, as has been attempted in previous studies, may distort the true union wage premium. Specifically, they emphasize the potential for overstating the true union wage premium if such a wage differential corresponds to unmeasured skill differentials across unionized and nonunionized workers. Hirsch and Schumacher (1998) demonstrate that although cross-section regression estimates of the union wage premium in their sample produce a statistically significant union wage premium estimate roughly equivalent to those found in previous studies (approximately 3.2%), a specification that estimates the union wage premium using the change in wages for individuals who switch into or out of union membership over a 1-year period suggests a statistically insignificant estimate of 1.1%. This implies that the cross-section union wage differential may represent a compensating differential for unmeasured worker ability. Schumacher and Hirsch (1997) further this point in their work analyzing the magnitude of hospital wage premiums, finding a substantial wage premium realized by hospital nurses, with little of this premium due to union membership. Though the authors acknowledge that their identification strategy is likely to bias the results toward an underestimate of the true union wage effect, their findings parallel those of Bruggink *et al.* (1985) who find no direct impact of nurse unions on RN wages.

In the only analysis of the effects of unions on the distribution of wages, Spetz *et al.* (2010) find little difference in the pay structure of unionized versus nonunionized nurses. Though a number of their findings fail to achieve statistical significance, notable in their study are results indicating that nurses' unions decrease the disparities in income between nurses with dissimilar levels of education, and also lower the return to experience for unionized nurses. They conclude that, contrary to Freeman (1980, 1982), who found strong evidence that unions reduce wage dispersion and rationalize the wage structure, unions' primary effect in hospitals is to raise wages with no noticeable effects on the wage distribution.

Explanations for the Evidence on Union Wage Premiums for Nurses

Although the estimates of the union wage premium for nurses is substantially lower than the 15% average effect that persists in the overall economy, a number of factors likely contribute to the underestimation of the true premium. First, as Kaufman (2007) notes, the effects of unions may vary when wages and employment are not determined within a competitive labor market. Reports of nursing shortages in the USA in every decade since the 1950s, coupled with the concentration of nursing employment in relatively few settings, have led economists to characterize the nursing market as the "textbook example of monopsony" (Hirsch and Schumacher, 2004, p. 1). **Figure 3** indicates that approximately 60–70% of nurses are employed by hospitals, and more than 85% are employed by either hospitals, ambulatory care, or community health centers.

The existence of monopsony power can generate union wage effects that differ from those predicted by the standard competitive model where the market power of unions over labor supply is assumed to enable them to bargain for higher wages. Specifically, a union's market power in a monopsonistic labor market may be partially offset by an employer's dominance in the labor market, resulting in a wage level closer to that which would prevail in a competitive, nonunionized market. Thus, depending on the relative bargaining position of the firm versus the union within a market, collective bargaining in a monopsonistic labor market could lead to smaller wage premiums than would prevail in a competitive labor market, and studies estimating the union wage premium that omit variables that are correlated with hospital monopsony power could tend to underestimate the true union wage effect. Although empirical support for monopsony is mixed (Adamache and Sloan, 1982; Hirsch and Schumacher, 1995, 2005; Matsudaira, 2010), a sufficient number of studies have found evidence consistent with the presence of monopsony power for firms that employ nurses, which lends credibility to this argument (Hurd, 1973; Link and Landon, 1975; Bruggink *et al.*, 1985; Robinson, 1988; Sullivan, 1989; Currie *et al.*, 2005; Staiger *et al.*, 2010).

Second, both Sloan and Steinwald (1980) and Salkever (1984) find that union effects vary depending on the number of years a union has existed, with greater wage effects found for older, more established unions. Given the relatively new status of nurses' unions during the period when many of these studies were conducted, the full impact of bargaining may not yet be fully established. Third, as Nicholson (2003) notes, economists such as Pencavel (1984) and MaCurdy and Pencavel (1986) have modeled unions as utility-maximizing entities that negotiate with firms over both worker rents as well as the quantity of union members employed. Although no studies have explicitly focused on the employment effects of nurses' unions, the inclusion of minimum staffing language in most union contracts (Clark and Clark, 2006), as well as recent efforts by unions to mandate staffing levels at hospitals and nursing homes, is consistent with these models. Finally, Adamache and Sloan (1982), and Hirsch and Schumacher (1998) find evidence of a substantial union threat effect, wherein nonunion employers may offer higher wages to their workers to reduce the threat of unionization. As Ichniowski

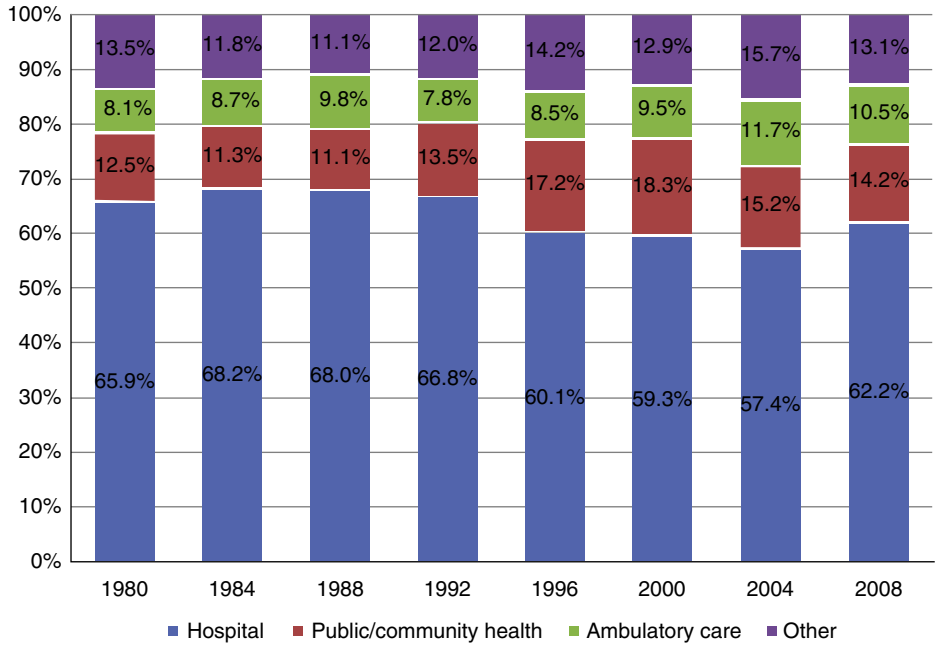

Figure 3 Employment settings of registered nurses, 1980–2008. Data from Health Resources and Services Administration (2010). *The registered nurse population findings from the 2008 National Sample Survey of Registered Nurses*, U.S. Department of Health and Human Services. Available at: http://bhpr.hrsa.gov/healthworkforce/rnsurveys/rnsurveyfinal.pdf (accessed 27.06.13).

et al. (1989) indicate, failure to adequately control for threat effects may underestimate the full effect of unions on employee compensation.

Nurses' Unions and Firm Performance

What unions do to productivity is one of the key factors in assessing the overall economic impact of unions. Given the importance of nurses for the firms in which they are employed, nurses' unions have the potential to substantially affect firm performance. Health care production is particularly labor intensive, with nurses accounting for 30% of hospital costs (McCue *et al.*, 2003). Nurses are a crucial part of the hospital production function and are, as one hospital Chief Executive Officer said, "the heart and soul of the hospital" (Draper *et al.*, 2008, p. 2). The nursing staff in a hospital is by far the most productive labor input, with a marginal product nearly three times as large as that of any other hospital input (Jensen and Morrisey, 1986).

Hirsch (2007) identifies three routes through which unionization-induced productivity gains can be realized: (1) union-induced wage increases may induce increases in technical efficiency; (2) reductions in turnover costs; and (3) productivity-enhancing personnel policies resulting from increased employee involvement in the production process. Although wage increases have been found to induce factor substitution and reduce quality for nursing homes (Cawley *et al.*, 2006), a number of studies document the beneficial effects of turnover reduction and increased employee involvement in hospital settings in both the USA and the UK (Propper and Van Reenen, 2010; Cebul *et al.*, 2008; Phibbs *et al.*, 2009).

Nurses' Unions and Hospital Output

Older studies analyzing the long-term performance effects of nurses' unions in the hospital industry have generally concluded that unions adversely affect health care production, and that the effects are especially relevant for hospitals with an established union presence. Sloan and Steinwald's (1980) estimates indicate that average hospital costs increase 2–3% in the year collective bargaining is introduced, with larger effects of 4–6% for more established unions. Salkever (1982, 1984) also finds evidence of larger union effects for established unions. His analysis suggests that union impacts on total costs are not positive during the first 2 years of unionization, but that a union presence increases hospital costs by 3.3–9% overall. Though not focused on nurses specifically, Sloan and Adamache's (1984) analysis of a national sample of AHA member hospitals shows an increase in hospital costs per adjusted patient day and adjusted admission of 3.5% and 4.1%, respectively, at unionized hospitals in which there were no recent incidents of labor strife. Their results are larger for unionized hospitals with a recent strike or job action; costs per adjusted admission in these hospitals are 9–10% higher than at nonunionized hospitals.

Of note in this literature are the suggested mechanisms through which these cost increases occur. Sloan and Adamache (1984) attribute their findings entirely to the cost impacts of the union wage effect, implying no union productivity effect. Salkever (1984) and Groshen and Krueger (1990), however, attribute their findings primarily to nonwage factors. Salkever (1984)

estimates that nonwage components account for two-thirds of the cost increase due to unionization, whereas Groshen and Krueger (1990) indicate that unionized hospitals are more limited in their ability to adjust wages and staffing levels than are nonunionized hospitals. Furthermore, both of Salkever's studies attribute hospital cost increases to employee groups other than nurses; when nurse unions are separately analyzed, he finds negative and insignificant effects of RN unions on costs.

Register's (1988) analysis of the union effect on hospital production was the first to examine the productivity effects of unions using data collected after the introduction of Medicare's Prospective Payment System (PPS). Although hospital reimbursement was cost-based before the introduction of PPS in 1983, under PPS, hospitals were reimbursed a fixed amount for each diagnosis-related group regardless of the actual expenses incurred in caring for a patient. Because this created new incentives for efficient operation, it became more important to realize beneficial union productivity effects after the introduction of PPS. His study finds evidence of productivity effects using both a national sample and state-specific data, and indicates that average costs at unionized hospitals are approximately 9% lower than at nonunionized hospitals.

Effects on Quality

Although the aforementioned studies base their conclusions on measures of hospital output such as total discharges and patient days, none of these studies are able to account for the quality of production. Quality is a major concern in health care, and is often thought of as a more important dimension of production than in other industries (Gaynor, 2006). Furthermore, quality is costly; Romley and Goldman (2008) find that an interquartile improvement in hospital quality would increase hospital costs by nearly 50%. Thus, an analysis of the effects of nurses' unions on hospital production that fails to account for the role of nurses' unions on the quality of hospital services could lead to erroneous conclusions regarding the full extent to which unions affect productivity.

Seago and Ash (2002) and Ash and Seago (2004) are the only studies to directly address this concern in their study of 344 California hospitals from 1993. Their studies analyze the effects of nurses' unions on heart attack mortality, using risk-adjusted heart attack mortality rates collected as part of a California Hospital Outcomes Project. Their findings indicate that risk-adjusted heart attack mortality rates for hospitals with unionized nurses are 5.5% lower than at nonunionized hospitals. Though their identification strategy cannot rule out the potential for nonrandom selection of unions into high-quality hospitals, they argue the potential for the selection of unions into low-quality hospitals is likely as well, given the potential for poor employee morale in these facilities. Consequently, though their study addresses the issue of patient selection in a particularly thorough manner given the constraints of their data, their discussion stops just short of arguing for a purely causal interpretation of their results.

Impact of the Labor Relations Environment

The state of the labor relations environment can also greatly impact productivity within a unionized firm. A number of multi-industry studies provide evidence that productivity can deteriorate as a result of strikes and labor unrest (Neumann, 1980; Neumann and Reder, 1984; Becker and Olson, 1986; Kramer and Vasconcellos, 1996; Kleiner *et al.*, 2002). Strikes and poor labor–management relations have also been shown to negatively impact the quality of production. For example, Krueger and Mas (2004) found that tire defect rates were particularly high at a tire plant during periods of labor unrest, and Mas (2008) found that workmanship for construction equipment produced at factories that experienced contract disputes was significantly worse relative to equipment produced at factories without labor unrest, as measured by the resale value of the equipment.

Given the importance of nurses to health care production, coupled with the complex nature of health care delivery where workers exhibit a high degree of interdependence (Cebul *et al.*, 2008), it is perhaps not surprising that health care quality has been shown to be particularly susceptible to labor unrest. Mustard *et al.* (1995) found that the incidence of adverse newborn outcomes increased during a month-long Ontario nurses strike, conjecturing that disruption in the normal standards of care was a contributing factor to the elevated rate of adverse outcomes. Gruber and Kleiner (2012) also find evidence of deterioration in patient outcomes in their study of 50 hospital strikes in New York State. Their results indicate that nurses' strikes increase in-hospital mortality by 18.3% and 30-day readmission by 5.7% for patients admitted during a strike. Furthermore, their results highlight the importance of employee tenure within a firm, as they find that hospitals staffed by replacement workers during strikes perform no better during these strikes than those that do not hire substitute employees.

Conclusion and Areas for Future Research

Although a considerable literature has investigated the effects of nurses' unions in the health care sector, the conclusions of this literature are far from definitive. Although the current body of research could be characterized as suggesting that nurses' unions raise wages and contribute to reductions in firm performance, sufficient evidence exists within this literature to challenge these conclusions. Further research could contribute to our understanding of the role of nurses' unions in five ways. First, the conclusions of the existing literature are based largely on old data that do not reflect the current state of the health care industry. For example, of the studies examining the production effects of health care worker unions, only Register (1988) uses data from a period following the implementation of PPS, and none of these studies examine the impact of unions after the growth of managed care and subsequent restructuring of the health care system. As Norrish and Rundall (2001) indicate, this restructuring affected aspects of nursing such as staffing ratios, and workload, both of which are likely to affect the role of nurses within the institutions for which they work. Thus, our understanding of the effects of nurses' unions would greatly benefit from research utilizing more recent data. Second, with the exception of Hirsch and Schumacher's research on union wage premiums, the aforementioned studies rely on cross-sectional variation to identify

their results. Given the potential for selection of unions into firms with higher wages and poor labor relations (which may contribute to reduced productivity), future work should employ updated econometric techniques to better account for this possibility. Third, more work on the impact of nurses' unions on the quality of hospital production is needed. With the exception of Ash and Seago's demonstration of a positive relationship between union status and patient outcomes, and Gruber and Kleiner (2012), who find a short-run decrease in quality due to strikes, little attempt has been made to quantify these effects, despite the claims of nurses' unions that patient care is a priority in negotiations (Clark and Clark, 2006). Fourth, although nurses' unions are similar in their objectives across countries (Clark and Clark, 2003) and union wage and productivity effects have been documented in a number of developed nations (Blanchflower and Freeman, 1992), little is known about the wage and productivity effects of nurses' unions in countries other than the USA. Finally, the mechanism by which nurses' unions affect hospital performance is not well understood. A better understanding of the means by which these unions affect productivity would assist in managerial and public policy decision making.

Nutrition, Economics of

M Bitler, University of California Irvine, Irvine, CA, USA
P Wilde, Tufts University, Boston, MA, USA

Introduction

The close relationship between economics and nutrition runs in two directions.

- First, nutrition influences economic conditions. Economic historian Robert Fogel has argued that improved nutrition was a decisive factor for improved health and successful economic development in Europe and the United States during the nineteenth and twentieth centuries (Fogel, 2004). More recently, rising rates of obesity have affected rates of chronic disease in developed countries, raising health-care costs.
- Second, economic conditions influence nutrition. Prices and incomes are leading determinants of food choices, dietary quality, and household food security.

This article addresses selected aspects of the economics of nutrition in developed countries. The economics of nutrition in developing countries are discussed in other chapters. Developed countries (and some less-developed countries) simultaneously face nutrition problems from both overconsumption and underconsumption. Throughout this article, the United States is taken as a case study for the developed world, in part because of the easy availability of data.

Four leading causes of death in the United States are influenced by dietary choices: heart disease, cancer, stroke, and diabetes. Increased rates of overweight and obesity in recent decades have been associated with each of these diseases. This has happened at the same time as rates of being overweight or obese among adults have increased from 50% of men and 40% of women in the early-1960s to 73% of men and 64% of women in the mid- to late-2000s (National Center for Health Statistics (2011)). In the United States, obesity may be responsible for $147 billion per year in medical costs, approximately 10% of all medical expenditures (Finkelstein *et al.*, 2009), with some economists estimating even larger effects.

Meanwhile, the federal government assesses the extent of food-related hardship in the United States using a survey-based measure of food insecurity, which is defined as not being able to afford sufficient food for an active healthy life for all household members at all times. Based on responses to questions in the Current Population Survey, the US Department of Agriculture (USDA) estimates that 17 million households (or 14.7% of all US households) were food insecure in 2009. In 4.6% of US households in 2009, the survey respondent reported experiencing hunger at some point during that year.

This article focuses on economic principles and research that are useful for understanding policy decisions about nutrition issues. Section The Effect of Economic Conditions on Nutrition describes how prices, income, and other factors may affect nutrition. Section A Framework for Nutrition Policy Options summarizes economic as well as commonly applied noneconomic perspectives on policy options to address nutrition concerns. The remaining sections review real-world applications related to four leading categories of policy responses to nutrition concerns: The next four Sections Food Assistance Programs, The Economics of Information Policy, Direct Interventions: Taxes and Subsidies, and Government Supply Interventions discuss food assistance programs; policies to improve nutrition information; taxes and subsidies to guide consumer food choices; and other government interventions to affect supply. The final Section Behavioral Economics: Nudges discusses recent insights from behavioral economics regarding policies to nudge consumers in the direction of healthier choices.

The Effect of Economic Conditions on Nutrition

As theoretical foundations, economists use both (1) a traditional simple theory of consumer choice and also (2) more elaborate theories that more specifically address health and nutrition issues.

The traditional economic theory of choice suggests that rational consumers seek to purchase a bundle of goods (x_1, x_2,..., x_k) that satisfies their preferences (represented by the utility function U) and is feasible given the budget constraint. Because the budget constraint depends on the consumer's income (Y) and the prices of the goods (p_1, p_2,..., p_k), the theory suggests that consumer choices respond in a systematic way to prices and incomes. Formally, the consumer solves the choice problem:

$$\text{Max } U(x_1, x_2,..., x_k),$$
$$\text{subject to } p_1x_1 + p_2x_2 + ... + p_k\, x_k \leq Y$$

For normal goods, if income increases, then the quantity purchased increases. In standard cases, if the price increases, then the quantity purchased decreases. Goods whose consumption amounts tend to rise and fall together (such as peanut butter and jelly) are complements: if the price of a good increases, then the quantity purchased of a complementary good decreases. Other goods (such as beef and pork) are substitutes: if the price of a good increases, then the quantity purchased of a substitute good increases. The responsiveness of these price and income effects is measured using elasticities, which denote the percentage change in consumption of a food in response to a 1% increase in the explanatory variable.

In studying nutrition issues, economists have in various ways extended the simple traditional theory of choice to take account of the health consequences of food choices. Consider a consumer who must choose goods to purchase and the amount of time to spend on an array of activities (z_1, z_2,..., z_k), including daily hours of sleep, work, watching TV, exercise,

grocery shopping, and cooking. Just as there is a budget constraint for total purchases, there is also a time constraint for the total number of hours available in a day. Such extended theories of choice offer insight into nutritionally relevant decisions. For example:

- Weight change from one month to the next depends on the amount of food energy consumed and the amount of energy expended on daily activities;
- Dietary quality depends in part on how the consumer combines purchased food with time spent in activities (as when a consumer chooses between a fast-food meal and a home-cooked meal);
- The time costs of preparing food may influence consumer choices among restaurant meals, convenience food, and home-cooked meals;
- The quality and convenience of healthy food options in the local food retail environment may influence consumer food choices;
- Consumer choices about food purchases and activities may reflect preferences in direct ways (as when one eats the foods one likes or does the activities one enjoys) and also indirect ways (as when one spends time in difficult physical exercise or eats less-preferred foods because of their healthiness). Recent work using household-level data from the US, France, and the UK, by Dubois *et al.* (in press) suggests preferences may play a large role in food choice across countries in addition to the role of prices and nutrient characteristics.

The traditional theory of choice points our attention toward trends in food prices and incomes. With regard to prices, one important pattern in the United States is that the price of food has fallen relative to the price of other goods and services. A second pattern is that prices evolve differently for some food groups than for others. Using 1981 as the base time period, Figure 1 shows in subsequent months how each food group's price increased relative to the average increase in the level of prices for all foods and beverages combined. Thus, by 2008, the price of fruits and vegetables had increased most rapidly (index ≈ 130%), the price of food away from home had increased at the same rate as overall food and beverage average prices (index ≈ 100%), and the price of soda and other nonalcoholic beverages had increased much more slowly than the overall average (index ≈ 75%). These trends have raised the concern that comparatively more healthy choices have become relatively more expensive. For example, a French study found that energy dense foods like fats and oils, sugar, refined grants, and others were the cheapest (Drewnowski and Darmon, 2005).

With regard to incomes, the United States is sufficiently prosperous that food uses up less than 10% of income for most households. Yet, there remains a significant population of low-income Americans for whom the income constraint is more influential. The overall US poverty rate (share of persons in families with incomes below the official poverty line) recently increased from 11.3% in 2000 to 15.1% in 2010, which nearly equals the peak levels of 15.2% during the recession of the early-1980s. Real median household income rose only slowly from 1980 to 2000 and did not increase further after 2000.

Beyond prices and incomes, more elaborate nutrition-oriented theories point our attention toward additional broad trends in recent years. Time spent preparing food has fallen as technologies have changed. At the same time, work has

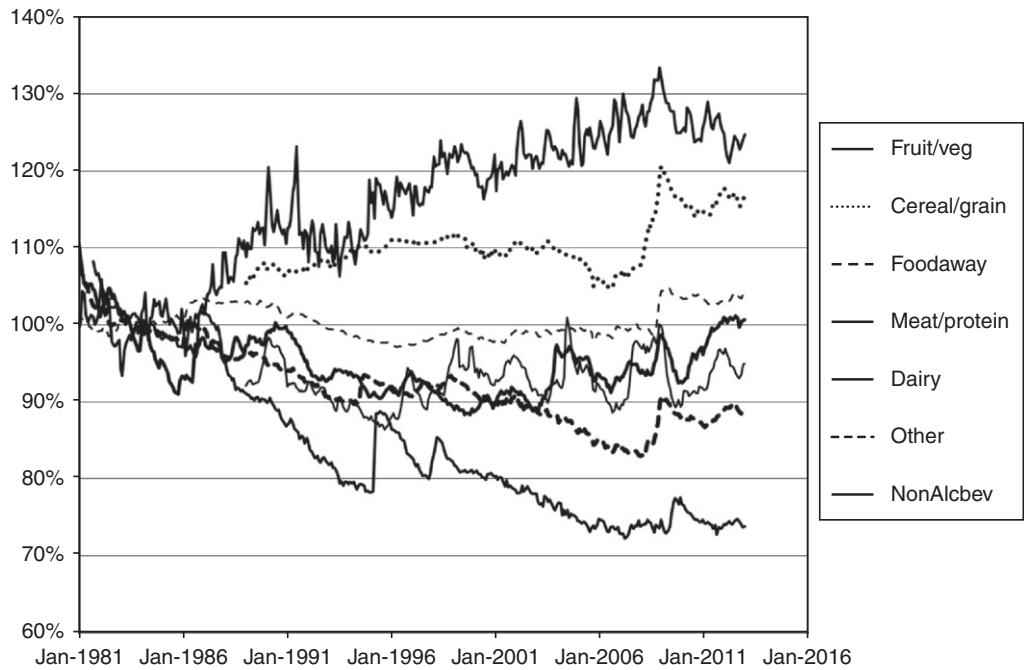

Figure 1 Relative prices of various foods, seasonally adjusted US city averages, 1981–2010 (BLS Consumer Price Index).

changed, perhaps reducing calories expended thereby. Women are increasingly in the workforce and spending less time in home production. Restaurant food and convenience food have become more important food sources.

A Framework for Nutrition Policy Options

Market Outcomes and Market Failures

Economic theory suggests a rationale for society to rely predominantly on private-sector markets to produce and distribute food. At their best, markets can overcome major challenges in motivating economic actors to make socially beneficial production and consumption decisions, while also providing them with the information they need to do so. The traditional economic theory suggests that governments should defer to market outcomes except in specific circumstances of 'market failure.' Several market failures that have been suggested as motivations for government will be discussed. In addition, other noneconomic perspectives with influence in food and nutrition policy will be discussed.

Economists focused on nutrition concerns, particularly obesity, have suggested three market failures that could motivate government action.

- Food choices of children. Most economic theory assumes that consumers are rational adults who can make their own spending decisions. There is a strong justification for government institutions, such as public schools, to promote nutrition for children. (Public health motivations for policies that also affect adults are mentioned below.)
- Imperfect information. Market outcomes are efficient only if consumers (and other actors) have the information they need to make purchases that satisfy their preferences. Consumer preferences include nutritional qualities and food safety as well as the more obvious taste qualities of food. Private-sector markets offer plenty of profit incentive for providing food that tastes good, but they may offer an insufficient incentive for providing information about nutrition qualities. Asymmetric imperfect information (discussed in Section Imperfect Information) is a commonly cited justification for government activities that affect the food system.
- Negative externalities. Market outcomes may not be optimal if there are externalities, where one person's decisions affect other people's well-being through nonmarket interactions. One type of interaction comes from the operation of insurance and health programs. For a person who receives health care from the government, the financial costs of illness are paid largely by taxpayers. Even for people who have private insurance, through their employer or by paying their own insurance premiums, financial costs of illness are shared with other people in the same insurance risk pool. It seems possible that insurance markets could reduce the incentive to maintain a healthy weight. However, some economists suggest that labor markets may already partly compensate for variations in insurance costs, by paying some workers more than others, in which case the negative externalities through health insurance markets would be smaller (Bhattacharya and Bundorf, 2009).

There are several additional reasons why food and agricultural markets may not satisfy the traditional assumptions of perfect competition. In some industries, there may be few competing firms. In other industries, such as the seeds for genetically modified food crops, patent rights may give a small number of firms significant market power. In yet other industries, such as food manufacturing and quick service restaurants, the predominant industry structure may be monopolistic competition, where each firm supplies differentiated branded food products and yet must compete to a certain extent with other firms that provide similar products. The authors return to the topic of differentiated products in discussing food advertising in the Section The Economics of Food Advertising.

Imperfect Information

A situation of imperfect information is described as 'asymmetric' if the producer knows more about a food product's attributes than the consumer does. Relevant attributes may include taste, wholesomeness, safety, and nutrition qualities. Under asymmetric information, food product attributes may be classified based on how the consumer learns about the product:

- For 'search attributes,' the consumer can perceive a product's quality even before purchase.
- For 'experience attributes,' the consumer can discover a product's quality after purchasing it. Even though it may be impossible to reverse a particular purchase if the product quality was unsatisfactory, the consumer can learn lessons that are useful for future purchases.
- For 'credence attributes,' the consumer relies to a greater extent on information provided by others, including the seller or by a third party.

A single good may have several attributes. For example, a bag of organic carrots may be seen as a search good for a shopper trying to follow the Dietary Guidelines recommendation to consume orange vegetables; the same bag may be seen as a credence good for a shopper seeking organic produce. Common government responses to asymmetric information range from process regulations (such as specifying what additives are safe to use in food) to food-grading systems to labeling rules (discussed in Section Policy Response).

In addition to having imperfect information, consumers may not satisfy the traditional economic theory's assumptions about rationality. A lively and rapidly growing body of research addresses behavioral economics, including strategies for 'nudging' economic actors in the direction of more optimal food choices, without taking away their freedom to make their own decisions (see Section Behavioral Economics: Nudges).

Policy Response

Economists commonly favor government policies that narrowly target a market failure that has been identified. In situations where there is no market failure, such as when well-informed adults freely choose and accept the consequences of

unhealthy eating patterns, many economists say there is no need for a government policy response.

In addition to the economic perspective on diagnosing market failures, there are other motivations that strongly influence government policies regarding nutrition and thus are given attention here to help researchers understand ongoing policy debates.

- A 'public health' perspective gives less deference to market outcomes and favors use of a broad range of policies to affect food choices and dietary quality.
- A 'consumer activist' perspective argues that food and beverage companies create a toxic food environment and should be more strongly regulated.
- A wide variety of 'producer' perspectives favor government nutrition policies that promote the interests of particular sectors of the agricultural, food manufacturing, and food retail industries.
- An 'egalitarian' perspective focuses on income or resource inequality as a motivation for government intervention in food and agricultural markets. For example, a motivation for federal food assistance programs is not just nutrition promotion but also poverty alleviation.

Responding to both economic and noneconomic motivations, leading policies and policy proposals fall into four broad categories, discussed in the next four sections: food assistance programs, information policies, direct price interventions such as taxes and subsidies, or government restrictions or subsidies to supply. The authors conclude with a discussion of behavioral economics and nudges.

Food Assistance Programs

One way for governments to address nutrition concerns is directly, through food assistance and nutrition programs. This section provides some background about food assistance programs, explains how such programs affect household budgets, and describes research that seeks to measure program effects.

Background on Food Assistance Programs

Food assistance programs may provide food through several mechanisms, including the following: (1) broadly targeted food benefits that low-income consumers may use to purchase food through normal retail channels, (2) more narrowly targeted food vouchers for purchase of specific foods and beverages with particular nutritional qualities, and (3) direct provision of free meals. In addition to food assistance programs, more general income support programs may have benefits for nutrition or food security. This section principally uses US food assistance programs as examples of each type of program, because food assistance plays a bigger role in the social safety net in the United States than in other developed countries.

1. Broadly targeted food benefits. In the United States, the largest food assistance program is the Supplemental Nutrition Assistance Program (SNAP), formerly known as food stamps. SNAP provides targeted benefits for food and nonalcoholic beverages from authorized grocery retailers through Electronic Benefit Transfer (EBT) cards similar to debit cards. It served 40.3 million people per month on average during fiscal year 2010 at a total cost of $68.2 billion. Program eligibility historically has depended largely on having income less than 130% of the federal poverty standard, so the program is counter-cyclical, and caseloads have recently risen to record levels during the recent recession. The primary purpose of the program is to prevent hunger and promote food security.
2. Narrowly targeted food vouchers. The Special Supplemental Food Program for Women, Infants, and Children (WIC) provided nutrition counseling, services, and a package of particular high-nutrient foods and infant formula to approximately 9.2 million people per month, at a cost of $6.8 billion in fiscal year 2010. Only pregnant and postpartum women, infants, and children through the age of 4 years are eligible. Eligibility also requires household income less than 185% of the federal poverty standard or participation in one of several other safety net programs, plus evidence of nutrition risk broadly defined.
3. Direct provision of meals. The National School Lunch Program served 31.6 million lunches, and the smaller and newer School Breakfast served 11.6 million breakfasts, on average, each school day in fiscal year 2010, at a cost of $13.3 billion. A free meal requires income less than 130% of the federal poverty standard, though all school provided meals in schools participating in the federal school meals programs are subsidized to some extent. The Child and Adult Care Food Program served meals in centers and home day care settings, costing $2.6 billion. These programs have primary nutrition goals, but antihunger effects are acknowledged as important secondary purposes.
4. Cash assistance, cash-based social insurance, and tax credits. Finally, governments provide cash welfare, which can be used for food as well as other products. In 2009, 1.8 million families with children obtained Temporary Assistance for Needy Families cash benefits, with total cash benefit payments amounting to $9.3 Billion. Supplemental Security Income (SSI) provided $41 billion in cash assistance for 6.4 million low-income individuals who were disabled, blind, or elderly. Unemployment insurance is typically viewed as a social insurance program but is also another important part of the safety net, with payments of approximately $131 billion in 2009. Tax credits such as the Earned Income Tax Credit may also play a role.

How Food Assistance Affects Household Budgets

The effect of food assistance on food choices depends on the role of program benefits in the household budget. To understand this role in a rigorous way, it helps to compare the effects of: (1) providing a targeted food assistance benefit or (2) providing a hypothetical equivalent cash subsidy. For example, consider a monthly voucher that provides a family with $50 for use in purchasing qualifying food products. The hypothetical comparison program provides $50 in cash.

- If a family with the hypothetical cash benefit would have spent less than $50 per month on qualifying foods, the family is called extramarginal or constrained by the form of the benefits, because the voucher program causes more food spending than would otherwise have occurred.
- In contrast, if a family with the hypothetical cash benefit would have spent more than $50, the family is called inframarginal or unconstrained by the form of the benefits, because it is able to purchase its desired amount of qualifying foods under either the targeted voucher or the hypothetical cash program.

Economic theory predicts that a marginal increase in targeted food assistance benefit will strongly affect food spending for extramarginal participants, and the increase will only weakly affect food spending for inframarginal participants. Empirical research commonly finds bigger program effects than expected for inframarginal participants in targeted food assistance benefits programs (Meyerhoefer and Yang, 2011).

Measuring the Effects of Food Assistance Programs

A challenge discussed elsewhere in this volume is obtaining causal estimates of the effects of food assistance programs. Due to selection bias in who takes up these programs, one cannot merely compare the outcomes of recipients and others. Given that participation is tied to low income and asset holdings or poor nutritional status or both, it is clear that comparisons of outcomes for program recipients to those of the general population are likely to be biased estimates of the effects of these programs. Even among those eligible for the programs, recipients may be positively or negatively selected compared with eligible nonparticipants due to the fact that participation is a choice variable. If recipients are healthier, more motivated, or more knowledgeable about the programs than nonparticipants, comparisons may suggest the program has a more positive effect than it actually does. Alternatively, if participants are more disadvantaged than eligible nonparticipants, comparisons of these two groups could lead to underestimates of the effects of the program. For example, skeptics often attribute many of the positive effects of the WIC program to positive selection among women participating in the program, although Bitler and Currie (2005) find little evidence than WIC participants who also participate in Medicaid are positively selected.

There are several approaches that researchers have taken to avoid selection bias (Gundersen *et al.*, 2011). Just four approaches are mentioned here. One approach is to compare outcomes among individuals in geographic areas with different program rules. This approach is comparatively less useful for SNAP policies that are national in scope and comparatively more useful for SNAP policies that have substantial state-to-state variation (Ratcliffe *et al.*, 2011).

A second approach, when program rules do not vary across areas is to look at the effects of the introduction of programs; comparing otherwise similar individuals in places before and after programs are introduced. The introduction of the food stamp program led to increases in food consumption (Hoynes and Schanzenbach, 2009), whereas the introduction of the WIC program led to an increase in average birth weight (Hoynes *et al.*, 2011). A limitation with this approach is that program rules may change over time, potentially raising questions about the ongoing validity of historical estimates for evaluating programs today.

A third approach to studying the effects of programs is to use random assignment. If program administrators are able to randomly assign an offer of program participation to otherwise identical eligible individuals, then comparisons of those assigned to be eligible for the program with those denied the option to participate can yield unbiased estimates of the effects of the program. In the case of food stamps, there have been several demonstration projects funded by USDA, which have yielded evidence about the effects of cashing out food stamp benefits on food spending.

A fourth approach to studying the effects of such programs is to use variation in program rules that use exogenous thresholds in income, age, or other characteristics to assign program eligibility. These regression discontinuity approaches compare otherwise similar individuals who because of small differences in a characteristic such as age face different program rules, while controlling for age. These 'regression discontinuity' approaches typically bring both considerable internal validity and limited external validity given the local nature of the estimates they yield.

Much progress has been made on the effects of food assistance programs, yet there are outstanding questions. For example, how does a program like WIC obtain positive results with relatively low benefit levels? What channels do effects of these programs work through? What is the role of information in the effects of these programs?

The Economics of Information Policy

A second type of public policy intervention to address nutrition concerns is to seek to influence the information environment in which consumers make food-related decisions. For example, governments may seek to promote nutrition through dietary guidance, regulation of food labeling, and regulation of advertising. Private mechanisms that affect quality include brand names and reputation as well as standard setting.

Information policies may be classified on a spectrum, running from mandatory information, to voluntary information provision chosen freely by the producer, to voluntary information with restrictions imposed by the government, to outright prohibitions against a particular type of information provision. This spectrum is shown in **Figure 2** (adapted from Wilde (2013)).

At each point along this spectrum, the policy debate depends in part on what one believes are the real facts about the relationship between food decisions and health. Some information sources recommend diets that are low in carbohydrates; some recommend diets that are low in fat and high in plant foods; some say humans as omnivores can thrive on either of these diets so long as we avoid highly processed manufactured foods. In the United States, the federal government's 'Dietary Guidelines for Americans,' issued every 5 years, recommend a diet with plenty of fruits, vegetables, whole grains, and low-fat dairy products, within the context of

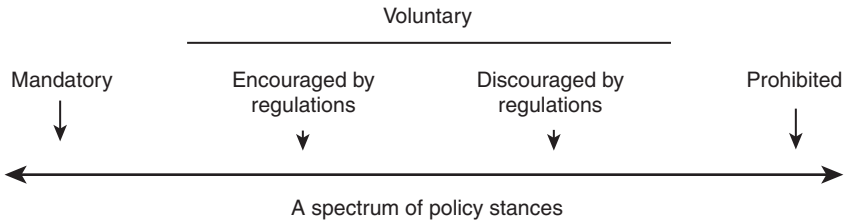

Figure 2 A spectrum of policy stances on information provision.

an overall diet that maintains a healthy weight by balancing total energy intake with energy expenditure needs. In promulgating dietary guidelines, the government seeks to remedy some of the confusion in private-sector information markets by identifying dietary principles that are supported by the balance of the scientific evidence.

There is comparatively little need for government regulation of food labeling and advertising for food attributes such as taste, which can be confirmed by search and experience, because correct information about such attributes is readily available to the consumer. The government has a more substantial role in regulating claims about nutrition and health qualities, which are credence attributes.

Yet, even for credence attributes, markets sometimes function well on their own. Even before nutrition facts panels became mandatory in the early-1990s, many food products carried nutrition information voluntarily. One might at first suspect that only the healthiest products would provide nutrition information, but competitive pressure may force a wider range of products to disclose information. Once consumers catch on that nondisclosure indicates that a product lacks a healthful characteristic that competitors have, there is an incentive for all but the least healthy products to disclose information voluntarily. This theory of competitive information disclosure works better in some situations than in others. For example, if all products in a food category share a certain characteristic, such as the dietary cholesterol in eggs, there is no incentive for companies to advertise the shortcomings of their competitors.

Regulation of Food Labeling

US food labeling policies include rules that mandate some kinds of information provision and rules that prohibit other kinds. In the first half of the twentieth century, the US federal government established standards of identity for many food products and began requiring disclosure of net weights and ingredients for manufactured food and beverages. Nutrition facts panels were introduced on a voluntary basis in the 1970s and became more widespread during the 1980s. Since the passage of the 1990 Food Labeling and Education Act (NLEA), nutrition facts panels have been mandatory on most packaged food in the United States. More recent legislation has required mandatory country-of-original labeling (COOL) on a wider variety of food products. The 2008 Farm Bill for the first time required disclosure of calorie information in chain restaurants. Bollinger *et al.* (2011) look at the effects of a policy in New York City requiring chains to post calories for food on purchases at Starbucks, finding that average calories per transaction fell, and this was through changes in purchases of food, not beverages.

Until the 1980s, the Food and Drug Administration (FDA) generally refused to permit health claims on food labels, fearing that consumers would be misled. The 1990 NLEA allowed health claims on food labels if there is 'significant scientific agreement' about the merit of the claims. For example, many low-sodium products may use a health claim that reducing sodium can lower high blood pressure.

Subsequent legislation and court cases have forced the FDA to allow a broader range of claims. The 1994 Dietary Supplement and Health Education Act (DSHEA) led to a weaker standard of evidence for what are called structure–function claims, which do not mention a specific disease as health claims do. For example, 'calcium builds strong bones' is a structure–function claim. More recently, in response to a successful lawsuit about health claims on dietary supplements, the FDA has begun to allow health claims for which the evidence is not strong enough to quality as significant scientific agreement, so long as the food package label includes a disclaimer describing the level of scientific evidence for the claim.

Remedies for the problem of misleading claims may come from the private sector, the government, or both in combination. The for-profit media frequently cover food issues, describing recent research in nutrition science and food safety. Private not-for-profit organizations also can serve as independent watchdogs. In some cases, government agencies can take steps to share information more widely, thereby allowing private sector market incentives to function better. Jin and Leslie (2009) study the question of reputational incentives through the example of restaurant hygiene. Using data from Los Angeles County, they find that reputational incentives indeed provide a market-based mechanism for quality, but that quality increased further when the government-issued hygiene report cards for restaurants.

In one business model, not-for-profit organizations and for-profit businesses may offer third-party certification of nutrition labeling claims made by food companies. For example, in return for a fee paid by food companies, the American Heart Association (AHA) allows food manufacturers to label qualifying products with an AHA heart-check symbol certifying that they are low in saturated fat and cholesterol or high in whole grains. In still other cases, the government helps set standards for a food label claim, which then may be used voluntarily by private-sector businesses that meet the standard. For example, the 'certified organic' label may only be used on foods that meet a checklist of process standards, which exclude the use of certain chemicals and practices in

agricultural production and food processing. Qualifying food producers choose voluntarily to produce food organically. Food retail chains have considerable influence over the adoption of voluntary food labeling strategies. If a retailer with a large market share increases its marketing of certified organic products, or develops a new front-of-pack nutrition label, these decisions influence decisions by food manufacturers and other suppliers throughout the food marketing chain.

The Economics of Food Advertising

Under perfect competition, producers of a standardized commodity have less incentive to advertise, because each firm's investment in advertising would reap gains in consumer demand that are shared with all of the firm's competitors. Each perfect competitor would have an incentive to be a 'free rider,' allowing competitors to bear the cost of advertising. Clearly, this model of industry structure does not provide a compelling description of the food and beverage manufacturing industries or the chain restaurant industry, where heavy advertising is widespread.

Instead, a model of industry structure that better describes these industries is monopolistic competition. In this model, each firm is the monopoly producer of its own branded product, and it competes to a certain degree with competitors who are similar. Competitors may be similar because they are physically nearby, as in the case of local food retailers who compete most strongly with other firms that are geographically close. Competitors also may be similar in a psychological sense, as in the case of quick-service restaurants that serve a similar clientele and occupy a similar marketing space. Under monopolistic competition, firms have a strong incentive to advertise.

Direct Interventions: Taxes and Subsidies

Some public-health advocates, researchers, and policy-makers recommend that the government go even further, guiding consumers toward healthier diets by altering prices, taxing less healthy foods and beverages and subsidizing their more healthy counterparts. In 2010, the Director of the Centers for Disease Control and Prevention, Thomas Frieden, and two CDC colleagues wrote: "A tax of 1 cent an ounce on sugar-sweetened beverages – about a 10 percent price increase on a twelve-ounce can – would be likely to be the single most effective measure to reverse the obesity epidemic" (Frieden *et al.*, 2010).

The success of such a proposal depends on the size of the consumer response to a change in the price of food. Recall from Section 2 that an own-price elasticity shows the percentage change in a product's quantity consumed, in response to a 1% increase in the product's price. Economists who study taxation policy recommend that taxes be placed on goods for which demand is inelastic (not responsive to a change in price), because such taxes raise more revenue and do not distort the market equilibrium as much as taxes on goods with elastic demand, causing smaller dead-weight losses from the policy. In contrast, health policy advocates tend to prefer that taxes be placed on unhealthy foods whose demand is elastic (responsive to a change in prices), because these taxes have the biggest impact on food choices. Some clever proposals seek the best of both worlds, by taxing an unhealthy food and earmarking the resulting revenue for health promotion programs.

Table 1 Selected own-price, cross-price, and expenditure elasticities for food demand

Description	*Elasticity*
Mean value of the own-price elasticity for selected foods (literature review by Andreyeva *et al.*, 2010):	
Food away from home	−0.81
Soft drinks	−0.79
Juice	−0.76
Beef	−0.75
Pork	−0.72
Fruit	−0.70
Poultry	−0.68
Dairy	−0.65
Sweets/sugars	−0.34
Eggs	−0.27
Own-price elasticities for salty snacks (Kuchler *et al.*, 2004):	
Potato chips	−0.45
All chips	−0.22
US beverage demand elasticities, 1998–2007 (Smith *et al.*, 2010):	
Caloric sweetened beverages (own-price elasticity)	−1.264
Caloric sweetened beverages (elasticity of response to price of juice)	0.233
Caloric sweetened beverages (expenditure elasticity)	1.054
Juice (own-price elasticity)	−1.012
Juice (elasticity of response to price of caloric sweetened beverages)	0.557
Juice (expenditure elasticity)	0.878

There is a large research literature that seeks to estimate consumer demand elasticities. A sampling of results from many such studies is presented in Table 1. To interpret such estimates correctly, the reader must keep in mind that food groups are defined differently in different studies. For example, own-price elasticity for a narrowly defined food group with many substitutes (such as potato chips) will be larger in absolute value than the own-price elasticity for a more broadly defined food group with fewer substitutes (such as all types of chips combined).

Also, to correctly anticipate the nutrition consequences of a proposed tax, the reader must consider cross-price effects. For example, Smith *et al.* (2010) combine data on consumer grocery purchases of beverages from the Neilsen Homescan panel with data from the National Health and Nutrition Examination Survey on individual consumption of beverages and height and weight. They first use the variation across places in beverage purchases to estimate a demand system for the effects of price changes for caloric sweetened beverages on consumption of drinks. The corresponding price elasticities are used to predict the effect of a proposed tax on caloric sweetened beverages, not only on consumption of the targeted beverages but also on potential substitutes, including juice. Using their estimates, Table 1 shows that each 1% increase

in the price of caloric sweetened beverages might reduce intake of these targeted beverages by 1.264%, whereas simultaneously increasing the intake of juice by 0.557%. After considering both direct effects and such substitutions toward other beverages, the authors estimated that a tax-induced 20% price increase on caloric sweetened beverages would change overall food energy intake by enough to reduce adult overweight prevalence from 66.9% to 62.4% (Smith *et al.*, 2010). The Smith *et al*. study addresses issues missed in some other demand studies; including careful attention to cross-good price elasticities and differentiating caloric sweetened beverages from diet beverages; and is also clear about what cannot be estimate (the effect of food purchased away from home is naturally absent from data on grocery store purchases).

However, there is still a challenge in applying these or other estimates to predict effects of a large tax change on sugar-sweetened beverages. Many such demand studies make use of time series variation in prices and aggregate data on expenditures, which may or may not be applicable to changes in taxes and individual-level consumption. It is also challenging to find appropriate data to estimate effects fully on complements and substitutes for specific goods, and often the analyst has data only on purchases at grocery stores, or alternatively, consumption data with no corresponding price and location of purchase. One study that comprehensively analyses purchases across categories of goods using household data for 2002–07 while also accounting for local access to particular store types, demographics, prices, and nutrients is Harding and Lovenheim (2013), who simulate the effects of both product specific and nutrient taxes. Yet, ideally data on food at home and away from home would be available along with prices and quantities.

An alternative approach uses individual-level data and tax changes. Fletcher *et al.* (2010) find that for children and adolescents, tax-induced reductions in soft drink consumption are offset with increases in consumption of milk and other beverages, raising doubt about the value of such taxes in reducing obesity. Unfortunately, one limitation to this approach is that samples in datasets like NHANES are relatively small, and the combined state-year panel are limited by sample design.

Nutrition taxes face several sources of opposition. First, they generally are regressive, with a higher relative budget impact for low-income populations than for higher-income populations. Second, as noted throughout the article, there may be disputes over the nutrition science on which they are based, although one exception with somewhat broader – but far from universal – scientific support is a tax on caloric sweetened beverages. Quantifying the causal effects of prices and taxes on food consumption and health is an ongoing area of research where new approaches and data would be useful. New causal evidence awaits more policy interventions, better data on purchase prices and quantities at and away from home, or both.

Government Supply Interventions

The final set of policies we consider is related to increasing or restricting access to food. One subject which has received much attention is whether some areas have sufficient access to appropriate food. In a relatively large public-health literature, evidence is presented about the correlations between areas with a high concentration of low income residents and a dearth of large retail food stores selling healthy foods such as food and vegetables. Congress mandated in the 2008 Farm Bill that USDA study this so-called problem of food deserts (areas with limited access to affordable and nutrition food) and suggest policy responses, resulting in a report (USDA Economic Research Service, 2009), a food desert locator, as well as other action. Although there is ample evidence that some local areas have limited food access, little or no research has established the causes of such limited access, and such information is a key input to designing appropriate policies (Bitler and Haider, 2011). For example, limited access could be the result of supply or demand factors, and if it is the result of demand factors, supply interventions are not likely to ameliorate deficiencies. Yet further policy intervention seems likely, and may provide useful variation for new research.

Another policy lever that is widely discussed is zoning or other regulations limiting the types of food establishments or types of foods available in various locations. This is in part based on findings about locations of fast food outlets affecting calorie intake and obesity (Currie *et al.*, 2010).

Policy-makers also may limit sales of competitive foods in schools (competitive foods are all foods offered for sale at schools besides those provided by USDA school meals programs). Should more localities enact policies banning such sales, it may provide variation to understand how access to such foods affects school health. Schools facing financial pressures are more likely to allow competitive food sales and have students with larger BMI (Anderson and Butcher, 2006). However, some research finds that such sales do not necessarily lead to more consumption of junk food, suggesting substitution across in school and out of school locations (Datar and Nicosia, 2012).

Behavioral Economics: Nudges

The economic understanding of consumer responses to prices and income and the policy proposals for new subsidies or taxes and supply interventions all rely on an economic theory of consumer choice. A lively body of current economic research investigates situations where consumers do not behave rationally, perhaps leading to opportunities for 'nudging' consumers toward more healthful choices (Thaler and Sunstein, 2008).

Neoclassical theory predicts that consumers will eat less when the marginal cost of an additional unit – the price to the consumer – is higher. They will tend to overeat at an all-you-can-eat restaurant, because the marginal cost of additional food is zero, no matter what the entry price of the meal. Yet, surprisingly, recent research found that consumers of an all-you-can-eat pizza meal actually consumed more pizza if the price of the meal was higher (Just and Wansink, 2011).

These differences between actual consumer behavior and traditional economic assumptions about rational behavior do not mean consumers are irrational or foolish in the everyday sense of the term. Instead, these behaviors may show that consumers need to simplify the cognitive burden of difficult

decisions by following predefined heuristics or 'rules of thumb.' Some of these heuristics are the subject of considerable research:

- Default offerings may affect consumer choices. For example, if a quick service restaurant chain includes milk by default in children's meals, customers may agree to purchase the milk with the meal. Yet, if the chain includes soda by default, the customers may more frequently keep the sugar-sweetened beverage rather than make a special effort to request milk.
- Distractions also may affect consumer choices. For example, it has been found that consumers who were required to make other decisions at the same time were more likely to choose cake over fruit salad, whereas consumers who were not distracted were more likely to choose the healthier offering (Shiv and Fedorikhin, 1999). Hunger or time stress also may affect people's decisions.

This new approach to behavioral economics has raised some hopes for inexpensive nutrition improvements, by making subtle changes to the setting or environment in which choices are made. For example, some suggest that students in school meals programs might make better decisions if the location of the salad bar were altered, or if a different tender (cash or school meals program card) were required for different products. This approach also has generated renewed scrutiny of the empirical evidence for other health policy proposals, such as taxes on less healthy food or new labeling rules for restaurants (Loewenstein, 2011). Of course, many of the same lessons can also be used by food marketing professionals to promote food options with any health profile. Future research will determine whether these new tools of behavioral economics make a small or big difference for consumer choices. And, if the effect is big, future developments in both social and commer cial marketing will determine whether the changes are helpful for dietary quality. In either case, the willingness to scrutinize assumptions and follow the empirical evidence in new directions is entirely good news for future research on the economics of nutrition.

Nutrition, Health, and Economic Performance

DE Sahn, Cornell University, Ithaca, NY, USA

Glossary

Demographic dividend The period of time during the process of economic development where there is a dramatic drop in the dependency ratio owing to the lag between the drop in fertility that follows from reductions in child and infant mortality rates that can contribute to more rapid economic growth.

Health inequality Differences in the incidence of health care spending, access to health care, incidence of disease, and/or health outcomes between different populations groups.

HIV/AIDS Human Immunodeficiency Virus/Acquired Immunodeficiency Syndrome.

Life course An approach that examines how early events in a person's life influences future decisions and outcomes, and thus examines the sequencing of events in the life of an individual.

Worker productivity Measures the efficiency of production of a unit of labor, and is formally the total output per unit of input of labor.

Introduction

Health and nutrition outcomes are critical to the well-being of households and individuals and their economic productivity and prosperity. Although it seems evident that a debilitated worker will be less productive, there are numerous indirect, subtle, and complex pathways that link poor health and nutrition to economic output, such as sick children, or children of sick adults, being less likely to accumulate other forms of human capital, and disease-ridden societies with high infant and child mortality rates having higher fertility, with the consequent economic burdens associated with the risks of child bearing and a higher population growth rate. Compounding the challenges in understanding the impact of health on economic outcomes is the complexity of the temporal dimensions, as the productivity consequences of poor health extend far beyond the short term and affect outcomes across the life course and from one generation to the next.

The relationship between health and economic outcomes is particularly important in developing countries. First, health problems are most severe in these countries, and the ability to perform hard physical labor most important for employment. Second, self-employment and self-provisioning are of particular importance, and under such circumstances, reduced levels of output, from temporary ailments and disease, for example, can contribute to large consumption shortfalls – an outcome less likely to occur in more market-oriented economies. Third, the propensity for market failures, such as those of credit markets, will also simultaneously contribute to economic inefficiencies as mediated by the underinvestment in health and agricultural capital. This raises the prospect of the poor being caught in a low-level equilibrium with binding constraints in terms of time available to devote to the production of health, home production (e.g., care of children), and farm production.

It is also notable that the link between health and productivity is of special importance for women, who often assume a predominant role in the production of food crops. The greater vulnerability of women also results from the extraordinarily high maternal mortality and morbidity, with one of nine women dying during childbirth in some regions of the world. Additionally, women suffer the acute burden associated with social norms and behaviors that have resulted in them bearing the brunt of the ravages of human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS), especially in Africa. Finally, women have unique responsibilities in the home, particularly in terms of care of children. Health and nutrition shocks that adversely affect women not only adversely affect their productive role in labor markets but also impact their joint production role as caregivers for their children, and thus they induce a recurring and intergenerational cycle of crisis and deprivation.

Before turning to a discussion of the evidence on the relationship among health, nutrition, and economic outcomes, the author emphasizes that the imperative of, or justification for, improving health and nutritional status goes beyond their importance in promoting economic growth. Rather, well-being is multidimensional, comprising factors such as good health and adequate nutrition. These capabilities are intrinsically important, and merit recognition above and beyond their impact on productivity, output, and money metric measures of poverty. Although this article focuses on the contribution of health and nutritional status to productivity and economic outcomes, this may be of secondary importance relative to the intrinsic value of health.

Impact of Health on Economic Development

Macro and Cross-Country Evidence

Economic historians have argued persuasively that nutrition and health have contributed in an important way to increases in productivity and economic growth. Among the seminal work in this area are papers by Robert Fogel who showed that inadequacies in diet contributed to disease and early mortality, greatly limiting the possibility for productive work in eighteenth century England and France. His estimates indicate that

 doi:10.1016/B978-0-12-375678-7.00107-3

50% of Britain's growth since 1800 was attributable to increases in dietary energy available for work and improvements in the efficiency in the transformation of nutrients, particularly calories, into work.

Numerous other authors have examined cross-country associations among health, economic growth, and poverty. Some work employs general measures of health, such as life expectancy, whereas other studies focus on specific diseases, such as the impact of malaria, tuberculosis, and HIV/AIDS on economic output and growth. Among the numerous studies to directly estimate the impact of aggregate measures of health, particularly life expectancy, on economic output, it has been estimated that an increase in life expectancy of 10% will lead to an increase in economic growth of 0.4% per year. These estimates are consistent with similar research, including work that indicates that an increase in life expectancy of 1 year raises gross domestic product (GDP) per capita by 4%. Using adult survival rates to measure health, it has been reported that if health status were equalized across countries, the variance of log GDP per worker would be reduced by 9.9%. The results also suggest that eliminating health gaps would reduce disparities in country level mean incomes. But overall, the results show relatively small effects of poor health on economic development compared to studies that rely on cross-country regressions. Another article suggests an even more limited impact of health on economic outcomes, using an instrumental variable (IV) approach to tell a surprising story of how improvements in life expectancy led to lower GDP per capita. This unexpected result is explained by the fact that increases in worker productivity were offset by rapid population growth in the face of fixed land and a base of physical capital that was slow to adjust, contributing to declines in income. Despite the rigor and compelling nature of this article, it has been criticized for many underlying assumptions, particularly that lagged health has no effect on economic outcomes, and likewise, that it does not address possibilities such as whether reductions in fertility will offset population increases accompanying lower mortality.

In disease-specific literature, a malaria ecology index has been used as an instrument in estimating cross-country regressions of GDP per capita. The results show a dramatic impact of malaria on growth. A concern with this work, as with other such articles, is that of omitted variables contributing to the malaria index having a greater negative effect than it would otherwise have in a more fully specified model.

More recently, much of the attention on macroeconomic impacts of disease has focused on HIV/AIDS. Early work observed little impact on economic growth. This optimism was in fact based on a Solow-type growth framework where the impact of disease on growth was mitigated by a drop in the supply of labor relative to that of capital, which in turn increases the productivity of labor. It has further been suggested that there is a low impact of HIV/AIDS on growth through a process of the epidemic contributing to reduced fertility and a decline in the dependency ratio that subsequently leads to increases in per capita consumption as well as savings. It is assumed that such changes will not only increase investment but also provide resources for health and related support for those suffering from AIDS. Another article also shows little impact of HIV/AIDS. Using an IV technique that relies on the rate of male circumcision as an instrument, it argues that the differences are attributable to exogenous cultural factors. Although the exclusion restrictions are certainly open to debate, the authors show that the circumcision rate is a strong predictor of HIV prevalence, and that it is uncorrelated with other determinants of growth.

These optimistic assessments stand in contrast with other more sobering findings. One report, for example, finds that a 1% increase in HIV prevalence will contribute to a marginal impact on income per capita of negative 0.59%. It argues that the excess labor arguments that have mitigated the macroeconomic impacts of AIDS are not being realized. Another article estimated that GDP was reduced by 17% and per capita incomes by 8% between 1997 and 2010 as a result of the AIDS epidemic in South Africa. Another group of researchers have published an article discussing the possibly devastating effects of HIV/AIDS if the epidemic in Southern Africa continues unchecked.

Although such estimates are informative, the challenges of arriving at actual details of the impact of these communicable diseases on economic growth are clearly daunting. They depend on the economic structure of each country, the relative importance of agriculture, whether land or labor are greater constraints to growth, and the existence of economic and social infrastructure. Thus, there is a need to better understand the intricacies of how HIV/AIDS (and other diseases) are impacting economic relationships and performance and the role that mediating factors, such as the effects of large number of orphans on education capital, play.

Likewise, the extent to which interventions such as the provision of antiretroviral therapy (ART) are available will have an enormous impact on such estimates, both through mitigating the productivity consequences of the disease and the fiscal costs associated with governments contributing to the treatment costs. Most estimates of the economic costs of HIV/AIDS were made before treatment with antiretroviral drugs was widely available. Recent studies have shown a dramatic reversal in the physical well-being of those being treated, clearly reducing the costs of disease in terms of productivity losses. At the same time, the costs of treatment will be staggering. Although these may be largely born by foreign donors, the ability or willingness of the international community to sustain the financial support for ART is questionable and will likely result in more of the burden falling on patients and local health systems.

As the costs of disease in developing countries is considered, there is an epidemiological transition underway as infectious diseases become less prominently a cause of death and disability; instead, there is an emerging epidemic of chronic disease. For example, in 2000 there were more than 7 million cases of diabetes in Africa alone, and it is estimated that direct treatment costs would exceed purchasing power parity US$1000 per person. Treating diabetes and other noninfectious lifestyle diseases in the future will be a formidable challenge for households and governments, with both incurring large financial costs.

Finally, another channel through which improved health will impact economic outcomes is the so-called 'demographic dividend.' The pathway is quite simple: improvements in health services and availability of modern technology will

bring about a decline in mortality, and after a considerable lag, fertility will fall in response to the expectation for longer life spans and higher probabilities of survival into adulthood. This will lead to a bulge (which in the case of East Asia has been estimated to last nearly 50 years) in the working age population relative to the rest of the population. This demographic transition will in turn contribute to a large economic dividend. However, it has been suggested that the demographic dividend will not necessarily materialize in sub-Saharan African countries for a range of reasons, including the slow rate of fertility decline and HIV/AIDS. A recent article revisits this issue and concludes that the demographic dividend can be expected to materialize in Africa. However, the article also points out the importance of institutional reform and a transparent political and economic environment as a prerequisite for the bulging number of working individuals to be productively engaged.

In sum, caution is necessary in interpreting literature on the macroeconomics of health, even that which makes efforts to deal with problems of omitted variables and endogeneity. Specifications are often ad hoc, data are often unreliable, and most importantly, even the best attempts to deal with problems of omitted variables and unobservables that may jointly affect health status and income are open to serious criticisms. Perhaps a greater lesson is that there is a need to better understand the (primarily microeconomic) pathways, such as the impact on worker productivity and schooling, through which health impacts economic outcomes. Similarly, to the extent that certain factors have reduced the potential impact of health improvements on economic outcomes, such as population growth, this suggests that policymakers consider emphasizing programs to control fertility, and similarly, consider promoting economic opportunities for the burgeoning labor force through, for example, encouraging foreign investment.

Microeconomic Evidence

Pioneering work on the efficiency wage theory links health and nutrition to labor market outcomes, with the basic idea being: output is a concave function of labor inputs, including the number and level of effort among workers. Higher wages will thus improve nutritional intake of workers, and subsequently effort. From the producer's perspective, therefore, the optimal wage will minimize the wage bill in terms of the wage rate divided by the effort level.

The test of this theory involves determining whether wages respond to nutritional intake of workers. The correlation between health and wages of individuals has been well established with household survey data, but making a causal argument is far more challenging. For example, healthier workers may also be better educated, and likewise, healthier workers may have parents who make choices that not only contribute to their better health but also instill a greater work ethic.

Several microeconomic studies have made serious attempts to overcome the econometric problems inherent in examining such as relationship. Much of the evidence has been comprehensively reviewed.

Among the research that relies on nonexperimental methods, height, which largely reflects health conditions and investments both *in utero* and during early childhood, is often employed as an indicator of general healthiness. There is compelling evidence of the productivity effects associated with greater stature in numerous studies from developing countries. There is evidence from the historical literature that height affected the price of slaves, presumably reflecting the expected probability gains associated with greater stature.

Another anthropometric indicator that is widely used is the body mass index (BMI), and results indicate a loss of productivity associated with leanness. Similarly, estimates of a farm production function for Sierra Leone finds that calories per adult equivalent have significant positive effects on the marginal product of agricultural labor. One study from Sri Lanka instruments per capita household calories using prices, and its results indicate that there is a positive effect on market wages for rural men but not women. Many academics, however, emphasize the limitations of relying on household calorie intake to measure the effect on productivity. Research on workers in Ghana and Côte d'Ivoire indicates that wage returns to height and BMI in Ghana were also quite large, with a centimeter increase being associated with an 8–10% increase in wages.

Other studies of the impact of nutrient consumption rely on individual 24 h recalls and the measuring of food prepared and/or consumed in the household. Here, the evidence is more mixed. One article studied the impact of individual calorie consumption on agricultural production functions and wage equations. Employing fixed effects to control for individual heterogeneity, results show no impact of calories on either the marginal product of agricultural labor or agricultural wage rates. Interestingly, an impact of weight-for-height, a measure of leanness like BMI, on these outcomes is found to be consistent with the findings of other work. A further study on rural India finds some interesting seasonal effects: calories have a greater impact on productivity in the peak season for men, but weight-for-height is more important in the preharvest season when work is less demanding. Another study on agricultural workers from the Philippines finds that individual calorie intake from 24 h recall has no significant impact on productivity, unlike BMI where the effects on earning are significant. Noteworthy is that all these findings ignore that there are likely additional labor productivity effects that operate through occupation choice.

The impact of days ill on productivity has also been examined in a number of articles. Researchers found that each extra day of illness in Peru contributed to a 1% decline in hourly earnings among male wage workers and a 3% decline among the self-employed. For females, the comparable figure is a 2% decline. Overall, however, the general picture emerges of reduced labor supply in response to illness, although the impacts on productivity are more mixed. This perhaps reflects that such studies are examining agricultural productivity, and as mentioned previously, there is considerable latitude for substitution of labor, either with other family members or hired labor.

Recently, a great deal of attention has been accorded to examining the micro impact of HIV/AIDS on productivity. A comprehensive review of this issue notes numerous studies that focus on the impact of AIDS illness and death on household incomes and expenditures, largely mediated through declines

in labor supply, a fall in farm production, and the burdens associated with spending on health care and funerals. Likewise, there is troubling evidence that these economic stresses often lead to household dissolution, and, of course, a dramatic increase in orphanage, which is shown to have significantly deleterious economic and social consequences.

There is also evidence that declines in labor availability due to illness lead households to change cropping patterns and cultivation practices. One study shows that although Kenyan households afflicted by AIDS protect land under food cultivation, land devoted to cash crop production declines. A similar finding has been reported for Uganda. Other studies, however, have not found such changes in labor supply. An interesting study that focuses on the impact of the provision of ART for AIDS patients in Kenya reports a 20% increase in the probability of being in the labor force 6 months after treatment and that the hours worked increases by 35% among the treated. Ethical consideration naturally precluded randomization of treatment, and instead the authors needed to rely on other survey data collected during the same time on households without treatment to control for time varying factors that could bias the estimate.

Even more compelling evidence on the links between health and productivity comes from experiments designed to isolate the causal impact of health on productivity and labor market outcomes. There has been a considerable amount of experimental research on the impacts of micronutrients on labor market outcomes, with perhaps the greatest attention given to examining the impact of iron deficiency. Two biological pathways have been identified. First, aerobic capacity declines with decreasing levels of hemoglobin. Depletion of iron stores also contributes to reductions in the amount of oxygen available to muscles. As a consequence, endurance suffers, and there are greater demands on the heart in order to achieve the same activity. Iron deficiency also raises susceptibility to disease and is associated with fatigue and impaired cognitive development. Noteworthy among the many studies that examine causal effects of iron supplementation are the impacts on the output of rubber workers in Indonesia, cotton mill workers in China, and tea plantation workers in Sri Lanka. Additionally, several studies have demonstrated how the cognitive development of children is impaired by iron deficiency.

A particularly interesting field experiment is the Work and Iron Status Evaluation study that provides iron supplements to older adults in Central Java, Indonesia. Approximately half the male workers in the study are self-employed (primarily as rice farmers), and the other half are paid a time-wage. There is no evidence that hours of work corresponded to the treatment for time-wage workers, although those receiving treatment reduced the amount of time spent sleeping, and there is evidence that after a year they took on more work in self-employment. Among males who earned a time-wage, there is no evidence of changes in productivity as indicated by their hourly earnings; of course, if their wages are set by an employer, it is not obvious the worker will reap the benefits of greater productivity. This is not true for the self-employed. Males who were self-employed and iron deficient at baseline reported approximately 20% higher hourly earnings after 6 months of supplementation relative to similar controls. Although the study demonstrates that iron deficiency has a causal impact on time allocation and economic productivity, it also highlights the importance of including behavioral responses to the experiment itself in assessing the impact of treatment.

Experimental evidence of other forms of nutrition interventions is less compelling. One study that randomized food supplementation of sugarcane cutters in Guatemala indicated that those living in treatment villages were not more productive than the control villages. Another study in Kenya found a limited impact of food supplementation on the productivity of road workers. An experiment in Indonesia exploited the application of user fees at randomly selected 'treatment' districts while prices were held constant (in real terms) in neighboring 'control' districts. Two years after the intervention, relative to control areas, health care utilization and labor force participation had declined in treatment areas (where prices had increased). Reductions in employment were particularly large (and significant) for men and women at the bottom of the education distribution, those whom we would expect to be the most vulnerable. The most plausible interpretation is that the average treatment effects on labor supply indicate a causal role of improved health on the allocation of time to the labor market.

Beyond the issue of worker productivity and labor market outcomes, the impact of health on schooling and cognition has also been widely studied. One study reports that in a randomized control trial, treatment of helminthic infections in schools contributes to a reduction in absentee rates by one-quarter, although it does not find an improvement in test score outcomes. Another study uses IVs and a fixed effects estimator and finds that stunted growth among young children will lead to delayed enrollment, but not eventual attainment. A further study from Zimbabwe that employs a quasi-experimental approach indicates a large impact of heights on school attainment. Finally, there is strong evidence from the Philippines that children's performance in school is enhanced by better nutritional status.

Similar evidence indicates that specific diseases contribute to worse school outcomes. One report finds that in Paraguay and Sri Lanka, reducing the prevalence of malaria by 10 percentage points would increase years of schooling by 0.1 years and raise the probability of being literate by 1–2%. Corroborating results were reported elsewhere in Latin America.

Finally, beyond these impacts of the health of the child on schooling and cognition, there is also evidence that the health of the parents may impact a child's human capital accumulation, particularly through illness of mothers and fathers contributing to early withdrawal from school. For example, one study reports that the death of a 15-year-old child's mother raises the probability of the child dropping out of school within 3 years by 15.8% points. Similarly, the death of a 15-year-old's father raises the probability of dropout by 18.7% points. Illness among parents also has a large impact on the likelihood of dropout. Among 15-year-olds, for example, a child is 13.1 percentage points more likely to drop-out if her father has a prolonged illness that interferes with work and other normal activities. The comparable number for the mother is 14.8 percentage points.

Life Course and Intergenerational Issues

Poor health and nutrition will not only limit a worker's productivity and earnings, but, as discussed in the Section Microeconomic Evidence, will also contribute to a cycle of poverty, poor health, and poor human capital outcomes across generations. Of particular concern is the evidence that traumas *in utero* or in early childhood, such as exposure to toxins (including alcohol and tobacco), or nutrient deficiencies of folate or iodine will contribute to permanent dysfunction over the entire life course. The Barker hypothesis (Barker *et al.*, 2005) argues that nutritional and other stresses to the fetus contribute to imprinting on the genes and metabolic changes, which in turn contribute to heightened risks of obesity, diabetes, heart disease, and other chronic disease later in life.

There is a growing body of evidence in support of the fetal origins of disease theory. One study suggests that reduced infections during childhood contributed dramatically to adult height and longevity due to lower levels of inflammation. Another observes the importance of the year in which children were born in the business cycle in the Netherlands in the nineteenth- and early twentieth-centuries on mortality rates. Likewise, work using data from the US observes longstanding and major consequences for the schooling, productivity, and health of the offspring of mothers afflicted during the flu pandemic. Finally, there exists compelling evidence that raising birth weights will contribute to better labor market outcomes, particularly among low birth weight babies.

One particularly informative set of studies was conducted in Guatemala, where a randomized experiment of children who had been enrolled in an early childhood nutrition supplementation program were followed as young adults. Adult men, who had received the protein-rich nutrition supplement as children, were found to have hourly earnings that were US$0.67 greater than the control group that had received a drink containing no protein. This represented a 46% higher average wage rate. One important finding, however, is that the largest impact of the supplementation resulted from treatment during the first 2 years of life; there was no impact of receiving the supplement from ages 36 to 72 months. These strong positive effects were not observed for women. These results were consistent with other follow-up studies of this cohort that found increased schooling and cognition among the treated.

Another study, using panel data from Brazil, Guatemala, India, the Philippines, and South Africa, addressed the question of the relative importance of low birth weight, and weight gain in the first 2 years of life and between the ages of 2 and 4 years on schooling outcomes. Although not able to examine causality, the researchers report that from 0 to 24 months of age, weight gain had a particularly important impact on schooling, whereas there was no significant effect between 2 and 4 years of life. To get a sense of the magnitude of the effects, their comparative statistics suggested that children whose growth was stunted at 2 years or age were likely to have completed nearly 1 year less of schooling and suffer from a 16% increased risk of failing at least one grade. The authors' calculations, based on returns to schooling in the population, indicate that child stunting during the first 2 years of life would be associated with a reduction in lifetime income of approximately 10% in the countries studied.

Another avenue through which poor health has implications over the life course arises from the expectations for a short life span, which will in turn reduce savings and thus investment in physical capital. Related to the accumulation of physical capital is the fact that disease and early mortality among the children themselves have adverse intertemporal effects. Illness and malnutrition among children reduces the incentives for parents to invest in their education. The difficulties of identifying the impact of health on investing in human capital, and specifically distinguishing those effects from how health may directly effect human capital through other channels, such as the impact on school attendance and ability of children to learn, has resulted in few studies that causally show this relationship. One notable exception is a study from Sri Lanka that shows that the decline in maternal mortality risk by 4.1% resulted in a 2.5% increase in female literacy. The elasticity of human capital with respect to life expectancy was thus calculated as between 0.6 and 1.0.

Finally, one manifestation of poor maternal health and inadequacy of health care for women is the prospect of unwanted pregnancy. A woman's lack of control over her fertility has long-term impacts on members of her household and the accumulation of human capital of her children.

Inequalities in Health

There is a potential relationship between inequalities in health and various socioeconomic outcomes. It has been proposed that inequality in health contributes to a lack of social cohesion. There is evidence that relative deprivation contributes to stress, as well as other outcomes such as loss of dignity, shame, and stigmatization, which may have effects on labor market opportunities and incomes. High inequality also lowers the likelihood that social networks and mutual assistance relationships will mitigate the deleterious effects of health shocks that compromise health status directly. Inequalities in health (and other dimensions) may also contribute to differences in preferences and thus reduce political support for investments in public goods. Health inequality, therefore, may partially explain why public institutions are both inefficient and fail to protect and promote the needs of those in greatest need. Furthermore, where inequality reduces trust and increases crime and violence, or where low social status makes people feel disrespected, it may generate violence or, at the very least, add to the political tensions contributing to disproportionate shares of budgets and state and private resources being allocated to political repression, internal security, and other nonproductive spending.

Yet another aspect by which health inequalities can slow economic growth is that there are decreasing returns in terms of productivity to health: populations with more health inequality will have lower productivity on average.

In regressing GDP, both in levels and growth rates, on health inequality and a range of other covariates, it has been found that the reduction in health inequality caused by a reduction in the number of children who die before the age of 5 of approximately 4.25 per 1000 children per year born to

mothers with a low education level leads to an almost 8% increase in GDP per capita after a period of 10 years. Although this study is relatively unique and plagued by several serious methodological and data limitations, it does add to the limited empirical evidence on the relationship between health inequality and growth, and will hopefully motivate further research in this area.

Conclusions

There is considerable theoretical and empirical evidence that points to large productivity increases and economic gains from improved health and nutrition over the life course and across generations in developing countries. These are mediated by a wide range of pathways, including increases in strength and stamina, impacts on schooling (age of entry, duration, and attendance) and cognitive abilities, reduced fertility, and increased savings associated with reduced expenditures on health and greater incentives to invest in children who are expected to live longer and be more economically productive over their life course.

Information asymmetries, as well as market failures, such as for credit and insurance, will likely contribute to underinvestment in health-related human capital. This adds further justification for government policies to address these market failures. Additionally, there are likely to be large economic externalities associated with improving health that even further support government investments in the health sector. Thus, the large efficiency gains from investment in health find further justification in the likelihood that social rates exceed private rates of return.

Glossary

Average treatment effect (ATE) The average of the individual level treatment effect over all individuals i in the population of interest. This is in contrast to other parameters of interest such as the average treatment on the treated and the complier average causal effect. Mathematically:

$$ATE = E[\Delta] = E[Y(1) - Y(0)]$$

where the expectation is taken over the population of interest.

Average treatment on the treated (ATT) The average of the individual level treatment effect over all individuals i in the population of interest who were observed in the dataset to have actually received the treatment. This is in contrast to other parameters of interest such as the average treatment effect and the complier average causal effect. Mathematically:

$$ATT = E\left[\Delta \middle| T = 1\right] = E\left[Y(1) - Y(0) \middle| T = 1\right]$$

where the expectation is taken over the population of interest, and the conditional statement constrains the effect to those in the dataset who actually received the treatment.

Complier average causal effect (CACE) The average of the individual level treatment effect over all individuals i in the population of interest who had their treatment level changed by the instrumental variable. This is in contrast to other parameters of interest such as the average treatment effect and the average treatment effect on the treated. When the treatment has more than two levels, this effect is generally known as the local average treatment effect (LATE).

Hidden bias Variables which do not appear in the analyst's dataset (unobserved), are not the treatment variable or outcome variable, are not posttreatment, and (unless appropriately controlled for) bias the effect estimate of the treatment. Methods which exploit randomization within the treatment assignment are often used to mitigate hidden bias, such methods include instrumental variables or difference-in-differences. When no randomization in treatment can be used, sensitivity analysis may be performed in order to put bounds on the impact of hidden bias on the estimation of treatment effects.

Individual level treatment effect The difference, for individual i, between the outcome under different levels of the treatment (e.g., difference in outcome for an individual under treatment vs. control). Except for contrived situations, this quantity is never directly observable because taking the treatment precludes taking the control and vice versa. Mathematically:

$$\Delta_i = Y_i(1) - Y_i(0)$$

Neonatal intensive care unit (NICU) An intensive care unit staffed with specially trained medical providers and equipped with technology meant to provide care for premature or medically complicated newborns.

Overt selection bias Variables which appear in the analyst's dataset (observed), are not the treatment variable or outcome variable, are not posttreatment, and (unless appropriately controlled for) bias the effect estimate due to sorting of individuals into different levels of the treatment. The notion of overt selection bias is often invoked by assumptions of 'strongly ignorable treatment assignment' or 'conditional independence.' Overt selection bias is often believed to be controlled for by common statistical approaches such as regression, matching, and inverse weighting; this is in contrast to hidden bias.

Strongly ignorable treatment assignment assumption Loosely, one can think of this assumption as saying: selection into the treatment is occurring only on variables which are observed. Formally, this assumption is often written as

$$(Y(0), Y(1)) \perp T \middle| X, \quad 0 < pr\left(T = 1 \middle| X\right) < 1$$

where $\perp$ denotes the conditional independence between the treatment and the joint distribution of the counterfactual outcomes. Two random variables are conditionally independent given a third variable if and only if they are independent in their conditional distribution given the conditioning variable.

Nomenclature

$\boldsymbol{\Delta_i}$ The individual level treatment effect. This is the difference, for individual i, between the outcome under different levels of the treatment (e.g., change in outcome for an individual under treatment vs. control).

$\boldsymbol{A \perp B}$ Denotes the independence random variables A and B.

$\boldsymbol{Y(T=t)}$ Denotes the distribution of the outcome, Y, when treatment is set to level $T=t$. This is from 'Potential Outcomes Framework.'

$A \perp B \middle| C$ Denotes the conditional independence random variables A and B, when B is conditioned on random variable C.

Introduction

The goal of an economic evaluation of medical interventions is to provide actionable information for policy makers. Modern policy decision makers are driven by data-backed arguments regarding what might change as a result of an intervention. As analysts, this requires specific attention to determining the causal impact between a given intervention and future outcomes. To justify a change in the way medicine is practiced, correlation is not sufficient; detecting and quantifying causal connections is necessary.

Medicine has relied on randomized controlled studies as the gold standard for detecting and quantifying causal connections between an intervention and future outcomes. Randomization offers a clear mechanism for limiting the number of alternate possible explanations for what generates the differences between the treated and control groups. The demand for causal evidence in medicine far exceeds the ability to practically control, finance, and/or conduct randomized studies. Observational data offer a sensible alternative source of data for developing evidence about the implications of different medical interventions. However, for studies using observational data to be considered as a reliable source for evidence of causal effects, great care is needed to design studies in a way that limits the number of alternative explanations for observed differences in outcomes between intervention and control. This article highlights a number of the techniques and tools used in high-quality observational studies. A few of the common pitfalls to be aware of are also discussed.

Example

The development of medical care for premature infants (preemies) has been a spectacular success for modern medicine. This care is offered within neonatal intensive care units (NICUs) of varying intensity of care. Higher intensity NICUs (those classified as various grades of level 3 by the American Academy of Pediatrics) have more sophisticated medical machinery and highly skilled doctors who specialize in the treatment of tiny preemies.

Although establishing value requires addressing questions of both costs and outcomes, the example will focus on estimating the difference in rates of death between the higher-level NICUs and the lower-level NICUs. Using data from Pennsylvania from the years 1995–2005, the authors start with a simple comparison of the 1.25% rate of death at low-level facilities to the 2.26% rate of death at high-level facilities. This higher death rate at high-level facilities is surprising only if one assumes preemies were randomly assigned to either a high or low-level NICU, regardless of how sick they were. In fact, as in most health applications, the sickest patients were routed to the highest level of intensity. As a result, one cannot necessarily attribute the variation in the outcome to variation in the treatment intensity. Fortunately, the data provide a detailed assessment of baseline severity with 45 covariates including variables such as gestational age, birth weight, congenital disorder indicators, parity, and information about the mother's socioeconomic status. Yet even with this level of detail, the data cannot characterize the full set of clinical factors that a physician or family considers when deciding whether to route a preemie to a high-intensity care unit. As can be seen, these missing attributes will cause considerable problems later on.

What is wanted is not the naïve comparison of rates of death – that is the percentage of preemies who died at the different types of NICUs – but one would like to have the difference in probabilities of death for each preemie given whether the preemie was to be delivered at a low-level facility or a high-level facility. This will be called the causal effect of treatment. This concept is formalized in Section Parameters of Interest.

The Fundamentals

The Potential Outcome Framework

The literature has made great use of the potential outcomes framework (as described in Neyman, 1990; Rubin, 1974; Holland, 1986) as a systematic, mathematical description of the cause-and-effect relationship between variables. Suppose for the moment, assume there are three variables of interest: the outcome of interest Y, the treatment variable T, and $\boldsymbol{X}$ as a vector of covariates. For most of this article, it will be assumed that there are only two treatment levels (e.g., the new intervention under consideration vs. the old intervention), though this assumption is only for simplicity's sake and treatments with more than two levels are permissible. These two levels shall be referred to using the generic terms 'treatment' and 'control,' without much discussion of what those two words mean aside from saying that they serve as contrasting interventions to one another. In the potential outcomes framework, the notion is that each individual has two possible outcomes – one which is observed if the person were to take the treatment and one if the person were to take the control. In practice one is only able to observe one of these outcomes because taking the treatment often precludes taking the control and vice versa. The notation used for subject i taking the treatment is $T_i=1$ and for patient i taking the control is $T_i=0$. To formally denote the outcome subject i would experience under the treatment and control the authors write $Y(T_i=1)$ and $Y(T_i=0)$, respectively. Informally the notation is simplified to $Y_i(1)$ and $Y_i(0)$ for the potential outcome under treatment and the potential outcome under control. This article will think of Y being a scalar, though it is possible to develop a framework where Y is a vector of outcomes.

Excellent resources exist for reading up on the potential outcomes framework: Rosenbaum (2002), Pearl (2009), and Hernan and Robins (2013).

Now there is enough mathematical language to describe the ultimate, often unattainable, quantity of interest – namely, 'the individual level treatment effect:'

$$\Delta_i = Y_i(1) - Y_i(0)$$

Thus Δ_i will tell us the difference in outcome, for subject i, between taking the treatment and control. If one could observe this quantity then the benefit from intervention would be known explicitly. But, in practice only one is observed or the other of the potential outcomes. To see this, one may write

the observed outcome, denoted Y_i^{obs} for the ith individual, as a function of the potential outcomes (Neyman, 1990; Rubin, 1974):

$$Y_i^{obs} = T_i * Y_i(1) - (1 - T_i) * Y_i(0)$$

Observing one of the potential outcomes precludes observing the other. In all but the most contrived settings, this problem is intractable. One will not be able to observe both the treatment and control outcomes. So one must turn to other parameters of interest.

Parameters of Interest

Suppose we, as the analysts, have collected characteristics of the subjects in our study. It is important to stress that these baseline characteristics should be based on the state of the subject before the intervention to avoid the potential to bias the treatment effect (see Cox, 1958, section 4.2 and Rosenbaum, 2002, pp. 73–74). For example, say a new drug is being tested for its ability to lower the risk of heart attack. High blood pressure is known to correlate with higher risk of heart attack, so it is tempting to control for this covariate. Controlling for blood pressure is likely to improve the precision of the estimate if a pretreatment blood pressure measure is used. It would be a mistake to use a posttreatment measurement of blood pressure as a control because this measurement may be affected by the drug and would thus result in an attenuated estimated causal effect. Intuitively, this is because the estimation procedure is limiting comparison in outcome not just between people who took the drug and who didn't but between people who took the drug and then had a certain level of blood pressure to people didn't take the drug and had the same level of blood pressure. The impact from the drug may have already happened via the lowering of the blood pressure.

Let us denote these measured pretreatment characteristics as X_i for the ith subject. Furthermore, the subjects are likely to have characteristics which were not recorded. Let us denote these unobserved characteristics as U_i for the ith subject. There is a not unreasonable belief that the observable outcomes can be thought of as a function of these covariates (in this notation you can think of the treatment level as being an observed covariate). That is $Y_i^{obs} = f(X_i, U_i)$. To keep things simple it will be assumed that the covariates are linearly related to the outcomes like so

$$Y_i(1) = X_i\beta(1) + U_i\alpha(1)$$

$$Y_i(0) = X_i\beta(0) + U_i\alpha(0)$$

Note that one needs to index the coefficients by the treatment level in order to account for interactions between the treatment level and the covariates. Also, it may appear strange putting coefficients on the unobserved variables, but this is required at the bare minimum to make the dimensions agree. In practice one gets a bit sloppy and write $\varepsilon_i(T)$ in place of the clunkier $U_i\alpha(T)$, but this is a move of convenience rather than discipline. It is known that there is not just one scalar, unobservable covariate that has been omitted from the dataset, so it is more realistic to write $U_i\alpha(T)$. Note that this means something a bit magical is happening when an author proposes a functional form for $\varepsilon_i(T)$.

Combining the equations for the observed outcome and the linear models, one gets a decomposition of the observed outcome in terms of covariates, both observed and unobserved, as well as the treatment.

$$Y_i^{obs} = X_i\beta(0) + T_i[(X_i\beta(1) - X_i\beta(0)) + (U_i\alpha(1) - U_i\alpha(0))] + U_i\alpha(0)$$

It is standard in econometrics to think of the above model as a regression, where the coefficient on the treatment variable comes from two sources of variation – the first source is the variation due to the observed covariates $(X_i\beta(1) - X_i\beta(0))$ and the second is the variation due to the unobserved covariates, $(U_i\alpha(1) - U_i\alpha(0))$. It is common to interpret the first source of variation as the gains for the average person with covariate levels X_i, and the second source of variation to be referred to as idiosyncratic gains for subject i. The idiosyncratic gains are the part of this model which allows persons i and j to differ in outcomes even when $X_i = X_j$.

For reasons laid out in the last subsection, one moves from estimating Δ_i for an individual and instead consider population level parameters. Historically, the quantity of interest for many studies has been the average treatment effect (ATE):

$$ATE = E[\Delta] = E[Y(1) - Y(0)]$$

Note that it is more common to use the conditional ATE:

$$ATE(X) = E[\Delta|X] = E[Y(1) - Y(0)|X]$$

This quantity $ATE\ (X)$ is interpreted as being the expected change in outcome for everyone with characteristics X if they were to go from taking the control to taking the treatment. This is a useful quantity if the researchers are considering a total replacement of a standard treatment ('control') with a new treatment ('treatment').

Another quantity of interest is the average treatment on the treated (ATT):

$$ATT = E[\Delta|T = 1] = E[Y(1) - Y(0)|T = 1]$$

Which is also more usefully thought of as a conditional quantity:

$$ATT(X) = E[\Delta|T = 1, X] = E[Y(1) - Y(0)|T = 1, X]$$

This quantity limits itself to considering the change in outcomes for only those people who actually received the treatment. The ATT is the pertinent quantity to estimate if people who received the treatment in the dataset are similar to the people who are anticipated to take the treatment in the future. Differences between the ATT and ATE often arise when a new treatment is introduced into a population. As an example, say that a new, more invasive, surgical procedure is introduced as a replacement to a technique which is less invasive, though also believed to be less efficacious. You might imagine that the new technology, because of the acute stress of the procedure, would be used on a relatively healthy subset of the population until the relative efficacy and burdens of the two procedures are well known. Sometimes the difference between the group which receives the treatment is observed and recorded in the covariates. As a simple example of this, let

us say the new treatment group has only patients who are less than 40 years old. If this is the case, to estimate the ATE one may have to extrapolate into parts of the overall population for which there are no people who were treated. The problem here is that the efficacy of the treatment may vary for different parts of the population. But if one is not careful to present the estimate as ATT (i.e., appropriate for just a subset of the population) it is quite possible that it will be interpreted as an ATE which may lead to incorrect estimates of the benefit on the entire population. This problem is made even more difficult to address when the treated group is different from the entire population in some unobserved way. See the Sections Methods to Address Selection Bias and Methods for Overt Bias and Bias Due to Omitted Variables on methods for overt bias and bias due to omitted variables for more discussion on this.

Perhaps more is made out of the ATE and ATT distinction than is really necessary. Both of them are discussed in order to make the researcher aware of potential issues of the population of interest and generalizability. Careful thought about the kinds of people who will be impacted by the proposed intervention will typically guide the researcher to the correct choice of either ATE or ATT. For a more exhaustive discussion see Imbens (2004).

Note that ATEs are discussed over populations. These are valuable quantities and are often quite useful for designing policy interventions. But one should point out that it is often plausible that there are subpopulations within the larger group that experience either bigger or smaller treatment effects. This variation in the individual unit's treatment effect is an important problem and deserves attention, but this issue will not be addressed (except for briefly in the IV and RD sections). The study of 'treatment heterogeneity' is gaining attention in the literature and this will add to the usefulness for policy interventions. The quest for 'personalized medicine' is in large part an acknowledgment that treatments often vary across subgroups within the population.

Selection Bias

One of the biggest problems with observational studies is that there is selection bias. Loosely speaking, selection bias arises from how the subjects are sorted (or sort themselves) into the treatment or control groups. The intuition here is: the treatment group was different from the control group even before the intervention, and the two groups would probably have had different outcomes even if there had been no intervention at all. Selection bias can occur in a couple of different ways, but one way to write it is

$$f(X,U|T=1) \neq f(X,U|T=0)$$

that is, the joint distribution of the covariates for those who received the treatment is different than for those who received the control. (A bit of a warning: Some confusion may arise when using a conditional statement. This confusion occurs because different academic traditions tend to think of the conditional statement in slightly different ways. For example, a statistician may read a statement like $f(X,U|T=1)$ to mean roughly 'the joint distribution of X and U when the researcher intervenes and sets T level 1.' This is in contrast to the way an econometrician may read the statement as, roughly, 'the joint distribution of X and U limited to those units of observation which were observed to have $T=1$.' For a more detailed discussion of what is being asserted in the conditional statement we suggest reading about the 'do operator' introduced by Judea Pearl. It is a quite enlightening discussion. See Pearl, 2009 for details.) If this is true, that there is selection bias, then

$$E[Y(1)-Y(0)|X] \neq E[Y(1)|X,T=1] - E[Y(0)|X,T=0]$$

This is problematic because the left-hand side of this equation is the unobservable quantity of interest but the right-hand side is made up of directly observable quantities. But it seems like the above equation is used in other settings, namely, experimentation. Why is that acceptable?

In an experiment, because of randomization it is known that

$$(X,U) \perp T$$

And it follows that

$$E[Y(1)-Y(0)|X] = E[Y(1)|X,T=1] - E[Y(0)|X,T=0]$$

Though it is often a dubious claim, many of the standard techniques require an assumption which essentially says that the only selection between treated and control groups is on levels of the observed covariates (X). This is sometimes referred to as overt selection bias. Typically, if overt selection bias is the only form of bias then either conditioning on observed covariates (e.g., by using a regression) or matching is enough to address overt bias. One particular assumption that is invoked quite often in the current health literature is the absence of omitted variables (i.e., only overt bias) and this is used to justify recovering ATT and ATE in some settings. Overt bias will be covered in the propensity score section.

Hidden bias exists when there are imbalances in the unobserved covariates. Let us use the observed outcome formula again, rewriting it like so:

$$Y_i^{obs} = X_i\beta(0) + T_iE[\Delta|X] + U_i\alpha(0) + T_i(U_i\alpha(1) - U_i\alpha(0))$$

A least-squares model of Y on T based on the model above will tend to produce biased estimates for $E[\Delta|X]$ when T is correlated with either $U_i\alpha(0)$ or $(U_i\alpha(1) - U_i\alpha(0))$. This can arise from unobserved covariates which influence both outcome under both treatment and control and selection into treatment. The resulting bias, referred to as hidden bias, is given by

$$E[U_i\alpha(1)|X,T=1] - E[U_i\alpha(0)|X,T=0] \neq 0$$

Methods to Address Selection Bias

In a randomized experiment setting, inference on the causal effect of treatment on the outcome requires no further assumption than the method for randomizing subjects into the treatment or control (Fisher, 1949). The randomization guarantees independence of assigned treatment from the covariates. And one should pause to stress the point that this independence is for all covariates, both observed and unobserved. By observed covariates it is meant that those

covariates which appear in the analyst's dataset and unobserved all of those that do not. If the sample is large enough then this independence means that the treatment group will have quite similar covariate distribution as the control group. Therefore, any variation noted in the outcome is more readily attributed to the variation in the treatment level rather than variation in the covariates.

The primary challenge to observational studies is that selection into treatment is not randomly assigned. Usually there are covariates, both observed and unobserved, which determine who receives treatment and who receives control. In such a case variation in the outcome is not easily attributable to treatment levels because covariates are different between the different levels as well. There are study designs which were created to address this selection bias and we introduce these methods here. These methods will be classified as (roughly) into two groups: (1) those methods which address only the observed selection bias and (2) those methods which attempt to address selection bias on both the observed as well as unobserved covariates.

Methods Which Address Only Overt Bias

Methods which address selection bias based only on observed covariates tend to be easily implemented, but they also tend to leave the analyst open to major criticism. The assumptions required for the methods in this section are hefty. The authors hope that as the electronic medical records come in to common use; the quality and detail of the covariates available to the health policy researcher will begin to make it more believable that one has access to all of the important covariates. Better quality data is always much appreciated. Better methods can only help so much.

Model-based adjustment (e.g., linear regression)

Across much of the applied econometric literature, model-based adjustment is the most common method for addressing selection on observed covariates. The most common form of model-based adjustment is linear regression. More complex methods can be developed from maximum-likelihood models, Bayesian hierarchical methods, or other more complex methods. These methods are often designed to estimate the ATE under a powerful assumption. Loosely, one can think of this assumption as saying: selection into the treatment is occurring systematically only on variables which are observed. Formally, this assumption is often written as

$$(Y(0),Y(1)) \perp T|X, \quad 0<pr(T=1|X)<1$$

where $\perp$ denotes the conditional independence between the treatment and the joint distribution of the counterfactual outcomes. Two random variables are conditionally independent given a third variable if and only if they are independent in their conditional distribution given the conditioning variable. The above assumption, essentially saying one has all the covariates one needs, has a few different names: strongly ignorable treatment assignment (Rosenbaum and Rubin, 1983), selection on observables (Heckman and Robb, 1985), conditional independence, no confounders (in the epidemiology literature), or 'overt bias' and 'the absence of omitted variable bias' (in the econometrics literature). This article tries to use the 'overt bias'/'absence of omitted variable bias' labels consistently, but please feel free to mentally replace those terms with your favorite.

Propensity score methods

Propensity score methods, propensity score matching in particular, have been of particular interest in the health policy literature. It is speculated that the reason for this interest is related to the fact that with propensity score methods it is possible to mimic the feel of the familiar and salient randomized controlled experiment. The propensity score is defined as:

$$e(x)=pr(T=1|X)$$

Rosenbaum and Rubin (1983) showed that assuming there is only overt bias, conditioning on the propensity score will lead to independence of the treatment and the potential outcomes. That is,

$$(Y(0),Y(1)) \perp T|e(x)$$

This conditioning statement is quite useful; it justifies matching techniques and inverse weighting techniques (see Sections Propensity score matching and Inverse probability weighting). But what is the difference between conditioning on the propensity score and the assumption that there is only overt bias? The assumption, as laid out in the formula above, seems to require that there are two people with exactly the same values of all of their covariates before treatment selection is independent of the potential outcomes. That would mean that if even one covariate value was different between two subjects then one would be concerned that treatment was still being confounded by the covariates, and the treatment estimate would be biased. Finding two identical units of observation is quite difficult (but not impossible, see difference-in-differences and before-and-after study designs discussed in Section Before-and-after (difference-in-differences)). The usefulness of the propensity score is that, assuming only overt bias, it shows that one does not need to find identical units merely needed to find units with the same probability of treatment assignment. This makes the analyst's job easier, because one only requires agreement on the propensity score in order to get a valid estimate of the causal effect. And matching on a one-dimensional feature is more easily accomplished than a high-dimensional vector. Said another way, the propensity score (a scalar) contains all of the requisite information contained in the covariates (often quite high dimensional).

It should be noted that exact matching on the propensity score (i.e., matching individuals i and j such that $e(\boldsymbol{x}_i)=e(\boldsymbol{x}_j)$) does not lead to exact matching on the covariates even in infinite samples. This means that the covariates within a pair match are likely to never be exactly the same (i.e., $x_i \neq x_j$). But what matching on the propensity score does guarantee (asymptotically) is that $f(X|T=1)=f(X|T=0)$. Is this a problem? Having two units of observation which are identical on all of their observed covariates, $\boldsymbol{x}_i=\boldsymbol{x}_j$, would be ideal because one could give unit i the treatment and unit j the control and any variation observed in the outcome would be plausibly

(we only say 'plausibly' because it is still quite likely that there are differences on the unobserved covariates, $\boldsymbol{u}_i \neq \boldsymbol{u}_j$) attributed to the variation in treatment. But that is not even what happens in a clinical trial. In a clinical trial one may match on important variables, but it is the randomization on which the inference is built. In a randomized trial the joint distribution of the covariates is similarly guaranteed to be equivalent, but the inference requires only that the randomization to be understood. For a discussion of both the relative benefits of exact matching (a.k.a. reducing heterogeneity) and propensity score match (i.e., randomization-based inference), as well as the intellectual history behind these two drives in research, refer to Rosenbaum (2005).

Typically the propensity score is estimated using a logistic regression, though this is not required. Conceivably, other techniques which estimate the probability of treatment given a unit's covariates would be valid.

Once the propensity score has been estimated there are several ways that it can be used to adjust for selection bias. A very simple technique is to enter the propensity score in the regression estimating the relationship between the treatment and the outcome. In this simple example, the propensity score acts very much like the model-based adjustment methods described in Section Model-based adjustment (e.g., linear regression). (The analyst should be aware that there are a few hefty assumptions required to use the propensity score in the regression framework.) There are other techniques for implementing propensity scores such as propensity score matching and inverse probability weighting. These more sophisticated techniques have distinct advantages when the treatment effect is not equivalent across the entire distribution of the X's because these methods focus the estimation on the part of the distribution where there is a substantial probability that either treatments might be selected.

Propensity score matching

Once the propensity score is estimated, $\hat{e}(x)$, then units are ideally matched to each other so that treated units with a particular value of $\hat{e}(x)$ are matched to control units with the same value of the propensity score. It is most common to do pair matching (one treated unit matched to one control unit) though it is also possible to match more than one treated unit to one control, or more than one control unit to one treated unit. (see Hansen, 2004, for more on full matching and K to 1 matching.)

Propensity score matching is often thought of as attempting to replicate a randomized controlled experiment. As such, once matching has taken place it is common to assess the covariate balance between the control and treated units. This is often done using the means of the covariates (citation). Once a properly balanced study design has been achieved, something as simple as a paired t-test is often run to estimate the treatment effect.

Matching also has the benefit of forcing the analyst to be aware of covariate overlap, or lack thereof. In many applications the treatment group and the control groups have different values of the covariates. For example, the control group may have people who are younger than the treatment group – say the youngest person in the treatment group is 50 but half of the control group is less than 30. This is important because part of the assumption of only overt bias, $0 < pr(T = 1|X) < 1$, requires there are units at all covariate levels which take on treatment and control. Model-based approaches leave the unaware-analyst at a disadvantage because it is not routine to check for covariate overlap between the treated and control groups. Nonoverlap is a significant violation of a fundamental assumption.

One of the more famous applications of propensity score matching was a study of right heart catheterization – see Connors *et al.* (1996).

Inverse probability weighting

Inverse probability weighting (IPW) takes each unit and weights it by the inverse of the propensity score. That is a weight, suppose we choose $w = \frac{1}{e(x)}$, is assigned to each unit of observation. If a unit has a particularly low probability of treatment then the weight will take on a very large value. Once all the observations have been weighted as such, the treatment is independent of the potential outcomes and inference on the treatment effect is trivial. When there are extremely low values of the propensity score (i.e., certain covariate values are strongly associated with selection into the control), the standard errors associated with IPW inference can get quite large. This problem is not unique to IPW methods, matching and regression face similar challenges. There are a number of different estimators based on IPW.

Although uncommon in some health policy settings, inverse probability weighting has been applied to great advantage in epidemiology. Many of the statistical techniques of analysis with IPW can be ported over from the survey sampling literature where sampling weights are heavily used.

Combining propensity score methods and covariate adjustment

Rubin (1973) used simulation studies to examine the tradeoffs between model-based approaches and matching-based approaches. Models tended to be more statistically efficient than matching-based techniques, with the significant caveat that this was true with the model was correctly specified (i.e., that the proposed model was exactly the right model for the process which actually generated the data). In fact, if the proposed model is incorrect, then model-based methods may actually exacerbate the bias. Matching-based methods were shown to be fairly consistent in reducing overt bias. The study concluded that a combination of the two methods produced estimates which were both robust and efficient. A diligent analyst, with strong justification for a specific model, may first match to ensure covariate overlap between the treated and control and then run the model-based inference on the subjects which were part of the matching.

Methods for Overt Bias and Bias Due to Omitted Variables

Regression, propensity score matching and any methods predicated on only overt bias do not address selection on unobserved covariates. It is important to be aware of this because a well-informed researcher needs to judge if available covariates are enough to make a compelling argument for the absence of omitted variables. This is often a dubious claim

because (1) a clever reviewer will usually find several variables missing from your dataset and/or (2) there are 'intangible' variables that are difficult, or perhaps inconceivable, to measure. The following study designs are presented below in order to help you address these situations.

It is important to note that none of the designs below come 'for free,' that is without some hefty assumptions. It is important to consider these assumptions carefully before proceeding.

Instrumental variables

An instrumental variable (IV) design takes advantage of some randomness which is occurring in the treatment assignment to help address imbalances in the unobserved variables. IV methods go beyond simple methods (like propensity score or multivariate regression) which are only designed to address imbalances in observed covariates.

An instrument is a haphazard nudge toward acceptance of a treatment that affects outcomes only to the extent that it affects acceptance of the treatment. In settings in which treatment assignment is mostly deliberate and not random, there may nevertheless exist some essentially random nudges to accept treatment, so that use of an instrument might extract bits of random treatment assignment from a setting that is otherwise quite biased in its treatment assignments. Holland (1986) offers an intuitive introduction to how an ideal IV would work. Angrist *et al.* (1996) used the potential outcomes framework to bring greater clarity to the math of IV.

This intuition for IV discussed above enhances the classic econometric presentation of IVs where the focus is on correlation with the error term. To introduce this more formally, the authors will introduce the 'complier terminology' from Angrist *et al.* (1996).

Notation first: Z is used to denote the instrument. If these random variables have subscripts one is referring to an individual's values. If the random variables are in bold then one is referring to the vector of values for all observations in our dataset. This section will assume that the treatment is binary (i.e., $T_i=1$ if the ith unit takes the treatment and $T_i=0$ otherwise) and that the instrument is binary (i.e., $Z_i=1$ if the ith unit is encouraged to take the treatment and $Z_i=0$ otherwise). The notation $T_i(z=1)$ is used to denote the treatment that the ith unit actually receives if encouraged, $z=1$, to take the treatment.

The story goes, the instrument either encourages the unit to receive the treatment ($Z_i=1$) or not ($Z_i=0$). The unit is then allowed to either comply with that encouragement or not. Because both the treatment and the instrument are assumed to be binary, it follows that there are four compliance classes. Using counterfactuals, the authors label these compliance classes like so:

1. Always takers: $T_i(Z_i=1)=T_i(Z_i=0)=1$
2. Compliers: $T_i(Z_i=1)=1, T_i(Z_i=0)=0$
3. Never takers: $T_i(Z_i=1)=T_i(Z_i=0)=0$
4. Defiers: $T_i(Z_i=1)=0, T_i(Z_i=0)=1$

Under any possible random assignment of the instrument one will never be able to discern the treatment effect for the always-takers nor the never-takers because no matter what one will never be able to observe the counterfactual treatment assignment. Assumption 4 (monotonicity) says that the defiers do not exist. Thus one is only able to estimate the treatment effect for the compliers, those who are randomly assigned by the instrument. This estimand is often referred to as the local average treatment effect (LATE) because it is only true for a subpopulation (a 'local' group). It has also been referred to as the complier average causal effect (CACE). CACE is a special case of LATE; CACE is often used when the treatment and instrument are binary. LATE is more broadly defined. A more fundamental estimand, the local instrumental variable (LIV), can be derived from the use of an instrument. The LIV is capable, assuming the proper specification of the model and proper weighting of population covariates, of estimating the ATE and TT (Heckman and Vytlacil, 1999, 2000). Thus the LIV is a useful tool which allows the analyst to shift between estimating effects on different parts of a populations.

An instrument is weak if the random nudges barely influence treatment assignment or strong if the nudges are often decisive in influencing treatment assignment. Another way to think of a 'strong' versus 'weak' instrument is to think of the percentage of compliers. A strong instrument will induce higher rates of compliance. A study with a weaker instrument will have a lower percentage of compliers. Although ideally an ostensibly random instrument is perfectly random and not biased, it is not possible to be certain of this; thus a typical concern is that even the instrument might be biased to some degree. It is known from theoretical arguments that weak instruments are invariably sensitive to extremely small biases – Bound *et al.* (1995); for this reason, strong instruments are preferred.

The most common method for implementing IV is two-stage least squares (2SLS). 2SLS is valid when the outcome of interest is continuous, and all of the typical model requirements for least squares are met. If the instrument is binary and the outcome is linear, then the 2SLS estimate is the Wald estimator (Angrist, 1991). If the outcome of interest is something other than nonlinear then there are a couple of other methods available. The two methods the authors cite are both rather new to the literature and are only beginning to work their way into use. Two-stage residual inclusion (2SRI) method is a parametric method for dealing with nonlinear outcomes (Terza *et al.*, 2008). Near/far matching is a nonparametric method that attempts to replicate the structure of a randomized controlled experiment (Baiocchi *et al.*, 2010). Near/far matching may feel a bit similar to propensity score matching, with the addition feature of taking into account the randomness from the instrument.

As laid out in Angrist *et al.* (1996), there are five assumptions for IV when you have a binary instrument and a binary treatment. This is a bit surprising to some folks because we typically only discuss two assumptions. The two assumptions from econometrics are broken apart into assumptions 1, 2, and 3 below. Assumptions 1 and 2 are often combined. Assumptions 4 and 5 are often overlooked in the literature. All of these assumptions are important and thus need to be justified before an IV analysis is to be taken seriously.

(1) Uniform Random Assignment

$$\Pr(Z=z)=\Pr(Z=z')$$

for all possible treatment assignments z and z' such that $1^T z = 1^T z'$, where 1 is the N-dimensional column vector with all elements equal to one.

This assumption guarantees that the instrument (Z) is randomly assigned, it says nothing directly about the treatment actually received. This assumption can be restated such that the probabilities are conditional on the observed covariates. See the section on 'Instrumental Variables – Complier Terminology.'

(2) No direct effect of the instrument on the outcome (Angrist *et al.* (1996) refers to this as this assumption as the 'exclusion restriction,' which may be a bit confusing given the use of this term in the econometrics literature to refer to both assumptions 1 and 2 in the Angrist *et al.* (1996) framework.)

$$Y(Z,T) = Y(Z',T) \quad \text{for all } Z,Z' \text{ and for all } T$$

Intuitively, this assumption says that the instrument has no impact on the outcome except through the instrument's influence on which treatment the unit actually receives. There are a number of ways to violate this assumption. One way this would be violated is in the study of a treatment if there is reason to believe in a 'placebo effect' – whereby merely believing in the treatment has an effect – where the unit will have a different outcome based merely on whether being assigned to take the treatment or not, rather than through the actual treatment taken. This assumption is quite important and is often a source of difficulty in justifying the validity of an IV method.

(3) Nonzero Average Causal Effect of Z on T.

The average causal effect of Z on T, $E[T_i(Z_i = 1) - T_i(Z_i = 0)]$ is not equal to 0.

This assumption ensures that the instrument actually has an impact on the treatment. If the instrument does not change the probability of the treatment assignment, then the instrument is useless because one cannot harness any of the randomization from the instrument to examine the effect of the treatment on the outcome. Note that the average causal effect is estimating the percentage of compliers. If there are more compliers in the study, then one has a stronger IV. If this connection between the instrument and the treatment received is weak then serious problems can arise – see Bound *et al.* (1995) for a discussion on weak instruments.

(4) Monotonicity

$$T_i(Z_i = 1) \geq T_i(Z_i = 0) \quad \text{for all } i = 1, \ldots, N$$

The monotonicity assumption means that the instrument must either encourage units to take the treatment or discourage units from taking the treatment, it cannot have both effects. The monotonicity assumption says that the defiers – those who do exactly the opposite of what they are encouraged to do – are not present in our study. This is an interesting addition to the literature.

(5) Stable Unit Treatment Value Assumption (SUTVA):

$$\text{If } Z_i = Z_i', \quad \text{then } T_i(Z) = T_i(Z')$$

$$\text{If } Z_i = Z_i' \text{ and } T_i = T_i', \quad \text{then } Y_i(Z,T) = T_i(Z',T')$$

SUTVA implies that the potential outcomes for each person i are unrelated to the treatment status of other individuals. This assumption means that settings in which one unit's treatment assignment impacts another unit's outcome are outside of our investigative range. Some examples of tricky situations: immunizations because the probability of unit i being infected depends on how many immunized people there are in the community (i.e., 'herd immunization') and the effect of academic ability from a teacher on a student is tricky to identify because students will learn from peers who potentially receive instruction from other teachers.

Some informal thoughts about the IV assumptions: Assumption 1 (Uniform Random Assignment) is challenging to defend because the assumption is about unobserved quantities. One method for reassuring the reviewer that Assumption 1 is at least plausible is by checking to see if the observed covariates look reasonably random across the different values of the instrument. This is not a guarantee of the randomness of the instrument (nor is it technically a disproval), but it is perhaps reassuring. Assumption 2 is sometimes dubious and will be a point of contention if the reviewer is clever. Assumption 3 is testable from the data because the association is observable in the data. Assumption 4 is often feasible; see the 'complier' terminology below to see why. Assumption 5 (SUTVA) is most often violated in studies involving infectious disease and settings where there is a 'spillover' effect from one subject to another.

Heterogeneity and compliance classes

If the treatment is believed to affect people differently, then it is possible that the compliance classes can be thought of as arising from heterogeneity. It is likely that the always-takers know they will benefit from the treatment, possibly more than others. The never-takers possibly have lower expected benefit. And the compliers would have an unknown level of benefit. This is not necessarily how things work in an example, but is a plausible enough scenario to show that estimating LATE is likely to be different than estimating ATE. The analyst needs to be aware of this issue. The estimate that we get from an IV analysis is only on a subset of the population, and perhaps this subset of the population is not representative of the overall population.

A few examples of an instrument in the medical literature: travel time to treatment facility (McClellan *et al.*, 1994), regional variation in treatment practices (Hadley *et al.*, 2003), and for drug utilization the instrument of prior patient's drug prescription (Brookhart *et al.*, 2006).

Regression Discontinuity

Regression discontinuity (RD) designs take advantage of an abrupt difference in treatment assignments. An example: say we are interested in the effects of a new blood pressure drug. An RD design might be available if there were protocols for treatment selection based on weight. Let us say that there was a policy requiring that anyone lesser than 70 kg is ineligible for the new drug. It might be possible, if physicians and patients strictly adhere to this policy, that the patients who weigh 69.5 kg and the patients who weigh 70.5 kg are actually quite similar in terms of their important covariates but face quite

different prospects for receiving the new blood pressure medicine.

RD designs can be thought of as a special case of IVs, where the analyst has a dichotomized instrument (i.e., whether the subject is above or below the discontinuity). Like an IV design, the assumption of random assignment to the levels of the treatment needs to be discussed. Continuing with the blood pressure medicine example, one might justify the 70 kg cut-off as being similar to random assignment because (1) the scales are likely to have measurement error, (2) patients' weights can vary throughout the day, and (3) the method for weighing (e.g., with clothing or without) will impact the patient's estimated weight. These arguments help with Assumption (1) for the IV assumptions, but the other assumptions need to be similarly addressed.

Often an RD estimate is valid for only those people who are 'near' the discontinuity. In the example, it is likely that one is looking at similar patients if one is considering people who are 69–69.9 kg versus 70.1–70.9 kg. However, it seems likely that the groups defined by 50–69.5 kg and 70.5–90 kg are quite different. This is a case of LATE, where the compliers are additionally restricted to some neighborhood around the discontinuity point. The authors have heard this estimand referred to (in jest) as 'very LATE.'

Before-and-after (difference-in-differences)

The before-and-after and the difference-in-differences (DiD) methods are common techniques to address the possibility that there are unobserved covariates which are causing confounding. Both techniques take advantage of multiple measurements taken at different periods in time. These techniques have been used to great benefit – see Card and Krueger (1994). Both are important techniques in the field, but the authors will do little more than mention them here. For a more detailed discussion the authors recommend looking in standard econometric textbooks for 'panel data' techniques.

Sensitivity analysis

In one sense sensitivity analysis is a 'meta' method because it functions as an analysis of the results of an already existent analysis. The researcher must first select a method, possibly one of the methods described in Sections Methods to Address Selection Bias and Methods for Overt Bias and Bias Due to Omitted Variables, and then perform a sensitivity analysis on that. Acknowledging that the assumptions are just that, merely assumptions, a sensitivity analysis will reanalyze the analysis considering violations of the assumptions occur. A general formulation of a sensitivity analysis is difficult, because it is dependent on the underlying method of analysis. But sensitivity analysis offers a powerful tool for observational studies to explore the effect of the assumptions necessary to make a causal interpretation of the data analyzed.

In an experiment, the randomization to treatment or control allows the researcher to address unobserved variation. In observational studies, the analyst is forced to rely on assumptions to address unobserved variation. Again, the clever reviewer knows how to come up with plausible scenarios and variables which will invalidate the assumptions required to use the method you are employing. (This is not unique to observational studies, in experimental settings it is often called into question whether or not the experimenters did the proper kind of adjustments and randomization in order to truly randomize the experimental subjects.) The good thing about a sensitivity analysis is that it switches the burden of defending your analysis from a case-by-case defense against each possible scenario and instead moves the argument to an order of magnitude (e.g., yeah, each of these arguments are interesting, but they would need to increase selection into the treatment group by a factor of 5 and at the same time increase the rate of death by four times).

A detailed description of sensitivity analyses can be found in Rosenbaum (2002, Chapter 4). Note that a sensitivity analyses will only indicate the magnitude of hidden biases that would alter a study's conclusions but does not address how to overcome these biases.

Example Revisited

NICUs have been established to deliver high-intensity care for premature infants (those infants born before 37 weeks of gestation). If one looks at all of the preemies that were delivered in Pennsylvania between 1995 and 2005, it is seen that 2.26% of the preemies delivered at high-level NICUs died whereas only 1.25% of the preemies who were delivered at low-level NICUs died. No one believes the difference in outcomes reported above is solely attributable to the difference in level of intensity of treatment. People believe it is due to difference in covariates. Based on the observable covariates, this is plausible because it is seen that preemies delivered at high-level NICUs weighed approximately 250 g less than the preemies which were delivered at low-level NICUs (2454 at high-level NICUs vs. 2693 at low-level NICUs). Similarly preemies delivered at high-level NICUs were born a week earlier than their counter parts at low-level NICUs on average (34.5 vs. 35.5 weeks). If you perform a propensity score matching using the observed covariates then the analysis will give you an estimate saying that there is a reduction of 0.05% of deaths if the preemies were to be delivered at high-level NICUs. Inverting a paired *t*-test, the confidence interval for this goes from $(-0.05\%, 0.15\%)$, and is thus an insignificant result. This is meaningful result for policy if the assumption of overt bias only, which is a necessary assumption in propensity score matching, holds in this example.

But one does not have access to medical records. One only has access to health claims data. It is quite likely one does not have all necessary covariate in our dataset, so assuming only overt bias is likely to lead to biased estimates. To attempt to deal with this problem Baiocchi *et al.* (2010) used an IV approach. They used distance to treatment facility as an instrument, because travel time largely determines the likelihood that mother will deliver at a given facility but appears to be largely uncorrelated with the level of severity a preemie experiences. Using this approach Baiocchi *et al.* (2010) estimated a CACE of 0.9% with a confidence interval of (0.57%, 1.23%). Be aware that the authors are estimating a different parameter. It is only appropriately thought of as estimating for a subset of the population, so one cannot readily compare the two estimates. But it is suggestive to note the larger estimated effect, as well as the significance of the result.

You should not walk away from this example thinking that IV methods are always preferred over propensity score matching methods. That is most definitely not the point here. But you should be aware that there are several different methods out there, and you should be comfortable thinking about what is the appropriate method to use in a given situation. In the NICU example, because one only has access to medical claims data – instead of medical charts – it is likely one is missing covariates that would inform us about what we believe to be important selection bias. Given that, one needs to use some method to address the unobserved selection bias, above and beyond the approaches one used to deal with the observed selection bias.

Occupational Licensing in Health Care

MM Kleiner, University of Minnesota and NBER, Minneapolis, MN, USA

Introduction

Many developed countries require occupational licenses for everyone from surgeons to interior decorators. Licensing in effect creates a regulatory barrier to entry into licensed occupations, and thus results in higher income for those with licenses. However, licensing is assumed to protect the public interest by keeping incompetent and unscrupulous individuals from working with the public. According to data collected in a 2008 national survey of the US workforce, 76% of all nonphysician medical occupations were licensed, the highest among all occupations in the survey conducted by the Krueger (2008). The goal of this article is to outline the major tensions between the monopoly face of licensing and the consumer protection face of occupational regulation in the health care industry. To do this, a theory of licensing is presented, which includes how it is used and some of the controversies surrounding its implementation, and the limited empirical results examining its effectiveness in enhancing quality or restricting competition.

To distinguish various forms of regulation, licensing, certification, and registration is defined below.

- Licensing: Licensing refers to situations in which it is unlawful to carry out a specified range of activities for pay without first having obtained a license. This confirms that the license holder meets prescribed standards of competence. Workers who require such licenses to practice include doctors, lawyers, and nurses.
- Certification: Certification refers to situations in which there are no restrictions on the right to practice in an occupation, but job holders may voluntarily apply to be certified as competent by a state-appointed regulatory body. Two examples of certification would be a certified financial analyst or a certified respiratory therapist.
- Registration: Registration refers to situations in which one can register one's name and address and qualifications with the appropriate regulatory body. Registration provides a standard for being on the list, but complaints from consumers or improper listing of credentials can result in removal from the list.

Licensing has been among the fastest growing labor market institutions in the US. Figure 1 shows the growth of occupational licensing relative to the decline of union membership since the 1950s. By 2008, occupational licensing in the US had grown to 29% of the workforce, up from below 5% in the 1950s. In contrast, unions represented as much as 33% of the US workforce in the 1950s, but declined to less than 12% of the US workforce by 2008. Much of this change was because of the shift from manufacturing employment to service sector employment such as medical services (e.g., nurses), where unions have continued to grow.

A similar trend exists for the UK with declining unionization trends, but growth in occupational licensing. Figure 2 shows that these trends in UK for the period 1978–2008 are consistent with the US trend line. In contrast to the US, approximately 14% of the UK workforce are licensed, but only approximately 22% belong to unions (Hummphris *et al.*, 2011). The data were compiled from the British Labour Force Survey for both unions and licensed occupations. With the growth in the service industries, the percentage of the workforce in licensed occupations appears to be rising in the UK.

The Theories of Occupational Licensing

Here the evolution of theories of occupational licensing is reviewed, ranging from the mechanistic ones to those that utilize human capital theory. It begins by outlining the simplest theory of occupational licensing, which draws more heavily on administrative procedures than on economics. Insights from more complex theoretical models is then incorporated that challenge some of the straightforward assumptions of the simple theory and which thereby provide richer insights into the operation and effects of regulation.

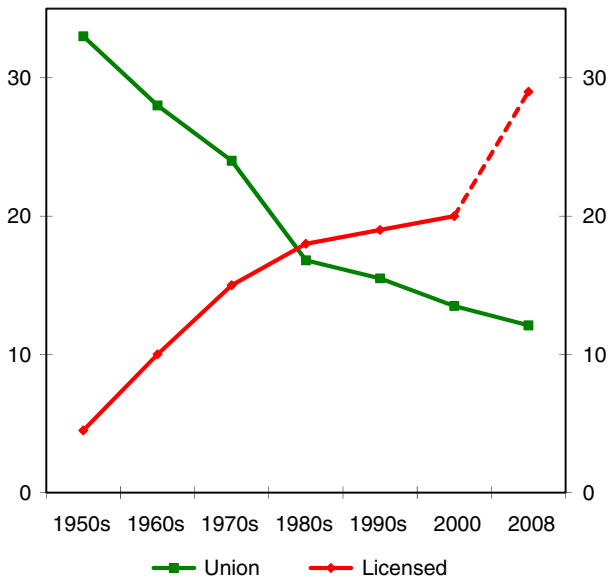

Figure 1 Comparisons in the time-trends of two labor market institutions in the US: Licensing and unionization. The dashed line shows the value from state estimates of licensing based on the Gallup survey and PDII survey results. The union membership estimates are from the current population survey.

 doi:10.1016/B978-0-12-375678-7.01101-9

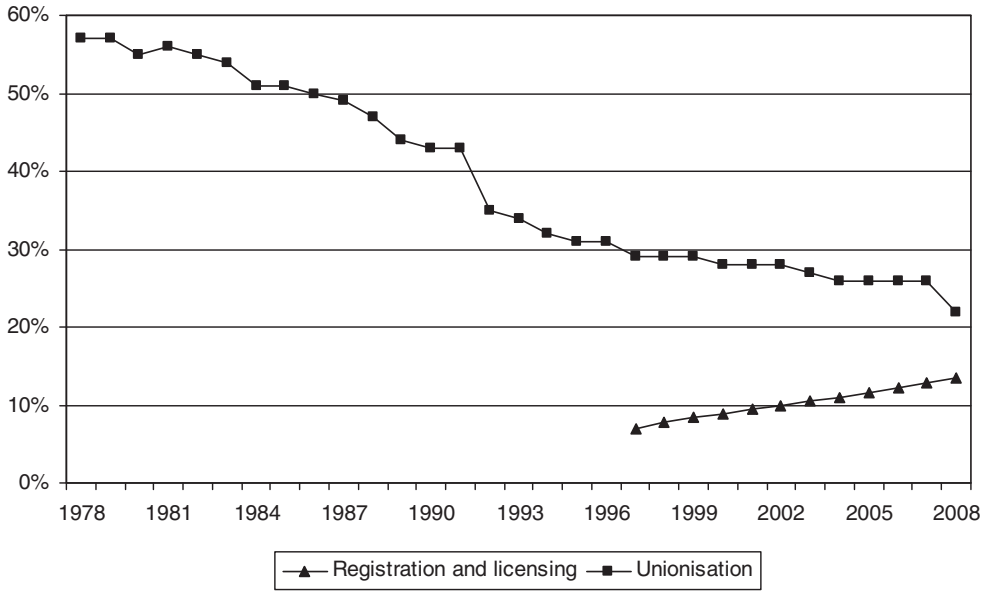

Figure 2 Comparisons of two labor market institutions: Licensing and unionization in the UK. Labour Force Survey (2008).

An Administrative Theory of Licensing

A simple theory of occupational licensing envisions a costless supply of unbiased, capable gatekeepers and enforcers. The gatekeepers screen entrants to the occupation, barring those whose skills or character suggest a tendency toward low-quality output. The enforcers monitor incumbents and discipline those whose performance is below standard with punishments that may include revocation of the license needed to practice. Assuming that entry and performance are controlled in these ways, the quality of service in the profession will almost automatically be maintained at or kept above standards that are set by the gatekeeper to the profession. Within this approach only those who have the funds to invest in training and the ability to do the work are able to enter the occupation.

Introducing economics to this otherwise mechanical model by noting that a key discipline on incumbents – the threat of revoking one's license – may not mean much if incumbents can easily re-enter the profession, such as by moving to a new firm, or by shifting to an alternative occupation with little loss of income. Because grandfathering (i.e., allowing current workers to bypass the new requirements) is the norm when occupations seek to become licensed, incumbent workers are usually supportive of the regulation process. In the absence of grandfathering, lower skilled workers in the occupation may have to seek alternative employment. For example, if sales skills are the key to both providing licensed sales of heart monitors and the nonlicensed selling of shoes or cars, then individuals may shift between these lines of work with little loss of income.

Under these circumstances, meaningful discipline for license holders may require deliberate steps to ensure that loss of license entails significant financial loss. Such additional steps could include imposition of fines, improved screening to prevent expelled practitioners from re-entering the occupation, or requiring all incumbents to put up capital that would be forfeited upon loss of the license. To offset the possibility that incumbents could shift to other occupations with little loss of income, entry requirements could be tightened to limit supply and create monopoly rents within the licensed occupation. The threat of losing these monopoly rents could, in principle, give incentives to incumbents to maintain quality standards. This may also result in some increases in human capital investments in order to attain the additional requirements. The rents could also motivate potential entrants to invest in high levels of training in order to gain admittance. This suggests that licensing can raise quality within an industry by restricting supply, raising labor wages and output prices. Increasing prices may signal either enhanced quality because of perceived or actual skill enhancements or restrictions on the supply of regulated workers.

State-regulated occupations can use political institutions to restrict supply and raise the wages of licensed practitioners. This is assumed to be a once-and-for-all income gain that accrues to current members of the occupation who are 'grandfathered' in, and do not have to meet the newly established standards (Perloff, 1980). Generally, workers who are 'grandfathered' are not required to ever meet the standards of the new entrants. Individuals who attempt to enter the occupation in the future will need to balance the economic rents of the field's increased monopoly power against the greater difficulty of meeting the entrance requirements.

Once an occupation is regulated, members of that occupation in a geographic or political jurisdiction can implement tougher statutes or examination pass rates and may gain relative to those who have easier requirements by further restricting the supply of labor and obtaining economic rents for incumbents. Restrictions would include lowering the pass rate on licensing exams, imposing higher general and specific requirements, and implementing tougher residency requirements that limit new arrivals in the area from qualifying for a

license. Moreover, individuals who have finished schooling in the occupation may decide not to go to a particular political jurisdiction where the pass rate is low because both the economic and shame costs may be high.

One additional effect of licensing is that individuals who are not allowed to practice at all in an occupation as a consequence of regulation may then enter a nonlicensed occupation, shifting the supply curve outward and driving down wages in these unregulated occupations. If licensing requirements contain elements of required general human capital, then it is possible that these workers may raise the average skill level in their new occupation.

Applications to Health Care

Standard economic theory of the effects of occupational licensing regulations on prices and quantities in the health care industry begins with the analysis of Friedman and Kuznets (1945) and Friedman (1962). In this line of reasoning, licenses act as a barrier to entry that can restrict supply and increase wages and other prices relative to a counterfactual competitive market. By contrast, paternalistic arguments and the existence of asymmetric information favor regulating health service providers. The issue is that because providers (e.g., physicians, nurses and physical therapists) may know more about a patient's health condition and the available treatment options, consumers may unwittingly receive low-quality care and possibly that this low-quality care will have larger and sometimes irreversible consequences. Governments might fear that by allowing 'lower skill' providers – such as nurses relative to doctors – to provide health services they may be exposing consumers to increased risk. In some situations the risks could also impose externalities: for instance, if low-skill health providers increase the transmission of an infectious disease then there might be a case for regulation. This raises two issues. One is that a paternalistic regulator might want to increase the quality of care received in the market. Another is that a regulator might want to ensure that providers have a minimum level of competency to minimize the negative consequences of asymmetric information. Both of these issues are supported by evidence and analysis.

A major argument for the licensing of medical occupations is that it eliminates or reduces the patient's health risk of seeking the services from an occupation. If testing and background checks 'eliminate charlatans, incompetents, or frauds' (Council of State Governments, 1952), then consumers may be willing to pay a higher price for the services offered by the regulated occupation. A review of the body of theory from experimental economics and psychology shows that consumers value the reduction in downside risk more than they value the benefits of a positive outcome (Kahneman *et al.*, 1991). This preference by consumers for the status quo or reducing the risk of a highly negative outcome has been called 'loss aversion,' which is an element of prospect theory developed by Kahneman and Tversky (1979). For example, as discussed earlier, social welfare may be increased substantially by minimizing the likelihood of a poor diagnosis as a consequence of going to an incompetent physician, because the incompetent physicians have been weeded out as a result of licensing. Consequently, licensing may also reduce patients' perceived benefits of receiving nonstandard but potentially highly effective treatment from an unlicensed practitioner of traditional medicine. Using the power of the state to both limit the downside risk of poor quality care and reduce the possibility of an upside benefit may be a trade-off that maximizes consumer utility or welfare. Evidence of the acceptance of this trade-off can be found in the growth of occupational licensing during the past century across virtually all nations that have been studied.

The gains from an unregulated service can be potential benefits from free market competition of lower prices and greater innovation without the constraints of a regulatory body, such as a licensing board. This upside potential gain can be achieved through both the use of nonstandard methods or new research that has not been approved by the licensing agency as appropriate for the service (Rottenberg, 1980). Deviations from the prescribed methods of providing a service are discouraged by licensing boards, and may even be found to be illegal. For example, not having a dentist on site is illegal in the US when providing a service such as teeth cleaning. Dental hygienists generally are not allowed to 'practice' without a dentist on site, with the 'site' being defined by statute or the dental board. In addition, dental hygienists are not allowed to open offices to compete with dentists. Although this policy reduces the chance that a dental hygienist will fail to find a major disease that may require immediate attention, it also reduces the ability of the hygienist to provide the limited services that particular patients require. Moreover, there is little leeway for the dental service industry to provide new or innovative services without the risk being found in violation of the licensing laws. The licensing laws give rise to the labor relations concept of 'featherbedding,' whereby dentists are on the premises – but do little work.

Consequently, regulation through licensing medical services can be the equivalent of a closed shop in unionized markets. Theoretically, higher wages are likely to result from restricted labor supply. Because closed shops in unionized markets are illegal in both the US and the UK, it is interesting that, with respect to organized labor markets, the equivalents of closed shops are nevertheless permitted in licensed occupations.

Illustrations in Medical Markets

One illustration of the potential outcome of licensing in medical markets is presented by the Nobel laureate economist Milton Friedman. Consistent with his work cited earlier in this section, he finds licensing to have an overall negative influence for consumers. The argument can be found on YouTube as follows (Milton Friedman – Health Care in a Free Market, YouTube video, 9:03, from a question-and-answer session with medical professionals at the Mayo Clinic in 1978, posted by 'LibertyPen,' 25 September 2009):

http://www.youtube.com/watchv=-6t-R3pWrRw&feature=related – Milton Friedman

Further illustrations of the influence of licensing on markets can be found in commercial media as well. For example, libertarian commentator John Stossel poses additional questions regarding the value of licensing in an excerpt from his

television show that featured several episodes on occupational regulation ('Stossel Show – Licensing! (Part 1/6),' YouTube video, 9:43 (part 1), posted by 'TheChannelOfLiberty,' 17 March 2010). The excerpt on YouTube, at the link below, serves as an overarching illustration of the influence of licensing on labor and consumer markets:

http://www.youtube.com/watch?v=f0JGu4tlmmk – The Stossel Show – Licensing

On a more practical basis, however, the entry requirements for many health care occupations are often presented as including the requirement for being licensed, as illustrated in another YouTube video ('How to Get Medical Jobs: How to Become an Occupational Therapist,' YouTube video, 0:50, posted by 'expertvillage,' 26 September 2008):

http://www.youtube.com/watchv=GM9ohB2qyQM

As with many occupations in the health care field, the requirements for being licensed are becoming more stringent. For example, the requirement for becoming a physical therapist in the US has increased within the past 5 years from 2 years of post-high school training to requiring a doctor of physical therapy in order to conduct many of the required tasks.

Empirical Evidence in Licensed Health Care Markets

The initial empirical work in medical markets was based on data from the 1930s. The classic and often cited study completed through the National Bureau of Economic Research by Nobel Prize-winning economists Milton Friedman and Simon Kuznets estimated that the 33% earnings premium of physicians relative to dentists could be attributed to more than just 1 year's difference between the requirements to become a doctor versus a dentist (Friedman and Kuznets, 1945). They estimate that the difference in earnings between doctors and dentists should be approximately 17% based on human capital and other observable factors, but that the additional 16% residual gap is in large part a consequence of physicians' greater ability to restrict labor supply. Milton Friedman's book, Capitalism and Freedom, argues that physicians were able to obtain substantial earnings gains over dentists during the 1920s and 1930s because they were able to limit new student enrollment in medical school (Friedman, 1962). More recently, however, a reversal of these trends has taken place.

During a relatively recent period of time (1990–2000), the number of new physicians increased by almost 22% (Public Use Sample, US Census, 2000). In contrast, the total number of dentists during the same period of time decreased. Dental school enrollment increased by only 1% each year during the 1990s, and the number of dentists in the US declined by almost 2% over the decade as a result of both retirements and individuals leaving the occupation (Public Use Sample, US Census, 2000).

A more general review of empirical research on licensing (in the US?) found that licensing is associated with consumer prices that are 4–35% higher than those found among unlicensed occupations, depending on the type of commercial practice and location (Kleiner, 2006). Kleiner and Kudrle (2000), for example, found that tougher state-level restrictions and more rigorous pass rates for dentists were associated with hourly wage rates that were 15% higher than in states with few restrictions, with no measurable increase in observable health benefits.

Occupational licensing appears to increase wages in several nations in the European Union (EU), but the estimates usually are lower than in the US. In the EU nations with greater overall wage disparities, such as in the UK, wages in the licensed occupations of medical practitioners, pharmacists, pharmacologists, and dental practitioners were an estimated 6–65% higher than otherwise similar workers in unlicensed occupations (Kleiner, 2006). In contrast, physicians and dentists in France earn an estimated 8–21% more than their unlicensed colleagues, whereas workers in those professions in Germany, which has lower overall wage disparities, have similar wages relative to unlicensed occupations.

In Europe, according to Dubois *et al*. (2006), a recent trend in the case of medicine and allied professions has been a shift from a system of self-governance that has traditionally granted professional associations' disproportionate power in setting and monitoring standard toward one that grants the state more influence in the process.

Given the high level of licensing within the health care occupations, it is not surprising to find that one of the evolving issues is the question of who is responsible for tasks, and how the government determines the market. For example, dentists control the market for dental care and in most US states dental hygienists must work for a dentist and cannot open their own establishments (Kleiner and Park, 2010). The result is that in those few US states that allow hygienists to open their own offices they make approximately 10% more and have faster employment growth relative to hygienists in more restrictive states.

A complementary study by Wanchek (2010) found that using a detailed dental hygiene professional practice index and a simultaneous equation approach to reduce the potential influence of endogeneity of wages and employment, entry requirements are negatively correlated with dental hygienists' employment and that practice restrictions that limit hygienists' ability to do tasks within the dental office are negatively correlated with their wages. Higher wages and lower employment of hygienists both reduce access to care, as observed in the prevalence of dental office visits. Finally, the author finds that the results are consistent with a state's entry and practice regulations jointly affecting access to oral healthcare.

Similarly, for nurses and doctors, in those US states that allow nurses to do simple procedures, such as 'well-baby' exams without the supervision of a physician, health insurance spending is approximately 10% lower (Kleiner *et al*., 2012) than in more restrictive states with no apparent influence on the quality of health care. Licensing not only influences wages and prices relative to unregulated situations, but also influences wages and prices across regulated occupations.

Kyoung-Hee Yu and Frank Levy (2010) examined the reasons why one might expect it to be more difficult to do offshore licensed professional work than manufacturing work in a globalized world. The authors conduct numerous interviews and provide data on a specific case: the offshoring of diagnostic radiology from the US, the UK, and Singapore, and find that regulation of the occupations matters. As far as professional services in healthcare are concerned then, institutional barriers are real and useful for the professions in

terms of restricting entry. To the extent that institutional frameworks differ across nations, globally integrated markets have yet to emerge for professional services in healthcare.

Conclusions

Licensing can in effect create a regulatory barrier to entry into licensed occupations, and thus results in higher income for those with licenses. Although more research is needed for a definitive answer, preliminary evidence points to licensing raising wages and prices in health care, but with no clear influence on the quality of care or with a clear impact on downside outcomes such as hospital readmissions, repeat visits to a health care professional, or deaths due to incompetent or unscrupulous purveyors of health care services. More detailed analysis using experimental data and field experiments with elements of random assignment would enhance the ability to make policy recommendations regarding the licensing of health care occupations.

Introduction

It is a commonplace to observe that the healthcare delivery system in the US is in crisis: costs are high and rising rapidly, the quality of care is inadequate along important dimensions, and the delivery system is rife with inefficiencies and waste. What is less commonly acknowledged is that many of the prominent strategies for reforming healthcare delivery systems are based on strong, largely untested beliefs about how organizations can best coordinate and motivate the physicians involved in patient care.

The crisis in the US system is especially severe and there is a large literature that discusses the US experience. For these reasons, this article focuses heavily on the US healthcare system. But many other countries are experiencing similar difficulties with their healthcare delivery systems and many of the issues and ideas discussed will have application beyond the confines of the US.

Health services researchers have long argued that a central problem with healthcare delivery in the US is fragmentation. Individual patients are frequently treated by numerous care providers who have only weak organizational ties with one another, resulting in poor information flows and inadequate care coordination. This fragmentation especially inhibits the close coordination between diverse providers that is required to manage costly chronic diseases and to prevent errors and missteps. The obvious fix, according to this view, is to induce physicians to join or construct more integrated care delivery systems. As a step in this direction, the Patient Protection Affordable Care Act of 2010 directs the Centers for Medicare and Medicaid Services to create a voluntary program for Accountable Care Organizations (ACOs). This program is designed to nudge the US healthcare system toward more integrated care delivery.

In contrast to the health services research community, many economists have argued that the fundamental problem with the delivery system is poor incentives, primarily physician incentives. From this perspective, the continuing dominance of fee-for-service payment systems and flawed payment rates within these systems create strong incentives for physicians to deliver high-cost services. Incentives to improve care quality are largely indirect and weak – patients presumably seek out higher quality physicians but have little ability to evaluate physician quality. Expensive and inefficient practice styles are further supported by overly generous insurance coverage, a consequence of tax breaks for employer-based coverage and the widespread use of supplemental Medicare coverage.

The result is a bloated system where neither physicians nor patients are held directly accountable for the financial consequences of their care decisions. The obvious fix, according to this view, is to get incentives right by reforming payment systems and tax policy. Thus ACOs are encouraged to adopt new payment systems that, in principal, reward physicians for adopting practice styles that reduce costs and improve quality. At the heart of these payment reform proposals is an economic theory of how best to motivate physicians using material incentives.

This article presents an overview of organizational economics as it applies to physician practices. The first section, A Descriptive Overview, offers a brief descriptive overview of the structure of physician practices. Our point will be that the long-anticipated triumph of integrated care delivery has largely gone unrealized. Although fewer physicians are working in solo practices than in the past, self-employed physicians in small group practices remain the industry norm. Integration of physicians' business functions has increased through a variety of cross-group and group-hospital affiliations, but integration of clinical activities has lagged. In the next section, Agency and Pay for Performance, the problem of pay for performance from the perspective of principal agent (PA) models is discussed. Building on these models, the next two sections take up the organizational economics of integrated care. The section Professional Autonomy versus Integration examines the professional norms of autonomy and other factors that complicate effective integration between hospitals and physicians. The section Coordination, Specialization and Innovation, considers how medical specialization affects coordination across providers. Finally the section Prospects for Accountable Care Organizations considers how the problems of motivation and coordination play out in ACOs.

A Descriptive Overview

The physician workforce has evolved overtime in both size and composition. In the mid-twentieth century, there were approximately 14 physicians per 10 000 persons in the US, almost half of whom practiced general primary care (Table 1). In response to concerns about an impending physician shortage, the Kennedy and Johnson administrations successfully championed legislation subsidizing medical schools, doubling the number of medical school graduates from 1965 to 1980, and eventually doubling the physician-to-population ratio from 1970 to 2000. Despite a subsequent stabilization of medical school graduation rates, entry into the medical profession continued to modestly outpace population growth largely through an increase in international medical graduates, who now comprise a quarter of active physicians.

As medical knowledge and technology grew, the share of general practitioners in the medical profession declined

more than 60% between 1949 and 1970, at which time fewer than 20% of active physicians practiced general primary care. The share of general practitioners continued its steep decline through the 1980s, though the decline was partially offset by growing shares of physicians practicing in specialties that typically involve primary-care services, i.e., pediatrics, obstetrics/gynecology, and internal medicine. Since 1990, the share of primary-care physicians (general practitioners plus primary-care specialties) has largely stabilized at 39% of all active physicians. Although the physician–population ratio in the US is similar to that in other developed countries, its share of primary-care physicians is substantially lower and this has been cited by numerous health policy experts as an important deficiency in the US healthcare delivery system.

The trend toward an increasing concentration of medical specialists has been accompanied by an increasing 'feminization' of the physician workforce and, more recently, by a decline in the labor supply of individual physicians. Historically, the medical profession was overwhelmingly dominated by male physicians. In 1970, approximately 7% of active physicians were women but the share of female physicians has grown consistently since then, reaching 31% by 2008. Coinciding with this change has been a decline in the number of hours physicians work each week, especially since the mid-1990s. Thus, although active physicians per capita increased 17% since 1990, physician work hours per capita increased less than 7%.

Table 2 documents trends in care delivery settings. Chief among these is a dramatic decrease in the amount of inpatient care provided. Since 1975, hospital admission rates have declined approximately 25%, whereas the length of hospital stays fell by almost one-half, representing a substantial decline in the amount of care physicians provide on an inpatient basis. In contrast, hospital-based outpatient care increased dramatically over this time, driven in part by a steep rise in

outpatient surgeries. Meanwhile, the per capita rate of office-based visits increased 17% since 1975, but this aggregate figure combines two very different trends. The rate of primary-care visits was relatively flat over this period, consistent with relative stability in the (per capita) number of primary-care physicians, whereas per capita office-based visits to specialists increased by more than 50%.

Thus a twofold story emerges from Table 2. First, physicians spend less time 'making rounds' and performing procedures in an inpatient setting than they did in the past, decreasing the dependence of physicians on hospitals as the setting for delivering services. Second, the decrease in inpatient care has coincided with a dramatic increase in ambulatory care delivered by medical specialists.

Tables 3 and 4 document how physician employment and practice arrangements have evolved over time. The results in Table 3 report statistics derived from a series of physician surveys conducted by the American Medical Association (AMA) – the Periodic Survey of Physicians (1975), the Socioeconomic Monitoring Study (1983–99), and the Patient Care Physician Survey (2001) – through 2001. More recent trends are documented in Table 4 drawing on data collected by the Center for Studying Health Systems Change (HSC) – four waves of data from the Community Tracking Study (CTS) Physician Survey and the HSC 2008 Health Tracking Physician Survey. Caution is always warranted in evaluating trends across different surveys. A special concern in this case is the sampling methodology of the CTS Physician Survey, which focused on 60 communities in the US. All statistics are weighted to be nationally representative, but trends in these communities may have differed from those in other areas, which could confound some of the cross-study patterns we observe. Nonetheless, these results allow us to draw a number of conclusions.

Physician self-employment has declined, but remains the norm: for much of US history the prototypical physician was self-employed and in solo practice. Even as recently as 1983, more than 40% of physicians fit this model but its numbers have

Note: Statistics calculated to be nationally representative of all nonfederal physicians who spend at least 20 h a week in direct patient care. Self-employed physicians are defined as those with full or part ownership in their main practice. Practice setting category 'Other' includes physicians practicing in community health centers, freestanding clinics and other settings, as well as independent contractors. Group size statistics restricted to physicians in solo or group practice.

been declining. By 2001, fewer than 25% of physicians were self-employed in solo practices. Overall rates of physician self-employment largely track the decline in solo practitioners, falling from 76% in 1983, to approximately 64% in 2000 (in AMA data), to less than 56% in 2008 (HSC data). In the CTS data, self-employment rates were somewhat lower than in AMA data, but a similar modest decline in self-employment rates is observed.

Institutional employment increased, but then appears to have stabilized (probably): the AMA data indicate that that the share of physicians working as employees of institutions (e.g., hospitals, medical schools, HMOs, etc.) grew from 20% to 28% from 1988 to 1994 – during the ascent of managed care – and then was fairly stable to 2001. The HSC data similarly find that approximately 28% of physicians were employees of institutions in 2008, suggesting little change over the last decade. The CTS data tell a somewhat conflicting story over the decade from 1996 to 2005, with rates of institutional employment seeming to increase from 31% to 36%. Given the nature of the CTS sampling methodology, one is inclined to believe this trend may not be representative of the nation as a whole, and that national rates of institutional employment have probably stabilized at a level less than 30%. It is likely, however, that local healthcare markets are quite heterogeneous in this regard.

Practice groups have gotten larger, but small practices remain the norm: health-system analysts have been predicting the demise of solo and small group practices for decades. Based on AMA data, it appears that a majority of noninstitutional physicians were in solo practice in 1975, declining to a third by 2001. Meanwhile, the share of employment in physician groups with more than 10 physicians grew from 12% to 19% between 1988 and 2001. The CTS data indicate that the share of noninstitutional physicians in solo or two-physician practices declined from 59% in 1996–97 to 51% in 2004–05, whereas the share in groups with six or more physicians increased from 23% to 34%. The historic record, then, is one of decreasing shares of physicians in the very smallest practices, and increasing shares in larger groups. Despite this, however, small groups remain a common feature of the physician labor market. In 2008, 65% of noninstitutional physicians were in practices with five or fewer physicians, accounting for 46% of the physician workforce overall.

Practice size and the prevalence of physician institutional employment (in hospitals and staff-model HMOs) provide an incomplete picture of the extent that individual physicians coordinate activities with one another and with other providers in the healthcare system. Over the last few decades, physician groups have increasingly joined a variety of cross-group and group-hospital organizations intended to facilitate the collective goals of their participants.

Independent practice associations (IPAs) have emerged to provide solo and small group practices many of the benefits associated with larger group practice – economies of scale in insurance contract negotiations, contract oversight, and other administrative functions – while allowing participating physicians greater autonomy over their individual practices. According to the Managed Care Information Center, there are currently approximately 500 IPAs with approximately 264 000 participating physicians, which equates to approximately 55% of the active physicians in group practice.

A variety of organizations have emerged linking physicians and hospitals, with the goal of integrating service delivery and financing. The most common of these, physician-hospital

organizations (PHOs), represent joint ventures between hospitals and private physicians to negotiate and manage insurance contracts. PHOs also frequently operate clinics, employ physicians and staff, and acquire medical practices. Some have established their own insurance products. At the apex of managed care in the mid-1990s, nearly a third of hospitals had one or more PHOs. The fraction has subsequently declined, falling to 13.4% by 2008.

A third type of organization, known as management service organizations (MSOs), are organizations owned by physician groups, by physician-hospital ventures, or by investors in conjunction with physicians. MSOs generally exist to provide practice management and administrative support, thus relieving practices of nonmedical business functions. In some cases, MSOs acquire the facilities and equipment of their client physicians which they then lease back to the physicians.

The widespread existence of such organizations can give the impression that physicians, even those in small practice, are often tightly aligned with one another and frequently integrated with hospitals in their geographic area. However, closer inspection suggests a more nuanced story. The rise of cross-group and group-hospital organizations was largely due to the market pressures imposed by managed care organizations (MCOs). Consolidating business functions allowed groups to achieve economies of scale in nonmedical activities and, more importantly, increased the clout of providers in contract negotiations. These organizations, however, were largely unsuccessful at integrating clinical activities across participating providers. As managed care backed away from capitated contracts, the impetus to integrate clinical activities largely faded.

Agency and Pay for Performance

Physicians know more than patients or insurers about the set of effective treatment options available for an individual with a specific condition. A patient's own physician knows better than other physicians the specifics of the patient's clinical and personal situation. Specialists, with their advanced training and narrow focus on a small set of clinical issues, have a better understanding of treatment options in their specialty than the primary-care providers who refer patients to them. Each of these informational asymmetries creates an agency problem, i.e., a situation in which well-informed physicians recommend or implement courses of action that benefit the well-informed physician at the expense of patients, payers, and other less well-informed parties.

One way to resolve information asymmetries is to design incentive contracts that motivate the best informed agent to 'do the right thing.' Economics offers a well-developed theory for tackling these incentive design problems, the PA model. The canonical PA model considers how a principal might structure incentives to elicit optimal behavior from better informed agents whose interests do not completely conform to the interests of the principal. The principal conditions pay on observed outcomes and the actions taken by the agent reflect the influence of these incentives. The starting point for the vast literature on PA models is a remarkable and quite general result: it is possible to implement a reward structure that can elicit efficient behavior on the part of the agent even when agents are entirely self-interested and even when performance measures are noisy and imperfect.

On the basis of this fundamental result, one might expect that the economist's prescription for efficient healthcare delivery would be widespread use of pay for performance contracts. Unfortunately economic theory does not support such a simple policy prescription. The qualifications on the fundamental PA result are almost as far reaching as the result itself.

The first qualification has to do with the basic statistical properties of performance measures. Clinical outcomes are often influenced by some unknown combination of good actions (taken by the healthcare provider and/or the patient) and good luck. Because of the great diversity of possible medical conditions a patient can manifest and the limited number of patients in a physician's panel of patients, it is not at all clear that an individual physician's practice offers enough observations to reliably distinguish good luck from good medical practice.

Noise in performance measures becomes even more important when agents are risk averse. To see this, consider a setting in which physicians operate under a contract that rewards them for coming in under a threshold level of costs for their entire panel of patients. If costs vary substantially in a year due to actions outside of a physician's control, then large payouts for coming in under target add a considerable component of randomness to a physician's compensation. For risk-averse physicians, the increase in the variability of payments that result from incentive pay imposes a real cost. To make matters worse for incentive design, income variability rises with the intensity of the incentive. As a practical matter, insurers or HMOs that ignore the cost of this increased risk when implementing pay for performance will find they will need to pay more to attract physicians to their networks.

The problems posed by the low statistical power of clinical performance measures and the risk aversion of physicians can be mitigated by pooling information across many physicians. From an economic perspective, pooling or averaging performance measures is problematic because it makes agency problems worse. The larger the physician panels across which outcomes are measured, the less will be the effect of an individual physician's actions on group outcomes. The phenomenon of group incentives weakening as the size of the group increases is well understood in the economics literature where it is often referred to as the 'free-riding' problem.

The relevance of free-riding problems is evident when one looks at the pay practices of physicians groups. Physicians who work in group practices often share revenues among themselves. Revenue sharing has the appeal of allowing physicians to buffer variations in income (doctor A's extra income in a good year will help offset doctor B's poor income in a down year), but this insurance comes at the cost of weakening incentives. If revenues are equally shared, a doctor in a three-person group keeps one-third of each dollar he or she earns. Incentives weaken as the size of the group grows: a doctor in a five-person group keeps one-fifth of the marginal dollar in revenues they earn and so on.

If it is costly or difficult to use incentives to resolve agency problems with meaningful pay for performance systems, organizations might find it profitable to reduce the need for incentives by seeking out physicians who have their principal's

interests at heart. Consider a hypothetical physician who is committed to providing patients with the level of care the patient would choose for themselves if they knew as much as the physician knew and if the marginal cost of care were zero. Finding physicians with such 'altruistic' preferences may not be as hard as it seems. Many aspects of medical education can be understood as efforts to inculcate this attitude into young physicians. It might appear that having physicians with such pro-social, intrinsic motives eliminates the most important agency problem facing doctors: the problem of ensuring that physicians act in the interests of their insured patients. But physicians face more than one agency problem and it is unlikely that the sort of intrinsic motives just described would resolve the agency problem for the insurers and MCOs that have the responsibility of paying for care. Indeed, if insurance contracts were such that the patients themselves had to pay the direct cost of their care, they also might prefer a physician whose internal values moved them to balance the marginal benefit of care against its marginal cost.

A deeper, but more speculative, limitation on the use of intrinsic motives to resolve agency problems is that these preferences may not coexist easily with the use of material incentives. A growing body of theoretical and experimental evidence in economics and psychology points toward the provocative possibility that powerful extrinsic rewards can actually weaken the efficacy of such pro-social motives as altruism, reciprocity, intrinsic motivation, and a desire to uphold ethical norms. If true, this suggests that organizations that rely on a mix of material incentives and intrinsic motivators might be less efficient than organizations that rely solely on one or the other strategy to resolve agency issues.

To sum up, the economics literature suggests that incentives matter, but that high-powered pay for performance schemes may be too blunt a tool for handling the many agency problems that raise the cost and reduce the quality of healthcare. This depressing conclusion is offset by some more recent results in the organizational economics literature suggesting that it may be possible to resolve agency issues with very low-powered incentives by employing physicians in integrated healthcare delivery organizations. It is to that issue that the authors now turn.

Professional Autonomy versus Integration

Hospitals and physicians together deliver the bulk of medical services in the US, yet they are strangely divided from each other. Within hospitals, physician decisions are central to resource allocation and care processes, yet most physicians are quite independent of hospital management, working (as most still do) in small single-specialty groups that they own. Some physicians have 'privileges' at more than one hospital and many more split their time and attention between hospital inpatient care and their office-based practices. It is hard to think of another industry – outside of movie making and construction – that relies so heavily on independent contractors as key decision makers. In virtually every industry that, like hospitals, relies on the mass-production of goods or services, key decision makers are either employees of the enterprise or, much more rarely, its owners. Does this difference matter for the efficiency of the healthcare system? Organizational economics suggests that it might.

For hospitals, the great advantage of having physicians as employees rather than independent contractors is that the employment relationship offers the possibility of resolving agency issues without the distortions created by high-powered incentives. This feature of employment relationships has been most clearly analyzed in the context of multitask models, where agents have more critical tasks to perform than can be included in performance measures. High-powered incentives will, in this context, cause the agent to deliver too much of the metered tasks and not enough of the unmetered tasks. Employment relationships offer a straight-forward fix for these multitask problems because employers have the ability to tell employees the tasks included in their job. By restricting the range of tasks the employee can work on while at work, the employer reduces the opportunity cost of doing the tasks the employer favors. As a result, a small amount of incentive can have a large effect on performance with lower levels of distortion. Put slightly differently, employment relationships differ from market-based relationships in that firms can exert a high degree of influence on employee actions using very little pay for performance. The strength of these low-powered incentives is increased when combined with other features of well-run organizations: the careful selection of new employees combined with their subsequent socialization into the goals and procedures of the enterprise. The effectiveness of the combination of appropriate job design, careful selection, socialization, and low-powered incentives is captured by the term of art used in the management literature, 'high performance human resource systems.'

To see the power of weak incentives in the context of employment relationships imagine that a hospital wishes to improve the way in which surgical tools are sterilized and delivered to operating rooms – a surprisingly complicated process that involves surgeons, operating room nurses, hospital managers, and sterilization technicians. Suppose further that operational efficiency can be improved by reducing the number and variety of surgical tools available to surgeons but that negotiating this change involves meetings and consultations with surgeons. If surgeons are independent contractors paid per operation, any additional meeting takes time away from the next operation. Attending such a meeting then, is a very expensive task for the surgeon and the surgeon requires equally large benefits in order to be induced to participate. This incentive problem is made worse by the fact that the benefits to the independent surgeon of reducing the number of surgical tools in circulation are clearly less than the benefits accruing to the hospital as a whole, especially if the surgeon divides his operating time across a number of hospitals.

Contrast these incentives with those of a surgeon who is employed by a hospital and is paid on salary. In this setting, attending meetings and participating in improving the sterilization process is not nearly so costly to the surgeon because the opportunity cost of his time is relatively low. These incentives to participate are further strengthened by the relationships the physician builds with coworkers and also by the extent of tacit, firm-specific knowledge, acquired over the course of the employment relationship.

Low-powered incentives of the sort discussed can complement higher-powered incentives and may help explain the anomalous findings of the Physician Group Demonstration project, an experiment in pay for performance involving large provider groups. Allowing these groups to keep 80% of their savings (after the first 2% of savings) elicited only small and uneven cost reductions. Very little is known about why some physician groups succeeded and others failed to achieve savings. Free riding can, as seen, undermine the incentive effects of conventional pay for performance – but the low-power organizational incentives discussed in this section can easily 'scale up' for large organizations. It is possible that the variation observed in the demonstration project may be the result of unobserved variations in low-powered incentives that can augment under powered explicit pay for performance incentives.

Given their considerable advantages, why hospitals employing physicians and forming large, integrated care delivery systems are not seen? In most economic settings, the efficiency advantages of integrated systems should enable them to generate the resources to attract large numbers of physicians and members. What prevents this from happening? Surprisingly little attention has been devoted to this important issue. The studies that do address it tend to focus on three potential explanations: the nature of economic competition in healthcare, strategic complementarities between payment systems and healthcare delivery, and the sociology of the medical profession. Each of these in turn are considered.

Regarding economic competition, if payers are unable to measure and reward high value-added producers, then it may be that the enhanced efficiency of integrated systems will not translate into a sustainable competitive advantage. Medicare, the biggest single buyer of healthcare services, does not evaluate the benefits associated with new medical technologies when setting prices, and it is forbidden from using cost-effectiveness analysis and from selectively contracting with more efficient physician groups. Medicare regulatory boards charged with evaluating new technology are concerned primarily with whether new drugs or procedures offer positive benefits. Private insurance coverage is heavily influenced by Medicare coverage. In addition, private payers typically use Medicare prices as a reference point in bargaining, and contracts based on value creation are scarce. Indeed it may be that some employers who purchase insurance for employees are not interested in or capable of evaluating the quality of care their employees receive. The key challenge for the 'failure of competition' explanation for the absence of integrated systems is explaining why competition in healthcare is different than in other sectors where markets do appear able to assess and reward efficient organizational designs.

In contrast, the 'strategic complementarities' explanation for the scarcity of integrated health delivery organizations refers to a generic set of explanations for the failure of advanced production methods to defuse rapidly across industries. Indeed much of this work was originally inspired by the difficulties American manufacturers had in imitating and adopting more efficient 'lean' manufacturing techniques that originated in Japan and the difficulties firms had in realizing productivity gains from the revolution in information. Suppose that managers have identified two complementary innovations, A and B. Each innovation on its own produces a small benefit, but introducing A and B simultaneously yields a big improvement in productive efficiency. For concreteness suppose that innovation A involves redesigning job responsibilities in ways that tap the tacit information and problem solving abilities of front line employees to solve customer problems and that innovation B involves hiring more educated workers. Implementing either of these changes is not easy or inexpensive and so it is reasonable to expect firms to experiment with one or the other innovation rather than implementing them both simultaneously. Thus, a firm might try action A and be disappointed in the result and therefore not follow-up with step B, hiring a more highly educated work force. Similarly, firms might start with B, but not see much productivity gain because they did not implement step A and redesign job responsibilities in ways that allow the more educated workers to use their superior problem solving and communication skills. It is only when firms reorganize and reskill the workforce that the powerful complementarities between the two innovations are realized. Put differently, incremental experimentation might not reveal the full productivity benefits of complementary innovations and so the true value of innovations might not be discovered by managers.

If complementarities can impede innovation within one organization, it becomes even harder when the complementary innovations span multiple organizations, i.e., when innovations are what game theorists call strategic complements. According to this argument the full efficiency gains of integrated care delivery can only be realized under bundled prospective payment systems. But in communities with highly fragmented care delivery, it is hard to find providers who can carry the risks entailed by such payments. As a result, payers do not innovate away from the status quo fee-for-service payment system and there is little competitive advantage for providers to move out of their currently fragmented delivery organizations. One of the interesting implications of the 'strategic complementarities' explanation is that it offers a natural role for public policy. Specifically, the big public payers (Medicare and Medicaid) can force the issue by announcing that they will be moving toward a bundled prospective payment system that will benefit large integrated organizations. This is the intellectual basis for the ACO initiative discussed below.

The third explanation for the relative scarcity of integrated care delivery organizations concerns social norms. The simplest version of the social norms explanation is this: physicians value professional autonomy and do not want to be employed by anyone else. There is considerable historical evidence that physicians as a learned profession did and do value their autonomy. Unfortunately, this fact alone is not likely to support a satisfactory explanation for fragmented delivery systems. If fragmentation between physicians and hospitals was simply the result of a preference for 'being your own boss,' then one should observe that physicians working for integrated systems enjoy a significant wage premium to compensate them for the disutility of their status as employees. One is not aware of any study that documents such a pay differential.

More sophisticated models of social norms, however, offer a more promising line of investigation. In models with a more

sociological flavor, agents compare their actions with a prescribed set of behaviors or with the actions of others in their reference group.

In a conventional microeconomic analysis, if a physician decides to work as an employee at a hospital, only the hospital and the physician are involved in the transaction. All else equal, if the hospital offers a pay differential that exceeds the value the physicians personally place on autonomy, the physicians will choose to abandon the autonomy of their independent practice and go to work as an employee of the hospital. Things work quite differently, however, when norms enter the picture. Norm violating transactions necessarily precipitate actions or changed perceptions (and loss of reputation) by third-party physicians who are not party to the transaction. The involvement of these third parties allows professional norms to persist even when the gains to individuals from violating norms are large relative to their preference for the norm. The involvement of third parties also suggests that stubbornly persistent norms may be greatly weakened by shocks that change the actions or perceptions of many physicians at once.

Just such a change is currently taking place in the medical profession. For most of the twentieth century, professional norms in medicine, law, and other learned professions were shaped by a labor force composed almost entirely of men, and most of these men had stay-at-home wives. In the 1970s, however, women began entering professions in large numbers and today they account for a significant proportion of the labor force in both medicine and law. For our purposes, the significance of this demographic transition is that these new entrants are likely to be influenced by a different set of norms than the male incumbents. Specifically, these women are often married to male professionals who work long hours and they are for this reason quite likely to have to balance norms of medical practice against family responsibilities. To the extent that employment in a hospital or other large integrated delivery organization enables physicians to have shorter and more predictable hours than working as an entrepreneur in a small practice, women might be drawn to these positions and this may have the effect of undermining the norm of professional autonomy that has played such an important historical role in the US healthcare delivery system.

Norms-based models of professions shift attention from a narrow focus on individual incentives to a broader view that also includes incentives for action governing the entire profession. From this perspective it is interesting to observe that in the early-twentieth century the AMA successfully lobbied for the introduction of 'corporate practice of medicine' laws that made it illegal for physicians to be employed by other organizations, especially hospitals. The legal impact of these laws has diminished overtime (as witnessed by the rise of professional hospitalists, an issue taken up below), but their influence is still observed in some states.

If physician professional norms are important for understanding the failure of physician-hospital integration in the US, then they might also be important for understanding other market outcomes in healthcare. Consider, for example, that MCOs compete for patients (who are the paying customers) and for physicians to participate in their network of providers. Patients cannot directly perceive quality and use as a proxy the number of physicians included in the managed care network. The MCOs compete for physicians by offering a combination of salary and cost-containment incentives. MCOs that write contracts with strict cost-control incentives have lower costs and lower premiums but they also have a harder time recruiting physicians to their network of providers than other MCOs do. In equilibrium, MCOs will segment the market. Some will operate with stringent cost-control incentives, small physician panels, and low premiums. MCOs in this part of the market profit by attracting cost-conscious customers. Other MCOs will have more lax cost-control incentives, bigger provider panels, higher premiums, and they profit by attracting customers who put a greater emphasis on provider choice than they do on the cost of insurance. This product differentiation creates disparities in treatment because physicians will use more resources treating policyholders in the high-cost MCOs than the low-cost MCOs. Given the many agency problems in this setting, an increase in competition is likely to cause a decline in medical costs – what some have referred to as a 'race to the bottom.'

Suppose now, that a physician norm against treatment disparities is introduced, perhaps because physicians do not like to deliver care that uses fewer resources than that delivered by other physicians in the market. This norm makes it more difficult for low cost plans to attract physicians and so they must pay them more (while also reducing cost-containment incentives). With low-cost plans behaving more like high-cost plans, there is less product differentiation and no race to the bottom. Indeed heightened competition reduces product differentiation and increases the overall level of resource utilization in the market. In this way, norms of professional practice can help explain why the managed care revolution of the 1990s failed to deliver on its promise to control the rise of medical costs. The model also can account for the absence of the widely predicted 'race to the bottom' in the managed care market of the 1990s.

Coordination, Specialization, and Innovation

The economic ideas discussed so far have been primarily concerned with the problem of motivating physicians. A second less well-developed economics literature focuses on problems of coordinating care among physicians who must specialize in specific aspects of care because no single individual can master all medical knowledge.

In his famous dictum that specialization is limited by the extent of the market, Adam Smith neatly summarized the role that markets play in coordinating the activity of highly efficient, specialized producers. More recent work has augmented Smith's analysis by considering the amount of specialization that will emerge in different economic settings.

Specialization increases the productive efficiency of a team performing complementary tasks. As specialization increases, however, so does the size of the team as well as the costs of coordinating activities among the increasingly specialized producers. These coordination costs are determined by available technologies, especially communication and transportation technologies, but they can also be influenced by agency problems. Increases in the stock of knowledge

increase the payoff to team members of investing in more specialized knowledge. Heightened specialization, it turns out, also increases the payoff to generating new knowledge. Applied to medicine, this suggests a positive feedback in which dramatic increases in medical knowledge coincide with dramatic increases in the number of narrow medical subspecialties.

The trade-off between coordination costs and specialization can be used to analyze the growth of hospitalists. Hospitalists are a new medical subspecialty whose purpose is to care for patients when they are hospitalized and then return them to the care of their primary physicians after discharge from the hospital. Primary-care physicians have superior information about their patient's specific situation and handing off inpatient care to hospitalists creates the risk that key information will not be communicated. For this reason, the rise of the hospitalist specialty creates coordination costs that were not present under the traditional US model in which primary-care doctors supervised their patient's care in both ambulatory and inpatient settings. Improvements in communication technologies have the effect of reducing coordination costs and thus increasing the demand for hospitalists, but this is not the whole story.

Coordination costs are also determined by the switching costs of moving from ambulatory to inpatient settings. It is costly for physicians to switch from office-based care to visiting their hospitalized patients, and some of these costs are fixed (think of the time and effort costs of leaving the office and traveling to the hospital to see patients). In the presence of these fixed switching costs, anything that reduces the number of patients a physician has in the hospital will reduce a primary-care physician's willingness to supervise their patient's inpatient care. For this reason, reductions in hospital length of stay, increases in the use of outpatient procedures in doctors' offices or even a reduction in physician work hours and patient load can have the effect of increasing demand for hospitalists.

The efficiency gains from specialization are not the only gains from the use of hospitalists. Hospitalists are often employed by hospitals but they may also work as contractors employed by outside firms or physician groups. Whatever their formal status, hospitals are likely to have more influence over hospitalist activities than they do over independent, primary-care physicians. Hospitals will therefore find their hospitalists relatively easy to engage in process improvement initiatives. By the same token, however, hospitals might use this heightened influence to encourage their hospitalists to shift costs onto other parts of the healthcare system. Recent findings about the effect of treatment by hospitalists on Medicare patients give some cause for concern in this regard.

The theories of specialization discussed so far are appealing, but they do not consider the referral patterns observed in medicine. In medicine, primary-care providers are generalists trained to recognize and treat common and less difficult conditions. When less common or more difficult patients arrive, the primary-care physicians refer them to specialists who have the extra training and experience required to handle these cases. It follows from this that a fall in the time and effort cost of communication with specialists increases the number of conditions that primary-care physicians will refer to specialists whereas a fall in the costs of learning about rare conditions (e.g., via internet search) broadens the number of cases the primary-care providers will handle themselves.

The process of referral from generalist to specialist creates an agency problem. Consider, for example, a patient who approaches her primary-care doctor for treatment for a rash. The primary-care physician can either refer the patient to a dermatologist or treat the condition themselves and generate extra revenues. If the dermatologists' in-depth knowledge leads to superior and cost-effective treatment, the referral is efficient. Efficient referrals may not occur, however, if the primary-care physician loses too much revenue by referring the patient. Although there may be little concern that an internist will fail to refer a breast cancer patient to a breast surgeon and oncologist, there are a very large number of conditions that fall into a gray area where the skills and knowledge of the generalist and specialist overlap.

In medicine where generalists make the decision to refer to more highly trained specialists, professional partnerships may have a distinct advantage. This is because the revenue sharing agreements in these partnerships allow the referring primary-care doctor to earn some money from the fees the specialist generates. This suggests that to best realize the advantages of efficient referrals, multispecialist groups ought to be composed of physicians working in areas where agency issues are likely to arise. Thus there might be good incentive reasons to include internists and dermatologists in the same group, but not cardiac surgeons.

As already observed, innovation in healthcare has resulted in a division of labor in which specialists with advanced training focus on the most difficult and advanced sort of medical practice. It is also possible, however, that innovations in treating the most common and routine sorts of care might also be very important.

Consider that healthcare delivery in the US must be concerned with treating two very different kinds of medical issues. One the one hand, there are the difficult, hard to assess cases that require sophisticated pattern recognition and nonroutine decision making by the physician (think, here, of the many conditions featured on the TV show 'House' whose etiology or treatment protocol is murky). On the other hand, there are the familiar cases whose treatment can be handled by clear, evidence-based protocols. In the typical physician practice, the responsibility for both of these cases falls to the physician. This division of labor makes some sense as individual patients can unexpectedly acquire one or the other type of condition, and their primary-care physician is in an excellent position to coordinate care across both these types of issues. But this approach to coordinating care also increases costs and dampens important innovation. Care for the protocol-based conditions, if broken out of the physician's practice, will be less expensive because the caregiver is not an expensive or highly trained generalist. In addition, organizations that specialize in protocol-based care for common issues can use the techniques of modern management to implement continuous improvement processes that drive down costs and improve effectiveness. The job of implementing these techniques will be made simpler by the fact that physicians will not play a central role in these organizations. More provocatively there is evidence from other industries suggesting that innovations originating

in the low-cost, low-prestige parts of an industry often end up transforming the production processes required for high-end goods and services as well. If this pattern holds true for medicine, improvements in the delivery of care through 'mini-clinics' and other limited care delivery operations may end up increasing the rate of innovation in the entire industry.

Prospects for Accountable Care Organizations

ACOs are an organizational innovation created as part of the Medicare Shared Savings Program of the Patient Protection and Affordable Care Act that was signed into law by President Obama in 2010. Although ACOs are only a small part of a huge piece of legislation, they have attracted a great deal of attention from policy-makers, physicians, and managers.

ACOs are a network of hospitals and providers that contract with the Center for Medicare and Medicaid Services (CMS) to provide care to a large bloc of Medicare patients (5000 or more). The contracts, which last for 3 years, create a single risk-bearing entity with incentives to control costs. ACOs that come in under their specified cost benchmarks earn a fraction of the savings. To receive these payments the ACO must also meet stringent standards on 65 quality indicators that reflect patient and caregiver experience, care coordination, patient safety, preventative health, and health of at-risk frail and elderly populations.

It is interesting to consider the ACO experiment from the perspective of organizational economics. For the statistical reasons we discussed in the Section on principal-agent models ACOs must enroll large numbers of Medicare patients in order to generate reliable measures of savings. But, as emphasized, implementing pay for performance in large groups creates free-riding problems that can dramatically weaken incentives. Put differently, if the ACO is comprised of independent contractor physicians connected only by a common hospital and a common incentive plan, they are unlikely to achieve the desired changes in provider behaviors. Selection, socialization, training, and careful job design are what gives a large organization the ability to influence the behavior of physicians in large groups. If these elements are missing, it is hard to see ACOs having much effect on the way healthcare is delivered.

To achieve savings, the ACO has to manage the capabilities of hospitals and the primary-care physicians who make up of the ACO. The most straightforward way to manage these very different capabilities would be for hospitals to simply employ physicians, but as discussed there are historical, legal, strategic, and sociological obstacles to achieving this goal. Simply purchasing physician practices, as many hospitals, and PHOs did during the 1990s, will not do the trick, but it may not be necessary for ACOs to employ all their primary-care physicians. Some organizations appear to be able to incorporate a significant number of nonemployed physicians into ACO-like arrangements and this offers some hope for expanding the range of hospital–physician coordination. A critical element in these organizations is to build legitimacy among independent physicians by making them part of the governance of the organization.

Incorporating specialists into the ACO will be challenging because specialists are not required to limit themselves to a single ACO. The economic model of referrals suggests that ACOs can reduce referrals by introducing training and computer-assisted decision support that make it easier for generalists to substitute their own decisions for those of the specialists. It may, for example, be better to train primary-care physicians to treat rashes and acne rather than sending every case of rash or acne to a dermatologist. However, the vast explosion in medical knowledge implies that there are limits to the substitution of generalist for specialist care. In this case, it may be that efficiently managing referrals to specialists will entail bringing some specialists into the ACO. Keeping these specialists fully occupied will also exert upward pressure on the optimal scale of ACOs.

Given their size, it is likely that free-riding issues will cause ACOs to operate with under-powered incentives, i.e., with incentives that are too weak, by themselves, to elicit meaningful changes in behavior. From this perspective it is helpful to think of the ACO's incentive problem as analogous to the provision of effort when effort is a public good. The experimental literature on public goods provision suggests that the effects of incentives on public good provision depend critically on the 'meaning' agents give to the incentive. Well-designed incentives should communicate that they are intended to achieve a socially beneficial outcome rather than threatening individual autonomy or sense of justice. Extending this logic to the case of intrinsically motivated physicians; managing ACOs likely involves paying careful attention to assigning meaning to the payments, but it is unclear if this meaning is more easily constructed within conventional employment relationships or within hybrid organizations in which doctors participate under looser arrangements. Given the medical profession's long history of battling to preserve its status as an autonomous and learned profession, low-powered incentives in ACOs built on a hybrid organizational form might be workable. However, conventional organizations may have greater opportunities to train, screen, and socialize for physicians who might respond well to low-powered incentives.

To the extent that successful ACO's have organizational capabilities that rely on training, screening, socialization, and constructing the 'meaning' of incentives they likely also involve relational contracts. Relational contracts are based on informal trusting arrangements whose credibility is enforced by the continuing value of the relationship between parties. The great advantage of relational contracts for ACOs is that they can complement more formal relationships such as those involved in pay for performance. Incentives that would be under powered in the sense of a principal–agent model may be quite a bit more effective if performance this period determined the continuation of a valuable ongoing relationship. Relational contracts can also be used to reduce some of the distortions of high-powered formal incentives.

Taken together, our analysis suggests that as a policy intervention, ACOs are likely to have the biggest effect where care is already integrated. Advocates of ACOs know this and see ACOs as emerging from five different practice arrangements. In order of ease of implementation these are: integrated delivery systems that combine insurance, hospitals, and physicians; multispecialty group practices; PHOs; IPAs, and virtual physician organizations.

Conclusions

This article applies the conceptual tool-kit of organizational economics to the economics of physician practices. Our discussion has focused on three broad themes from organizational economics: PA problems (both conventionally economic and behavioral); inefficiencies in the market for organizational form (resulting from social norms and various market failures); and the trade-off between the productivity gains from specialization and the coordination costs specialization entails.

These themes have been applied to important features of physician practices. Much of the attention has focused on understanding the stubborn persistence of fragmented care delivery via small, physician-owned practices, but other important issues have been considered as well. These include: the mixed record of pay for performance – especially in large healthcare organizations; the difficulties of achieving efficient levels of referrals between generalized and specialized providers; and the emergence of a fast-growing new medical specialty, hospitalists, as a result of changes in the tradeoffs between specialization and coordination costs. The final section brings all the themes together in an assessment of the prospects for ACOs, an important public policy initiative in the US aimed at reforming both incentive systems and the organizational forms within which care is provided.

In each of the applications it was found that the ideas of organizational economics yielded genuine and sometimes unexpected insights. This gives one some confidence that the idiosyncratic features of physician practices do not invalidate insights gleaned from the study of other, more standard, economic entities. In the long-struggle to improve healthcare efficiency, organizational economics will likely help providers, managers, and policy makers better understand how best to coordinate and motivate the physicians who guide patient care.

This article is a shortened and abridged version of a longer essay 'Organizational Economics and Physician Practices' James B. Rebitzer and Mark Votruba, NBER Working Paper 17 535 (October 2011, updated February 2013). Please consult that essay at the National Bureau of Economics website (www.nber.org) for a full list of relevant citations as well as a more extensive discussion of the literature.

Panel Data and Difference-in-Differences Estimation

BH Baltagi, Syracuse University, Syracuse, NY, USA

Introduction

Panel data refer to data sets consisting of multiple observations on each sampling unit. This could be generated by pooling time series observations across a variety of cross-sectional units, including countries, hospitals, firms, or randomly sampled individuals, like nurses, doctors, and patients. This encompasses longitudinal data analysis in which the primary focus is on individual histories. Two well-known examples of the US panel data are the Panel Study of Income Dynamics, and the National Longitudinal Surveys of Labor Market Experience. European panels include the German Socioeconomic Panel, the British Household Panel Survey (BHPS), and the European Community Household Panel (ECHP). Panel data methods in health economics have been used to estimate the labor supply of physicians and nurses; study the relationship between health and wages and health and economic growth; examine the productivity and cost efficiency of hospitals; and estimate the effect of pollutants on mortality. They have also been used to study the relationship between obesity and fast food prices; determine whether beer taxes will reduce motor vehicle fatality rates; and whether cigarette taxes will reduce teenage smoking, to mention a few applications. For example, Askildsen *et al.*, 2003 estimate nurse's labor supply for Norway. The panel data used include detailed information on 19 638 nurses observed over the period 1993–98. The policy question tackled is whether increasing wages would entice nurses to supply more hours of work. Contoyannis and Rice, 2001 estimate the impact of health on wage rates using the first six waves of the BHPS. Abrevaya (2006) utilizes the federal Natality Data Sets (released by the National Center for Health Statistics) from 1990 to 1998, to estimate the causal effect of smoking on birth outcomes. Identification of the smoking effect is achieved in this panel from women who change their smoking behavior from one pregnancy to another. Abrevaya constructs a matched panel data set that identifies mothers with multiple births. With the most stringent matched criterion, this data set contains 296 218 birth observations with 141 929 distinct mothers. Baltagi and Geishecker (2006) estimate a rational addiction model for alcohol consumption in Russia. Their panel data set includes eight rounds of the Russian Longitudinal Monitoring Survey spanning the period 1994–2003. These are four examples of micropanel data applications in health economics and as clear from these data sets, they follow a large number of individuals over a short period of time.

In contrast, examples of macropanels in health economics include Ruhm (1996) who uses panel data of 48 states (excluding Alaska, Hawaii, and the District of Columbia) over the period 1982–88 to study the impact of beer taxes and a variety of alcohol-control policies on motor vehicle fatality rates. Greene (2010) who uses the World Health Organization's panel data set to distinguish between cross-country heterogeneity and inefficiency in health-care delivery. This panel follows 191 countries over the period 1993–97. Becker, Grossman, and Murphy (1994), who estimate a rational addiction model for cigarette consumption across 50 states (and the District of Columbia) over the period 1955–85. Baltagi and Moscone (2010) who use a panel of 20 Organization for Economic Co-operation and Development countries observed over the period 1971–2004 to estimate the long-run economic relationship between health-care expenditure and income. Macropanels follow aggregates like countries, states, or regions and usually involve a longer period of time than micropanels. The asymptotics for micropanels has to be for large N, as T is fixed and usually small, whereas the asymptotics for macropanels can be for large N and T. Also, with a longer time series for macropanels one has to deal with issues of nonstationarity in the time series, like unit roots, structural breaks, and cointegration (*see* Chapter 12 of Baltagi, 2008). Additionally, with macropanels, one has to deal with cross-country dependence. This is usually not an issue in micropanels where the households are randomly sampled and hence not likely correlated.

Some of the benefits of using panel data include a much larger data set. This means that there will be more variability and less collinearity among the variables than is typical of cross-sectional or time series data. With additional, more informative data, one can get more reliable estimates and test more sophisticated behavioral models with less restrictive assumptions. Another advantage of panel data is their ability to control for individual heterogeneity. Not controlling for these unobserved individual-specific effects leads to bias in the resulting estimates. For example, consider the Abrevaya (2006) application, where one is estimating the causal effect of smoking on birth weight. One would expect that mothers who smoke during pregnancy are more likely to adopt other unhealthy behavior such as drinking, poor nutritional intake, etc. These variables are unobserved and hence omitted from the regression. If these omitted variables are positively correlated with the mother's decision to smoke, then ordinary least squares (OLS) will result in an overestimation of the effect of smoking on birth weight. Similarly, in the Contoyannis and Rice (2001) study, where one is estimating the effect of health status on earnings, one would expect the health status of the individual to be correlated with unobservable attributes of that individual, which, in turn, affect productivity and wages. If this correlation is positive, one would expect an overestimation of the effect of health status on wages. Cross-sectional studies attempt to control for this unobserved ability by collecting hard-to-get data on twins. However, using individual panel data, one can, for example, difference the data over time and wipe out the unobserved individual invariant ability.

Another advantage of panels over cross-sectional data is that individuals 'anchor' their scale at different levels, rendering interpersonal comparisons of responses meaningless. When you ask people about their health status on a scale of

1–10, Sam's 5 may be different from Monica's 5, but in a cross-sectional regression you assume they are the same. Panel data help if the metric used by individuals is time-invariant. Fixed effects (FE) makes inference based on intra- rather than interpersonal comparisons of satisfaction. This avoids not only the potential bias caused by anchoring but also bias caused by other unobserved individual-specific factors.

Limitations of panel data sets include problems in the design, data collection, and data management of panel surveys. These include the problems of coverage (incomplete account of the population of interest), nonresponse (due to lack of cooperation of the respondent or because of interviewer error), recall (respondent not remembering correctly), frequency of interviewing, interview spacing, reference period, the use of bounding to prevent the shifting of events from outside the recall period into the recall period, and time-in-sample bias. Another limitation of panel data sets is the distortion due to measurement errors. Measurement errors may arise because of faulty response due to unclear questions, memory errors, deliberate distortion of responses (e.g., prestige bias), inappropriate informants, misrecording of responses, and interviewer effects. Although these problems can occur in cross-sectional studies, they are aggravated in panel data studies. Panel data sets may also exhibit bias due to sample selection problems. For the initial wave of the panel, respondents may refuse to participate or the interviewer may not find anybody at home. This may cause some bias in the inference drawn from this sample. Although this nonresponse can also occur in cross-sectional data sets, it is more serious with panels because subsequent waves of the panel are still subject to nonresponse. Respondents may die, move, or find that the cost of responding is high.

The Model

Most panel data applications use a simple regression with error component disturbances:

$$y_{it} = \alpha + X'_{it}\beta + \mu_i + v_{it} \quad i = 1,\ldots,N; \quad t = 1,\ldots,T \qquad [1]$$

with i denoting individuals, hospitals, countries, etc. and t denoting time. The i subscript, therefore, denotes the cross-sectional dimension, whereas t denotes the time series dimension. The panel data are balanced in that none of the observations are missing whether randomly or nonrandomly due to attrition or sample selection. α is a scalar, β is $K \times 1$, and X_{it} is the it-th observation on K explanatory variables. μ_i denotes the unobservable individual-specific effect and v_{it} denotes the remainder disturbances, which are assumed to be independent and identically distributed IID$\left(0,\sigma_v^2\right)$. For example, in the Contoyannis and Rice (2001) study of the impact of health on wage rates using the first six waves of the BHPS, y_{it} is log of average hourly wage, whereas X_{it} contains a set of variables like age, age$_2$, experience, experience$_2$, union membership, marital status, number of children, race, education, occupation, region indicator, etc. The variable of interest is a self-assessed health variable, which is obtained from the response to the following question: "Please think back over the last 12 months about how your health has been. Compared to people of your own age, would you say that your health has on the whole been excellent/good/fair/poor/very poor?" Contoyannis and Rice constructed three dummy variables: (sahex = 1, if an individual has excellent health), (sahgd = 1, if an individual has good health), and (sahfp = 1, if an individual has fair health or worse). They also included a General Health Questionnaire: Likert Scale score which was originally developed as a screening instrument for psychiatric illness but is often used as an indicator of subjective well-being. Contoyannis and Rice constructed a composite measure derived from the results of this questionnaire which is increasing in ill health (hlghq1).

Fixed Effects

Note that μ_i is time invariant and it accounts for any individual-specific effect that is not included in the regression. If the $\mu_i^{'}$s are assumed as fixed parameters to be estimated and the X'_{it}s are assumed independent of the v_{it} for all i and t, the FE model is obtained. Estimation in this case amounts to including $(N-1)$ individual dummies to estimate these individual invariant effects. This leads to an enormous loss in degrees of freedom and attenuates the problem of multicollinearity among the regressors. Furthermore, this may not be computationally feasible for large micropanels. By the Frisch–Waugh–Lovell Theorem (Baltagi, 2008) one can get this FE estimator by running least squares of $\tilde{y}_{it} = y_{it} - \bar{y}_{i.}$ on the $\tilde{X}_{it}$'s similarly defined, where the dot indicates summation over that index and the bar denotes averaging. This transformation eliminates the μ'_is and is known as the within transformation and the corresponding estimator of β is called the within estimator or the FE estimator. Note that the FE estimator cannot estimate the effect of any time-invariant variable, such as race or education. These variables are wiped out by the within transformation. This is a major disadvantage if the effect of these variables on earnings is of interest. Note that, if T is fixed and $N \to \infty$ as typical in short labor panels, then only the FE estimator of β is consistent; the FE estimators of the individual effects $(\alpha + \mu_i)$ are not consistent because the number of these parameters increases as N increases. This is known as the incidental parameter problem. Note that when the true model is FE, OLS suffers from omission variables bias and inference using OLS is misleading. For the sample of 859 males in the Contoyannis and Rice (2001) study, the OLS estimate for excellent health is 0.065 and significant, whereas the OLS estimate for good health is 0.019 and insignificant (both are contrasted against a baseline of fair, poor, and very poor health). The FE estimates are 0.013 for excellent health and 0.010 for good health, and both are insignificant. The OLS estimate for the General Health Questionnaire: Likert Scale score (hlghq1) is -0.002 and insignificant, whereas the FE estimate is -0.003 and significant. More dramatically, for the Ruhm (1996) study, OLS gets a positive (0.012) and significant effect of real beer taxes on motor vehicle fatality rates, whereas FE obtains a negative (-0.324) and significant effect of real beer taxes on motor vehicle fatality rates.

Janke *et al.* (2009) examine the relationship between population mortality and common sources of airborne pollution in England. The data covers 312 local authorities over the period 1998–2005. They find that higher levels of $PM10$

(particulate matter less than 10 mm in diameter) and ozone (O_3) have a positive and significant effect on mortality rates. The OLS estimate for ($PM10/10$), controlling for three other measures of pollutants (carbon monoxide, nitrogen dioxide, and O_3), smoking rate, employment rate, etc. is 2.33, whereas that for FE is 2.74. The OLS estimate for ($O_3/10$) in the same regression is -0.55, whereas that for FE is 0.80. Only the FE estimates for these pollutants are significant at the 5% level.

One could test the joint significance of the individual effects, i.e., $H_0; \mu_1 = \mu_2 = \ldots = \mu_{N-1} = 0$, by performing an F-test. This is a simple Chow test with the restricted residual sums of squares being that of OLS on the pooled model and the unrestricted residual sums of squares (URSS) being that which includes the $(N-1)$ individual dummies. By the Frisch–Waugh–Lovell theorem (Baltagi, 2008), URSS can be obtained from the within regression residual sum of squares. In this case

$$F_0 = \frac{(RRSS - URSS)/(N-1)}{URSS/(NT-N-K)} \underset{\sim}{H_0} F_{N-1,N(T-1)-K} \qquad [2]$$

For the Contoyannis and Rice (2001) application, This F-statistic is 12.50 and is distributed under the null hypothesis as $F(858, 3406)$. This is significant and rejects H_0. One can infer that the OLS estimates are biased and inconsistent and yield misleading inference.

Difference-in-Differences

Note that the FE transformation ($\tilde{y}_{it} = y_{it} - \bar{y}_i$) is not the only transformation that will wipe out the individual effects. In fact, FD will also do the trick ($\Delta y_{it} = y_{it} - y_{i,t-1}$). This is a crucial tool used in the difference-in-differences (DID) estimator. Before the approval of any drug, it is necessary to assign patients randomly to receive the drug or a placebo and the drug is approved or disapproved depending on the difference in the health outcome between these two groups. In this case, the FDA is concerned with the drug's safety and its effectiveness. However, one runs into problems in setting this experiment. How can one hold other factors constant? Even twins which have been used in economic studies are not identical and may have different life experiences. With panel data, observations on the same subjects before and after a health policy change allow us to estimate the effectiveness of this policy on the treated and control groups without the contamination of individual effects. In simple regression form, assuming the assignment to the control and treatment groups is random, one regresses the change in the health outcome before and after the health policy is enacted on a dummy variable which takes the value 1 if the individual is in the affected (treatment) group and 0 if the individual is in the unaffected (control) group. This regression computes the average change in the health outcome for the treatment group before and after the policy change and subtracts that from the average change in the health outcome for the control group. One can include additional regressors which measure the individual characteristics before the policy change. Examples are gender, race, education, and age of the individual. This is known as the DID estimator in econometrics. Alternatively, one can regress the health outcome y on d_g d_t and their interaction $d_t \times d_g$. d_g is a dummy variable that takes the value 1 if the subject is in the treatment group, and 0 otherwise; d_t is a dummy variable which takes the value 1 for the posttreatment period, and 0 otherwise. In this case, $d_t \times d_g$ takes the value 1 only for observations in the treatment group and in the posttreatment period. The OLS estimate of the coefficient of $d_t \times d_g$ yields the DID estimator. Another advantage of running this regression is that one can robustify the standard errors with standard software.

In economics, one cannot conduct medical experiments. Card (1990) used a natural experiment to see whether immigration reduces wages. Taking advantage of the 'Mariel boatlift' where a large number of Cuban immigrants entered Miami, Card (1990) compared the change in wages of low-skilled workers in Miami with the change in wages of similar workers in other comparable US cities over the same period. Card concluded that the influx of Cuban immigrants had a negligible effect on wages of less-skilled workers. Gruber and Poterba (1994) use the DID estimator to show that a change in the tax law did increase the purchase of health insurance among the self-employed. They compared the fraction of the self-employed who had health insurance before the tax change 1985–86 with the period after the tax change 1988–89. The control group was the fraction of employed (not self-employed) workers with health insurance in those years.

Donald and Lang (2007) warn that the standard asymptotics for the DID estimator cannot be applied when the number of groups is small, as in the case where one compares two states in 2 years or self-employed workers and employees over a small number of years. They reconsider the Gruber and Poterba (1994) paper on health insurance and self-employment and Card's (1990) study of the Mariel boatlift. They show that analyzing the t-statistic, taking into account a possible group error component, dramatically reduces the precision of their results. In fact for Card's (1990) Mariel boatlift study, their findings suggest that the data cannot exclude large effects of the migration on blacks in Miami.

Bertrand *et al.* (2004) argued that several DID studies in economics rely on a long time series. They warn that in this case, serial correlation will understate the standard error of the estimated treatment effects, leading to overestimation of t-statistics and significance levels. They show that the block bootstrap (taking into account the autocorrelation of the data) works well when the number of states is large enough. Readers are advised to refer to Hansen (2007) for inference in panel models with serial correlation and FE and to Stock and Watson (2008) for a heteroskedasticity-robust variance matrix estimator for the FE estimator. Hausman and Kuersteiner (2008) warn that both the DID and the FE estimators are not efficient if the stochastic disturbances are serially correlated. The optimal estimator in this case is generalized least squares (GLS), but this is rarely used in applications of DID studies. Hausman and Kuersteiner (2008) use higher order Edgeworth expansion to construct a size-corrected t-statistic (based on feasible GLS) for the significance of treatment variables in DID regressions. They find that size-corrected t-statistic based on feasible GLS yields accurate size and is significantly more powerful than robust OLS when serial correlation in the level data is high.

Conley and Taber (2011) consider the case where there are only a small number N_1 of treatment groups, say states, that

change a law or policy within a fixed time span T. Let N_0 denote the number of control groups (states) that do not change their policy. Conley and Taber argue that the standard large-sample approximations used for inference can be misleading especially in the case of non-Gaussian or serially correlated errors. They suggest an alternative approach to inference under the assumption that N_1 is finite, using asymptotic approximations that let N_0 grow large, with T fixed. Point estimators of the treatment effect parameter(s) are not consistent as N_1 and T are fixed. However, they use information from the N_0 control groups to consistently estimate the distribution of these point estimators up to the true values of the parameter.

DID estimation has its benefits and limitations. It is simple to compute and it controls for heterogeneity of the individuals or the groups considered before and after the policy change. However, it does not account for the possible endogeneity of the interventions themselves (Besley and Case, 2000). Abadie (2005) discusses how well the comparison groups used in nonexperimental studies approximate appropriate control groups. Athey and Imbens (2006) critique the linearity assumptions used in DID estimation and provide a general changes-in-changes (CIC) estimator that does not require such assumptions.

The DID estimator requires that, in the absence of the treatment, the average outcomes for the treated and control groups would have followed parallel paths over time. This assumption may be too restrictive. Abadie (2005) considers the case in which differences in observed characteristics create nonparallel outcome dynamics between treated and controls. He proposes a family of semiparametric DID estimators which can be used to estimate the average effect of the treatment for the treated. Abadie *et al.* (2010) advocate the use of data-driven procedures to construct suitable comparison groups. Data-driven procedures reduce discretion in the choice of the comparison control units, forcing researchers to demonstrate the affinities between the affected and unaffected units using observed quantifiable characteristics. The idea behind the synthetic control approach is that a combination of units often provides a better comparison for the unit exposed to the intervention than any single unit alone. They apply the synthetic control method to study the effects of California's Proposition 99, a large-scale tobacco control program implemented in California in 1988. They demonstrate that following the passage of Proposition 99, tobacco consumption fell markedly in California relative to a comparable synthetic control region. They estimated that by the year 2000, annual per capita cigarette sales in California were approximately 26 packs lower than what they would have been in the absence of Proposition 99.

Athey and Imbens (2006) generalize the DID methodology to what they call the CIC methodology. Their approach allow the effects of both time and the treatment to differ systematically across individuals, as when new medical technology differentially benefits sicker patients. They propose an estimator for the entire counterfactual distribution of effects of the treatment on the treatment group as well as the distribution of effects of the treatment on the control group, where the two distributions may differ from each other in arbitrary ways. They provide conditions under which the proposed model is identified nonparametrically and extend the model to allow for discrete outcomes. They also provide extensions to settings with multiple groups and multiple time periods. They revisit the Meyer *et al.* (1995) study on the effects of disability insurance on injury durations. They show that the CIC approach leads to results that differ from the standard DID results in terms of magnitude and significance. They attribute this to the restrictive assumptions required for the standard DID methods.

Laporte and Windmeijer (2005) show that the FE and FD estimators lead to very different estimates of treatment effects when these are not constant over time, and treatment is a state that only changes occasionally. They suggest allowing for flexible time-varying treatment effects when estimating panel data models with binary indicator variables. They illustrate this by looking at the effect of divorce on mental well-being using the BHPS. They show that divorce has an adverse effect on mental well-being that starts before the actual divorce, peaks in the year of the divorce, and diminishes rapidly thereafter. A model that implies a constant instantaneous effect of divorce leads to very different FD and FE estimates, whereas a model that allows for flexibility in these effects lead to similar results. In general, the FE estimator is more efficient than the FD estimator when the remainder disturbance $v_{it} \sim \text{IID}(0,\sigma_v^2)$. The FD estimator is more efficient than the FE estimator when the remainder disturbance v_{it} is a random walk (Wooldridge, 2002). These estimators are affected differently by measurement error and by nonstationarity (Baltagi, 2008).

Certainly, this analysis can be refined to account for perhaps better control and treatment groups. If a policy is enacted by state s to reduce teenage smoking or motor vehicle fatality due to alcohol consumption or healthcare service for the elderly, then, for the two periods case, d_t takes the value 1 for the postpolicy period, and 0 otherwise; d_s takes the value 1 if the state has implemented this policy, and 0 otherwise; and d_g takes the value 1 for the treatment group affected by this policy like the elderly, and 0 otherwise. In this case, one regresses health-care outcome on d_t, d_s, d_g, $d_t \times d_g, d_t \times d_s, d_s \times d_g$ and $d_t \times d_s \times d_g$. The OLS estimate of the coefficient of $d_t \times d_s \times d_g$ yields the difference-in-difference-in-differences estimator of this policy. This estimator computes the average change in the health outcome for the elderly in the treatment state before and after the policy is implemented, and then subtracts from that the average change in the health outcome for the elderly in the control state, as well as the average change in the health outcome for the nonelderly in the treatment state.

Carpenter (2004) studied the effect of zero-tolerance (ZT) driving laws on alcohol-related behaviors of 18–20-year olds, controlling for macroeconomic conditions, other alcohol policies, state FE, survey year and month effects, and linear state-specific time trends. ZT Laws make it illegal for drivers under age of 21 years to have measurable amounts of alcohol in their blood, resulting in immediate license suspension and fines. Carpenter uses the Behavioral Risk Factor Surveillance System, which includes information on alcohol consumption and drunk driving behavior for young adults over the age of 18 years for the years 1984–2001. He estimates the effects of ZT Laws using the DID approach. The control group is

composed of individuals aged 22–24 years who are otherwise similar to treated individuals (18–20-year olds) but who should have been unaffected by the ZT policies. Let d_{ZT} be a dummy variable that takes the value 1 if the state has ZT in that year, and 0 otherwise; and d_g is a dummy variable that takes the value 1 if the subject is in the treatment group, and 0 otherwise. Alcohol consumption is regressed on d_{ZT}, d_{1820}, $d_{ZT} \times d_{1820}$, and other control variables mentioned above. The OLS estimate of the coefficient of $d_{ZT} \times d_{1820}$ yields the DID estimator of the ZT laws. Carpenter's results indicate that the laws reduced heavy episodic drinking (five or more drinks at one sitting) among underage males by 13%. For a recent review of DID health economics applications as well as a summary table of these applications, *see* Jones (2012).

Random Effects

There are too many parameters in the FE model and the loss of degrees of freedom can be avoided if μ_i can be assumed random. In this case, $\mu_i \sim \text{IID}(0,\sigma_\mu^2), v_{it} \sim \text{IID}(0,\sigma_v^2)$ and the μ_i is independent of the v_{it}. In addition, the X_{it} is independent of the μ_i and v_{it}, for all i and t. This random-effects (RE) model can be estimated by GLS, which can be obtained using a least squares regression of $y_{it}^* = y_{it} - \theta \bar{y}_{i.}$ on X_{it}^* similarly defined. $\theta = 1 - (\sigma_v/\sigma_1)$ where $\sigma_1^2 = T\sigma_\mu^2 + \sigma_v^2$. The best quadratic unbiased estimators of the variance components depend on the true disturbances, and these are minimum variance unbiased under normality of the disturbances. One can obtain feasible estimates of these variance components by replacing the true disturbances by OLS or FE residuals (*see* Chapter 2 of Baltagi (2008) for details).

Under the assumption of normality of the disturbances, Breusch and Pagan (1980) derived a Lagrange multiplier (LM) test to test H_0; $\sigma_\mu^2 = 0$. The resulting LM statistic requires only OLS residuals and is easy to compute. Under H_0, this LM statistic is asymptotically distributed as a χ_1^2 (*see* Chapter 4 of Baltagi (2008) for details.) For the Contoyannis and Rice (2001) application, this LM statistic is 3355.26 and is significant. This means that heterogeneity across individuals is significant and ignoring it as OLS does will lead to misleading inference. The RE estimates are 0.028 for excellent health, 0.013 for good health, and -0.002 for the General Health Questionnaire: Likert Scale score (hlghq1), with only the good health estimate being statistically insignificant.

Hausman Test

A specification test based on the difference between the FE and RE estimators is known as the Hausman test. The null hypothesis is that the individual effects are not correlated with the X'_{it}s. The basic idea behind this test is that the FE estimator $\tilde{\beta}_{FE}$ is consistent, whether or not the effects are correlated with the X'_{it}s. This is true because the within transformation $\tilde{y}_{it}$ wipes out the μ_i's from the model. However, if the null hypothesis is true, the FE estimator is not efficient under the RE specification because it relies only on the within variation in the data. However, the RE estimator $\hat{\beta}_{RE}$ is efficient under the null hypothesis but is biased and inconsistent when the effects are correlated with the X'_{it}s. The difference between these estimators $\hat{q} = \hat{\beta}_{FE} - \hat{\beta}_{RE}$ tends to zero in probability limits under the null hypothesis and is nonzero under the alternative. The variance of this difference is equal to the difference in variances, $\text{var}(\hat{q}) = \text{var}(\tilde{\beta}_{FE}) - \text{var}(\hat{\beta}_{RE})$, because $\text{cov}(\hat{q}, \hat{\beta}_{RE}) = 0$ under the null hypothesis. Hausman's test statistic is based on $m = \hat{q}'[\text{var}(\hat{q})]^{-1}\hat{q}$ and is asymptotically distributed as χ_K^2 under the null hypothesis. For the Contoyannis and Rice (2001) application, Hausman's test statistic is 322.39 and is distributed as χ_{29}^2. But the $\text{var}(\hat{q})$ is not positive definite. Using an alternative computation of this Hausman (1978) test based on an artificial regression, the null hypothesis is rejected and one can infer that the RE estimator is inconsistent and should not be used for inference.

Powell (2009) uses four waves of the 1997 National Longitudinal Survey of Youth and external data to examine the relationship between adolescent body mass index (BMI), fast food prices, and fast food restaurant availability. The OLS estimate of the fast food price elasticity of BMI is -0.095, whereas the RE estimate is -0.084. The latter is closer to the FE estimate of -0.078, but the RE estimator is rejected by the Hausman test. The number of fast food restaurants per capita was not found to be significant.

Hausman and Taylor Estimator

The RE model is rejected because it assumes no correlation between the explanatory variables and the individual effects. The FE estimator, however, assumes that all the explanatory variables are correlated with the individual effects. Instead of this 'all or nothing' correlation among the X and the μ_i, Hausman and Taylor (1981) consider a model where some of the explanatory variables are related to the μ_i. In particular, they consider the following model:

$$y_{it} = X'_{it}\beta + Z'_i\gamma + \mu_i + v_{it} \qquad [3]$$

where the Z_i is cross-sectional time-invariant variable. Hausman and Taylor (1981), hereafter HT, split X and Z into two sets of variables: $X = [X_1; X_2]$ and $Z = [Z_1; Z_2]$ where X_1 is $n \times k_1$, X_2 is $n \times k_2$, Z_1 is $n \times g_1$, Z_2 is $n \times g_2$, and $n = NT$. X_1 and Z_1 are assumed exogenous in that they are not correlated with μ_i and v_{it}, whereas X_2 and Z_2 are endogenous because they are correlated with μ_i, but not with v_{it}. The Within transformation sweeps the μ_i and removes the bias, but in the process it would also sweep the Z'_is and hence the Within estimator will not give an estimate of γ. To get around that, HT suggest obtaining the FE residuals and averaging them over time:

$$\hat{d}_i = \bar{y}_i - \bar{X}'_i\tilde{\beta}_{FE} \qquad [4]$$

Then, one can run 2SLS of $\hat{d}_i$ on Z_i with the set of instruments $A = [X_1, Z_1]$ to get a consistent estimate of γ which is called $\hat{\gamma}_{2SLS}$. For this to be feasible, the order condition for identification has to hold ($k_1 \geq g_2$). This means that there has to be as many time-varying (X_1) exogenous variables as there are time-invariant endogenous variables (Z_2). The intuition here is that every X_{it} can be written as the sum of $\tilde{X}_{it} = (X_{it} - \bar{X}_i)$ and $\bar{X}_i$. It is the latter term that contains μ_i as it is swept away from the former. If X_2 is correlated with μ_i, it must be in $\bar{X}_2$, which makes $\tilde{X}_2$ the ideal instrument. HT use X_1 twice because it is exogenous, once as $\tilde{X}_1$ and another time as $\bar{X}_1$. Z_1

is exogenous and Z_2 can be instrumented by the additional instruments gained from X_1. With consistent estimates of the disturbances obtained from $\tilde{\beta}_{FE}$ and $\hat{\gamma}_{2SLS}$, one can obtain consistent estimates of the variance components and hence θ. This, in turn, allows us to compute $y_{it}^* = y_{it} - \theta\bar{y}_i$ and X_{it}^* and $Z^* = (1-\theta)Z$. HT suggest an efficient estimator that can be obtained by running 2SLS of y_{it}^* on X_{it}^* and Z^* using $A_{HT} = [\tilde{X}, \bar{X}_1, Z_1]$ as instruments.

1. If $k_1 < g_2$, then the equation is underidentified. In this case, $\hat{\beta}_{HT} = \tilde{\beta}_{FE}$ and γ cannot be estimated.
2. If $k_1 = g_2$, then the equation is just-identified. In this case, $\hat{\beta}_{HT} = \tilde{\beta}_{FE}$ and $\hat{\gamma}_{HT} = \hat{\gamma}_{2SLS}$.
3. If $k_1 > g_2$, then the equation is over-identified and the HT estimator is more efficient than the FE estimator.

A test for over-identification is obtained by computing

$$\hat{m}_2 = \hat{q}_2'[\text{var}(\tilde{\beta}_{FE}) - \text{var}(\hat{\beta}_{HT})]^{-}\hat{q}_2 \qquad [5]$$

with $\hat{q}_2 = \tilde{\beta}_{FE} - \hat{\beta}_{HT}$ and $\hat{\sigma}_v^2 \hat{m} \overset{H_0}{\rightarrow} \chi^2_{k_1 - g_2}$.

Contoyannis and Rice (2001) applied the HT estimator, choosing race to be exogenous (the only time-invariant Z_1) and education to be endogenous (the only time-invariant Z_2). They also chose the health variables that are time varying to be endogenous (sahex, sahgd, and hlghq1) as well as (prof, manag, skllnm, and skllm). The HT estimates are 0.013 for excellent health, 0.010 for good health, and -0.003 for the General Health Questionnaire: Likert Scale score (hlghq1), with only the latter estimate being statistically significant.

Dynamic Panel Data Models

Many economic relationships are dynamic in nature and one of the advantages of panel data is that they allow the researcher to better understand the dynamics of adjustment. For example, a key feature of the rational addiction theory studied by Becker, Grossman, and Murphy (1994) is that consumption of cigarettes is addictive and will depend on future as well as past consumption. Consumers are rational if they are forward-looking in the sense that they anticipate the expected future consequences of their current actions. They recognize the addictive nature of their choices but they may elect to make them because the gains from the activity exceed the costs through future addiction. The more they smoke the higher is the current utility derived. However, the individual recognizes that he or she is building up a stock of this addictive good that is harmful. The individual rationally trades off these factors to determine the appropriate level of smoking. Finding future consumption statistically significant is a rejection of the myopic model of consumption behavior. In the latter model of addictive behavior, only past consumption stimulates current consumption, because individuals ignore the future in making their consumption decisions.

More formally, dynamic relationships are characterized by the presence of a lagged dependent variable among the regressors, i.e.,

$$y_{it} = \delta y_{i,t-1} + x_{it}'\beta + \mu_i + v_{it} \quad i = 1,\ldots,N \quad t = 1,\ldots,T \qquad [6]$$

where δ is a scalar, x'_{it} is $1 \times K$ and β is $K \times 1$, where $\mu_i \sim \text{IID}(0,\sigma_\mu^2)$ and $v_{it} \sim \text{IID}(0,\sigma_v^2)$ independent of each other and among themselves. This dynamic panel data regression model is characterized by two sources of persistence over time. Autocorrelation due to the presence of a lagged dependent variable among the regressors and individual effects characterizing the heterogeneity among the individuals. As y_{it} is a function of μ_i, it immediately follows that $y_{i,t-1}$ is also a function of μ_i, Therefore, $y_{i,t-1}$ is correlated with the error term. This renders the OLS estimator biased and inconsistent even if the v_{it} are not serially correlated. For the FE estimator, the Within transformation wipes out the μ_i, but $(y_{i,t-1} - \bar{y}_{i-1})$ where $\bar{y}_{i-1} = \sum_{t=2}^{T} y_{i,t-1}/(T-1)$ will still be correlated with $(v_{it} - \bar{v}_{i.})$ even if the v_{it} are not serially correlated. This is because $y_{i,t-1}$ is correlated with $\bar{v}_{i.}$ by construction. The latter average contains $v_{i,t-1}$ which is obviously correlated with $y_{i,t-1}$. In fact, the Within estimator will be biased of $O(1/T)$ and its consistency will depend on T being large (Nickell, 1981). Therefore, for the typical micropanel where N is large and T is fixed, the Within estimator is biased and inconsistent. It is worth emphasizing that only if $T \rightarrow \infty$ will the Within estimator of δ and β be consistent for the dynamic error component model. For macropanels, some researchers may still favor the Within estimator arguing that its bias may not be large. Judson and Owen (1999) performed some Monte Carlo experiments for $N = 20$ or 100 and $T = 5$, 10, 20, and 30 and found that the bias in the Within estimator can be sizable, even when $T = 30$. This bias increases with δ and decreases with T. But even for $T = 30$, this bias could be as much as 20% of the true value of the coefficient of interest.

Arellano and Bond (1991) suggested FD model to get rid of the μ_i and then using a Generalized Method of Moments (GMM) procedure that utilizes the orthogonality conditions that exist between lagged values of y_{it} and the disturbances v_{it}. It is illustrated with the simple autoregressive model with no regressors. With a three-wave panel, i.e., $T = 3$, the differenced equation becomes:

$$y_{i3} - y_{i2} = \delta(y_{i2} - y_{i1}) + (v_{i3} - v_{i2})$$

In this case, y_{i1} is a valid instrument because it is highly correlated with $(y_{i2} - y_{i1})$ and not correlated with $(v_{i3} - v_{i2})$ as long as the v_{it} are not serially correlated. But note what happens if the fourth wave is obtained:

$$y_{i4} - y_{i3} = \delta(y_{i3} - y_{i2}) + (v_{i4} - v_{i3})$$

In this case, y_{i2} as well as y_{i1} are valid instruments for $(y_{i3} - y_{i2})$ because both y_{i2} and y_{i1} are not correlated with $(v_{i4} - v_{i3})$. One can continue in this fashion, adding an extra valid instrument with each forward period, so that for period T, the set of valid instruments becomes $(y_{i1}, y_{i2}, \ldots, y_{i,T-2})$. The optimal Arellano and Bond (1991) GMM estimator of δ utilizes all these moment conditions weighting them by a sandwich heteroskedasticity auto-correlation estimator of the variance–covariance matrix of the disturbances. Arellano and Bond (1991) propose testing for serial correlation for the disturbances of the first-differenced equation. This test is important because the consistency of the GMM estimator relies on the assumption of no serial correlation in the v'_{it}s. Additionally, Arellano and Bond (1991) suggest a Sargan test for over-identifying. One has to reject the existence of serial correlation in the v'_{it}s and not reject the over-identifying

restrictions. Failing these diagnostics renders this procedure inconsistent.

Using Monte Carlo experiments, Bowsher (2002) finds that the use of too many moment conditions causes the Sargan test for overidentifying restrictions to be undersized and have extremely low power. The Sargan test never rejects when T is too large for a given N. Zero rejection rates under the null and alternative were observed for the following (N,T) pairs (125,16), (85,13), and (40,10). This is attributed to poor estimates of the weighting matrix in GMM. Using Monte Carlo experiments, Ziliak (1997) found that there was a bias/efficiency trade-off for the Arellano and Bond (1991) GMM estimator as the number of moment conditions increase and that one is better off with suboptimal instruments. Ziliak attributes the bias in GMM to the correlation between the sample moments used in estimation and the estimated weight matrix.

Blundell and Bond (1998) attributed the bias and the poor precision of the first difference GMM estimator to the problem of weak instruments. They show that an additional mild stationarity restriction on the initial conditions process allows the use of a system GMM estimator which captures additional nonlinear moment conditions that are ignored by the Arellano and Bond (1991) estimator. These additional nonlinear moment conditions are described in Ahn and Schmidt (1995) and can be linearized by adding a set of equations in levels on top of the set of equations in first differences of Arellano and Bond, hence a system of equations (*see* Baltagi, 2008, Chapter 8, for details). In this case, one uses lagged differences of y_{it} as instruments for equations in levels, in addition to lagged levels of y_{it} as instruments for equations in first differences. The system GMM estimator is shown to have dramatic efficiency gains over the basic first-difference Arellano and Bond GMM estimator as $\delta \to 1$, i.e., as the process tends to unit root and nonstationarity.

Baltagi *et al.* (2000) estimate a dynamic demand model for cigarettes based on panel data from 46 American states over the period 1963–92. The estimated equation is:

$$lnC_{it} = \alpha + \beta_1 lnC_{i,t-1} + \beta_2 lnP_{i,t} + \beta_3 lnY_{it} + \beta_4 lnPn_{it} + \mu_i + \lambda_t + \nu_{it} \quad [7]$$

where the subscript i denotes the i-th state ($i=1, \ldots, 46$), and the subscript t denotes the t-th year ($t = 1,\ldots,30$). C_{it} is real per capita sales of cigarettes by persons of smoking age (14 years and older). This is measured in packs of cigarettes per head. P_{it} is the average retail price of a pack of cigarettes measured in real terms. Y_{it} is real per capita disposable income. Pn_{it} denotes the minimum real price of cigarettes in any neighboring state. This last variable is a proxy for the casual smuggling effect across state borders. μ_i denotes the state-specific effects, and λ_t denotes the year-specific effects. OLS, which ignores the state and time effects, yields a low short-run price elasticity of -0.09. However, the coefficient of lagged consumption is 0.97 which implies a high long-run price elasticity of -2.98. The FE estimator with both state and time effects yields a higher short-run price elasticity of -0.30, but a lower long-run price elasticity of -1.79. Both state and time dummies were jointly significant with an observed F-statistic of 7.39 and a p-value of .0001. This is a dynamic equation and the OLS and FE estimators do not take into account the endogeneity of the lagged dependent variable. The Arellano and Bond (1991) GMM estimator yields a lagged consumption coefficient estimate of 0.70 and an own price elasticity of -0.40, both highly significant (Baltagi, 2008). The two-step Sargan test for over-identification does not reject the null, but this could be due to the bad power of this test for $N=46$ and $T=28$. The test for first-order serial correlation rejects the null of no first-order serial correlation, but it does not reject the null that there is no second-order serial correlation. This is what one expects in a first-differenced equation with the original untransformed disturbances assumed to be not serially correlated. Blundell and Bond (1998) system GMM estimator yields a lagged consumption coefficient estimate of 0.70 and an own price elasticity of -0.42, both highly significant, but with higher standard errors than the corresponding Arellano and Bond estimators. Sargan's test for over-identification does not reject the null, and the tests for first- and second-order serial correlation yield the expected diagnostics for system GMM.

Scott and Coote (2010) applied the dynamic panel data system GMM estimator to estimate the effect of regional primary-care organizations on primary-care performance. They utilize a panel of 119 Divisions of General Practice in Australia observed quarterly over the period 2000–05. Using four different measures of primary-care performance, a high level of persistence was found. The results show that Divisions were more likely to influence general practice infrastructure than clinical performance in diabetes, asthma, and cervical screening. Other applications of dynamic panel data GMM estimation methods include Baltagi and Griffin (2001) to a rational addiction model of cigarettes and Suhrcke and Urban (2010) to the impact of cardiovascular disease morality on economic growth.

Ng *et al.* (2012) study the relative importance of diet, physical activity, and health behavior of smoking and drinking on weight for a set of Chinese males, using panel data from the China Health and Nutrition Survey. The authors use a dynamic panel system GMM approach that explicitly includes time and spatially varying community-level urban city and price measures as instruments, to obtain estimates for the effects of diet, physical activity, drinking, and smoking on weight. Results show that approximately 5.4% of weight gain is due to declines in physical activity and 2.8–3.1% is due to dietary changes over time.

Limited Dependent Variable Panel Data Models

In some health studies, the dependent variable is binary. For example, individual i may be in good health at time t, i.e., $y_{it}=1$ with probability p_{it}, or in bad health, $y_{it}=0$ with probability $1-p_{it}$. Good health occurs when a latent unobserved index of health y^*_{it} is positive

$$\begin{aligned} y_{it} &= 1 \quad \text{if } y^*_{it} > 0 \\ &= 0 \quad \text{if } y^*_{it} \le 0 \end{aligned} \quad [8]$$

with $y^*_{it} = x'_{it}\beta + \mu_i + \nu_{it}$. So that

$$\Pr[y_{it}=1] = \Pr[y^*_{it} > 0] = \Pr[\nu_{it} > -x'_{it}\beta - \mu_i] = F(x'_{it}\beta + \mu_i) \quad [9]$$

where the last equality holds as long as the density function describing F is symmetric around zero. This is true for the logistic and normal density functions which are the most used in practice. This is a nonlinear panel data model because F is a cumulative density function, and one cannot get rid of the individual effects as in the linear panel data case with a within transformation. Hsiao, 2003 showed that unlike the linear FE panel data case, where the inconsistency of the μ'_is did not transmit into inconsistency for the β's. For the nonlinear panel data case, the inconsistency of the μ'_is renders the maximum likelihood estimates of the β's inconsistent. The usual solution around this incidental parameters problem is to assume a logistic function and to condition on $\sum_{t=1}^{T} y_{it}$, which is a minimum sufficient statistic for μ_i maximizing the conditional logistic likelihood function

$$L_c = \prod_{i=1}^{N} Pr\left(y_{i1}, \ldots, y_{iT} / \sum_{t=1}^{T} y_{it}\right) \qquad [10]$$

yields the conditional logit estimates for β. By definition of a sufficient statistic, the distribution of the data given this sufficient statistic will not depend on μ_i. In contrast to the FE logit model, the conditional likelihood approach does not yield computational simplifications for the FE probit model. But the probit specification has been popular for the RE model. In this case, $u_{it} = \mu_i + v_{it}$ where $\mu_I \sim \text{IIN}(0,\sigma_\mu^2)$ and $v_{it} \sim \text{IIN}(0,\sigma_v^2)$ independent of each other and the x_{it}. Because $E(u_{it}u_{is}) = \sigma_\mu^2$ for $t \neq s$, the joint likelihood of $(y_{1t}, \ldots, y_{Nt})$ can no longer be written as the product of the marginal likelihoods of the y_{it}. This complicates the derivation of maximum likelihood which will now involve T-dimensional integrals. Fortunately, Butler and Moffitt (1982) showed that for the probit case, the maximum likelihood computations involve only one integral which can be evaluated using the Gaussian–Hermite quadrature procedure. For an early application of the RE probit model, Sickles and Taubman (1986), who estimated a two-equation structural model of the health and retirement decisions of the elderly using five biennial panels of males drawn from the Retirement History Survey. Both the health and retirement variables were limited dependent variables and MLE using the Butler and Moffitt (1982) Gaussian quadrature procedure was implemented. Sickles and Taubman found that retirement decisions were strongly affected by health status and workers not yet eligible for social security were less likely to retire.

Contoyannis *et al.* (2004) utilize seven waves (1991–97) of the BHPS to analyze the dynamics of individual health and to decompose the persistence in health outcomes in the BHPS data into components due to state dependence, serial correlation, and unobserved heterogeneity. The indicator of health is defined by a binary response to the question: "Does your health in any way limit your daily activities compared to most people of your age?" A sample of 6106 individuals resulting in 42 742 panel observations are used to estimate static and dynamic panel probit models by maximum simulated likelihood methods. The dynamic models show strong positive state dependence.

Hernández-Quevedoa *et al.* (2008) use eight waves of the ECHP over the period 1994–2001 to estimate a dynamic nonlinear panel data model of health limitations for individuals within the Member States of the European Union. The RE probit specification conditions on previous health status and parameterizes the unobserved individual effect as a function of initial period observations on time-varying regressors and health (Wooldridge, 2005). Results reveal high state dependence of health limitations, which remains after controlling for measures of socioeconomic status. There is also heterogeneity in the socioeconomic gradient across countries. The importance of regarding health as a dynamic concept has implications for policy development. They imply that medical interventions or health improvement policies that create health gains, will have multiplier effects in the long run.

Further Readings

The panel data econometrics literature has exhibited phenomenal growth and one cannot do justice to the many theoretical contributions to date. Space limitations prevented the inclusion of many worthy topics including attrition, sample selection, semiparametric, nonparametric, and Bayesian methods using panel data. Unbalanced panels, problems associated with heteroskedasticity, serial as well as spatial correlation in panels, measurement error, duration, and quantile panel data models to mention a few. More extensive treatment of these and other topics are given in textbooks on the subject by Baltagi (2008), Wooldridge (2002), and Hsiao (2003). Also see the survey by Imbens and Wooldridge (2009) for an extensive discussion of alternative econometric methods to program evaluation besides the DID method. Also see Angrist and Pischke (2009) for a textbook discussion of DID. For recent applications of panel data methods to health economics, see the special issue of *Empirical Economics* edited by Baltagi *et al.* (2012) and Jones (2012).

Patents and Other Incentives for Pharmaceutical Innovation

PV Grootendorst and A Edwards, University of Toronto, Toronto, ON, Canada
A Hollis, University of Calgary, Calgary, AB, Canada

Introduction

Innovation – the discovery of ways to get more value from limited resources – is critically important for society's health and material standard of living. Despite the salience of innovation, there is no consensus on how much investment in innovation there should be, or how to ensure that the optimal investments are made, or how much the public sector should pay. These issues are particularly contentious in the pharmaceutical industry, given the high cost of drug development and the extraordinary importance of pharmaceuticals for human health.

Pharmaceutical research and development (R&D) takes place within both not-for-profit and for-profit organizations. The not-for-profit sector – comprising both academic and public sector labs – tends to focus on basic research, whereas for-profit drug companies exploit this basic research, as well as their own research, to develop, test, and market new drugs. Public support of basic research is usually by way of grants, administered by charitable foundations and public agencies, such as the Wellcome Trust in the UK and the National Institutes of Health in the US. Government support for the subsequent steps in the drug development process is composed of three core approaches: (1) tax subsidies for clinical trials and other R&D costs; (2) patents and other forms of intellectual property (IP) protection that provides the innovator with an exclusivity period in sales of newly developed products; and (3) prescription drug subsidies (often extended to seniors and those with high drug costs relative to income). These policies increase the profits to firms that undertake R&D, either by decreasing R&D costs (in the case of tax subsidies) or increasing revenues earned on the sale of new drugs (prescription drug subsidies, IP protection). Policies that decrease firms' costs of drug development are commonly referred to as 'push' incentives, whereas policies that increase the revenues accruing to firms that manage to bring new drugs to market are termed 'pull' incentives.

During the past decade or so, there has been considerable interest by academics, activists, politicians, and others in the manner in which governments support pharmaceutical R&D undertaken by for-profit firms. Of particular concern is the declining productivity of the pharmaceutical R&D sector. Recent academic studies place the capitalized cost of drug development to be between US$1.5 and US$1.8 billion. Other estimates are even higher. Different types of push and pull incentives, it is argued, would yield more therapeutically novel drugs per dollar of public support. But although there is agreement that reform is needed, there is less agreement over what should be done to improve matters.

This article reviews the contours of the academic debate, focusing on the advantages and deficiencies of existing forms of government support for drug R&D, and the features of the alternative arrangements that their proponents suggest will improve in the current system.

Intellectual Property: Advantages and Disadvantages

Much of the analysis of the defects of current arrangements focus on the system of IP protection afforded to new drugs. This is not surprising, considering that IP privileges constitute one of the most expensive of all the forms of public support extended to the pharmaceutical sector.

There are two distinct kinds of IP currently available for pharmaceuticals: patents and data exclusivity. A patent provides its owner with a 20-year period of exclusive use of the invention disclosed in the patent. Typically, drugs will be protected by a number of patents, each of which may have a number of claims disclosing distinct inventions. Because the innovation process is long, some of the relevant patents are filed many years before the drug comes to market. The result is that the average period of exclusivity owing to patents is roughly 10 years.

Data exclusivity is another important IP tool. The patent protects the invention, and can therefore protect the drug if it embodies the invention and there is no way of circumventing the patent. Data exclusivity protects the data produced by the innovator for the purpose of obtaining regulatory approval. Regulators such as the US Food and Drug Administration (FDA) require extensive testing of drugs, and running the clinical trials to obtain data that will demonstrate safety and effectiveness is extremely costly – typically approximately half of the total cost of drug development. During the term of data exclusivity, which begins after the drug receives regulatory approval and varies by country from five to ten years, no generic drug is approvable based on a reference to the clinical trial data of the innovator's drug.

IP allows the innovator to earn more sales revenue than would be possible without exclusivity. The variable costs of production and distribution of drugs are typically only a small fraction of the brand drug price, ranging approximately 5–25%. After covering other costs, such as marketing and administration, the remainder (often called the mark-up or the margin) can be paid as dividends or reinvested into R&D. IP thus creates very powerful incentives to develop therapeutically novel drugs (among other innovations). The chief appeal of this system of market exclusivity is that it automatically generates a relationship between the reward to the innovator (the mark-up times, the volume of sales) and the value of the innovation to society, as Adam Smith himself noted. More therapeutically valuable drugs are expected to earn greater sales revenues. IP, however, also has some drawbacks, five of which are focused in the following sections.

Drug R&D Costs

The first drawback is that the IP system can increase the cost of drug R&D for two reasons. Basic research conducted in academic or public sector labs will occasionally identify cellular

 doi:10.1016/B978-0-12-375678-7.01219-0

proteins, known as 'targets,' implicated in disease pathways. Multiple companies will then attempt to develop drugs that act on these targets. But drug development is very difficult because human biology is very complicated. As a result, many drugs simply do not work as expected and many of those that successfully disrupt the disease pathway either show no therapeutic benefit or do so only at doses that are toxic. It is also difficult to deliver an agent to its target in sufficient concentration and for an appropriate duration to achieve the desired therapeutic effect.

Often the viability (or otherwise) of a drug candidate or a disease mechanism becomes apparent only after much time and money have been spent. Ideally, drug companies would share this information. Sharing would reduce duplication of R&D costs, would eliminate unnecessary experimentation on human subjects, and would advance the understanding of human pathophysiology and pharmacology. But commercial drug R&D has historically been conducted in a culture of secrecy. Some of this secrecy, no doubt, is due to normal competitive behavior, present to varying degrees in all technology-intensive industries. But pharmaceutical companies are hesitant to share information, at least before patent filing, owing to the risk that this information may be used by a competitor that is developing patents in the same area. Such a competitor may preemptively patent a class of molecules with therapeutic promise, or worse, attempt to patent the target or pathway itself.

Of course, patents, once filed, publicly disclose the claimed inventions, so they do help to disseminate knowledge. Also the 'first to file' rule for patents gives incentives to patent, and therefore disclose, early. And companies routinely report scientific and clinical progress at academic and medical meetings. But the information that is disclosed in patents or at meetings is typically incomplete, and certainly does not prevent multiple drug companies from pursuing leads that are known by other competitors to be dead ends.

IP can hinder drug development in another way. Many research inputs, such as disease-linked human genes and techniques to manipulate deoxyribonuclic acid and proteins, are patented. Innovating firms must therefore conduct R&D cognizant of the landscape of existing patents. One way is to conduct R&D in ways that do not infringe on existing patents. But if it is not possible (or prohibitively costly) to use a circuitous technique, the firm must anticipate the threat of legal action by patent holders. One way to deal with such threats is to pay licensing fees, assuming that the entrant can strike a mutually beneficial deal with possibly numerous patent holders. Another approach is to wait until relevant patents have expired. The potential entrant might also mount a legal challenge to the validity of patents perceived as being weak. Yet another tactic is to amass a portfolio of patents so that the firm can credibly threaten to counter-sue for infringement of some of its own patents. Each of these strategies can increase the costs of research substantially.

'Follow-on' Drugs

A successful new 'first-in-class' drug will often face competition from a series of 'me-too' or 'follow-on' drugs that are therapeutically similar to the first-in-class drug. Often, follow-on drugs are simply the natural outcome of simultaneous research programs into the same therapeutic target. In other cases, they are the result of an intentionally imitative research program. The angiotensin converting enzyme (ACE) inhibitors, a class of drugs routinely used to manage high blood pressure, is illustrative of this. The first ACE inhibitor, captopril, was introduced in the US in 1981. Since then, over 10 ACE inhibitors have been launched, the last one in the mid-1990s. It appears that some of these later arriving ACE inhibitors were launched to capitalize on the commercial success (and clinically proven mechanism of action) of the earlier ACE inhibitors.

The proliferation of follow-on drugs is the subject of some debate. Proponents note that some follow-on drugs are therapeutically superior to the pioneer. Indeed, this appears to be the case for the ACE inhibitors. Moreover, if patients respond idiosyncratically to any one in a group of similar drugs, it is very useful to have alternatives. But the threat of imitative drug development also reduces the incentive for firms to develop first-in-class drugs. The reason is that follow-on drugs decrease the expected sales revenues and increase the costs of the pioneer. Lichtenberg and Philipson show that competition from follow-on drugs decreases the pioneer drug's revenues more than the competition from generics after patent expiry, in large part because the competition from follow-on drugs occurs early in the life of the pioneer drug. Costs increase because the pioneer firm typically spends on marketing and promotion to defend market share from capture by competitive products. Follow-on drugs may therefore dull the incentive to develop first-in-class drugs. As evidence of this, critics point to the protein kinases; these cellular proteins represent the most common targets for drug discovery. However, although there are 518 protein kinases in the human genome, more than half the current drug discovery programs focus on the handful of kinases for which there is already an existing drug.

A related criticism concerns the large outlays on the marketing and promotion of branded pharmaceutical drugs, more generally. Estimates of promotional expenditures are somewhat uncertain, but data compiled by Gagnon and Lexchin suggest that in 2004 the US pharmaceutical industry spent at least as much on promotion as it did on R&D. (Gagnon and Lexchin's estimate includes two particularly notable components of promotional cost: They include samples, representing 27.7% of total promotional dollar value; and estimated 'unmonitored' expenditures, representing 25%. The samples are valued at the retail prices, which are probably on average at least 10 times the cost of manufacture; and the estimate of unmonitored expenditure is highly uncertain. Removing these components reduces promotional expenditures to an amount closer to the amount spent on R&D.) Economic theory predicts that firms will continue to spend on promotion as long as the last dollar spent results in a compensatory increase in unit sales and gross profits. Thus IP, to the extent that it increases the margins earned on unit sales, encourages promotion.

No doubt some, perhaps the majority, of this promotion is socially valuable, alerting consumers about the availability of effective therapies for an untreated health condition, or providing prescribers with information on the properties of new

drugs. However, critics charge that a significant portion is more persuasive than informative, and in some cases is misleading. This kind of advertising is socially wasteful, as it represents a zero-sum competition between firms for market share; in the worst cases it might lead to worse health outcomes if clinicians are persuaded to prescribe drugs that are unnecessary or inferior to other therapies.

Drug Pricing

In most markets, consumer willingness and ability to pay is an important constraint on the price charged. Pharmaceutical markets are different. Most consumers in developed countries have insurance that covers some or all of the cost of prescribed drugs. If consumers do not pay for their drugs, what constrains prices? The answer, of course, is that insurers set limits on what they will pay. Indeed, many drug plans wield substantial bargaining power on account of their large size. France, UK, and Australia, for instance, operate national drug plans that account for the majority of drug sales. Federal states without national drug plans typically have large-scale plans operated by regional governments. These plans increasingly exploit their negotiating power to extract price concessions from drug companies that wish to have their products listed on the drug plan formulary. These price concessions directly reduce the margins that are ostensibly there to recoup R&D costs. Negotiation costs and costs of applying for formulary listing can also be substantial; Cohen reports that drug manufacturers often need to contract with hundreds of different drug plans in the US.

The price concessions are sometimes directly negotiated with insurers. For instance, the public drug plan operating in the province of Ontario, Canada, extracts confidential discounts off list prices. Other insurers set a maximum price that they are willing to pay, not for tablets or pills, but for expected units of health generated by the use of a new drug. These health units are usually denominated in 'quality-adjusted life-years' (or 'QALYs') – which measure both survival and quality of life gains. Typically, insurers' willingness to pay for a QALY are well below consumers' expressed willingness to pay. The UK National Institute for Health and Clinical Excellence (NICE), for instance, uses a threshold of £20 000 to £30 000 per QALY. Consensus estimates of consumers' valuation of a life year in normal health in the US are closer to US$100 000 (~£65 000).

The UK's NICE is perhaps the most well known national health technology assessment body, but it is not the only such initiative. Other countries that have created such agencies include Australia (Pharmaceutical Benefits Advisory Committee), Canada (Common Drug Review), Scotland (Scottish Medicines Consortium), Sweden (TLV), and Germany (IQWiG). Although the US has no national-level body, Cohen notes that many insurers informally consider cost effectiveness when making formulary decisions.

One reason that public insurers are willing to pay less than consumers is that public health-care budgets are constrained. The relevant consideration for NICE is its opportunity cost: if the threshold payment per QALY is too high, it will displace other, more cost-effective nonpharmaceutical interventions. A relatively low willingness to pay for drugs is thus appropriate if the public health authority wishes to maximize health given a constrained budget, although this raises questions about the adequacy of the health budget.

The use of QALY assessments reflects a growing tendency on the part of insurers to assess value for money when considering whether, and under what conditions, they will reimburse a drug. The insurers that used to cover almost all new drugs that received regulatory approval are now becoming much more selective consumers. An innovator, of course, can elect to forgo formulary listing in a given insurance plan; beneficiaries always have the option of paying cash for drugs that are not insured. But if the insurer has a large market share (as is typical for most public drug plans), then exclusion from the formulary will markedly reduce sales. There is a double effect from exclusion: nonformulary drugs tend not to be used, not only because of the cost to consumers, but also because physicians are not accustomed to prescribing them.

In summary, IP affords innovators some market power and this market power is complemented by widespread insurance coverage, which renders consumer demand less price sensitive. This has naturally resulted in high prices. However, more and more insurers are exercising countervailing market power and, by so doing, are reducing innovators' margins and hence the incentive to conduct R&D. Many payers now require innovators to demonstrate that their new drugs provide sufficient value for money as a condition for reimbursement. This has reduced margins both directly (when low willingness to pay thresholds are applied) and indirectly (by requiring firms to incur the time and expense of conducting economic appraisal studies).

Drug Access

Scholars distinguish between two separate drug access issues. The first is that IP may result in less drug use, relative to a world in which the drug is available for sale at a competitive (generic) price. More precisely, some consumers, who can be labeled as 'price sensitive,' are unable or unwilling to pay the brand price but may be willing and able to pay the marginal production cost, which would be the generic price in a well-functioning generic market. These sales are valued at more than their resource cost, so society would gain if the drug company lowered its price for the price-sensitive consumers. But to make these sales, the firm may need to reduce its price for everyone and, by so doing, may lose more revenues on its 'price-insensitive' customers – those who are willing to pay the brand price – than it earns on its price-sensitive customers. It would be profitable to sell at a lower price just to its price-sensitive consumers if it could prevent resale of the product to price-insensitive customers. But it is costly to prevent resale; indeed this appears to be the reason that drug companies were reluctant to sell acquired immunodeficiency syndrome (AIDS) drugs at discounted prices in low-income countries. There is also pressure from higher-income countries to get the same discounted prices offered in low-income countries. Recently some companies have used 'tiered pricing' in which the price in the lowest-income countries is essentially just the manufacturing cost. However, even then, as observed by Flynn,

Hollis, and Palmedo, within many developing countries the most profitable price may be the one that targets chiefly price-insensitive, high-income consumers.

Although access problems are most acute in developing countries, they also affect insured residents of developed countries. With prices of over US$50 000 for many new biologic therapies, insurers (and especially government drug plans) are not listing some products in their formularies.

The second access issue is that IP directs R&D into therapeutic areas where expected revenues exceed anticipated drug development costs. Thus diseases with limited market demand have traditionally received little attention from drug companies. This includes diseases affecting large numbers of individuals in poor countries (such as drug resistant TB, malaria, and other tropical diseases). This inequity in the distribution of R&D effort is morally problematic. It is true that this problem is not caused by IP. Diseases of poverty will tend to be neglected regardless of whether or not society extends IP protections to commercial drug developers. For such diseases to be the focus of R&D effort necessarily requires that affluent people underwrite R&D costs. However, if the decision has been made for the affluent to subsidize the costs of developing drugs with limited market demand, then it does not follow that IP is the best way to incentivize such R&D.

'Profit Raiding'

The final drawback of IP is that some portion of the innovator's potential sale revenues will simply be lost. The reason is that the high profit margins provided by market exclusivity attract 'raiders' who attempt to appropriate these margins. The potential profits from IP protection therefore decline, both by the profits actually appropriated by raiders and by the resources expended by the innovator to fend off raiders. Hence the threat posed by raiders dulls the financial incentive to innovate in the first place.

Counterfeiters, the clearest example of a profit raider, are attracted to patented drugs owing to their high margins and low transport costs. Historically, drug companies ignored the problem given that most contraband was sold in low-income countries, where potential profits were low. This has changed. Advances in counterfeit technology, the entry of organized crime syndicates into the counterfeit industry, and the introduction of patent protection (and hence higher drug prices) in several emerging markets following the 1994 ratification of the Trade-Related Aspects of Intellectual Property Rights (TRIPs) agreement, resulted in large increases in counterfeit sales. This counterfeit is increasingly difficult to distinguish from the genuine product and is infiltrating developed country markets. Drug companies have responded by changing the design of their pills, tablets, and packaging to make imitation more costly; they have also invested in radio-frequency identification and other technologies to secure their distribution channels from infiltration. Despite these efforts, losses from counterfeiting have been estimated to be as high as US$45 billion (US) annually. Lybecker reports that counterfeiting remains a pervasive problem "impacting nations of every size and income level and drugs of every description."

Drug resellers are another type of profit raider. International differences in price regulation regimes and national income, as well as exchange rate fluctuations and other factors, result in differences in the maximum price that a multinational drug company can charge in different markets. These variations present drug companies with a dilemma. On the one hand, profit maximization requires that they charge as much as each market will bear, so that less affluent countries will pay less toward the cost of R&D than richer countries. But drug resellers are quick to exploit price differences. Moreover, price regulators in Canada and elsewhere mandate that they pay no more than what is paid in a set of comparator countries. So listing at a low price in one country might cannibalize profits elsewhere. Faced with this tradeoff, a drug company might sacrifice profits in a country with limited willingness to pay (by delaying listing or listing at a higher than optimal price) to preserve more substantial profits in a country with greater willingness to pay. Nevertheless, it is difficult to eliminate all arbitrage opportunities. For instance, Bart presents estimates of the value of the drugs resold in the EU as being in the order of EUR€ 5–6 billion in 2006.

Generic competition can also be a form of raiding, to the extent that it undermines the legitimate and expected exclusivity period. Generic firms have an obvious financial incentive to enter large markets as soon as possible and will mount legal challenges to patents perceived as being weak. Brand firms have responded by increasing the number of patents listed on each drug. Indeed, Frank reports that branded drug firms in the US now carry an average of 10 patents for each drug – as compared with an average of 2 a decade earlier. Two studies have examined the impact of these developments on exclusivity periods. Grabowski and Kyle examine drugs in the US for which there was generic entry in the period 1995–2005, and find that there was an increase in generic challenges in both small and large 'blockbuster' pharmaceutical markets, which reduced market exclusivity periods. Hemphilll and Sampat, examining data for 2001–10, confirm increased numbers of challenges by generics, especially those that occur within the first five years of a drug being on the market. In contrast, however, they find that exclusivity periods have not changed significantly. Their explanation for this is that generic firms are chiefly challenging low-quality patents, so that generic challenges are simply 'maintaining' the traditional patent life by preventing low-quality patents from extending exclusivity.

In addition to strategic patenting, brand drug companies have used two other strategies to mitigate profit loss from generic competition. First, a brand firm may launch a generic version of its branded drug product – a so-called 'authorized generic' – to compete with independent generics for price-sensitive consumers. Second, if generic entry is likely, there may be an arrangement between the firms to delay generic entry. Such arrangements can be profitable because the brand firm, should it retain market exclusivity, can typically earn a higher margin on the generic firm's unit sales than the generic could itself earn. So the brand firm can pay the generic firm the margins that it would have made and still have money left over. These arrangements have attracted considerable attention under antitrust laws; naked pay-for-delay settlements are now prohibited in the US. More recently the US Federal Trade

Commission has challenged settlements in which the compensation to the generic for delayed entry is a promise of less aggressive competition.

Finally, noting that the market entry of follow-on drugs can be considered as a form of profit raiding, although unlike the case of counterfeiters, follow-on drugs provide benefits to consumers, in the form of expanded treatment choices, some of which are therapeutically superior to the pioneer drug.

Alternative Push and Pull Schemes

Analysts have proposed a variety of different push and pull schemes that are claimed to yield more therapeutically valuable drugs per dollar of public support. These proposals are outlined as follows.

Alternative Push Programs

Push programs aim to reduce the cost of conducting R&D to drug companies. Governments are already heavily involved in basic medical research, and this research substantially reduces the cost of bringing new drugs to market. However, there has been much interest recently in push programs that extend beyond basic clinical research, and into development problems that have traditionally been the domain of pharmaceutical companies. Of these, two proposals have received the most attention: (1) public subsidies for translational research and (2) public subsidy of Phase III clinical trials.

Public subsidies for translational research

A key determinant of the cost of bringing new drugs to market is the rate of failure of drugs in late stage clinical trials (where drugs are tested on large number of subjects with the disease). Drug candidates that are abandoned at this stage can be enormously costly. A high profile example was the failure of Pfizer's drug torcetrapib in Phase III trials in 2006; the development costs on this ultimately unsuccessful product totaled US$1 billion.

The failure of drug candidates is due to an incomplete understanding of human pathophysiology and pharmacology. Two aspects of the reward systems that drive commercial drug discovery inhibit learning. First, as was noted earlier, drug companies keep the results of their drug development programs secret, at least before patents are filed; this secrecy is in part due to the IP system. Second, due to the high risk of failure in pursuing risky hypotheses, companies tend to focus only on those targets that are well-studied in academic labs. But academia focuses on only a small fraction of potential targets. There are approximately 3000 targets in the human genome that are potentially susceptible to a drug. Of these, by 2006 only a few hundred targets had been shown to be therapeutically useful and modifiable by metabolically accessible, nontoxic drugs. Drug companies are understandably reluctant to invest significantly in their own target validation programs given the high risk of failure and concerns that competitors will use this information to develop competing drugs.

Rai *et al.* and Edwards *et al.* concur that this work requires the expertise and resources of both the academic and industrial pharmaceutical sectors, and therein lies the problem. Academic researchers collectively may have greater insight of the disease relevance of targets than do individual drug companies, given that the public sector collectively spends far more than industry does on understanding basic disease mechanisms. Drug companies have the expertise and resources needed to carry out the systematic steps of drug discovery. They also hold three other key inputs for target validation: (1) proprietary collections of small molecules that are needed to assess the functional attributes of proteins, (2) the expertise of medicinal chemists needed to produce new ones, and (3) the expertise and resources to develop and test biologics. To date, most collaborations between industry and academia are conducted within closed IP frameworks, in part because drug companies are reluctant to share their knowledge and resources widely, lest they benefit competitors.

To accelerate the process of target validation, Rai *et al.* propose that a trusted agency provide a sort of matchmaking service between academics and drug companies. The agency would assess targets discovered by academics using the small molecule libraries owned by drug companies and notify both parties if a target was hypothesized to have therapeutic potential. If both parties wanted to deal, the agency would help broker an IP agreement. Edwards *et al.* suggest that target validation, which only occurs after extensive clinical trials, is best conducted as part of an open-access, not-for-profit collaboration between the academic and commercial sectors. Placing research findings in the public domain in real time and unencumbered by IP restrictions would disseminate findings rapidly and widely, avoid duplication of effort, and conserve the considerable time and energy that is required to allocate IP rights over basic scientific discoveries. The open-access model would also prevent the exposure of research subjects to experimental drugs that are often ineffective, and known to be so by at least a few commercial players and regulators.

But why would academics and industry collaborate? Edwards and colleagues argue that drug companies that contribute their equipment, molecular libraries, and the expertise of their scientists would gain more from the collaboration (i.e., access to novel drug targets and influence over research directions) than they would lose from sharing their resources with potential competitors. To prevent free-riding, they propose that membership should be restricted to organizations that make a meaningful, and agreed-upon, contribution. For academics to commit fully, the collaboration must offer an attractive opportunity to conduct intellectually satisfying research and to receive peer recognition.

There is some evidence that such collaborations between academic and industrial scientists can be successful. The Structural Genomics Consortium (SGC), founded in 2003, accounts for approximately 15% of all the human protein structures in the public databases and is using this information to collaborate with industry medicinal chemists to generate open-access chemical inhibitors of new drug targets. The SGC is funded by the Canadian and Ontario governments, the Wellcome Trust, and eight drug companies, and all research output is released without restriction under an

open-access policy. Edwards and his colleagues are initiating a parallel effort in which a consortium of academic institutions and major drug companies collaborates openly to test the disease relevance of novel drug targets in humans.

Public subsidies for clinical research

Several commentators, including Lewis, Reichman and So, Baker, Boldrin and Levine, and Jayadev and Stiglitz, have advocated the public funding of Phase III clinical trials. Public funding of clinical trials would relieve drug companies of the single largest cost of drug R&D. At the same time, public spending on clinical trials would be relatively modest, for two reasons. First, governments already subsidize clinical trials through the use of tax subsidies. Second, governments likely face a cost of capital less than the 11% cost faced by the pharmaceutical industry. Because clinical trials must be conducted before marketing approval, development costs are very sensitive to the cost of capital. In addition to being relatively economical, publicly funded safety and efficacy trials can produce information that is more credible and clinically useful than industry-funded trials, which are naturally designed to maximize the expected profits rather than the expected clinical benefits.

The public agency responsible for the trials would presumably need a way of deciding which drug candidates are eligible for public funding. One concern is that the agency's choice of drugs whose trial costs are eligible for public subsidy may be subject to undue political interference. Moreover, the agency may not be well informed of the most promising drug candidates. These issues could be dealt with to some extent by providing public subsidies only to those drugs that cleared the clinical trials.

Product-development partnerships

As noted earlier, there are very weak incentives for commercial drug companies to invest in the development of drugs targeting malaria, tuberculosis, and other diseases prevalent in developing countries. Governments and private foundations, however, have made substantial investments in research that addresses the gap. But pharmaceutical companies themselves have the crucial advantages of substantial expertise, technological capabilities, and large libraries of potentially interesting compounds. So it was natural for 'product-development partnerships' (PDPs) to arise between governments or foundations and for-profit pharmaceutical companies. The difficulty was that for-profit companies wanted to be able to earn a return on their investment, whereas governments and foundations were especially interested in ensuring that the prices of products were low enough to enable widespread use in poor countries.

A key innovation in developing these PDPs was identifying how pharmaceutical companies could be rewarded for their participation, in a way that also allowed the 'public' partner to achieve its goals. Modern PDPs have typically satisfied the divergent goals of their partners by splitting the market for the product into a commercial one, left to the industry partner, and a humanitarian one, in which some arrangement was made to achieve wider access, usually through at-cost pricing or through licensing to competitive producers.

Thus, during the early 2000s, several important PDPs have been established, and some have been successful in delivering products to market. These PDPs have become a central component of the war on neglected diseases. The most substantial PDPs, according to funding received, are the International AIDS Vaccine Initiative and the Medicines for Malaria Venture (MMV), which are both funded at close to US$100 m annually. MMV has a large portfolio of products at different stages of development. Unlike a traditional drug company, which has a portfolio of drugs in different therapeutic areas, MMV is focused only on malaria. This approach would create undesirable risk for a for-profit company; but it is efficient for MMV because its advisory committee has the opportunity to compare many different prospective products and to choose a portfolio optimized to achieving success in addressing medical needs. Most other PDPs focus on one or two therapeutic areas, a feature that distinguishes them from private companies and offers a strategic advantage for development work.

Alternative Pull Programs

The push programs reviewed above aim to reduce the cost of conducting R&D to drug companies. Pull programs, conversely, provide rewards for the end products of the R&D process – new drugs. The alternative pull programs differ from the IP model in one key respect: instead of granting the innovator the right to exclude others from selling the drug, innovators are rewarded with payments that are proportional to the drug's value. This means that under the alternative models, competitive entry occurs sooner, so that sales volumes are greater and prices lower. With prices closer to competitive levels, drug access would be improved and resale, counterfeiting, and other forms of profit competition would be rendered less lucrative.

These proposals can be categorized along several dimensions.

Measurement of drug value

Under the current IP system, drugs that the market deems to be more valuable earn greater profits. But the market's measure of value – willingness to pay – is a noisy measure of a drug's value. In most markets, consumers assess whether a good or service is worth the price; consumer willingness to pay in such markets is a reasonable estimate of social value. Pharmaceutical markets are extraordinary because the consumer neither chooses the medicine (the physician does) nor pays for it (the insurer does). Market demand for drugs thus reflects physicians' prescribing decisions, insurers' coverage decisions (and related cost containment policies), and consumer willingness to pay for insurance and amounts not covered by insurers. Although physicians act as expert agents on behalf of patients, many physicians are doubly protected from pricing concerns, because they do not make even copayments.

Different schemes use different measures of drug value. Sanders' Medical Innovation Prize Fund Act would grant a public agency the power to decide on reward amounts and identify priority disease areas. The agency would be bound only by various guidelines, such as the guideline that more effective drugs should earn larger rewards. DiMasi and

Grabowski express concern that under a discretionary system, 'political rent seeking' and lobbying may distort research directions. Moreover, they suggest that for-profit drug developers are best able to identify and pursue the scientific opportunities that will lead to socially valuable products.

Other proposals would rely on forecasts of the profitability of new drugs. Kremer proposed that a public agency assess drug value by auctioning off IP rights to a new drug. In most cases – say, nine of ten auctions – the winning bid would be used only to set the reward payment to the innovator and the patents would then be placed in the public domain. In a randomly selected tenth auction, the winning bidder would receive the IP rights at the bid price. A defect of this scheme is that 10% of all new drugs remain under patent. However, this is necessary if auction participants are to take the bidding seriously.

David Levine has proposed a mechanism that could be useful in cases where a public sector agency or perhaps an open source drug discovery consortium has identified a compound with some therapeutic promise, but whose properties have not been subject to any clinical testing. Levine proposes that drug companies bid for the rights to these compounds. Bids consist of royalty rates that would accrue to the winner from all firms selling the drug, should the drug clear all the clinical trials and gain regulatory approval. The lowest bidder earns royalty income but is responsible for covering trial costs.

Levine's proposal is akin to the compulsory licensing schemes that have been used in Canada and elsewhere, but with one major difference. Historically, regulators set compulsory license royalty rates at some arbitrary amount, whereas Levine would let firms bid on the royalty rate. A firm's bid would depend on its ability to operate clinical trials and its expectations are: the likelihood that the drug will clear regulatory hurdles, the therapeutic value of the drug (vis-à-vis current therapies), the anticipated market size, and the number of competing firms.

How would drug companies fare under these proposed schemes relative to the existing IP system? In theory, Kremer's proposal would give innovators the present discounted value of their anticipated monopoly profits, so over the long term, firms would fare just as well as in the existing system, if expectations are unbiased. Indeed, because rewards are less variable under the Kremer approach, it might even be preferred to the IP system. Should Levine's proposal be adopted, competition among firms would decrease the rewards to the firms' opportunity cost – the most that they could earn in some other venture. Kremer therefore rewards the market value of the innovation, which itself is determined by the willingness to pay on the part of drug plans and consumers whereas Levine covers firms' cost of innovation.

The proposed Health Impact Fund (HIF) offers a mechanism that rewards firms in a way related to both value and cost. A drug enrolled in the HIF would be sold at cost but would earn payments proportional to its measured impact on population health in each of the 10 years following market launch. The proposal also allows for supplementary rewards for 5 years should its sponsor receive approval to use the drug for new indications. Each annual payment represents a share of a reward fund; the reward fund share for an enrolled drug in a given year is equal to the drug's share of the global health produced by all participating drugs in that year. Health impacts would be measured using many of the same health technology assessment procedures as currently used by drug plans when deciding whether or not to reimburse a new drug. For example, if all participating drugs were estimated to have produced 20 million QALYs in a given year, and if an enrolled drug had produced 2 million of these QALYs, then it would receive 10% of the fund. Contributions to the HIF reward fund by donor countries would be proportional to the donor's Gross National Income.

Participation in the HIF by drug companies would be voluntary; a drug developer could elect to exercise its IP privilege or relinquish high prices in exchange for the reward payments. By making the scheme optional, developers could earn at least as much as they would under the existing system. At the same time, because firms would compete over a fixed pool of rewards, the expected reward must be equal to the cost of development for the firm with a marginal project. Thus, this system makes rewards depend explicitly on the marginal cost of innovation.

Because the IP system, as well as the systems proposed by Kremer and Levine, are market-driven, firms have little incentive to conduct R&D into important diseases afflicting chiefly the poor. The HIF, in contrast, could be used to reward the development of drugs with large health impacts, even if the beneficiaries are themselves not funding the reward payments. The HIF could similarly incentivize the development of new uses of older drugs for which there would otherwise be no significant reward.

The HIF is but one approach that could be used to fund the development of drugs that are intended for use in low-income regions. The Advance Market Commitment is another. Several governments and the Bill & Melinda Gates Foundation have funded a US$1.3 billion program to subsidize the provision of the pneumoccal vaccine in the poorest countries. The subsidy is at a fixed rate per vaccine delivered, and firms were intended to compete for a share of the US$1.3 billion by accelerating the development of vaccines that would treat the most common strains of pneumonia in developing countries and by rapidly scaling up production.

A criticism of the HIF is that it requires a relatively complex centralized system of health impact assessment. However, many drug plans presently require forecasts of the health impacts of new drugs being considered for formulary inclusion, so the criticism is somewhat misplaced. It is true that the HIF requires measurements of actual – rather than anticipated – heath impacts, and also requires a standardized measure of health impact. These measures would likely vary somewhat by country, depending on the institutional features of health care, as well as health risks specific to each setting. So health impact assessment is front and center of the HIF approach whereas under existing assessment procedures, drug plans appear to be satisfied with a lower standard of evidence (i.e., anticipated, not actual health impacts), especially if the price charged is attractive. A pilot of the HIF could involve a performance-based reward applied in a single country to one or more drugs, to test the ability to measure impact in a credible way, and also to see whether firms would respond to the incentives inherent in the system.

It is also useful at this point to note some drawbacks of the auction mechanisms contemplated by Kremer and Levine. The auction format is widely used to elicit private information.

But Grinols and Henderson question the utility of the auction mechanism for reward determination given the substantial uncertainty over the profitability of a new drug. They argue that it is difficult to forecast profits owing to the introduction of competing drugs, and changes in disease prevalence and severity. Auctions are also subject to gaming by bidders, so they need to be carefully designed.

Kremer's proposal has one additional defect. The innovating firm receives a lump sum payment before the drug is actually sold and receives nothing thereafter. Hence there is little incentive for the firm to promote its drug (which is often an important component of achieving widespread sales) or to investigate new uses for the drug. The HIF, and the approach advocated by Levine, however, reward innovators in proportion to their market sales and therefore retain incentives for promotion and on-going product development.

Financing reward payments

The mechanisms proposed by Kremer, Sanders, and Hollis and Pogge would finance rewards using public funds, whereas Levine's scheme is self-financing.

Public funding has both pros and cons. On the one hand, because the technology embodied in a new drug is a classic public good, prices should ideally be close to competitive levels. With publicly financed rewards, drug prices would be lower than in royalty-based schemes, assuming that the funding scheme set limits on pricing, for example, by requiring generic licensing. Public funding could also simultaneously address equity goals through the distribution of the financial burden of R&D across taxpayers. In a privately financed scheme, this burden is distributed among drug users. The difference in drug prices would likely not be large for high volume drugs, but they could be for low volume drugs (including drugs used to treat rare disorders).

Public funding also has drawbacks. Public funding of investment into innovation requires taxation, which distorts labor-leisure choices and consumption decisions. This drawback should not be overstated, however, most prescription drug spending in developed countries is already publicly funded, either directly (through a public drug plan) or indirectly (through tax subsidies for private drug coverage). Under a rewards scheme, drug prices would drop markedly – likely by a larger percentage than the percentage increase in unit volume. Publicly funded drug spending should therefore decrease, and the savings could be directed toward the reward fund.

Both the existing IP system and the proposed publicly financed rewards system rely on contributions by different jurisdictions to finance drug R&D. One important advantage of a publicly financed reward system is that each jurisdiction's contribution to the rewards fund would be transparent, making it easier to ensure that financial commitments are being honored. International contributions to R&D in the existing patents system, by contrast, are opaque. The reason is that whereas the TRIPs agreement requires uniformity of patent length and nondiscrimination, it fails to prevent countries from negotiating aggressively on the prices of new drugs, or reducing the period of market exclusivity by delaying formulary approval. Ideally, countries would contribute toward innovation in proportion to their ability to pay. Such an allocation of contribution is not only ethically attractive, but it is also likely to be roughly efficient in a Ramsey sense.

A dedicated, publicly financed international reward fund has an additional advantage over the IP system. National governments are responsible for setting IP policy, but do not bear the full burden of higher drug prices; these costs are often borne by regional government drug plans or private plans. These plans do not receive much political kudos for supporting innovation, and, indeed, are rewarded by plan sponsors for reducing prices. Plan sponsors presumably care about innovation but if there is any impact of their price control on drug innovation, this is likely small and indirect and occurs only after a considerable lag. As a result these plans tend to focus myopically on cost control. A national government, conversely, could benefit politically from financing a drug innovation fund: it would create lower drug prices, no doubt popular with constituents, and it would support drug innovation in a very direct, visible way. In addition, it is the national government that has relationships with other national governments, and these relationships can be used to help deter free-riding.

Publicly financed reward schemes, then, are in some ways more transparent than existing arrangements. As a result, countries would be less able to shirk their responsibility to finance drug R&D. But this very transparency could make it difficult to strike a deal in the first place. Indeed, some commentators suggest that it would be very difficult for national governments to agree on a division of R&D costs and a means of enforcing the agreement. Moreover, these commentators suggest that it would be difficult to devise a sharing rule that is responsive to changes in countries' willingness and ability to pay.

Nevertheless, the calls for a global R&D treaty continue. The World Health Organization's 'Consultative Expert Working Group' on R&D Financing has expressed preliminary support for a recommendation that countries begin negotiations toward such a treaty, but because the possible components are disparate and vague (and indeed the proposal includes no specific items that should be included in the treaty) it is difficult to know what is being proposed.

Although prospects for an R&D treaty are unclear, other international agreements appear to be feasible. For example, Lawrence Gostin and colleagues have proposed a research program for a 'global health governance framework' which would set out minimal responsibilities for countries in terms of meeting health requirements of their citizens, as well as international obligations to help build the capacity of low- and middle-income states.

In summary, the alternative pull programs described here reward new drugs in differing ways. Sanders would vest a public agency in the US with the power to decide on rewards based on domestic sales only. Kremer would use anticipated market demand and Levine would use anticipated market demand and the risk adjusted cost of running the clinical trials required by the regulatory authorities. The HIF would set rewards in proportion to the health gains generated by the use of the new drug globally. The HIF proposal is unique in that it is intended to supplement, rather than replace the IP system. Levine's proposal is unique in that it is self-financing; any firm could sell a newly approved drug, but each seller would be required to pay a royalty to the innovator on each unit sold. This royalty rate essentially reflects the anticipated risk adjusted

cost of generating the evidence needed to gain regulatory approval. The remaining approaches require a dedicated, publicly financed reward fund to remunerate innovators. The funds required vary between proposals. Because the HIF is a supplement to the IP system, the financing required would be less than in the proposals advanced by Sanders and Kremer. A wholesale replacement of the IP system would undoubtedly require contributions by different countries. This requires that an international agreement be struck, an outcome that some analysts view as politically intractable.

Discussion

The proposed mechanisms described here hold the promise to enhance the effectiveness of public support for the drug discovery enterprise. Implementation of these initiatives, however, requires that a variety of issues be addressed.

These include the following: Which reforms are feasible? Of critical importance, revenue streams must be predictable if firms are to commit funds to R&D projects. Should the IP system be replaced with a rewards scheme, then there needs to be an agreement that binds governments to commit resources. An agreement that reallocates the hundreds of billions of dollars spent annually on pharmaceutical R&D at this time is likely not politically feasible. However, more modest reforms might be possible. In particular, push-type programs that seek to reduce the private cost of drug discovery and commercialization, and pull-type programs that supplement, rather than replace, the IP system would be less disruptive to the status quo, would have more predictable consequences on the firm's profitability, and would involve smaller public sector financial commitments. At the same time, push-type policies, should they be successful, would reduce private drug development costs and hence the reliance on IP to recover development costs. This may, in turn, facilitate further reforms to the IP system.

The public–private consortiums engaged in translational research are particularly promising. However, some critical problems need to be considered. How can the consortium satisfy the many competing interests? In particular, how should the consortium decide on which therapeutic areas to investigate? Should this be decided by a vote or by consensus? Should there be sanctions applied to members that are found to not cooperate fully? For example, it may become apparent that a drug company withheld from the consortium research output that would have been useful. Should this result in expulsion from the consortium? Which drug companies would conduct clinical trials on drug candidates that emerge from a consortium? What restrictions will there be on the pricing of such drugs, given the contributions by academics and public funders? More generally, how should a consortium interact with the existing IP regime? Resolution of these issues would appear to be vital to the success of a consortium.

Another promising avenue is public funding of Phase III trials. If there were public funds, however, there would likely be no shortage of drug candidates seeking funding. Should public funding be linked to the ultimate success of the trial, or simply to the promise demonstrated before the trial? How should conflicting priorities among different disease advocacy groups and among different jurisdictions be resolved?

Finally, more work is needed to operationalize the HIF's health impact measurement technology. Because the HIF relies on assessment of health impact, it is important to know how such an assessment would be performed and how firms would respond to being paid based on impact. A pilot trial could be done for a single drug in a country or region. The HIF also requires further analysis of antitrust issues and evaluation of its likely effectiveness.

Patents and Regulatory Exclusivity in the USA

RS Eisenberg, University of Michigan Law School, Ann Arbor, MI, USA
JR Thomas, Georgetown University Law Center, Washington, DC, USA

Introduction

Research and development (R&D) for pharmaceuticals, medical devices, and other healthcare technologies require not only the creation of new products, but also the production of information about their effects through preclinical research and clinical trials. Firms might underinvest in this costly, risky, and time-consuming R&D in the absence of subsidies or rewards. But intellectual property rights are a two-edged sword in the struggle to improve health. They both motivate the efforts that result in healthcare innovation, and limit access to the fruits of those labors. This contribution examines and critiques the patent and regulatory regimes that offer innovators in healthcare technologies temporary shelter from competition. The primary emphasis is on the US law pertaining to pharmaceuticals, with some attention to medical devices and diagnostics as well as to laws in other jurisdictions.

Pharmaceutical Patents

In comparison to firms in other industries, drug companies rely heavily upon the patent system to capture rewards from R&D. Most new drugs are covered by a series of patents with staggered terms pertaining to their active ingredients, particular pharmaceutical formulations, manufacturing techniques, methods of medical treatment, and related products and processes. Critics decry this patent layering strategy as 'evergreening,' whereas brand-name firms explain that they often improve their initial marketplace offerings through patentable innovation.

Patent Acquisition

To be protectable under US law, an invention must consist of patentable subject matter and be new, useful, and nonobvious. 35 US Code §§ 101, 102, 103, 112. The inventor must file a patent application that provides a written description of the invention and that enables a person skilled in the field to make and use it. 35 US Code § 112. Failure to satisfy these requirements may lead to rejection of a patent application or to invalidation of an improperly issued patent.

Patent law encourages innovative firms to file patent applications promptly. Patentability depends on how an invention compares to the 'prior art,' including publications, patents, and public knowledge or use. Patentability is denied if the prior art discloses an invention, either explicitly or inherently, or makes it obvious. Because the prior art is constantly expanding, broad patent claims in follow-on patents are often invalid.

For example, in Schering versus Geneva, 339 F.3d 1373 (Fed. Cir. 2003), the patent at issue claimed descarboethoxyloratadine (DCL), a metabolite of loratadine. The prior art included an expired patent on loratadine. Schering sought to enforce the DCL patent against sellers of generic loratadine by arguing that patients who ingested loratadine would necessarily produce DCL in their guts, thereby infringing the DCL patent. The court held the DCL patent invalid, reasoning that if, as both parties agreed, administering loratadine to patients inherently causes the production of DCL, DCL became prior art when the earlier loratadine patent disclosed administering loratadine to patients. A narrower claim to the metabolite in isolated form might have survived this challenge, but such a claim would not preclude competitors from selling loratadine.

Patents claiming modest changes that are sufficient to avoid a novelty challenge have often been held invalid for obviousness, including claims to new dosages, new formulations, combination products that package the drug with another familiar ingredient in a single capsule, and single enantiomers or diastereomers isolated from a racemate or other mixture of stereoisomers. To avoid invalidation for obviousness, the patent holder must show either that a person working in the field would not have found the modification obvious or that the modified version has surprising properties not present in the prior art. This has proven to be a significant obstacle for many follow-on patents.

Despite the advantages of early filing, the time lag between the discovery of a new molecule and the development of information necessary to use that molecule as a drug may make early filing difficult. First, without some research into the properties of a molecule, it may be difficult to satisfy the utility requirement. The patent statute limits protection to inventions that are 'useful,' a standard which the courts have explained falls far short of US Food and Drug Administration (FDA) approval standards of safety and efficacy for use in humans. As a general matter, promising *in vitro* test results have been held to support patentable utility. In re Brana, 51 F.3d 1560 (Fed. Cir. 1995). The Supreme Court has held, however, that it is not enough to show that as of the filing date the invention is merely the subject of research. Brenner versus Manson, 383 US 519, 536 (1966). In some cases courts have required clinical testing to support controversial claims of therapeutic utility.

Second, if a new drug is structurally similar to a prior art molecule, further research may be necessary to satisfy the nonobviousness requirement. The US Patent and Trademark Office (PTO) deems a new but structurally similar variation of a known molecule to be *prima facie* obvious. The patent applicant may rebut *prima facie* obviousness by showing that the new molecule has surprising properties (or particularly advantageous properties) not present in the prior art molecule. In re Dillon, 919 F.2d 688 (Fed. Cir. 1990). To make this showing, it may be necessary to perform tests on both the new molecule and the prior art molecule. If the obviousness challenge does not arise until after the product has been thoroughly tested, the patent holder may use studies

performed after the filing date to show surprising or advantageous properties. Knoll Pharmaceutical versus Teva Pharmaceuticals USA, 367 F.3d 1381 (Fed. Cir. 2004). But if the PTO rejects the application at the outset for prima facie obviousness, the need to develop rebuttal evidence may cause delays. Meanwhile, firms might hesitate to invest in costly testing while patentability remains in doubt.

Recent judicial developments in the US have called into question whether patentable subject matter includes certain biotechnology products obtained from nature (such as DNA molecules) and certain medical diagnostic methods that involve correlating observed biomarkers with a patient's condition, prognosis, or treatment. The US Supreme Court held in Association for Molecular Pathology v. Myriad Genetics, 133 S. Ct. 2107 (2013) that isolated DNA molecules that are otherwise identical to naturally occurring DNA are not patent-eligible, but that complementary DNA (cDNA) molecules that are not naturally occurring but are created artificially are patent-eligible. Previously, the US Supreme Court had held in Mayo Collaborative Services versus Prometheus Laboratories, Inc., 132. Ct. 1289 (2012), that a process patent claim directed to a method of determining whether a given dosage level for a drug was too high or low by comparing observed levels of a drug metabolite with reference values set forth in the claim was an invalid attempt to patent a natural law. The implications of these cases for other biopharmaceutical and diagnostic patents are not yet clear.

Patent Term

As required by the World Trade Organization (WTO) Agreement on Trade Related Aspects of Intellectual Property Rights (hereinafter TRIPS Agreement), patents on most inventions expire 20 years after their application filing dates. 35 US Code § 154. Pharmaceutical patents may be entitled to term extensions, however, under the Hatch–Waxman Act. In particular, drug patents may be extended for up to 5 years to compensate for some of the time lost during clinical trials and regulatory review. 35 US Code §§ 155, 156. The remaining patent life after extension may not exceed 14 years beyond the date of FDA approval. The period of extension includes one-half of the time spent in clinical trials and all of the time between submission and approval of the new drug application (NDA). Both periods are reduced by any time attributable to an applicant's lack of diligence. Only the first approval of a new active ingredient qualifies for a patent term extension, and only one patent may be extended per new active ingredient. The patent to be extended must be in force on the date of approval and must cover either the product, a method of using the product, or a method of manufacturing the product. These provisions present a firm with a strategic dilemma: Should it extend an early-filed patent that expires sooner but is more likely to survive a validity challenge, or a follow-on patent that potentially confers more years of exclusivity, but is narrower and more vulnerable to patent-defeating prior art?

Patent enforcement

The Hatch–Waxman Act fundamentally altered drug patent enforcement in the US. Before Hatch–Waxman, generic versions of previously approved drugs faced two major entry barriers: First, the FDA approval process, which generally required the same showing of safety and efficacy for a generic product as for a pioneering drug; and second, patents, which private owners had the burden of enforcing through infringement actions in the courts. The FDA entry barrier was usually sufficient to defer generic entry long after relevant patents had expired, because the costs of clinical trials were prohibitive for generic products that would be sold at competitive prices. The Hatch–Waxman Act lowered the regulatory entry barrier considerably by allowing approval of a generic product that is 'bioequivalent' to a previously approved product under an Abbreviated New Drug Application (ANDA), without requiring duplication of safety and efficacy trials. An ANDA does not require full reports of clinical trials to show safety and efficacy, so long as the conditions of use, active ingredients, route of administration, and strength are the same as a previously approved 'listed product,' the ANDA product is 'bioequivalent' to the listed product, and the labeling of the two products is the same. 21 US Code § 355(j)(2).

At the same time, the Hatch–Waxman Act fortified the patent entry barrier by creating a system within FDA for tracking drug patents and by deferring the approval of ANDAs during the patent term. The Hatch–Waxman Act set up a complex process to divert disputed patent issues to the courts and to motivate potential competitors to challenge the validity of patents. The FDCA requires that an NDA disclose any patent that claims the drug or a method of using the drug 'with respect to which a claim of patent infringement could reasonably be asserted if a person not licensed by the owner engaged in the manufacture use, or sale of the drug.' 21 US Code § 355(b)(1). Upon approval of the NDA, the FDA publishes this information, updated to include later patents, in a publication (available on the FDA website) called 'the Orange Book.' The statute requires that an ANDA include one of four prescribed 'certifications' with respect to each patent in the Orange Book for the previously approved 'listed drug,' 21 US Code § 355(j)(2)(A)(viii): a 'paragraph I certification' indicating that no patent information has been filed; a 'paragraph II certification' indicating that the patent has expired; a 'paragraph III certification' indicating the date on which the patent will expire; or a 'paragraph IV certification' indicating 'that such patent is invalid or will not be infringed by the manufacture, use, or sale of the new drug for which the application is submitted.' 21 US Code §§ 355(j)(2)(A)(7)(vii)(1)-(4). If no relevant patents remain in force, the ANDA may be approved without further delay, assuming it is otherwise approvable. If a patent is still in force, the ANDA may be approved upon its expiration date. The consequences of a paragraph IV certification are complex. An applicant making a paragraph IV certification must give notice within 20 days to each owner of the patent and to the holder of the approved NDA including 'a detailed statement of the factual and legal basis of the opinion of the applicant that the patent is invalid or will not be infringed.' 21 US Code § 355(j)(5)(B)(iii). The ANDA may then be approved immediately, unless a patent infringement action is brought within 45 days. The filing of a patent infringement action triggers a 30-month stay of approval of the ANDA, which may be adjusted by the court. The

statute gives the first firm to file an ANDA with a paragraph IV certification for a listed drug a 180-day market exclusivity period before the FDA will approve another ANDA for the same product. These provisions have been litigated extensively as firms have explored their strategic implications.

The Hatch–Waxman Act in effect shifts some of the burden of patent enforcement from patent owners to FDA by directing FDA to refrain from approving ANDAs during the patent term. Unless there is a paragraph IV certification, FDA will use its regulatory gatekeeper role to exclude competitors until the patents listed in the Orange Book expire, without the need for infringement litigation. Patent holders need not monitor competitors to detect infringement; the burden is on firms seeking to enter the market to address infringement of listed patents when they file ANDAs. Even when an ANDA filer challenges the patent in a paragraph IV certification, a patent holder who brings an infringement action gets an automatic 30-month stay of approval of the ANDA, without having to meet judicial standards for a preliminary injunction. These features of the statute fortify the exclusionary effect of patents beyond ordinary judicial remedies for patent infringement through the use of heightened regulatory entry barriers during the patent term.

A distinct advantage for patent holders of the FDA-administered remedies is that, unlike a court, FDA makes no effort to determine whether patents listed in the Orange Book are valid and infringed, or even whether they claim the listed drug or its use. FDA relies on the NDA sponsor to identify which patents are appropriate for listing in the Orange Book, and if anyone disputes the accuracy of the patent information or the propriety of listing a particular patent, FDA relies upon the sponsor to decide whether to change the listing or to leave it as is. FDA does not itself consider the merits of paragraph IV certifications, but simply defers approval of ANDAs for 30 months pending further instructions from the courts. All listed patents get the same administrative treatment regardless of their validity or scope.

Typically the patent holder has much more at stake in ANDA litigation than the generic challenger. If the patent holder prevails, the court will likely direct the FDA to defer approval of the ANDA until the end of the patent term. Assuming no other ANDA filer successfully challenges the patent, the patent holder could remain the sole source of the drug for the remaining patent life, an outcome that could be worth billions of dollars in the case of a blockbuster product. If the generic challenger prevails, its ANDA will be approved, and if it was the first ANDA with a paragraph IV certification for that product, it may be the only ANDA-approved generic on the market for 180 days. Because the first generic competitor in the market for a drug is typically able to charge higher prices and capture a larger market share until a second generic competitor enters the market, this period of generic exclusivity has significant value. The value of generic exclusivity is diminished if multiple ANDA filers on the same date share the exclusivity, or if the NDA holder decides to launch its own competing 'authorized generic' during the generic exclusivity period. Teva Pharmaceuticals versus Crawford, 410 F.3d 51, 54 (D.C. Cir. 2005). A recent US Federal Trade Commission (FTC) report on authorized generics reports that, on average, expenditures at wholesale prices of a generic during the 180-day exclusivity period equal 61% of expenditures on the brand name product during a comparable period prior to generic entry (Federal Trade Commission, 2009). Once the generic exclusivity period expires and more generic competitors enter, price competition is likely to reduce profits considerably. Even with generic exclusivity, the profits that a generic challenger hopes to gain in the patent challenge are thus likely to be a fraction of the profits the patent holder hopes to preserve.

Given uncertainty as to the outcome and litigation costs, this gap between the value and risks to the patent holder and to the generic challenger may tempt the parties to try to reach a settlement. Some settlement agreements have provoked antitrust scrutiny by providing for 'reverse payments' from the patent holder to the generic challenger in exchange for agreement by the challenger to defer market entry (Federal Trade Commission, 2010). Before 2003 statutory amendments, these 'pay-for-delay' agreements could potentially preclude all generic entry so long as any patents remained in the Orange Book for the listed drug. This is because under previous statutory provisions, FDA could not approve subsequent ANDAs with paragraph IV certifications until 180 days after either (1) the first commercial marketing of the product by the first ANDA filer or (2) a court decision holding the challenged patents invalid or not infringed. Settlements could prevent either of these triggers from occurring, thus postponing indefinitely the time when competing ANDAs could be approved. The revised statute addresses this problem with several different patches. Specifically, the revised statute allows multiple ANDA filers on the same date to share the 180-day exclusivity, 21 US Code § 505(J)(5)(B)(iv)(I), (II); redefines the trigger that begins the 180-day period to be the first commercial marketing by any of the first ANDA filers, including an 'authorized generic,' 21 US Code § 505(j)(5)(B)(iv)(I); and provides for forfeiture of the 180-day exclusivity period if an applicant fails to market the drug within specified periods, withdraws the application, amends the certification, fails to obtain tentative approval for the ANDA, enters into an agreement that is adjudicated to be in violation of the antitrust laws, or if the relevant patents expire. See 21 US Code §505(j)(5)(D).

The FTC, along with a number of antitrust scholars, sees most settlements that involve reverse payments to defer generic entry as agreements in restraint of trade in violation of the antitrust laws (Federal Trade Commission, 2010; Hovenkamp *et al.*, 2003). Although owners of valid patents are entitled to exclude competitors from the market until the end of the patent term, antitrust authorities may suspect that settlements with reverse payments signal weak patent claims. But in the ANDA litigation context, the inference of a weak patent is not as compelling as might first appear. Even a victorious patent holder could not recover damages from a defendant that is not yet selling a product, and even an optimistic patent holder would presumably give up some portion of expected profits in settlement to reduce the risk of a litigation loss that could bring patent-protected profits to an abrupt halt. One might therefore expect settlement of even strong patent infringement claims to involve reverse payments. The US Supreme Court held in Federal Trade Commission versus Actavis, 133 S. Ct. 2223 (2013) that reverse payments might sometimes be

justified to settle a patent infringement action, but that a large, unexplained reverse payment might indicate that the patent infringement suit is weak, and that courts should apply "rule of reason" analysis to determine whether such settlement agreements violate the antitrust laws.

In 2003, Congress implemented reforms suggested by the FTC to minimize anticompetitive abuses, including revisions to the 180-day exclusivity period, and ensured continuing antitrust oversight by requiring that ANDA litigation settlement agreements be filed with the FTC and the Justice Department within 10 days of execution. Medicare Prescription Drug, Improvement and Modernization Act of 2003, Title XI, § 1112 *et seq*. The scrutiny of antitrust authorities presumably reduces the expected value of settlements and prolongs litigation.

Current law reflects repeated compromises to rebalance the interests of innovators and generic competitors as Congress and FDA seek to block abuses, with each legislative patch inevitably introducing a new set of unintended consequences. This complex regime, which provokes costly litigation with unpredictable results, is clearly far from optimal.

Regulatory Exclusivity for Drugs

Congress has repeatedly acted outside the patent system to shelter pharmaceutical innovators from competition by controlling the timing of regulatory entry barriers. These nonpatent exclusivity provisions promote certain forms of R&D, such as the development of orphan drugs or new chemical entities or the testing of approved drugs for new uses or for use in children. The terms of protection vary. Sometimes regulatory exclusivity runs concurrently with patent protection and sometimes it extends beyond the patent term. Even when shorter in duration than patents, most forms of regulatory exclusivity are better synchronized with the timeline of drug development than patents at the front end, so that the entire period of exclusivity starts to run only once the product is launched rather than ticking away before product launch. When patent validity and infringement are contested and uncertain, regulatory exclusivity can provide a minimum period of exclusivity that is less vulnerable to challenge than patent protection. Moreover, legislators enjoy greater latitude in designing regulatory exclusivity provisions to meet the needs of the pharmaceutical marketplace, while the patent system applies essentially the same rules to all fields of technology.

Orphan Drugs: Market Exclusivity

The Orphan Drug Act of 1983 grants 7 years of market exclusivity for products to treat rare diseases and conditions affecting fewer than 200 000 patients in the US. Available for both drugs and biologics, Orphan Drug exclusivity does not merely defer the use of an abbreviated approval pathway (ANDA). It entirely prohibits approval of another application 'for such drug for such disease or condition' for 7 years after the initial product approval, even if the later applicant conducts its own clinical trials. It does not, however, preclude approval of either (1) another drug for the same disease or condition or (2) the same drug for another disease or condition. Genentech, Inc. versus Bowen, 676 F. Supp. 301 (D.D.C. 1987); Sigma-Tau Pharms. versus Schwetz, 288 F.3d 141 (4th Cir. 2002). FDA interprets the statutory language 'such drug' narrowly to permit approval during the 7-year term of a 'clinically superior' product that uses the 'same active moiety.' 21 C.F. R. § 316.3(b)(13)(i), (ii).

Market exclusivity under the Orphan Drug Act is somewhat like a patent on a particular use of a drug, enforced by FDA, with the drug narrowly defined to exclude 'clinically superior' formulations. Although Congress might have thought it was facilitating only products with markets too small to be lucrative, many products qualifying for orphan drug exclusivity for one indication have had large and profitable markets, usually as a result of nonorphan, larger indications. The Orphan Drug Act can also provide a nonpatent source of exclusive rights for new uses of old drugs that were taken off the market and for which early patents have expired, such as thalidomide. But because it does not preclude approval of other applications to sell the same product for other uses, Orphan Drug exclusivity is of little value for products that competitors are free to sell for other indications.

Hatch–Waxman: Data Exclusivity

In the 1984 Hatch–Waxman Act, Congress provided 5 years of data exclusivity for the first approval of a new chemical entity (NCE), 21 US Code § 355(j)(5)(F)(ii), and 3 years of data exclusivity for a supplemental NDA approval making changes in a previously approved product that required new clinical trials, 21 US Code § 355(j)(5)(F)(iii). In contrast to the Orphan Drug Act provisions, these Hatch–Waxman Act provisions do not prevent a competitor that is willing to conduct its own clinical trials from obtaining approval of its own NDA. They merely prevent competitors from relying upon the innovator's prior showing of safety and efficacy by using an ANDA. In this sense they look less like patents on products and more like proprietary rights in regulatory data. But if the costs of a full NDA are prohibitive for a product that will be sold at generic prices, the practical effect is to defer generic competition. The term 'data exclusivity' is often used to refer to periods of delay before a follow-on product may reference the originator's data as part of an abbreviated approval application, and the term 'market exclusivity' is used to refer to a more comprehensive exclusivity such as that available under the Orphan Drug Act, but usage is not entirely consistent.

NCE exclusivity

The period of exclusivity for a new chemical entity, which begins with first market approval, often runs concurrently with patent protection, although in some cases it may last longer. Although sometimes referred to as '5-year exclusivity,' the effective period of protection is generally longer than 5 years. During the statutory period a competitor may not even submit an ANDA to FDA; effective exclusivity continues thereafter until FDA approves the ANDA, a process that takes an average of 19.2 months (Food & Drug Administration, 2007). An ANDA with a paragraph IV certification may be submitted as early as 4 years after approval of the NCE, but if the patent

holder responds by bringing a timely infringement action, the 30-month stay is extended to give a total of 7.5 years from initial NDA approval to the time of ANDA approval. 21 US Code § 355(j)(5)(F)(ii). With these adjustments, in practice the period of exclusivity from first approval of the NCE until approval of an ANDA is likely to range from a low of 5.5 years (if an ANDA with a paragraph IV certification is filed after 4 years, no infringement action is filed, and FDA takes 1.5 years to approve the ANDA) to a high of 7.5 years (if an infringement action is filed and the 30-month stay is extended in accordance with the statute), although approval times vary. The court in the infringement action has statutory authority to lengthen or shorten the stay. In the absence of patents, the period of exclusivity is 5 years plus approval time, or approximately 6.5 years. Relatively few NDAs do not involve patents, but some involve invalid patents. NCE exclusivity provides 4 years before such a product might face a patent challenge and 7.5 years before a patent challenger can enter the market under an ANDA.

Supplemental NDA exclusivity

FDA approval of a supplemental NDA is necessary to market a drug for a new indication, or in a different dosage form or formulation, or to sell the drug over-the-counter (OTC) rather than by prescription only. When FDA approves a supplement to a previously approved NDA that required further clinical trials for approval, the applicant is entitled to a 3-year period of exclusivity for the supplemental approval. 21 US Code § 355(j)(5)(F)(iv). The 3-year period begins with approval of the supplemental NDA, making it advantageous to defer filing a supplemental NDA until other forms of exclusivity are about to end in order to prolong the total period of exclusivity. As a product approaches the end of its patent life, a firm might, for example, seek approval to switch from prescription to OTC sales, thereby gaining 3 years before it faces generic competition in the OTC market. FDA may not approve an ANDA for the same change during the exclusivity period, but it may receive and review applications and grant tentative approvals that become effective when the exclusivity expires. The additional years of exclusivity are only available if additional clinical trials were necessary to get the supplement approved.

The exclusivity thereby gained is limited to the terms of the supplemental approval, and will not prevent a competitor from using an ANDA to get approval to sell the product as previously approved. This is a significant limitation on the exclusive rights conferred by a supplemental NDA to market a drug for a new indication. Such exclusivity does not stop a generic competitor from getting approval to sell its product for the original indication. Once the generic version is on the market, physicians may prescribe it off-label for the new indication, and pharmacists may substitute the generic version unless physicians expressly require that the brand-name product be used. Indeed, unless the new indication involves a different formulation of the product, state generic substitution laws may require substitution of the cheaper generic product at the pharmacy. A similar problem limits the value of both Orphan Drug exclusivity and method of use patents for products with multiple therapeutic uses.

A 3-year exclusivity remains commercially valuable in circumstances where generic substitution is less likely, such as a prescription to OTC switch. If the branded product becomes available OTC and the generic product is available only by prescription because FDA may not yet approve it for OTC sales during the period of exclusivity, patients may buy the branded product directly at the pharmacy rather than going to a physician for a prescription, or a physician may advise the patient that the product is available without a prescription. Either way, the generic product is at a competitive disadvantage because it is available by prescription only. Further, insurance would generally not cover the product once it is available OTC. Three years of exclusivity in the OTC market may give the branded product a dominant position with consumers that persists even after generic entry in the OTC market.

In one controversial episode, 3-year exclusivity led to a sharp rise in the price of colchicine, an ancient remedy for gout that had previously been marketed for decades without FDA approval (Kesselheim and Solomon, 2010). In 2006, FDA launched an Unapproved Drugs Initiative to get manufacturers of old drugs that came to market before modern premarket approval requirements to test the drugs for safety and efficacy and to seek formal regulatory approval (Food & Drug Administration, 2011). FDA had previously approved two combination products including colchicine as one of multiple ingredients, but had never approved a single-ingredient colchicine product. Mutual Pharmaceutical submitted NDAs for the use of colchicine to treat familial Mediterranean fever and acute gout flares. FDA approved both applications and awarded 7 years of orphan drug exclusivity for the use of colchicine to treat familial Mediterranean fever and 3-year exclusivity for the treatment of acute gout flares. FDA subsequently announced its intention to take enforcement action against unapproved single-ingredient colchicine products (Food & Drug Administration, 2010). Its new position as sole source of this ancient drug enabled Mutual Pharmaceutical to increase the price of its colchicine product, Colcrys®, from $0.09 to $4.85 per tablet (Kesselheim and Solomon, 2010). Although regulatory exclusivity normally affects only products that have not yet become available at competitive prices, this unusual case provides a stark illustration of the very real costs that exclusivity imposes on patients and payers for products that might otherwise have been supplied more cheaply in competitive markets.

Pediatric Exclusivity: Prolonging Existing Rights

The Food and Drug Administration Modernization Act of 1997 added 6 months of incremental exclusivity for conducting pediatric trials of drugs. This 6-month period of 'pediatric exclusivity' is not contingent upon approval of the drug for use in children and is not limited to such use. The only requirements are that FDA must request the pediatric studies and they must be completed and submitted within the timeframe specified by FDA.

In contrast to the Hatch–Waxman and orphan drug exclusivities, the 6-month pediatric exclusivity does not start running immediately upon FDA approval. It simply adds 6 months to the end dates of any existing forms of exclusivity held by the submitter, whether under a patent, the Orphan

Drug Act, or Hatch–Waxman Act provisions, 21 US Code § 355a, further deferring the time when FDA may approve a competing generic product. Because it does not run concurrently with other forms of exclusivity, there is no advantage to be gained by deferring pediatric trials until other forms of exclusivity are at an end. The result has been a significant increase in available information about the effects of drugs in children, but critics have questioned whether 6 months of exclusivity is an excessive reward for rather modest expenditures on pediatric trials.

Regulatory Exclusivities in Other Countries

Longer periods of regulatory exclusivity are available in the European Union, dating back to a time when some members of the European Union did not allow patents on pharmaceuticals (Junod, 2004). Council Directive 87/21/EEC of 22 December 1986, amending Directive 65/65/EEC on the Approximation of Provisions Laid Down by Law, Regulation, or Administrative Action Relating to Proprietary Medicinal Products. The European regime currently provides 8 years of exclusivity before authorization for a generic may be submitted and 2 further years before it may be approved, and extends each of these dates by an additional year if, during the first 8 years, the holder of the authorization obtains further authorization for one or more new therapeutic indications for the product. By decoupling the duration of exclusivity from the timing of supplemental approval, the European approach encourages the testing and submission for approval of new indications and formulations earlier in the life cycle of a drug, while the US approach makes it advantageous to defer such testing and submission in order to maximize the duration of exclusivity.

The pharmaceutical industry has sought to establish regulatory exclusivity regimes throughout the world in the terms of trade agreements, with mixed success (Reichman, 2009; IFPMA, 2011). The TRIPS Agreement, in lieu of a proposed requirement for a minimum of 5 years of regulatory exclusivity, ambiguously requires WTO members to protect undisclosed data against 'unfair commercial use' and against 'disclosure, except where necessary to protect the public.' TRIPS Agreement, Article 39.3. Subsequent regional and bilateral free trade agreements more clearly specify time periods during which national regulators may not approve generic drugs on the basis of bioequivalence or otherwise rely upon data provided by the originator (Reichman, 2009). Some nations have implemented regulatory exclusivity in their national laws, while in other cases treaty provisions for regulatory exclusivity are self-executing.

Medical Devices

Medical devices, which range from bandages to artificial heart valves, vary significantly in the levels of risk they pose, with products in different risk categories facing different regulatory entry barriers. The Medical Device Amendments Act of 1974 divides devices into three classes. 21 US Code § 360c. Class III devices pose the greatest risks, and generally require premarket approval of a comprehensive NDA-like application before they may be sold. 21 US Code § 360e. Some Class III devices and most of the less risky Class II devices may instead get to market through a less onerous pathway in which they are 'cleared' under a '510(k)' submission, 21 US Code § 360k, based on a showing that the proposed device is 'substantially equivalent' to a legally marketed device, meaning that it is at least as safe and effective as that device. The 510(k) submission may include results of clinical trials. Some Class II devices and most Class I devices are exempt from the 510(k) process.

Although premarket review of new devices is generally more abbreviated than that of new drugs, FDA also regulates devices through postmarket surveillance and controls. 21 US Code § 360l. A pure generic industry does not exist in this sector; rather, some firms focus on 510(k) applications that they anticipate will not require clinical trials because they are similar to existing products. The absence of pure generics may reflect the much lower R&D costs and much shorter product life cycles for medical devices than for drugs. With incrementally improved products coming out every couple of years, by the time an originator product's patents expired and a generic version could legally enter the market, the original product design would be economically obsolete. Medical devices, like drugs, are eligible under the Hatch–Waxman Act for patent term extensions to compensate for marketing approval delays. 35 US Code §156(g). They obtain no regulatory exclusivity, however, perhaps due to differences in the nature of FDA oversight of the drug and device fields and/or to the absence of a market for true generics due to the short product life cycles.

Biosimilars

Regulatory exclusivity is a significant focus in legislation for the regulation of follow-on biological products, reflecting its growing importance to the biopharmaceutical industry. As discussed earlier, Congress provided for periods of regulatory exclusivity for pharmaceuticals ranging from 4 years to 7.5 years in the 1984 Hatch–Waxman Act. In 2010, Congress enacted a new regulatory approval pathway for biological products that are 'biosimilar' to and/or 'interchangeable' with previously licensed biological products, preceded by a 12-year period of regulatory exclusivity for the reference products, a period that may extend beyond the expiration of relevant patents. Some critics have argued that the 12-year period of exclusivity is excessive, while others have argued that it is necessary to compensate for deficiencies in patents and have argued for even longer periods.

Decoupling Regulatory Exclusivity from Patent Protection

The biosimilars legislation departs from the Hatch–Waxman model by decoupling regulatory exclusivity from patent protection. While under the Hatch–Waxman Act the dates when an ANDA may be filed or approved turn in part on the expiration dates of patents in the Orange Book for the listed product and on the status of litigation between the parties over those patents, these dates are fixed for biosimilars: Irrespective

of patents, an application for a biosimilar license may not be filed for 4 years, and its approval may not be made effective for 12 years, after the first licensing of the originator reference product. 42 US Code §§ 262(k)(7)(A), (B). FDA is not charged with maintaining an archive of relevant patents in the Orange Book. FDA receives notice and a copy of the complaint in any patent infringement action and publishes such notice in the Federal Register, but there is no provision for FDA to enter a stay of regulatory approval of the biosimilar license pending resolution of the litigation. Instead, the biosimilar applicant must give notice to the reference product sponsor 180 days before the first commercial marketing of its product, allowing the reference product sponsor to seek relief from the court in an infringement action.

In the place of the Hatch–Waxman Act's patent certification system, the biosimilars legislation creates an extraordinarily elaborate set of provisions for resolving patent disputes. These provisions entail considerable prelitigation activity, including disclosure of the biosimilar application to the reference product sponsor, ad hoc identification of relevant patents by each party, a negotiation process regarding which patents will be litigated, and a simultaneous double-blind exchange of patents designated for litigation. The meaning and implications of these provisions have yet to be tested, and many years will likely pass before relevant parties develop the familiarity firms, attorneys, and jurists now possess with the provisions of the Hatch–Waxman Act.

This approach nonetheless holds some advantages over the Hatch–Waxman regime. It does not put FDA in the role of patent enforcer, but leaves this task to the courts. Innovators thus have no incentive to list dubious patents in the Orange Book to obtain a 30-month stay of regulatory approval from an agency that is unwilling to evaluate patent claims. Remedies for infringement follow adjudication in the courts rather than arising automatically at the outset based upon the patent holder's allegations. The timing and duration of regulatory exclusivity are certain and do not depend on the vicissitudes of either infringement litigation or regulatory lag times (unless regulatory approval takes longer than the 8 years between the date when an application may be filed and the date when its license may become effective).

Supplemental Exclusivity

In contrast to the Hatch–Waxman Act, the biosimilars legislation does not offer additional exclusivity for minor product changes requiring supplemental approval. An important exception is made for 'a modification to the structure of the biological product' that results 'in a change in safety, purity, or potency.' Such a modification gets its own full 12-year period of regulatory exclusivity. The legislation also adds 6 months of 'pediatric exclusivity' both to the 4-year period before an application for a biosimilar license may be filed and to the 12-year period before the license may become effective, under the same conditions applicable to pediatric exclusivity for drugs.

The different approach to supplemental exclusivity in biosimilars legislation may reflect the limited value that biopharmaceutical innovators have found in supplemental exclusivity under the Hatch–Waxman Act. Although that Act nominally awards 3 years of additional exclusivity for supplemental approvals for changes such as new indications, the terms of exclusivity are limited to the terms of the supplemental approval, allowing approval of competing products for the old indications. If supplemental exclusivity does not defer FDA approval of a generic for the older indications, the generic will usually be substituted when the reference product is prescribed for the new indication.

On the other hand, for a structural change to the product that changes its safety, purity, or potency, generic substitution is unlikely and additional exclusivity is likely to be valuable. In these circumstances, the new legislation not only provides exclusivity, but expands it to the full 12-year term given for new products. This approach may both overreward structural changes and undermotivate other changes that require investments in clinical trials.

Limits of abbreviation in approval pathway for biosimilars

The biosimilars legislation does less to lower the regulatory entry barrier to follow-on competition for biologics than the Hatch–Waxman Act did for generic versions of small molecule drugs. Although a follow-on competitor need not make the showing required for an ANDA that the active ingredient is 'the same' as that of the listed drug, it must demonstrate that its product is 'biosimilar to a reference product' based upon data derived from analytical studies, animal studies, and one or more clinical studies 'that are sufficient to demonstrate safety, purity, and potency' in a use for which the reference product is licensed, unless FDA determines that one of these elements is unnecessary. 42 US Code §§ 262(k)(2)(A)(i), (ii).

While a showing of 'biosimilarity' is sufficient to obtain a biologics license, a more extensive showing is necessary to get an agency determination that the follow-on product is 'interchangeable' with the reference product. A determination of interchangeability requires showing that the biosimilar product 'can be expected to produce the same clinical result as the reference product in any given patient,' and for products administered more than once, that 'the risk in terms of safety or diminished efficacy of alternating or switching between use of the biological product and the reference product is not greater than the risk of using the reference product without such alternation or switch.'

Without a determination of interchangeability, additional marketing may be necessary to get physicians and pharmacists to switch their patients from the reference product to the biosimilar product. By contrast, a determination of 'bioequivalence' for a generic drug under an ANDA is enough to permit or even compel pharmacists to substitute the less expensive generic version unless the physician directs otherwise. Since most biologics are infusions that are dispensed by physicians in their offices, rather than by pharmacists, substitution of biosimilars will depend on incentives and decisions of physicians rather than on decisions of pharmacists.

The cost to show biosimilarity and interchangeability to the satisfaction of FDA is unclear at this point, but informed observers expect that the costs will be considerably higher than necessary to show bioequivalence in an ANDA. Moreover, further marketing costs may be necessary to persuade physicians, pharmacists, and payers to switch to these

products. This may in part be an inevitable consequence of differences between drugs and biologics, but it is also now in part a function of deliberate legislative policy in the US.

Exclusivity for Follow-on Products

The first follow-on product to receive a determination of interchangeability is entitled to a period of exclusivity before FDA will make a determination of interchangeability for a competing product. 42 US Code § 262(k)(6). A biosimilarity determination does not trigger exclusivity for the follow-on product, and exclusivity for the first product determined to be interchangeable with a reference product does not preclude licensure of a competing product that is determined to be merely biosimilar to the reference product but not interchangeable with it. Follow-on exclusivity ends at the earlier of 1 year after first commercial marketing, 18 months after a final court decision in a patent infringement action against the applicant or dismissal of such an action, 42 months after approval if the applicant has been sued and the litigation is still ongoing, or 18 months after approval if the applicant has not been sued.

These provisions reflect an effort to address some of the perceived flaws with generic exclusivity in the Hatch–Waxman Act. Rather than encouraging litigation by rewarding the first applicant to challenge a patent, the biosimilars legislation rewards the first applicant to receive a determination of interchangeability. This encourages applicants to make the more difficult showing of interchangeability in addition to biosimilarity, and encourages alacrity in securing a license from FDA rather than promising rights on the basis of application filing dates. Moreover, the proposal limits the duration of exclusivity in ways that may not be avoided by delays in marketing, litigation, or settlement agreements.

Whether the exclusivity for follow-on biologics will prove as valuable as Hatch–Waxman generic exclusivity remains to be seen. Although the periods of exclusivity appear longer under the biologics legislation than the 180 days provided under the Hatch–Waxman Act, other follow-on products may obtain licenses during the exclusivity period based on a showing of biosimilarity to the reference product, potentially eroding sales and profits for the first interchangeable product. As a result, incentives to introduce follow-on biologics may be limited.

Regulatory Exclusivities versus Patents

The growing duration of regulatory exclusivities in the US raises questions about their role relative to that of the patent system within the healthcare industry. Economic incentives for innovation are traditionally the province of the patent system. Failings of the patent system might better be addressed through patent law reform, rather than by creating additional sources of exclusivity outside the patent system. Moreover, in the healthcare context intellectual property barriers to generic competition are in tension with the competing interest in promoting affordable access to medicine. Perhaps regulatory exclusivities should do no more than compensate sponsors for their FDA approval expenses, rather than promoting biopharmaceutical R&D.

Yet reforming the patent system may be more challenging than fortifying regulatory exclusivity. The patent system remains a one-size-fits-all legal regime that applies essentially the same rules to inventions arising in biopharmaceutical research, automotive engineering, information technology, semiconductors, rocket science, and even business methods, although the need for patent protection across these fields differs greatly. Tailoring the patent laws to address the environment for innovation within the pharmaceutical industry might upset the balance of protection and competition in other industries.

Membership in the WTO also limits the ability of member nations to tailor the patent system to specific industries. The WTO TRIPS Agreement requires signatories to provide patent protection 'without discrimination as to the place of invention, the field of technology and whether products are imported or locally produced' TRIPS Agreement Article 27. The brand-name pharmaceutical industry favored the prohibition in the TRIPS agreement against discrimination as to field of technology, because it would require member states to eliminate provisions in national laws that weakened drug patents (such as compulsory licensing provisions). But the treaty language seems to prohibit discrimination in favor of drug patents as well as against them. On the other hand, the TRIPS Agreement places few restrictions on the award of regulatory exclusivities by WTO members.

Enhanced regulatory exclusivity offers other advantages for brand-name drug companies over stronger patent protection. First, patents provide not so much the right to exclude as the right to sue to exclude. Generic firms frequently make successful arguments that the brand-name firm's patents are invalid or not infringed. In contrast, regulatory exclusivity keeps competitors off the market without the need for owners to bring costly and risky infringement actions. This may be particularly advantageous in countries that do not have well-functioning institutions for patent enforcement, but even in the US the costs and risks of infringement litigation are considerable.

Second, apart from its more limited duration, regulatory exclusivity is a better temporal fit with the life cycle of a pharmaceutical product. Regulatory exclusivity periods typically do not begin until a product is on the market, while much or all of a patent term may run before that time. Finally, the scope of regulatory exclusivity generally corresponds better to relevant product markets than do patents. Regulatory exclusivity tracks the terms of FDA product approvals, while patent claims, drafted to distinguish an invention from the prior art, may not correspond as closely to any actual commercial product.

From a political economy perspective, it may be easier for interest groups to influence policy initiatives that focus narrowly on a particular industry (such as modifications to drug regulation) than it is to influence policy initiatives that have a broader impact (such as modifications to patent law), because the broader the implications of the policy, the more likely they are to encounter competition from other interest groups. The pharmaceutical industry has sometimes found itself in opposition to the financial services and information technology

industries, for example, in legislative debates about patent law reform (Kahin, 2007). However, the biopharmaceutical industry was quite successful in shaping the terms of recent biosimilars legislation to secure generous benefits for its members (Greenwood, 2010). Perhaps an industry-specific approach increases the risk that policy makers will be unduly influenced by industry rent-seeking to the detriment of other interests that are less vigorously represented in policy debates.

The proposed Modernizing Our Drug & Diagnostics Evaluation and Regulatory Network Cures Act, or MODDERN Cures Act, H.R. 3497, 112th Cong., 1st Sess., provides an example of a framework of innovation incentives that emphasizes regulatory exclusivity over patents when the sponsor asserts that patent protection would be inadequate to support development of the product. Under the proposed legislation, which has been endorsed by a long list of disease advocacy groups, professional associations, and biopharmaceutical firms, a drug sponsor could submit a request to FDA for 'dormant therapy' designation for a therapy that fulfills an 'unmet medical need' and that has 'prospectively insufficient patent protection.' The request must include a list of patents covering the therapy and a conditional waiver of the right to enforce those patents after the termination of regulatory exclusivity. If the FDA agrees that the indication for which approval is sought addresses an unmet medical need, it will grant the dormant therapy designation and the patent waiver will become effective. The sponsor then obtains 15 years of marketing exclusivity. All of the identified patents are given an extended term of up to 15 years after the product is approved, but pursuant to the patent waiver, the sponsor of the disclaims any patent term after the 15-year exclusivity period. Whether the MODDERN Cures Act will become law remains to be seen, but the proposal itself represents a significant shift in understandings of the roles of patents and regulatory exclusitivies in promoting innovation.

Regulatory exclusivities have other disadvantages. They place public health officials in the uncomfortable position of denying patients access to safe and effective generic substitutes for unpatented medications. They require FDA to devote considerable time and manpower toward drafting regulations, issuing guidance documents, and adjudicating disputes involving multiple regulatory exclusivity regimes. These resources might be more effectively spent in pursuit of the agency's core mission of protecting public health.

Regulatory exclusivities lack important limitations that are built into patent law. The US Supreme Court recently explained that "the results of ordinary innovation are not the subject of exclusive rights under the patent laws. Were it otherwise, patents might stifle rather than promote the progress of useful arts." KSR Int'l. versus Teleflex, 550 US 398, 427 (2007). Yet regulatory exclusivities are available for old products based upon the completion of routine clinical trials that would not qualify for additional patent rights. Perhaps the same considerations that justify withholding patent rights from 'ordinary innovation' in order to promote progress also caution against awarding regulatory exclusivity for 'ordinary innovation' in the context of drug testing. No other industry receives comparable guarantees of an exclusive market to induce them to bring their products to market. Perhaps the extraordinary protections afforded to the pharmaceutical industry are diminishing the motivation of drug-developing firms to become more efficient innovators.

Conclusion

The current overlapping legal protections for exclusivity in the pharmaceutical marketplace reflect a series of political compromises, repeatedly renegotiated to correct for unintended consequences in the last version of the rules. It is not easy to design a set of rules that provides the optimal balance between incentives for innovation and barriers to competition. On one view, patent law reform provides a more appropriate response to concerns over particular innovation environments than the creation of a gallery of additional regulatory exclusivities. The failure to make the patent system responsive to this intensely science-based industry threatens to allow the patent regime that has long served as the engine of innovation to become antiquated. It may also maintain deficiencies in patent doctrine for the great majority of innovative industries that do not benefit from regulatory exclusivities.

Another view is that a simpler and more effective legal regime would rely less upon patent protection and more upon well-designed regulatory exclusivity to support incentives for new drug development. It makes little sense for lawmakers and trade negotiators to extend the Byzantine Hatch–Waxman system into new legal regimes, either by duplicating it for biosimilars or by binding our trading partners to adopt similar systems in their national laws. Recent biosimilars legislation in the US, although controversial in specifics, corrects some problematic structural features of the Hatch–Waxman Act, disentangling regulatory exclusivity from patents and offering greater incentives to develop products that may be inadequately protected by a patent system that is often asynchronous with biopharmaceutical product development.

Pay for Prevention

A Oliver, London School of Economics and Political Science, London, UK

Introduction

The idea of paying people to engage in healthy activities, and to refrain from unhealthy ones, gained some traction in the health policy discourse in several developed and developing countries toward the end of the 2000s. The concept itself is simple and is informed by one of the most basic features of standard economics, the relative price mechanism, that is, if you pay someone to do something, there is an expectation that the person is more likely to do it, and the higher the cash incentive, the greater the effect. Here, payments to people to encourage healthier behaviors are defined as user financial incentives (UFIs), and might be expected to have a positive effect if the utility that an individual gains from the payment outweighs the personal disutility consequent on the behavior change.

UFIs exist when an individual can expect a monetary transfer, which is made conditional on them for acting in a particular way. Mostly, they are positive rather than negative financial incentives, rewards not punishments. Taxes on certain harmful products, such as cigarettes, are, however, a form of negative financial incentive and can be quite effective in changing people's consumption patterns. Moreover, this intervention has gained considerable exposure in recent policy debates internationally, with respect to, for example, the so-called 'fat taxes' (i.e., additional taxes on food with high calorific content) and 'soda taxes.' The imposition of such measures affects all those engaged in the targeted activity though: those who alter their behavior, by the very fact of them altering their behavior, and those who continue as before, when they are now subject to higher prices. It could be argued, therefore, that taxes are heavily paternalistic. UFI are more libertarian by comparison, in that those who continue to smoke, or eat too much, or refrain from exercise, are not directly affected by the payments at all. It is for this reason – even though UFI ought to be seen as a complement to, rather than a substitute for taxes – that the political leanings of those who currently govern much of the world may lead them to take an interest in positive financial incentives.

Aside from the simplicity of the theory that informs UFI, one must ask oneself, do they work? To answer this, one must turn to the evidence.

Evidence

Numerous experiments with UFI have been, and are being, conducted at the local practical policy level in a number of countries, including the UK, with the use of financial and payment in kind (iPods, hotel breaks, helicopter trips) incentives by healthcare purchasers, and the US, in employer-based wellness programs. These local level pilots are, however, rarely well evaluated. Fortunately, there is a reasonable amount of evidence reported in the academic literature on the effectiveness of mostly quite small UFIs to enable us to reach some informed conclusions.

Behavior change can be categorized as either complex or simple. Complex behavior change requires sustained effort over a length of time; simple behavior change requires single actions at a point in time. Some preventive activities – for example, smoking cessation and healthier eating – clearly require a sustained effort, whereas others, such as attending doctors' appointments and participating in vaccination programs, are more likely to be relatively simple. Sustained and 'one shot' behavior change require qualitatively different responses from the individual, and thus it makes sense to dichotomize the evidence according to these categories.

Sustained Behavior Change

The behavior changes discussed here are those associated with smoking cessation and weight loss. There have been systematic reviews in both areas, and the evidence is not auspicious. In relation to smoking, abstinence is measured through use of a biochemical test that records cotinine levels in saliva or urine. In 2008, Cahill and Perera reported a systematic review of studies that have analyzed the effectiveness of UFI for smoking abstinence, wherein only 1 of the 17 studies has demonstrated significantly higher cessation rates for those to whom incentives are offered as compared with those in control groups beyond 6 months from the start of the intervention. Unfortunately, cost information is usually absent from UFI studies and thus even when effectiveness is observed, the discernment of cost effectiveness is difficult.

A 2007 meta-analysis of nine randomized trials on the use of UFI to reduce obesity rates after 12 months following the initiation of the incentive as reported by Paul-Ebhohimhen and Avenell has concluded that an incentive of less than 1.2% of personal disposable income is associated with a zero mean weight change. Financial incentives of at least 1.2% of disposable income were, compared with no incentive, associated with a mean weight loss of 2.4 lb at 12 months and 1.5 lb at 18 months. Thus, the effect by 18 months postinitiation was small and dissipating, and cost-effectiveness information was, again, missing. Indeed, in the domain of weight loss interventions, it is probably difficult to gauge cost effectiveness without knowing the health implications of the loss in weight, which will occur (if at all) many years in the future, and are therefore likely to be confounded by an individual's broader behaviors, environment, and genetic profile. Rewarding people for weight loss could also feasibly incentivize some quite unhealthy behaviors.

One Shot Behavior Change

As noted above, various types of medical adherence require single, or limited, acts. In 1997, Giuffrida and Torgerson reported a systematic review of UFI to motivate medical

adherence (including adherence to a tuberculosis medical regimen, dental care for children, immunization, postpartum appointments, etc.). They identified 11 randomized controlled trials, of which, 10 demonstrated a positive effect. There have been additional studies in the intervening years, many (although by no means all) of which have shown similar promise. For example, a 2003 study by Seal and colleagues reported a randomized controlled trial on a population of hard to reach intravenous drug users in San Francisco. All of the drug users were given the first of three required hepatitis B vaccine doses and then they were divided into two groups, an 'outreach group' and an 'incentive group.' The third vaccine dose was administered 6 months after the first dose, and the outreach group was assigned a weekly contact with an outreach worker; the incentive group, however, received a monthly US$20 monetary incentive if they remained in the vaccine program. It turned out that 69% of those in the incentive group received all three doses of the vaccine as against only 23% in the outreach group.

In another study, this time from 2005, Slater and colleagues administered two types of mail-based interventions to women aged 40–64 years to encourage them to undergo mammography. Both of the interventions offered a free mammogram if the respondent rang a toll-free number, with one of the interventions also offering a small financial incentive if a person actually underwent the mammogram within 1 year. More than four times as many calls were received for the mail-plus-incentive intervention than the mail-only intervention, and the subsequent mammogram rate was significantly higher in the former intervention than the latter intervention, which in itself produced a significantly higher rate than 'do nothing.' As with the interventions to encourage sustained behavior change, however, those that focus on medical adherence are generally silent regarding value for money.

Summary

There is evidence to suggest that UFIs are potentially useful in many areas of medical adherence, but in terms of policy areas that demand more sustained efforts from the targeted groups, the effectiveness of this intervention has been generally poor. In short, for smoking cessation and weight loss, any early success tends to dissipate when the incentives are no longer offered. It may be the case that many studies have been somewhat underpowered, in terms of the size of the incentives offered and the length of time they are offered for. Indeed, a large trial reported in 2009 by Volpp and colleagues at the Center for Health Incentives and Behavioral Economics at the University of Pennsylvania, would seem to suggest that larger incentives may work.

In the trial, 878 people were randomized to either a control group or an incentives group. At baseline, all participants tended to smoke approximately one packet of cigarettes daily. The participants in both groups received information regarding smoking cessation programs, but the incentives group additionally received US$100 for completing a program, a further US$250 for exercising abstinence for 6 months into the trial, and an additional US$400 if they remained abstinent until 6 months thereafter. At 12 months from the initiation of the trial, the cessation rate in the incentive group was significantly higher than that for the controls (14.7% vs. 5%), and although there was some relapse in both groups, this pattern persisted beyond the lifetime of the incentive at 18 months (9.4% vs. 3.6%). Moreover, using incentives in excess of US$100 over a 4-week period, Charness and Gneezy have provided some evidence that gym attendance may be sustained at a significantly higher rate than would otherwise be the case post trial, at least in the relatively short term.

Generally, however, offering larger incentives over longer periods may not be feasible, particularly if financed by the public sector and targeted at broad population levels, given the current global fiscal environment. Therefore, it would make sense to examine whether the payment mechanism in UFI can be redesigned so as to improve its effect.

Strengthening the Payment Mechanism

It may be possible to improve the strength of the UFI payment mechanism by appealing to the findings of behavioral economics. For instance, theoretically, requiring participants to commit their own money (a 'deposit contract'), with the intention of receiving their money back if they achieve the target behavior, might be expected to improve effect. This is because in the behavioral economics literature, it has been observed that losses loom larger than gains; that is, people attach a greater magnitude of disutility to losing a particular good than the utility that they attach to winning the same good. Given this general observation of loss aversion, we might expect the loss associated with giving up money in deposit contracts to make them more effective than the conventional practice of simply giving people money if they meet their target behaviors. Moreover, some have highlighted the behavioral economic observation that people tend to be attracted to large rewards that have a small probability of occurring, and that therefore, instead of offering the target population a small financial incentive for certain, they ought to be offered, if they successfully change their behavior, a lottery that has the same expected value as the certain payment, but entails some probability of winning a relatively large monetary amount. In short, compared with conventional UFI, deposit contracts and lottery payment mechanisms do not necessitate increases in the average payment, but they may trigger cognitive effects that make respondents perceive the incentives to be more substantial.

In a selection of small studies that have not been specifically informed by behavioral economics, the performance of deposit contracts and lottery payment mechanisms in motivating sustained behavior change has been mixed, at best. There has, however, been at least one UFI for weight loss study that was informed directly by behavioral economics, with some interesting, if not spectacular, results. In this 2008 study by Volpp and colleagues, participants were assigned to one of three arms: (1) a weight monitoring program that required a monthly weigh-in; (2) the weight monitoring program plus a deposit contract, where at the beginning of each month participants could deposit between 1 cent and US$3 per day, with the deposited amount matched by the investigators in addition to a fixed payment of US$3 per day, with all refundable if the participant met the targeted weight loss at the end of each

month; and (3) the weight monitoring program plus a lottery incentive, where, if they met their weight loss target, participants played a daily lottery that had an expected value of approximately US$3, with some of the lotteries comprising of a large payoff with small probability but most comprising of a small payoff with larger probability. The trial end point target weight loss for all participants was 16 lb at 16 weeks. At 16 weeks, the mean weight losses in the control group, the deposit incentive group and the lottery incentive group were 3.9, 14, and 13.1 lb, and the percentage of those in each group achieving the 16 lb weight loss target were 10.5%, 47.4%, and 52.6%, respectively: At that point in time, the weight loss was statistically higher in both incentive groups, as compared with the controls. However, at 7 months, although both the incentives groups still on average weighed significantly less than they did at the initiation of the study, the mean weight losses in the control group, the deposit incentive group, and the lottery incentive group were now 4.4, 6.2, and 9.2 lb, respectively, a nonsignificant difference across the three groups. In both incentives arms, therefore, the earlier effectiveness had dissipated considerably.

More experimentation with different UFI payment mechanism designs, informed by the findings of behavioral economics, is warranted. If they can be shown to effect sustained as well as simple behavior change, then they might prove to be a very useful addition to the preventive health policy armory. For this, however, evidence of effect is necessary, but not sufficient. There are many moral and practical objections to the use of UFI that should not be ignored.

Objections

Moral Objections

Some believe that UFIs are unethical. One argument is that trading money for health (or, presumably, health-related behaviors) involves incommensurable values, in the same way that, for example, selling a child for an electoral vote is unacceptable. The commodification of health-related behaviors, according to this view, may lead to their denigration, devaluation, and/or corruption. UFI may denigrate the person's choices by failing to respect sufficiently the decision that the individual has reached, assuming that he or she has taken into account all of the pros and cons of their actions, which might be particularly dangerous in the field of mental health, where the voice of the patient has often traditionally been ignored.

Thus, there are concerns that UFI, by potentially interfering with the rights of self governance, may undermine some conceptions of fairness and justice. Moreover, in the area of personal lifestyle behaviors, such as smoking, diet, and exercise, it is possible that the general public will resent general tax revenues being used to reward people for doing what the majority believe they should be doing anyway. However, the general acceptance of UFI may prove context specific. For example, paying people to take their medications might garner general societal support, especially if it is perceived that patients underestimate the pros and/or overestimate the cons of medication. If patients do not fully appreciate the benefits of medication, and if their carelessness toward medication poses avoidable harm for themselves or for the communities in which they live, then the societal view may be that the use of UFI is justifiable.

If UFIs are targeted at the relatively poor, as they often are, they could generate further ethical problems, because even small monetary rewards may deter poor patients from terminating treatment when they feel that it is causing them harm. Furthermore, the offer of a financial incentive could be judged as a bribe when directed toward those with limited means. Conversely, it may be contended that UFIs, whereby those targeted can refuse to participate for any reason, are a model of respectful and equal exchange, that the notion of coercion is more usually associated with punishment than reward, and that it is hard for some to accept how a transparent financial inducement to take medicine in order to remain well undermines society's notion of fairness and justice.

Unintended Consequences of UFI

Other objections to UFI focus less on whether they are morally wrong, and more on their potential to have undesirable unintended effects. For example, some worry that the introduction of UFI for some aspects of medication adherence will encourage patients to stop taking their treatment so as to receive the payment for taking their treatment again. Similarly, in relation to broader lifestyle behaviors, it is possible that a few will temporarily initiate unhealthy activities, such as smoking, so as to receive payment for quitting.

A number of experts, across a range of disciplines, have warned that external rewards to act in a particular way may in the long run crowd out the intrinsic desire to alter one's behavior. For instance, if rewards are offered to people to quit smoking, those payments could potentially become an expectation, and thus people might be less willing to abstain under their own personal motivation. Thus, those who are targeted for UFI must be made aware that any financial incentive is there to serve as merely temporary support to help them achieve a personal goal. Similarly, perhaps, financial incentives to discourage particular unhealthy actions might crowd in other undesirable activities: for instance, an ex-smoker motivated by money rather than health may be more likely than a health-aware reformed smoker to substitute doughnuts for cigarettes.

A monetary payment, if administered from the doctor to the patient, might also crowd out the traditional trust-based nature of the doctor–patient relationship, possibly damaging the principal–agent interaction in this regard if some patients no longer follow advice in the absence of financial rewards. Moreover, attempts to change people's lifestyle choices are potentially patronizing and condescending to the targeted group; the obese, for instance, may feel unfairly stigmatized beyond the levels to which they have already been stigmatized. There are clearly a host of objections to the use of UFI; whether or not they are insurmountable in all contexts requires a broad public policy debate.

Conclusion

For some aspects of medical adherence, modest financial incentives can have an effect on people's behavior, although

little is yet known regarding the cost effectiveness of these interventions. However, there is currently little evidence of a positive sustained effect on changing lifestyle behaviors when associated with smoking or weight loss. Nonetheless, all hope in this domain should not yet be abandoned; further research that tests the differential impact – and value for money – of different incentive mechanisms that are informed by the findings of behavioral economics is warranted.

There are many ethical and practical objections to the use of UFI. Although the use of UFI is not intended to threaten individual liberty in that participants self-select into incentives programs, which target behavior change that they themselves are meant to desire, there is perhaps a legitimate concern that these interventions violate spheres of privacy and autonomy. For instance, if UFI are used as a public policy tool, it seems not unreasonable to worry that they may patronize people, and might single out a subset of the population (e.g., the obese), stigmatize them further, and treat them as if they lacked full use of reason. Clearly, more public debate is required in order to reach a consensus on the limits of acceptability to the use of UFI, assuming of course that they prove to demonstrate both reasonable effect and value for money in the areas toward which they are targeted.

Pay-for-Performance Incentives in Low- and Middle-Income Country Health Programs

G Miller, Stanford University, Stanford, CA, USA, and National Bureau of Economic Research, Cambridge, MA, USA
KS Babiarz, Stanford University, Stanford, CA, USA

Glossary

Contracting-out A government practice of contracting with private organizations for health service delivery.
Extrinsic motivation Incentives or motives that originate from without (e.g., financial rewards offered by others).
Intrinsic motivation Incentives or motives that originate from within (deriving enjoyment or personal satisfaction from completing a task, for example).
Multitasking A reduction in effort devoted to noncontracted outcomes when agents are responsible for multiple tasks or multidimensional tasks, but only rewarded for performance on a subset of them.

Introduction

Poor performance of health care providers plagues the delivery of health services in many low- and middle-income countries. The underlying reasons are complex and incompletely understood, but poor performance is not simply due to inadequate training or deficiencies in provider knowledge.

Instead, a growing body of evidence documents substantial deficits in provider effort. One striking example is the high absenteeism rates (as high as 75%) among health professionals documented in a number of studies. When providers are present, a sizeable 'know-do' gap (or failure to do in practice what a provider knows to do in principle) also contributes to low-quality medical care. Provider effort may also not focus directly on improving health – for example, health professionals may provide unnecessary services that are not medically appropriate (e.g., intravenous glucose drips to create the illusion of therapeutic effectiveness). Moreover, even when providers exert appropriate effort during a clinical encounter, they may do little to promote the health of their patients outside of the encounter (e.g., through prevention and outreach activities).

One might expect that given weaker market incentives, these problems would be more prevalent in public sector health service delivery. However, suboptimal provider effort can be sustained in equilibrium in all sectors, including private practice, due to well-known market failures. For example, a well-established literature demonstrates that asymmetric information limits the ability of patients and the lay public to observe provider effort or judge medical care quality. As a result, patients are unable to penalize underperforming providers through their choices. These problems are compounded by market conditions and rigidities common in low- and middle-income countries, including inadequate regulatory processes and a relatively large government role in financing and delivering health services (e.g., given the more prevalent infectious diseases and larger positive externalities in service delivery).

To better align provider incentives with patient and population welfare (or health – one argument of welfare), 'pay-for-performance' schemes have become increasingly common in developing country health service delivery. In principle, the idea is straightforward: drawing on the logic of performance pay in human resource management, this approach rewards providers directly for achieving prespecified performance targets related to health. Use of performance incentives in wealthy countries began in earnest during the 1990s with programs that rewarded both process indicators and measures of clinical quality. Examples of performance targets include immunization rates; disease screening; adherence to clinical guidelines; and the adoption of case management processes, physician reminder systems, and disease registry systems. The UK went further with the National Health Service's Quality and Outcomes Framework, tying physician practice bonuses to a comprehensive range of quality indicators. Performance pay in low- and middle-income country health programs emerged in the late 1990s, and its use has grown rapidly since then.

In practice, pay-for-performance contracts are complex and fraught both with difficult tradeoffs and with the possibility of 'multitasking' and other unintended consequences. This article outlines the key conceptual issues in the design of pay-for-performance contracts and summarizes the existing empirical evidence related to each. In doing so, it focuses on four key conceptual issues: (1) what to reward, (2) who to reward, (3) how to reward, and (4) what perverse incentives might performance rewards create. The article concludes by highlighting important areas for future research and by noting the overall lack of evidence on many key aspects of incentive design in the health sector.

What to Reward

If 'you get what you pay for,' then it presumably follows that one should pay for what one ultimately wants. If a health program's primary objective is good patient or population health outcomes, it would seem natural for performance incentives to reward good health or health improvement directly rather than the use of health services or other health inputs. Rewarding health outcomes rather than health input use not only creates strong incentives for providers to exert effort, but

it can also create incentives for providers to innovate in developing new, context-appropriate delivery strategies. Put differently, rather than tying rewards to prescriptive algorithms for service provision (often developed by those unfamiliar with local conditions), rewarding good health outcomes encourages providers to use their local knowledge creatively in designing new delivery approaches to maximize contracted health outcomes.

In practice, however, very few pay-for-performance schemes have rewarded good health. At the time of writing this review, the authors are aware of only two: performance incentives for primary school principals in rural China to reduce student anemia and incentives for Indian day care workers in urban slums to improve anthropometric indicators of malnutrition among enrolled children. In the Chinese study, researchers measured student hemoglobin concentrations at the beginning of an academic year, issued incentive contracts rewarding anemia reduction to principals shortly afterwards, and measured student hemoglobin concentrations again at the end of the school year. School principals responded creatively, persuading parents to change their children's diets at home as well as providing micronutrient supplementation at school; and anemia prevalence fell by approximately 25%. In the Indian study, researchers measured child anthropometrics at day care facilities, issued incentive contracts rewarding providers for each child with an improved malnutrition score, and repeated anthropometric measurement 3 months later. In response, day care workers visited mothers' homes and promoted the use of nutritious recipe booklets; malnutrition indicators declined by approximately 6%.

The fact that so few pay-for-performance programs reward health outcomes may reflect important limitations to doing so that arise in practice. Instead, performance incentives generally reward the use of prespecified health inputs. In the following sections, shortcomings and tradeoffs inherent in incentive contracts that reward health outcomes will be discussed.

Share of Variation in Contracted Outcome under Provider Control

One drawback to rewarding good health is that even when exerting optimal effort, a relatively small amount of variation in health outcomes may be under the control of providers. For illustration, consider the case of neonatal survival. Maternal health behaviors during pregnancy are key determinants of birth weight, and low birth weight is a leading risk factor for neonatal death. Although rewarding maternity care providers for neonatal survival could in theory motivate them to engage expectant mothers from an early stage of their pregnancy, providers may be unlikely to succeed or may believe a priori that they will be unable to change maternal health behaviors. Patients or community members may also respond to changes in provider behavior caused by performance incentives; in some cases, these responses may undermine provider actions. For example, if educators or health providers take direct action to improve nutrition because of performance incentives, parents may respond by reducing children's dietary quality at home. In both cases, if providers do not believe that their effort will ultimately be rewarded, they may simply not respond to the performance incentive.

A clear (and common) alternative is to reward the use of health services and inputs, particularly those that are relatively sensitive to provider effort. Providers generally have a greater influence on service use than health outcomes, and even more so on quality of clinical care. In several rigorous studies of pay-for-performance incentives in Rwanda, providers were rewarded for prenatal care visits, immunizations among children and pregnant women, institutional deliveries, HIV testing, and a wide range of service quality indicators. Incentive payments were offered for each service provided and were weighted using overall quality scores. This set of incentives motivated providers both to increase delivery of contracted services and to raise the overall quality of care. Researchers observed that the program increased institutional delivery rates by 23% and preventive service use among children under the age of 4 years by 25–50%, and it also reduced the 'know-do' gap by 20%. Although not directly contracted, infant weight-for-age and child (2–4 year old) height-for-age rose by approximately 0.5 and .25 standard deviations, respectively. Researchers also observed that the incentives led to a 15% increase in the rate of HIV testing and counseling among couples, and an 18% increase in the probability that both partners in HIV-discordant households had been tested for HIV at least once.

Interactions with Provider Skill/Human Capital Base

A second limitation to rewarding good health outcomes is that providers may not possess adequate ability to innovate if they lack the necessary skills and human capital. These skills can be both technical and interpersonal. Scholars suggest that providers may be unsuccessful in responding to performance incentives when success requires changing the patient behavior (which requires skills beyond clinical ability). In the Rwandan program, providers were unsuccessful in increasing contraceptive use and in persuading patients to complete the contracted sequence of four prenatal care visits in part because of local patient preferences (superstitions about acknowledging pregnancies at an early stage). To address this shortcoming, one program in the Democratic Republic of Congo paired performance incentives with consulting services for community outreach and business planning. Health facility managers were encouraged to submit quarterly business plans detailing their strategies to achieve incentivized targets, and consultants provided them with custom-tailored advice.

Measurement of Contracted Outcomes

A third obstacle to rewarding good health is that health outcomes can be more difficult and expensive to measure than health service or input use, particularly when physiological health indicators must be measured directly. For example, all else equal, the expense of measuring hemoglobin concentrations would potentially be an important barrier to scaling up the China performance pay program described above. Alternatively, incentives tied to service and input use have successfully relied on combinations of self-reporting and random

audits to measure contracted outcomes on a larger scale. Examples of contracted health inputs measured this way include well baby visits and adherence to clinical protocols during medical visits. Finally, measurement of contracted outcomes (either health input use or health outcomes) among patients in clinical settings may pose fewer measurement challenges than in community wide settings section (Perverse incentives and unintended consequences considers tradeoffs between rewards for outcomes among patients vs. population members).

Who to Reward

Another important issue in designing performance incentives is deciding who to reward. Which agents at what organizational level will be most efficient and effective in improving on contracted outcomes? This section describes conceptual issues in contracting at the macro- (or organizational) and the micro- (individual) level.

Macrolevel Incentives: Organizations and Local Government

At the macrolevel, international organizations (like the Global Alliance for Vaccines and Immunization and the Millennium Challenge Corporation) increasingly use 'results-based financing' in providing aid. Central governments in low- and middle-income countries also frequently contract with private organizations or transfer resources to local government to deliver health services – and performance incentives are often included in these schemes. As performance pay shifts risk to incentivized agents, the more risk averse the agent, the greater the expected compensation must be (all else equal). One advantage of organizational-level incentives is that collectively, organizational agents may effectively be less risk averse than individual employees. This is because idiosyncratic risk that effort will not result in good performance – and thus not be rewarded – is pooled across individuals within organizations. As a result, overall program costs may be lower when contracting at the organizational level (all else equal). However, contracted organizations must then solve their own internal principal–agent problems, and they may pass the costs of doing so on to the principals contracting with them.

There are many circumstances under which central governments 'contract-out' health service delivery to private organizations (typically non-governmental organizations (NGOs)). One is settings in which public sector facilities are largely absent – for example, regions of postconflict Afghanistan and Haiti. Under these conditions, governments and international organizations have contracted with NGOs to open facilities, recruit and train providers, and manage all aspects of service delivery. In the context of Afghanistan and Haiti, achieving performance targets was rewarded with operating budget transfers of up to 10% of the base contract amounts (paid by the World Bank and the US Agency for International Development (USAID), respectively). In Afghanistan, studies found that these contracting strategies were associated with improvements in service availability (measured as the ratio of facilities to population, which increased by approximately 30%, and the share of facilities providing antenatal care, which rose by 45–75%) and institutional delivery rates (which roughly doubled). In Haiti, research suggested that performance pay was associated with 13–24% point increases in full childhood immunization coverage and 17–27% point increases in institutional delivery rates.

Contracting-out also occurs when public sector facilities exist but perform poorly. For example, in 1999, the Cambodian Government began contracting with NGOs to manage health service delivery in five randomly selected districts (eight districts were chosen for contracting, but not all districts had suitable quality proposals from NGOs). Contracts rewarded eight explicit performance indicators (immunization rates, vitamin A supplementation, antenatal care use, medical supervision of deliveries, institutional delivery rates, contraceptive use, and use of public vs. private sector health facilities). Researchers found that after 5 years, performance-based contracting led to a 32% point increase in antenatal care use, a 16% point increase in completion of recommended childhood immunizations, and a 17% point increase in vitamin A supplementation. Cambodia's contracting strategy also improved the general facility operations (24 h service availability, staff attendance, managerial supervision, and equipment availability).

Macrolevel performance incentives have also become increasingly common in the public sector. In the 1980s, central governments in many low- and middle-income countries began transferring funds for service provision to local governments, decentralizing authority over policy design and management. One of the rationales for decentralization is that local governments have superior information about local preferences and are therefore better able to satisfy them. However, even if local governments have superior information about local preferences, they do not necessarily have strong incentives to satisfy them. Decentralization can therefore include performance-based incentives. For example, a recent initiative in Indonesia gave block grants to village leaders to provide maternal and child health services and to run schools. In a randomly selected subset of villages, the size of subsequent block grants was tied to performance according to 12 performance measures (8 maternal and child health indicators and both enrollment and attendance in primary and secondary schools). Scholars found that with performance incentives, midwives in treatment villages worked longer hours, increasing the availability of health services – and prenatal care visits rose by 37% points. Local administrators in incentivized districts also used central government funds more efficiently, negotiating savings in education (without any apparent decline in school attendance) and reallocating the savings to the health sector.

Under all of these circumstances, organizational autonomy may be critical for the success of incentive programs. The Cambodian program experimented explicitly with the degree of independence given to contracting NGOs, using both more restrictive 'contracting-in' and more autonomous 'contracting-out' arrangements. Management and facility indicators improved more in contracting-out districts, and there is suggestion that health indicators did as well. Other cases illustrate the breadth of responses to performance incentives enabled by autonomy. For example, hospitals in Sao Paulo, Brazil with

municipal health delivery contracts that rewarded hospital efficiency, patient volume, and service quality developed creative organizational strategies tailored to their own hospital settings. Hospital spending fell and efficiency indicators rose without measurable declines in service quality; researchers estimate that to produce comparable changes in patient discharges absent performance incentives, hospitals would need to increase spending by approximately 60%.

An important limitation of macrolevel incentives is that they may not translate into private rewards for organizational leaders. Although performance incentives could, in principle, be structured this way, to date they have generally been designed as operating budget transfers and eligibility for future contracts (rewards paid as budget transfers vs. private income is discussed in more detail in Section How to Reward). A related drawback is the possibility that organizational policies and regulations limit organizational or local government ability to solve their own internal principle–agent problems (e.g., if managers are not permitted to use budget transfers for employee bonuses). In Cambodia, contracting NGOs increased the use of many (presumably productive) health inputs, but actual health outcomes (the infant mortality rate and diarrhea incidence among children under 5 years) did not improve. NGOs managing hospitals in Afghanistan and Costa Rica (under similar programs) made improvements in facility management and service provision, but there were no measurable gains in health input use (e.g., immunizations).

Microlevel Incentives

At the microlevel, organizations often use performance incentives to solve principal–agent problems with individual employees. These incentives can target upper-level managers and/or rank-and-file providers that they supervise.

An important virtue of rewarding managers for good performance is that they possess greater flexibility for innovation in service delivery. In contrast, lower-level health workers often must follow detailed, highly prescriptive protocols from which they are not allowed to deviate. For example, a recent study shows that Chinese primary school principals (who manage schools) offered performance rewards for reducing student anemia not only supplemented school meals with vitamins, but they also took the initiative to discuss nutrition with parents, persuading them to increase their children,s consumption of iron-rich foods at home. As a result, anemia prevalence among participating children fell by roughly 25%. In Nicaragua, health facility managers were given performance incentives for offering and providing both prenatal care and well child services to a large share (90%) of local CCT program beneficiaries. In response, managers took the initiative to partner with community organizers (*promotoras*), school teachers, and the local media to conduct community outreach campaigns encouraging mothers to bring their children for checkups. These managerial efforts were reportedly successful: nearly all providers were judged to have achieved the performance targets, preventive care use increased by 16% points, and vaccination rates rose by 30% points.

In practice, many pay-for-performance schemes to date have rewarded individual providers rather than their managers for good performance. Although rank-and-file health workers may have less flexibility to innovate in service delivery, their effort may ultimately matter most for organizational performance. Additionally, because they have the most direct contact with target populations, individual providers may also have better knowledge about local conditions. For example, day care workers in the Indian program rewarding reductions in malnutrition made more frequent home visits in addition to providing more nutritious meals at day care facilities. Through these home visits, they encouraged mothers to use nutritious recipe booklets, and malnutrition among children at their day care centers declined by 4.2% over a 3-month period. In Rwanda, individual public sector providers responded to incentives for higher prenatal care and institutional delivery rates by partnering with midwives to identify and refer pregnant women for services. The associated increase in institutional deliveries was 10–25% points.

In addition to lacking flexibility to innovate in service delivery, there can be other limitations to incentivizing individual health workers as well. A potentially important one is that rewarding health workers for their own individual performance may create disincentives for teamwork or cooperation. Alternatively, rewarding providers for group performance creates incentives for free-riding because individual health workers do not bear the full cost of shirking – and may be rewarded for good performance among coworkers.

How to Reward

Using performance incentives to increase provider effort necessarily requires assumptions about what motivates providers. It is reasonable to assume the providers care about both financial compensation and patient welfare to varying degrees. However, human motives are complex, and other factors undoubtedly play a role too – professional recognition and the esteem of colleagues, pride in one's work, opportunities for professional advancement (career concerns), working conditions, and amenities where one lives, for example. From the standpoint of policy or program design, many of these other factors cannot be translated into performance rewards as easily as financial incentives. However, these other motives can interact with financial incentives in important ways.

This section discusses general conceptual issues in the structure of performance incentive contracts.

Balancing Fixed Versus Variable Compensation

As discussed in the literature outside of health (on executive compensation, for example), performance pay should optimally balance fixed (unconditional) and variable (performance-based) pay. On one hand, performance bonuses must be sufficiently large to influence provider behavior, and on the other aligning executive effort with firm interests may require that a large share of total compensation be tied to firm performance through performance pay. Several studies suggest that in health care, performance incentives may be ineffective if they are too small.

However, increasing variable pay as a share of total compensation increases the financial risk borne by providers. As providers are generally risk-averse (to varying degrees), they must be compensated for bearing additional risk inherent in pay-for-performance contracts. Negotiations over a health service delivery contract in Haiti between an NGO (Management Sciences for Health) and USAID illustrates this point. When renegotiating its contract, Management Sciences for Health was only willing to accept the additional risk imposed by performance pay if USAID would increase the total amount that could be earned to exceed contractual payments under the alternative unconditional contract (under the performance pay contract, fixed payments were set to 95% of the unconditional contract amount, and an additional 10% was made conditional on good performance).

The Functional Form of Provider Rewards

A second issue in the structure of performance pay contracts is the functional form mapping incentive payments onto performance indicators. Absent knowing what the contract theory literature suggests is needed for optimal incentive contract design, a simple approach is to offer rewards that are linear in contracted outcomes. Examples include constant incremental rewards per child reduction in malnutrition, per child reduction in anemia, or per infant delivery supervised by a skilled birth attendant.

Other programs have adopted a step-function approach, offering bonuses for surpassing one or more bright-line performance thresholds. Depending on its specific form, this approach can have theoretical grounding and may also be appropriate when thresholds have clinical significance (e.g., vaccination rates at levels that confer herd immunity). Contract theory suggests that optimal incentive contracts are likely to be nonlinear in contracted outcomes, and step functions could provide a reasonable approximation of these nonlinearities. Some scholars also argue that setting bright-line aspirational goals could change institutional culture to be more results or goal oriented. Although there is little evidence among studies of performance pay, bright-line performance incentives may help to focus attention on contracted outcomes when provider attention is scarce as well.

A drawback to the step-function approach can be a greater risk that provider effort will not be rewarded. Specifically, it creates strong incentives in the neighborhood of a threshold, but it may also be a poor motivator for health workers far below (or above) a threshold. The information required for optimal contract design (including the cost of provider effort, the health productivity of provider effort, and the utility functions of both providers and the contracting principal) is also unlikely to be available in practice.

Salary Versus Operating Budget Rewards

Structuring performance rewards as private income or operational budget revenue also requires assumptions about what motivates providers. In one extreme, if providers were purely motivated by private financial considerations, offering rewards as private income would presumably induce them to exert a greater effort. In the other extreme, if providers were purely philanthropic, incentive payments made as operational revenue could be more effective. Given that preferences are mixed in reality (and also include other things such as professional esteem, pride in one's work, career aspirations, etc.), predictions about the relative effectiveness of different types of financial incentives are ambiguous and may be context specific. One study suggests that NGO employees providing health services in Afghanistan responded markedly to performance incentives even though bonuses accrued to facilities and did not result in personal financial gain. In principle, combinations of the two are possible, although one is unaware of schemes that mixed the two. In practice, macrolevel rewards are often paid as operational revenue, whereas microlevel rewards are typically offered as private income.

Nonfinancial Incentives

Although pay-for-performance contracts strengthen extrinsic incentives, intrinsic motivation is commonly thought to be an important determinant of provider effort as well. Although not focused specifically on health care provider behavior, research on intrinsic motivation in psychology suggests that more altruistic individuals work harder to achieve organizational goals. In the health sector, altruistic individuals are more likely to work for health delivery organizations with explicit charity mandates, suggesting that intrinsic motivation may be heterogeneous across types of health facilities. Health care providers with greater intrinsic motivation may also be more responsive to professional recognition among community members or peers. In such cases, nonfinancial rewards as well as other psychological tools (such as priming, task framing, and cognitive dissonance) may be close substitutes (or may even be more effective) than financial incentives.

Qualitative and anecdotal evidence from field studies support the hypothesis that health care providers are intrinsically motivated. Health workers employed by NGOs in postconflict Afghanistan reportedly felt a great sense of pride and accomplishment after meeting contracted performance targets. A program (not formally evaluated) in Myanmar offered new scales for measuring patient weight to providers who met tuberculosis (TB) case identification and registration goals. In townships with these (essentially) nonfinancial incentives, identification of TB cases rose by 30% points relative to informal comparison townships. Anecdotal reports suggest that Zambian health workers participating in an incentive program (rewarding malaria treatment, infant and maternal care, and childhood immunizations) responded more favorably to trophies than to cash incentives. Finally, case studies suggest that health providers rewarded for good performance with t-shirts, badges and certificates, and recognition photographs may have been successful.

One rigorous quantitative study concurs with this qualitative and anecdotal evidence. In studying Zambian hair stylists with financial and nonfinancial incentives to sell condoms to salon clients, researchers found that public recognition outperforms monetary incentives. These results are heterogeneous across stylists and are largely due to strong behavioral responses among stylists believed to be more committed to the cause of HIV prevention.

Perverse Incentives and Unintended Consequences

The use of incentives to improve health program performance is fraught with the possibility of unintended and potentially perverse consequences. This section discusses some of these concerns and describe the empirical literature related to each.

Noncontracted Outcomes

One type of unintended behavioral response to performance incentives has been studied in the theoretical literature on 'multitasking.' When agents are responsible for multiple tasks or multidimensional tasks (some of which are unobservable or noncontractible), rewarding performance on a subset of contractible tasks or outcomes can lead to a reduction in effort devoted to noncontracted outcomes. The degree to which this occurs may depend in part on the extent to which noncontracted outcomes share inputs with contracted outcomes.

Empirically, some studies of performance incentives have found evidence of such behavioral distortions. A Kenyan school meal program rewarding improved pupil malnutrition rates found that subsidized meal preparation crowded out teaching time by 15%. Similarly, providing incentives to Chinese primary school principals for reductions in student anemia may also have displaced teaching effort, leading to lower test scores in some cases. Findings across empirical studies of performance incentives are heterogeneous, however. Several rigorous studies also report no clear evidence of distortionary or detrimental reallocation of effort or other resources in response to performance incentives.

Beyond the standard multitasking framework, performance incentives may lead to other closely related behavioral distortions. For example, although not studied empirically (to the best of our knowledge), performance incentives could lead to reallocation across multiple substitute activities related to the same disease or health outcome – or even the purposeful neglect of one to earn higher rewards for another (rewarding the successful treatment of a disease would undermine incentives to prevent it). Given the growing emphasis on 'impact evaluation,' another related example would be distortionary reallocation of effort and resources toward an evaluation's primary outcomes (and away from outcomes not emphasized by the evaluation). As demonstrating 'impact' can lead to new or continued funding, the evaluation process itself may therefore create important behavioral distortions (depending on the beliefs of the evaluated organization).

Heterogeneity in the Return to Effort across Contracted Outcomes

Among contracted outcomes, providers may also allocate effort to those that yield the largest (net) marginal return. In Rwanda, researchers found that rewards for good performance were most effective in improving outcomes that appear to have the highest marginal return or require the least effort. For example, performance incentives were more effective in increasing institutional delivery rates among pregnant women already in contact with community health workers (a relatively easy task because new patient relationships did not have to be created) than they were in initiating the use of early prenatal care (which the researchers suggest to be a relatively difficult task because doing so requires early identification of pregnant women not yet in contact with the health care system). Moreover, the incremental payment for institutional deliveries was relatively high (US$4.59), whereas the incremental payment for completion of quarterly prenatal care visits was relatively low (US$0.09). Ultimately, institutional delivery rates rose by more than 20% points, but there were no increases in the share of women completing all quarterly prenatal care visits.

Patient/Subpopulation Selection

In addition to altering how providers choose among tasks, performance incentives may also influence how providers allocate effort among patients or community members. Although not the focus of our review, incentives for patient selection are a ubiquitous concern with the use of high-powered incentives that emphasize cost containment (e.g., capitated contracts under managed care in wealthy countries). With performance incentives for good patient outcomes, selection against the sickest or most remote patients ('cherry picking') may occur if producing contracted outcomes among them is relatively difficult or costly.

Performance could alternatively be linked to population rather than patient outcomes, but providers could then be discouraged from providing services to individuals outside of the predefined population. Similarly, they may simply focus on the easiest to treat subpopulations within their defined service area. Some pay-for-performance schemes have tried to limit perverse incentive like these by offering larger rewards for services provided in more difficult or remote areas. Although such design features may reduce incentives for selection, eliminating them is a nearly impossible task (as the literature on risk adjustment suggests).

Erosion of Intrinsic Motivation

Finally, pay-for-performance incentives may have unintended consequences for the institutional culture of health care organizations and for the intrinsic motivation of individual providers. One study develops a model in which effort in the presence of rewards is a function of intrinsic motivation (operationalized as altruism, but which could also include pride in one's work, etc.), extrinsic motivation (material self-interest), and 'reputational' motivation (related to social- or self-image). In the model, monetary rewards undermine 'reputational' motivation and can therefore crowd-out effort by changing the perceived meaning of one's actions (an 'image-spoiling' effect). Both laboratory and field evidence lend some empirical support to this prediction. In one experiment asking students to perform an altruistic task (collecting charitable donations), evidence suggests that the net effect of small monetary incentives on prosocial effort is negative – students put more effort into the task when they were not compensated than they did when offered a small incentive.

Table 1 Partial list of pay-for-performance programs that have not been formally evaluated

Country	*Year*	*Who to Reward*	*What to Reward*	*How to Reward*	
Latin America					
Argentina		Provincial governments	Volume of poor women and children enrolled in health insurance; performance on 10 health indicators	60% of per-enrollee funding is fixed, 40% linked to performance on 10 targets.	[n]
Belize	2001	Public and private facilities		30% of total capitated service payments are paid monthly with deductions for failure to meet efficiency, quality, and administrative process indicators.	[u]
Costa Rica	1994	Public hospitals	Clinical performance (low delivery complications, low reinfection rates)	Budgetary bonuses	[h]
Honduas		Private hospitals	Health input quality indicators	Payment for each indicator given according to the extent to which the indicator is met (70% performance on a target translates to 70% funding for that indicator)	[n]
Europe/Asia					
Armenia	2008	Primary care providers	Unclear	Unclear	[o]
Bangladesh	2010	Primary care facilities	Infant and maternal care use, postpartum contraception	Unclear if institutional bonuses or provider-level bonuses	[k]
Indonesia	2007	Village governing bodies	12 Health and education indicators	20% of annual block grants determined by village performance on each of 12 contracted indicators	[i]
Nepal	2005	Health workers in public health facilities	Attended deliveries (home or institutional)	US$4.70 for each delivery attended	[l]
Africa					
Benin	2012	Public and private nonprofit health facilities	Maternal and infant health, malaria service use	Salary bonuses	[d]
Burundi	2006	Public health centers and hospitals	24 Specific services	Payment for each contracted service provided; payments weighted (up to 25% additional) for quality; payments up to 80% higher in poor and remote areas	[c]
Cameroon					
Central African Republic	2012	Private providers	Maternal and child health services, technical and capacity building indicators	Quarterly payments to facilities directly, used partly for worker bonuses and general operating budget	[t]
Egypt	2006	Public and private service providers in district provider Organizations	Family planning, immunization	Salary supplements to public and private service providers (up to 275% of base salary)	[e]
Ethiopia	2009	Commuity health workers	Peer and community based health education and outreach	nonfinancial incentives and recognition	[a]
Ghana	early-mid 2000s	NGO sector health workers	Varies across NGO provider	Varies across NGO provider	[f]
Liberia	2008	NGO health systems managers	Six administrative and managerial indicators and 12 targeted services	Operating budget bonuses	[d]
Malawi	2012	Primary care facilities	Quality as measured by a standards-based management and recognition tool		[b]

(*Continued*)

Table 1 Continued

Country	*Year*	*Who to Reward*	*What to Reward*	*How to Reward*	
Mali	2012	Primary care providers	Essential obstetric and newborn care service use	Unclear	[q]
Mozambique	2011	Community health workers	Institutional deliveries, vaccination completion rates, combination of input and output based indicators	Unclear	[r]
Senegal	2012	Public sector hospitals, health management teams, and health centers	Increased care use and quality indicators	Unclear	[p]
Somaliland	2009	Nurses and traditional birth attendants	Institutional deliveries	Nurses received bonuses for each attended delivery; traditional midwives received an incentive for each referral	[j]
South Sudan	2009	NGO health systems managers	Vaccination rates, Vitamin A supplimentation, insecticide treated bed net use, underweight children, staffing, sufficient drug supply, clinical vignette performance	Less than 80% of targets yields 95% contract payment; 80–99% leads to 100% payment; 100% of targets leads to 106% of contract payments	[j]
Tanzania	2011	Public health centers, nonprofit hospitals and dispensaries	Unspecified indicators contracted (set of indicators specified for each type of facility)	Operating budget bonuses	[d]
Uganda	2004	Private nonprofit health facilities	Increased patient volume, prenatal care visits, attended deliveries, immunization rates, contraception use, malaria treatment	Operating budget bonuses	[g]
Zambia	2004	Public providers	Malaria and sexually transmitted infection incidence; prenatal care, attended deliveries, postnatal care, patient satisfaction, immunization rates	Salary bonuses or nonfinancial awards (trophies)	[m]
Zimbabwe	2011	Provincial and district health executives, district hospitals, and rural health centers	Infant and maternal health indicators	Service payments for each service provided; payments weighted by score on quality indicator tool; payments upweighted for delivery of services in remote areas	[s]

In low- and middle-income countries, there is similar concern that the use of financial incentives may lead to demoralization (due to perceptions of 'bureaucratization'), reductions in intrinsic motivation, and less trust between patients and providers. Over time, the quality of individuals entering the public health workforce could also decline if the use of financial incentives selects against intrinsically motivated health care workers.

Even if extrinsic incentives appear to work in the short run, the erosion of intrinsic motivation can still be a longer-run concern. Psychology experiments suggest that individuals offered monetary incentives to perform an otherwise intrinisically rewarding task put substantially less effort into the task (compared with control groups) when the incentives were removed. This has been attributed to the effect of extrinsic rewards on individuals' perception of themselves, on the value of the rewarded task, and on social perceptions of the task. Although not yet studied in low- and middle-income country health programs, one study of performance pay in the US (at Kaiser Permanente Hospitals) supports these findings.

Conclusion

This article summarizes important conceptual issues in the design of pay-for-performance incentive schemes. These include choice of contracted outcomes, the organizational level at which to offer incentives, the structure of incentive contracts, and what the unintended consequences of performance pay might be. In doing so, the existing peer-reviewed evidence related (in varying degrees) to each was also surveyed. The authors highlight that despite the growing body of research on performance incentives, very little of it has studied the underlying conceptual issues that are outlines (which is critical for the design of better performance incentives). It is also noted that evaluation has not kept pace with growth in the use of performance pay: **Table 1** lists the programs that have not been studied (or studied rigorously) to the best of our knowledge. Strategically selected empirical research on these unstudied programs may provide a low-cost way of strengthening the body of evidence on foundational issues inherent in the design of performance incentives. In the conclusion, we also raise additional issues about which little is known.

The first is that there is substantial heterogeneity in responses to performance pay both across and within programs. The authors therefore caution against direct comparison of pay-for-performance schemes across different organizational, social, and institutional environments. However, it is also noted that understanding the underlying sources of this heterogeneity may provide insight into the circumstances under which performance pay is more or less effective (or socially desirable) too. For example, lack of autonomy among providers or health care organizations may be a critical obstacle to the effective use of performance pay in the public sector (because it restricts the range of behavioral responses that are possible).

Performance incentives may also interact with the preexisting incentives and social norms in important ways. In one study, the impact of performance pay varied across incentivized agents by a factor of three or more (and the underlying source of heterogeneity was not strongly correlated with demographic and socioeconomic characteristics). Another found that provider responses to performance pay varied significantly by baseline provider quality indicators. More generally, adequate bureaucratic capacity to enforce contracts, collect data, and verify performance is presumably necessary for pay-for-performance schemes to succeed. Analysis of heterogeneous responses to performance incentives is an important area for future research.

Second, pay-for-performance schemes may have important equity implications. Given that the net return to provider effort will undoubtedly vary across activities and subpopulations, performance pay may lead providers to focus on individuals with varying socioeconomic or health characteristics. Pay-for-performance contracts offered to village governments in Indonesia attempted to address this concern by allocating equal performance pay budgets across geographic regions with varying socioeconomic characteristics (to prevent some regions from benefitting disproportionately from the performance scheme). Competition among villages for performance rewards therefore occurred within, but not across, regions.

Finally, there has been surprisingly little rigorous empirical evaluation of the full welfare consequences of performance pay. The necessary building blocks for a cost–benefit analysis include a full understanding of the behavioral responses to performance pay and their magnitudes (including unintended ones) and a method for valuing each in common (typically monetary) units. Such evaluations are critical for understanding the ultimate social desirability of pay-for-performance schemes.

Peer Effects in Health Behaviors

JM Fletcher, Yale School of Public Health, New Haven, CT, USA

Introduction

Health economists have long been interested in examining the determinants of, and potential policies for, reducing unhealthy behaviors in the population. Although a main focus in this area has historically been on issues of policy involving taxation, access restrictions, advertising, etc., a shift toward evaluating the basic social or nonmarket determinants of unhealthy behaviors has occurred in the literature. This is perhaps most obvious in the research regarding children and adolescent behaviors, wherein peer pressure is often thought to play a substantial role in determining choices such as smoking decisions. Indeed, there is now a large and growing literature in health economics that asks variants of the question, "Do peers influence an individual's health behavior decisions?" The areas of interest range from substance use to eating behaviors and weight outcomes whereas the peer group definitions range from best friends to classmates, residential neighbors, and beyond. Indeed, although there have been several recent reviews of the literature examining social effects on health behaviors (Fletcher, 2010a, 2011a), these papers are being updated because of the rapid expansion in research in this area. This new research is based on previous work; moreover, quasi-experimental methods as well as new identification strategies are utilized in the research.

One reason for the increasing interest in achieving these research milestones is the policy implications of the existence of peer effects in health behaviors. Specifically, peer effects often imply a 'social multiplier' for interventions – if the health of one individual is increased, the effect of the intervention may be multiplied through peers. This type of social effect is seen as an 'endogenous social effect' in the literature of economics. In contrast, peer effects that operate through the characteristics of peers are labeled 'exogenous social effects or contextual effects' (see Manski, 1993). The presence of such endogenous social effects could increase the potential benefits of intervention without increasing the costs. In contrast to these benefits, the presence of peer effects could also work to spread unhealthy behaviors (such as smoking). The awareness of a social multiplier operating in determining health can also help to inform whether targeted (e.g., based on influential individuals within networks) or broad-based policy is more effective. Also, peer effects imply that the composition of a person's neighborhood and/or school could affect his/her health behavior; because many policies can reorganize peer groups, such as school ability grouping (tracking), busing, school grade-span configuration, and residential zoning, there are a host of potentially important policy domains that plays a role in reducing poor health behavior in the presence of peer effects.

Although research regarding health decisions of socially connected individuals may continue to expand along with the multiple growth of interaction within social ties, the empirical hurdles to credibly estimating peer influence remain relatively unchanged and difficult to overcome. This article discusses some of the general empirical issues with their brief history, current controversies, and future directions.

Empirical Issues

Just as the policy and health importance of peer effects is likely to be substantial, so too is the empirical difficulty of credibly estimating causal effects. There are (at least) four standard primary empirical issues that researchers face. In many empirical settings, some are generic problems of measurement and omitted variables, whereas others are somewhat specific to peer effects research.

First, researchers must define a relevant peer group. This step seems simple, but data limitations typically force researchers to define peers on the basis of convenience rather than on theory. This has created peer group definitions that range from state-based groups to nominated best friends, and everything in between. For example, Harding (2003) uses census tracts, Evans *et al.* (1992) use metropolitan level data, Case and Katz (1991) use city block level data, Fletcher (2010a) uses school grades, Fletcher (2010b) uses school classrooms, Mayer and Puller (2008) use 'Facebook Friends,' and Sacerdote (2001) uses roommates to create relevant reference groups for the outcomes to be examined. Although there are several data sets that include nominated friends and peers, the vast majority do not. New data sets may reduce this issue over time, particularly those collecting online social network data, but this will raise the issue of whether online social contacts represent an important and relevant peer group for the determination of health decisions, and if they do, what types of health decisions are relevant when considering online peers.

A second empirical difficulty is the endogeneity of peer groups. Does a person smoke because his friend smokes or did he choose his friend for the sake of smoking? Because individuals typically have some degree of choice over their interaction with others (schoolmates, neighbors, friends, etc.), separating peer selection from peer influence is a particularly difficult empirical problem, and peer selection effects would typically inflate standard estimates of 'peer effects.' In fact, there seems to be a 'relevance-endogeneity' trade-off between the first and the second empirical difficulties (Fletcher, 2010a). As the researcher broadens the definition of the peer group (such as pertaining to the state level), the endogeneity of the peer group probably diminishes, but the relevance of the peer group may weaken. In contrast, best friends are probably a relevant definition of a peer group for many health behaviors but the endogeneity of best friend is magnified.

A third empirical difficulty in peer effect research lies in its potential nature for omitted variable bias through shared influences. For example, smoking bans may reduce tobacco use in all members of a school-based or community-based

peer group. These shared factors can lead to inflated estimates of peer effects if sufficient control variables are not included.

A fourth empirical difficulty in peer effects research is the reflection problem (Manski, 1993), where the researcher may be unable to distinguish between whether Bill influences Ted or Ted influences Bill. Although it is not essential to disentangle these two influences in order to establish whether there is any social effect for determining health behaviors, it can be useful to separate these effects in order to understand the importance of the initial causal effect as against the feedback effects to further understand the processes of health spillovers. Although most researchers explicitly acknowledge each of these difficulties, they often adopt different approaches in attempting to overcome them.

Indeed, there is a two-decade-old history examining peer effects in many health behaviors, which can provide some examples of the difficulty with this research topic while outlining ways that other researchers have attempted to circumvent the empirical issues as outlined above. Typically, researchers have used neighborhood or school-based definition of 'peers' when examining health behaviors such as tobacco, alcohol, and drug use.

A Brief History of Empirical Approaches

Case and Katz (1991) provide a seminal look at the effects of neighborhood peers on risky behaviors and other outcomes, although they are unable to tackle many of the aforementioned empirical issues. In particular, the authors acknowledge that they are unable to control for all environmental confounders and their self-selection into neighborhoods. The authors use what has become a typical empirical framework in the literature:

$$Y_{ig} = X_{ig}B + \overline{X}_{-ig}\delta + W_g\theta + \alpha\overline{Y}_{-ig} + \varepsilon_{ig} \quad [1]$$

where, Y_{ig} is the health behavior choice of individual i in peer group g (e.g., neighborhood), individual and family characteristics are contained in a vector X, and peer characteristics are measured as group-level averages of the X vector excluding the individual, labeled $\overline{X}_{-ig}$. Unobserved factors are contained in the vector, W_g. Finally, $\overline{Y}_{-ig}$ is the group-level average outcome excluding the individual (e.g., the proportion of individuals in the same neighborhood who report smoking). The main coefficient of interest is the endogenous effect α, which indicates the extent to which individuals are influenced by their peers' choices. If α is positive, interventions that change the behavior of individuals (or subsets of individuals) within a reference group would be predicted to spillover on nontreated individuals in the same reference group. In addition to acknowledging the potential for omitted group-level variables as well as self-selection (where ε_{ig} and $\overline{Y}_{-ig}$ are correlated), the authors are also unable to resolve the simultaneity bias (this issue was not fully discussed until Manski, 1993). The authors find evidence of substantial correlation between own and neighborhood peer substance use, crime, and other behaviors.

Norton *et al.* (1998) focus on schoolmate peer effects in alcohol and tobacco use of teenagers, and they use an instrumental variables strategy to address the endogeneity of peer groups (see also Evans *et al.* (1992) for an analysis of teenage pregnancy). Although the focus on endogeneity is important, there is little scope to control for the shared environment due to both data limitations and the instruments (such as neighborhood drug availability and safety) being potentially invalid – in fact, the results have suggested that noninstrumented results are preferable for extremely large peer effects. The general approach of using schoolmates or grademates has been used by many subsequent studies (e.g., Gaviria and Raphael, 2001), wherein too the quality of the instruments are uncertain; specifically, all contextual effects are often assumed to not exist in order to use these variables as instruments.

More recently, Fletcher (2010a) has suggested this approach to be inappropriate and instead proposes a combined instrumental variables/fixed effects design with conceptually appealing diagnostic tests (following Bifulco *et al.*, 2011; Lavy and Schlosser, 2007) in order to validate a preferred instrument set, although the validity of the instruments is still widely questioned. Specifically, Fletcher argues that the increasing proportion of the smoking grademates is due to smoking status of individuals in their households (which can be empirically demonstrated), which does not directly affect respondent smoking even when school-fixed effects are controlled (which is a maintained, untestable assumption). Although Fletcher shows the evidence that exposure of smoking grademates from households of smokers is conditionally random within school, there are ways by which this instrument could be invalidated because, for example, if mothers of grademates are smokers, it simply implies that there is access to tobacco for the respondent. See also Fletcher (2011b) for an examination of peer influences in alcohol consumption.

There have been several alternatives to the instrumental variable approach in the literature. Clark and Loheac (2007) use panel data and a lagged measure of peer behaviors that is combined with school-fixed effects in order to adjust for endogeneity, a large portion of the shared environment, and the reflection problem:

$$Y_{igt} = X_{ig}B + \overline{X}_{-ig}\delta + W_g\theta + \alpha\overline{Y}_{-igt-1} + \varepsilon_{igt} \quad [2]$$

The reflection problem is eliminated because current smoking decisions cannot affect past schoolmate smoking decisions. Although school-fixed effects reduce the issue of contextual effects, a maintained assumption is that, within schools, students choose friends randomly. A second weakness of this design is the need to assume a specific time structure where individual decision making and social influence processes are concerned (e.g., 1 day, 1 week, 1 month, 1 year, 2 years, etc.) (Manski, 1995). Specifically, Manski (1995, p. 136) states, "Of course, one cannot simply specify a dynamic model and claim that the problem of inference on social effects has been resolved. Dynamic analysis is meaningful only if one has reason to believe that the transmission of social effects follows the assumed temporal pattern."

An alternative to implementing a lag structure research design or an instrumental variables strategy is to focus on estimating contextual social effects instead of endogenous social effects. The most convincing work in this area uses random assignment of peers. For example, Kremer and Levy

(2008) use data from a university that randomly assigns freshmen to shared dormitory rooms:

$$Y_{ig} = X_{ig}B + \overline{X}_{-ig}\delta + W_g\theta + \varepsilon_{igt} \quad [3]$$

where, in this case, $\overline{X}_{-ig}$ could be thought of as a lagged endogenous social effect examined in some studies or roommate's precollege alcohol consumption. What allows the estimate to produce a contextual effect rather than an endogenous one is that the individual is not exposed to the actual drinking behavior, but rather is being exposed to having a roommate who has the characteristic of being a past drinker. Additionally, the random assignment of roommates eliminates the concerns regarding the endogeneity of the peer group. Kremer and Levy show that a fresh student who is randomly assigned a roommate with alcoholic past during high school has lower college performance than the student who is assigned a nondrinking roommate. The focus on the roommate's predetermined high school drinking behavior as the peer effect of interest also eliminates issues of simultaneity bias.

Because not all data sets are able to leverage the random assignment of 'friends,' several studies attempt to leverage quasi-random variation in observational data. For example, Bifulco *et al.* (2011) use a cross-cohort, within-school design to link the outcomes of students to their (quasi-randomly assigned) classmates' characteristics:

$$Y_{ig} = X_{ig}B + \overline{X}_{-ig}\delta + W_g\theta + \varepsilon_{igt} \quad [4]$$

That is, the authors examine the 'peer effects' of having a higher share of grademates with educated mothers or a higher share of grademates who are racial/ethnic minorities. This focus on contextual effects sidelines the need for a solution to the reflection problem because student smoking cannot affect grademate race, but some of the important policy issues that are tied to a social multiplier through endogenous peer effects cannot be evaluated directly.

Newer Approaches and Extension of Outcomes

Although the more traditional literature examining peer effects and health behaviors has focused primarily on substance use outcomes and has used a range of empirical approaches, the more recent literature in this area has broadened research designs and has dramatically expanded the range of health outcomes under study – especially, weight and mental health outcomes.

Apart from the literature in health economics, the set of studies that has received the most media attention is from Nicholas Christakis, James Fowler, and a set of coauthors. Their first study has brought a new outcome of interest to the literature by examining whether obesity is 'socially contagious.' Specifically, the authors have found that the chances of an individual becoming obese increased by more than 50% when his/her friend has become obese. The authors have used the Framingham Heart Study data, which contain up to 32 years of longitudinal measures of BMI for individuals in one area of Massachusetts. To these data, the authors have matched information from the original respondents' records, on which respondents have individually been asked to name a person who can be contacted in case the survey team does not reach them directly at follow up; this contact person is treated by Christakis and Fowler (2007) as a 'friend.' Thus, the first issue with this research is whether the contact person is truly a peer. The authors estimate regressions using the following parsimonious empirical model:

$$\text{health}_{it} = \delta\,\text{health}_{jt} + \beta_1\,\text{health}_{it-1} + \beta_2\,\text{health}_{jt-1} + \beta_3 X_{it} + \varepsilon_{it} \quad [5]$$

where, the health (obesity) of person i is linked to person j and δ is the coefficient of interest – the endogenous social effect or 'social multiplier.' A positive estimate on δ suggests that an intervention which reduces the chances of an individual becoming obese will also reduce the chances of obesity in his/her peer.

To overcome endogeneity, Christakis and Fowler (2007) have assumed that lagged health outcomes for the friend (health_{jt-1}) is a sufficient control, that is, after controlling for lagged obese status of a friend, they have assumed that there is no additional issue of friendship selection. Unfortunately, to the extent that this control variable does not completely eliminate selection effects, the estimated coefficient of interest (δ) will probably be upwardly biased. The authors have controlled for own-lagged health in order to control for aspects of the individual's genetic disposition or other time-invariant characteristics. The second issue is confounding due to shared influences. Without explicitly controlling for shared environmental factors, the authors have appealed to a comparison between mutually nominated friends and nonmutual friends (with unreciprocated nomination), arguing that directionality of nominations does not matter if environmental confounding is the primary explanation. Finally, the authors neither discussed nor attempted to overcome the empirical complications from the reflection problem. Unfortunately, each of those empirical issues listed above would probably lead to upwardly biased estimates of peer effects. So, what proportion of the 50% estimated peer effect is due to bias and what proportion is an actual peer effect? To address these empirical concerns, Cohen-Cole and Fletcher (2008a) have provided an examination focusing on one of the empirical issues in peer effects models – shared environmental factors that may bias upward the estimates. The authors have used the National Longitudinal Study of Adolescent Health (Add Health), which includes the nationwide longitudinal data on adolescents in the US over approximately seven years. Although the Framingham study has a much longer time horizon and focuses on adults, the Add Health data contain information on actual 'best friends' who are named by the respondent; this is arguably a more appropriate peer than the contact person in the Framingham data. Cohen-Cole and Fletcher have first estimated eqn [5] on the basis of the Add Health data in order to replicate the baseline findings of Christakis and Fowler (2007) that are based on the Framingham data. Interestingly, both papers, using different data of different age groups, arrive at point estimates for δ from eqn [1] for the 'peer effect' of BMI of 0.05, meaning that a one unit increase in a friend's BMI over time is correlated with a 0.05 unit increase in one's own BMI. However, when

Cohen-Cole and Fletcher controlled for shared environmental factors such as school-fixed effects, the coefficient fell by approximately 40%, no longer being statistically significant. Thus, current evidence suggests that the empirical problems described above are problematic enough to reduce confidence in any peer effects in obesity resulting from this specific model.

In an attempt to further explore the potential upward bias in the Christakis/Fowler empirical model, Cohen-Cole and Fletcher (2008b) took an alternative approach. The authors asked the question: 'Is the empirical model [5] so weak that it would produce estimates of peer effects in behaviors where the true peer effect should be zero?', that is, the authors conducted a falsification test of the empirical model by showing that estimating eqn [5] with the Add Health data would also produce results suggesting 'social contagion' in outcomes that are unlikely to be contagious: acne, headaches, and height. Indeed, the estimates for peer effects in these health behaviors are in some case larger than the Christakis/Fowler estimates of peer effects in obesity. The results of the falsification exercise strongly suggest that the model is insufficiently specific to distinguish between true social effects and the alternative hypotheses as discussed above (e.g., endogeneity of friendships and exposure to shared environmental factors). As in previous work, Cohen-Cole and Fletcher (2008b) have shown that the magnitudes of the fictional social network effects are reduced and when shared environmental influences are controlled, these effects largely disappear.

Based on part on these findings, obesity and weight-related behaviors have been studied in several additional papers. Trogdon *et al.* (2008) use several empirical strategies to examine peer effects. They examine both grade-level peers, similar to the cross-cohort designs already discussed, as well as nominated friends. To control for shared environmental factors, the authors control for school-fixed effects. To address friendship selection and simultaneity bias, the authors use an instrumental variables strategy, where friend's birthweight, weight of parents of friend, and other measures are used as instruments. The limitation with this approach is that it is unclear whether these variables are good instruments for friendship selection. It appears that the instruments have been mainly employed to reduce the importance of the simultaneity issue, though the instruments still need to be excludable from the equation determining one's own weight. In addition to controlling for shared environmental influences, the authors use school-fixed effects to partially control for friendship selection. The implicit assumption with school-fixed effects is that within schools, friendships form randomly.

Like Trogdon *et al.* (2008), Renna *et al.* (2008) also use a single cross-section of the Add Health data to examine the correlation between own and friend's weight outcomes; however, these two papers use different subsamples and Renna *et al.* focus only on nominated friends. Renna *et al.* use school-level fixed effects to control for shared environmental factors and also attempt to reduce the simultaneity issue with an instrumental variables approach. The authors also use the obesity status of parents of friends as instruments. To control for selection of friends, the authors include additional control variables and acknowledge that the estimates are likely to be biased upward. The authors find evidence for peer effects for both genders in the baseline models, whereas only females in the IV models, although the point estimates are very similar. Overall, these papers are suggestive of peer effects but are unable to control for the empirical issues necessary to make the evidence more conclusive.

However, three recent papers have attempted to overcome the methodological issues with the above papers by pursuing alternative research designs. Yakusheva *et al.* (2011) use the roommate design described above with females from a private Midwestern university. The authors show negative correlations between having a heavy roommate and own weight outcomes. Carrell *et al.* (2011) stretch the literature further into the outcome of physical fitness by using random assignment to squadrons in the US Air Force Academy in order to show that squadronmates' level of physical fitness is highly correlated with one's own fitness. Finally, using a new instrumental variable strategy (characteristics of friend of peer), a so-called 'friend of friend' instrument pioneered by Bramoullé *et al.* (2009) and Fortin and Yazbeck (2011) show some evidence of peer effects in fast-food consumption. Although these papers have considerably strengthened the research designs from past work and have extended the set of health behaviors, additional work is needed to further understand the potential for whether obesity is indeed 'socially contagious.' This work requires different (and hopefully more representative) samples and further replication.

In addition to weight-related outcomes, the literature examining peer influences in health outcomes has also begun to examine the realm of mental health. Although some older papers have attempted to examine social influences on suicidal behaviors, this literature is yet to incorporate newer and more rigorous research designs. Hence, the existence of peer effects is still uncertain. However, other measures of mental health have been explored recently. Eisenberg *et al.* (2011) have applied the roommate design to a variety of anxiety and depressive symptoms using a sample of freshman college students from two universities. The authors find no evidence of peer influence in measures of happiness. However, symptoms of anxiety appear to be correlated between roommates and there is some suggestive evidence of depressive symptoms being correlated between male roommates. See also Fletcher (2010c) for evidence that classmate mental health may reduce school performance.

Considering that research has expanded the domain of health behavior under study, new directions have been adopted in empirical methods on the basis of nonexperimental data. For example, a new direction in the study of social networks with implications for the study of health is the analysis of interdependent duration decisions. Because many health outcomes and behaviors have important time components such as smoking and drinking histories, utilizing new methods in this area could prove useful. The current state of the art includes the theoretical framework as outlined in Brock and Durlauf (2008) as well as the empirical applications of de Paula (2009) and de Paula and Honore (2010). Likewise, Fletcher and Ross (2012) have attempted to combine a control function approach with a cross-cohort design (as outlined above) to estimate the effects of best friend's smoking and drinking behaviors on individual health choices. Work by Yves Zenou and colleagues have accumulated a set of papers that build a game theoretic model of network formation with interesting empirical implications (e.g., Calvó-Armengol *et al.*, 2009).

In addition to these new research methods, there are also new data opportunities as well as research design opportunities emerging. Mayer and Puller (2008) leverage data from the social networking website Facebook.com in order to examine correlations between friends' health behaviors, but they do not focus on causal inference. Mapping friendship networks through the use of cell phone usage information may also transform our ability to construct and track social networks in the future (Eagle *et al.*, 2009). However, these new data sources will not alleviate the need to confront the difficulties of estimating empirical models of social influence.

Conclusions

This article briefly outlines some of the history, empirical challenges, current research and controversies, and directions for the future of this research area. Indeed, it is important to point out that this article being necessarily unexhaustive, does not cover important research areas that share many of the same issues described herein. Perhaps most obvious are the exclusion of the neighborhood effects literature that focuses on health outcomes and the emerging literature that examines potential peer effects in other health related areas such as doctors' prescribing patterns and medical technology adoption. These important areas are beyond the scope of this article, which focuses only on the peer effects in health behaviors.

Research in the economics literature examining the effects of peers on health behaviors is now more than two decades old. There has been impressive progress as well as a stable set of challenges still not fully resolved. There has been a broadening of the set of behaviors and outcomes under consideration including weight and mental health besides the use of quasi-experimental research designs for additional outcomes of interest. In contrast, the growing volume of data on peer influence, especially online, has not been met by new research designs and methodologies that can produce entirely convincing results. This will be an important challenge to the researchers' work of expanding the literature on peer effects in health behaviors.

Acknowledgments

This article extends similar summaries of current work on peer effects/social network effects in health behaviors found in Fletcher (2010a, 2011a). The author thanks the Robert Wood Johnson Foundation Health & Society Scholars program for its financial support.

Peer Effects, Social Networks, and Healthcare Demand

JN Rosenquist, Harvard Medical School, Boston, MA, USA
SF Lehrer, Queen's University, Kingston, ON, Canada

Glossary

Actor (or node) An individual actor or agent in the network.
Homophily The tendency of individuals with similar characteristics to associate with one another. Also referred to as selection.
Peer Effects Actions, preferences, and norms of an individual's peer group that may influence an individual's behavior.
Social network A set of actors and relationships (or ties) linking the actors together. Social networks can be used to study the structure of a social organization and how this structure influences the behavior of individual actors.
Tie A tie connects 2 nodes. In social network analysis, a tie is determined through a self-reported and/or observed social tie.

Overview

The notion that social influences are important in both the development of numerous health outcomes and decisions related to healthcare use has great intuitive appeal. Health economists have modeled many potential mechanisms through which social influences affect outcomes ranging from practice patterns among providers to the choice to engage in risky behaviors. Effectively understanding the nature and scope of these effects is critical; if such influences are ignored estimates of the impact of policy interventions will in many cases be biased because they neglect the indirect pathway that occurs due to spillovers or what is known as the social multiplier effects. There have been many recent theoretical and empirical developments in this area on this topic. For example, studies on animal populations have shown that there is an association between social status and increased odds of specific diseases due to biochemical responses to low status affecting a creature's immune system. More abstractly, economic theorists are increasingly directly modeling concerns for social status in the specification of utility function because this is as important an aspect of human decision-making potentially including the choice of medicine as one's occupation.

Research on social interactions first appeared in the economics literature with Veblen's analysis of conspicuous consumption, where consumption levels are used to signal wealth. Formal analysis of the influence of social groups in economic models developed following Schelling (1971) who demonstrated how the existence of these interactions may result in the formation of ghettos and segregation of individuals across neighborhoods, even in situations where most individuals prefer living in an integrated neighborhood. Formal models generally include social interactions by allowing for strategic complementarities, which occur when the marginal utility to one person of undertaking an action is increasing with the average amount of action taken by one's peers. Although the initial developments in this literature were primarily made by theorists, there has been both a growing body of empirical work and policies proposed to take advantage of social interactions in health-related behaviors. This research is summarized in the following text.

Definitions of Peer Effects, Social Learning, and Social Network Effects

As with many topics which claim interdisciplinary roots, the concept of social network effects as it relates to behavior can fall prey to semantic differences that may confuse many readers. Here, first the concepts of peer effects and social learning are defined which, in addition to being common topics in the economic literature, are the key foundation of social network models and effects. This is then followed by the definitions of the concept of social network models, which represent social ties through which peer effects and social learning occur across defined communities.

Peer Effects and Social Learning

Peer effects are commonly studied in economics and studies take a broad view of what constitutes peer influence. For example, one study examined decisions by school children in Kenya of whether to take drugs that kill intestinal worms already in the body. These drugs directly helped the individual who takes them, and generate positive externalities by breaking the transmission cycle, a pathway commonly referred to as the social multiplier. Researchers often try to make a distinction of whether the peer's behavior versus their peer's characteristics influenced one's decision because only the former pathway would lead to a social multiplier.

For policy purposes, a key issue is to understand the channels through which peer effects operate. In this example, do children take these drugs because of information sharing from communicating with those who took the drug earlier, social learning by observing how others' behavior and subsequent outcomes, reduced stigma or identity/image concerns may be lessened because others have taken the drug, or is it simply imitation? Although understanding the pathway the

social interactions operate is important as discussed in the next subsection, even identifying these effects is challenging.

Part of the challenge researchers must face is how to properly define an individual's peer group. In many papers researchers make ad hoc assumptions on the structure of peer groups. For example, only people who work in the same department within an organization or all individuals in a certain geographic area are considered. Researchers thus rely on the use of aggregates – such as the average characteristics or lagged behaviors of all classmates – to proxy for the social network. Such a setup is constraining: It means that individuals within a group must interact with each other, rather than with individuals outside the group. This can be a strong assumption if, for example, groups are formed by the researcher at the grade level, which suggests that students only interact with kids in the same grade but not with kids in different grades at the same school.

Social Network Models

If the concept of a peer group is not defined correctly, measurement error can be introduced by potentially omitting relevant peers, and when those neglected channels are not considered the underestimation of actual information flows can occur. As a result, more recent research is trying to directly model the formation of social networks and utilizing methods from graph theory to consider the microstructure of interaction among individuals within a community. As **Figure 1** outlines, while direct peer effects (panel (a)) and social norms shared throughout a community (panel (b)), each capture potential avenues of social learning and influence, there is a third way of conceptualizing this pathway, where the structure of individual social ties throughout a community can capture these community effects (panel (c)). Generally, social networks are defined as a set of actors and relationships (or ties) linking the actors. Networks can be egocentric in which case the network is built out from a subset of a population, or sociocentric, where a full population of individuals is included. Most social networks measured are egocentric due to the challenges related to data collection, though sociocentric networks are more empirically appealing to study as there are no assumptions required about missing data from unobserved individuals and social ties biasing results. Social network analysis can be used to study the structure of a social organization and how this structure influences the behavior of individual actors. As such, this kind of analysis extends the study of peer effects and social learning beyond a given actor's social ties.

Social Network Effects and the Challenge of Identification

Both intuition and previous work suggest that social influences and, by extension, social networks, are important when driving economic behavior. Assuming that these factors are significant, there remains the difficult question of assessing the magnitude of such an effect. There are three main identification challenges facing an empiricist. The first was termed the 'reflection problem' by Manski (1993) and is an issue that mimics a simultaneity problem. For example, in studying cigarette smoking a reflection problem arises when student and peer smoking are determined simultaneously, which inherently convolutes the measure of peers' influence.

The next challenge for the analyst is more complicated because individuals generally choose their friends in part based on the characteristics they favor. This second challenge is a form of selection bias and leads to a correlated unobservables problem. Social networks are not created in a vacuum, as the result of a random stochastic shock. Rather, they are formed based on the preferences of individual actors (nodes) in the vast majority of cases. Therefore, it is entirely conceivable that sorting into networks (also known as homophily) may occur based on traits and behaviors that are linked with and/or signals of future preferences. Thus, one usually

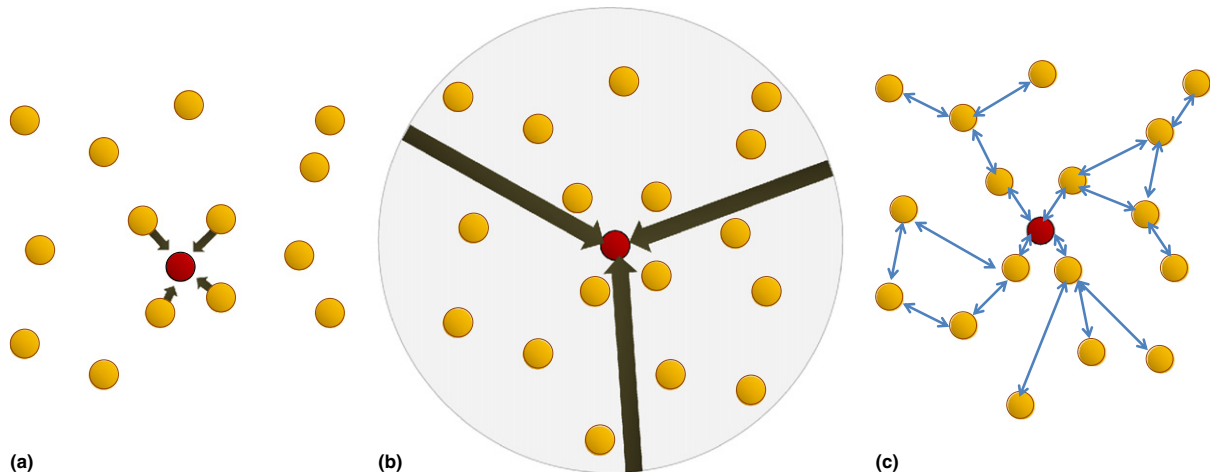

Figure 1 (a) Individual-level peer effects: Influence on an actor in a given community is exerted through direct social contacts. (b) Social norms: Influence on an actor is exerted only through the entire community, regardless of the relative strength of (or existence of a clear) social tie. (c) Social network effects: In social network models, the entire community can exert influence (even in the absence of a direct social tie between the actor and other community members), however, the relative influence of other members is measurable and related to the distance from the actor in Euclidean (or network) space.

does not know with certainty if an individual may be influenced to choose a specific diet or health plan because of the influence of their friend, or they chose their friend because of the friend's revealed preferences in the first place. In the latter case, it may be possible to observe what appear to be examples of social influence or contagion within a network, but are actually, primarily, artifacts of prior selection.

The third and final challenge involves the possible presence of unobserved group-level characteristics that affect both individuals and their peers. That is, some third confounding factor is responsible for the observed association between one's behavior and that of their peers. Taken together, if an individual is a member of some group, can the analyst distinguish a role for the characteristics and behaviors of others in the group in influencing that individual's choices?

More formally, much of the empirical literature on social economics has involved variations of a general linear model, dubbed by Manski the linear-in-means model.

$$Y_{igt} = \beta_0 + \beta_1 X_{igt} + \beta_2 Y_{-igt} + \beta_3 X_{-igt} + \beta_4 G_g + \varepsilon_{igt}$$

where Y_i is the health outcome under study for individual i who is a member of peer group g at time t, X_{igt} is a vector of individual exogenous controls, X_{-igt} is a vector of contextual controls common to all members of group g since the $-i$ notation indicates everyone but person i, Y_{-igt} is the mean peer choice in group g, G_g reflects common environmental influences affecting all members of group g, and ε_{igt} is a random error term with mean 0. β_1 expresses individual effects, β_3 contextual effects, β_4 correlated effects, and β_2 endogenous social effects. The linear-in-means model thereby provides a formal expression to three hypotheses often advanced to explain the common observation that individuals belonging to the same group tend to behave similarly.

The 'reflection problem' occurs if the peer variable measures peer group members at time t, which is obtained at the same time one's own health outcome is measured. It is called the reflection problem because it is similar to the problem of interpreting the almost simultaneous movements of a person and her reflection in a mirror. To overcome this challenge and identify the endogenous social effect, researchers generally ensure that all the regressors are known (predetermined) at the time of regression, which in theory avoids simultaneity problems. That is, the peer variable is constructed using earlier behaviors that were hopefully measured immediately before any interactions among the group g. Manski notes that if the transmission of peer effects really follows this temporal pattern, the identification problem is alleviated.

Empirical Approaches in the Estimation of Peer Effects in a Social Network

Given the challenges outlined earlier, how can a researcher infer true parameter estimates for social influence along networks? Although this is a thorny (some might argue intractable) challenge, there are in fact a number of experimental and analytical approaches that can be used to control for selection bias among other identification issues that economists are quite familiar with.

Overcoming Selection Bias

Researchers have attempted to overcome the selection bias in one of three main ways. Studies have used insights from randomized experiments to induce credible exogenous variation into aspects of social networks in an effort to identify their impacts. This research design can be seen in a number of papers, including the work of Duflo and Saez (2003) who explored not only the existence but also the mechanism underlying peer effects in the context of demand for benefits at the workplace. Specifically, they examined the role of social learning on the choice of employer-sponsored retirement plans, using individual data on employees of a large university a random sample of employees and focused on the question of whether people are influenced by the decisions of other employees in the same department. In a subset of departments some individuals were encouraged by an offer of a financial incentive to attend a benefits information fair organized by the employer. Not all departments were treated and the authors compared both benefits fair attendance and retirement plan enrollment decisions across departments and also looked within departments comparing outcomes of those who receive the treatment with their untreated coworkers. Receiving the letter led to a large increase in the likelihood of attendance and untreated individuals within departments where some individuals treated also had higher odds of attending the fair and plan enrollment 5 and 11 months after the fair. This presents convincing evidence that peer effects likely influence demand for benefit plan decisions.

Another method to identify the impacts of social factors on health outcomes is the use of instrumental variables to mitigate the correlation between unobservables and social network variables. This approach has been used in a large number of studies that have examined the role of peers on health behaviors such as cigarette smoking and obesity. However, these studies are frequently critiqued because the statistical properties and economic validity of these instruments are of debate. For example, some used their friends' birth weight as an instrument for whether their friend is currently obese in influencing whether one is overweight themselves. However, peer birth weight may influence other peer outcomes besides simply weight that may also directly affect one's own health outcomes.

Finally, several studies have attempted to use very rich data to control for unobserved confounders to identify the effects of social networks on health outcomes and show that those with greater levels of contacts with friends and neighbors have a reduced likelihood of enrolling in a Medicare-managed care plan relative to purchasing a medigap policy or having coverage through Medicare alone. Although the authors do account for a large set of unobserved confounders it remains possible that more sociable households are more risk tolerant or more optimistic than less sociable households, thus making these households more open to purchasing newer or 'riskier' insurance products, such as Medicare Health Maintenance Organizations (HMOs). This strategy is also used in international datasets. It has been found that social network effects are large and that both temporal and spatial proximity among household heads is the mechanism underlying this effect. However, one always can be concerned that those who lead

opinions in rural villages may also have certain characteristics favoring health plan adoption decisions.

Despite these limitations, it is worth noting that in certain contexts in the educational setting an explicit rule determines assignment to different peer groups. A sharp regression discontinuity design can be utilized when there is an explicit cutoff and individuals cannot change their behavior ex ante in an effort to sort to a specific side of the cutoff. This situation mimics a randomized experiment and one can simply compare individuals who just lie on either side of the cutoff. In an education setting, several countries share competitive admissions policies to secondary school leading to very different peer groups. For example, in China and Romania the secondary school system differs markedly from that of the USA which enabled researchers take advantage of the features and institutional structure of these systems. Specifically, students compete for positions in the higher ranked secondary schools by writing a high school entrance examination at the completion of junior middle school. Administrators at each senior high school grant admission to students whose exam performance is above a cutoff score. Thus, students who just get into a higher ranked school (perhaps by scoring only a point above the cutoff) have access to much stronger peers as measured by performance on the entrance examination, than students who scored just below the cutoff and now must attend a lower ranked school. One can imagine situations in healthcare settings where individuals are assigned to different treatment centers or nursing homes on the basis of health statistics creating an opportunity to examine how peers in different centers/homes affects one's health.

In addition to the examples listed so far, a number of other methodological approaches have been advanced in the statistical community so as to mitigate the strength of assumptions in social network models. One model is to assign all subjects into two separate groups randomly, and within them assess whether there appears to be a contagion effect from nonneighbors by using time series results in the first bin to predict results in the second. Nonzero results suggest social influence has traveled along the network over time. Another, simpler approach, relates to setting parameter bounds. In this approach, bounded parameters greater than zero would show that the entirety of the observed effect could not be due to selection (homophily) alone, though the magnitude of the effect may be significantly decreased.

Selected Application of Social Network Models to Health and Healthcare

A number of data sources such as the Add Health Study that collects survey data on self-reported friendship networks, and a growing number of social network data from electronic sources such as Facebook, LinkedIn, and others present researchers with new opportunities to study the impact of social learning and peer effects within networks on health behaviors over time. An earlier version of this approach is provided in Christakis and Fowler (2007) who used 32 years of data on 12 000 people from the Framingham Heart Study. This study garnered substantial attention from the popular press with a conclusion that obesity appears to spread through social ties. Fortunately, these spirited academic debates have led to a multitude of methodological improvements that should shed new and more convincing light on the role of social networks in the spread of obesity.

In contrast to risky health behaviors, there have been relatively few studies that have performed true social network analyses in the context of demand for healthcare and health insurance. There have, however, been a number that have looked broadly at peer effects as they relate to purchasing decisions in health or in areas (such as insurance) closely related to health. The most convincing evidence on the role of social networks relates to health plan decisions addressing the question of whether the information one receives from their peers affects their choices; even when product quality is difficult to ascertain. This information may come from direct communication with peers who have already purchased a particular health insurance bundle. Alternatively, it may arise from the observation of peers' purchasing decisions. This phenomenon as noted earlier is often referred to as social learning.

Whereas social learning has been extensively studied in theory, the empirical evidence is limited because social learning is difficult to identify in practice. Empirical analyses on the effects of social networks have difficultly providing direct evidence of causal relationships from consumption decisions and/or the product satisfaction of other members of one's social networks on individual decisions related to consumption of health products due to various conceptual and data problems including selection bias. Selection bias arises because people tend to associate with others based in part on some group characteristics they favor that are unobserved by the researcher. Thus, observing that individuals in the same group make similar consumption decisions may simply reflect shared preferences and not informational spillovers.

Exploring social effects in universities is a popular research design. Sorensen (2006) subsequently examined that health insurance selections are correlated across employees within the same department to multiple campuses in the University of California system. Nearly all full-time and some part-time employees are eligible to enroll in one of the health plans offered through the benefits program. He uses statistical models to examine whether individual- or department-level factors influence the decision to choose specific health plans. His empirical evidence provides convincing evidence that social effects (i.e., decisions of coworkers) play a role on individuals' choices of employer-sponsored health plans that is as large as many individual factors including age, income, and family status. The strength of the effect depends on factors such as the department's size or the employee's demographic distance from his coworkers. His research results have large policy implications because if all of one's coworkers in a specific department have chosen the same plan, then the social influence may overpower any individual incentives to switch plans when the provider raises the premium.

Another study uses data from a field experiment that changed the size of work-related social networks for those who were randomly assigned the intervention. These changes in the size of social networks are not due to choices by the individuals themselves and are free from selection bias, thereby providing the authors a unique opportunity to

estimate the causal impact of social networks on self-assessed measures of health. The effect of social networks on different health measures depends crucially on whether one holds a job. Those assigned to have a larger social networks report greater satisfaction with their mental and physical health when they are employed and the authors show that this effect is not due to the income channel.

In summary, the estimates (only a subset of which are discussed in the preceding paragraphs) indicate that social networks are an important determinant of the health insurance choices, health behaviors, and health as well. There is a large literature demonstrating positive associations between network size and mental health outcomes whereas another literature interestingly, finds that peers play small roles on actors in the medical system such as doctors in terms of their treatment choice and decisions to specialize. Future study of physician networks and social influence within them will benefit from new datasets being created by research teams.

Not only has there been studies investigating whether social influences exist but one may also wonder whether policies that aim to influence group dynamics subsequently shape individual health outcomes. Indeed social influences have been incorporated in many recent areas of health policy including efforts to reduce obesity. For example, weight-loss support groups have been in place for many years and use social influences in a manner similar to Alcoholics Anonymous to shape health behavior. In 2007, the academic journal *Obesity* devoted an entire issue to the evaluation of workplace interventions to reduce obesity. Last, several states including Arkansas have built policies around the mechanism of stigmatization as the channel of endogenous social effects, by providing students with weight report cards that provide information on their rank in the body mass index (BMI) distribution. Whereas each of these policies is built around specific social mechanisms that are hypothesized to alter obesity, their design does not appear to be based on a large body of evidence. Further, most seem to not have undergone a rigorous ex post policy evaluation of their effectiveness. Designing and evaluating policies that aim to take advantage of social multipliers are clearly areas for further research.

Final Comment

There is substantial evidence that individuals' beliefs, actions, and choices in the health sector are impacted by beliefs, actions, and choices of their peers. Insights from behavioral economics on framing and social influences are increasingly being used by the healthcare industry to influence individual choice in regards to specific products. Although substantial progress has been made on the econometrics of identification of social interactions, more careful work is needed to understand the mechanisms driving these social effects as well as whether there are moderators. The authors believe that this can be accomplished using field experiments and credible research designs. Further, in the education literature there is growing evidence that peer impacts can be distributed unevenly and more work in health economics is needed to understand the consequence of heterogeneity among peers. In the sciences, research conducted with animal populations demonstrates that social influences operating within the environment an individual engages in also directly affect gene expression, suggesting biological mechanisms underlying the social interaction effects. Findings from further empirical studies on the form and mechanisms of peer interactions are needed to guide further theoretical work. Naturally, the converse holds and despite a burgeoning literature over the past 15 years, an incomplete understanding of such effects remains. When studies are performed and results are interpreted with an appropriate amount of care and caution, one believes that there can be a great deal inferred from peer and social network models of influence to researchers in the health economics community and both health policymakers and the healthcare industry.

Performance of Private Health Insurers in the Commercial Market

J Abraham and P Karaca-Mandic, University of Minnesota, Minneapolis, MN, USA

Introduction

Private health insurers play a large role in providing financial protection against the high cost of medical care in the United States. In 2010, approximately 64% of the overall US population had some form of private health insurance. The Centers for Medicare and Medicaid Services' National Health Expenditure Accounts (NHEA) project that aggregate private health insurance premiums across all market segments will reach $888.6 billion in 2012. This article examines the performance of private insurers operating in the fully insured, US employer group and individual markets. Although many private insurers cover Medicare and Medicaid beneficiaries, and serve as third-party administrators for self-insured employers, this article does not consider these aspects of production.

Later in this article, the authors present a conceptual framework to introduce and link the health insurance concepts of premiums, profits, administrative costs, loading fees, and medical loss ratios (MLRs). Following this, it summarizes the empirical evidence on insurers' performance with respect to premiums as well as loading fees and MLRs.

The types of private insurance demanded by individuals vary by their age and employment status as well as other factors. For individuals under the age of 65 years, the dominant form of coverage is employer-sponsored insurance (ESI). According to the Kaiser Family Foundation/HRET Survey, ESI premiums averaged $5 429 for single policies and $15 073 for family policies in 2011. ESI premiums have grown rapidly over the past decade and have contributed to the erosion of ESI, particularly among small employers. From the Medical Expenditure Panel Survey – Insurance Component, only 35.7% of private sector employers with fewer than 50 employees offered coverage in 2011, down from 47.2% in 2000.

Individuals who lack ESI may purchase coverage directly from an insurer. Nationally, the individual market is small relative to ESI, with an estimated 18.9 million (7%) nonelderly individuals reporting coverage purchased directly from an insurer based on the Annual Social and Economic Supplement to the 2010 Current Population Survey. Unlike ESI, persons demanding individual coverage often seek to bridge short-term coverage gaps, including the time period between two jobs, between school and a job, or between retirement and Medicare eligibility.

For the individual market, the average premium for single coverage was $2985, whereas it was $6328 for family coverage, based on a 2009 survey by America's Health Insurance Plans, the national association representing the health insurance industry. Although reported premiums are often lower for individual policies relative to ESI, they typically have lower actuarial values, defined as the percentage of total average costs for benefits that the plan will cover. Actuarial values are directly affected through a plan's cost-sharing provisions, including deductibles, coinsurance rates, and out-of-pocket maximum spending limits.

During the legislative debate over the Patient Protection and Affordable Care Act (ACA) of 2010, policymakers raised several concerns about the functioning of private health insurance markets and insurer behavior, particularly within the individual and small employer group markets. Central to this discussion was whether individuals and small businesses were getting poor value for their premiums because of insurers' high administrative costs and excessive profits. With passage of the ACA, dramatic changes to US health insurance markets are expected. This article provides important baseline information and evidence regarding the performance of US health insurers in the ESI and individual markets.

Conceptual Framework for the Production of Health Insurance

The premium charged by an insurer for a given level of coverage includes three basic components: expected claims, administrative expenses, and profit. Expected claims represent the amount of money that an insurer expects to pay hospitals, physicians, and other providers during the coverage period for the services incurred by a policyholder. Expected claims depend on both the negotiated prices between an insurer and providers as well as the types and quantities of medical services demanded. Expected claims are also related to the policy's benefit design, including the size of the deductible if there is one, the level of coinsurance and/or copayments, and out-of-pocket maximum limits as well as the quantity and types of medical services covered by the policy.

Insurers incur expenses for several different types of administrative functions. These functions may include general administration, information technology, product development and provider network management (e.g., contracting), sales (e.g., marketing, agent or broker commissions, underwriting, enrollment, and member services), medical management (e.g., utilization review or case management for high-cost enrollees), claims adjudication, and regulatory compliance. Insurers also incur expenses for premium taxes and fees. Finally, insurers are expected to incorporate some level of (normal) profit into the premium.

An insurer's production can be summarized more formally. In a differentiated goods industry, like the market for health insurance, with similar but not identical products, one can assume, for simplicity, each firm f of F firms sells one product. The profits π_f of firm f can be written as

$$\pi_f = (p_f - mc_f)Ms_f(p) - C_f \qquad [1]$$

where p_f is the price of firm f product, mc_f is the marginal cost of production, M is the exogenously determined size of the market, $s_f(p)$ is the share of firm f product, where p is the vector of all firms' prices, and C_f is the fixed cost of production. Average profits per policy can be expressed by dividing eqn [1]

 doi:10.1016/B978-0-12-375678-7.00911-1

with the term $Ms_f(p)$:

$$\text{avgprofit}_f = (p_f - mc_f) - \left(C_f / Ms_f(p)\right) \quad [2]$$

For health insurance products, p_f is the premium of the policy (prem_f) and mc_f includes expected claims paid out by the insurer (claims_f) and administrative expenses (admin_f) per policy such that

$$\text{avgprofit}_f = \text{prem}_f - \text{claims}_f - \text{admin}_f - (C_f / Ms_f(p)) \quad [3]$$

Assuming for simplicity that the fixed costs are sunk, such that $C_f = 0$, eqn [3] can be rewritten to obtain the standard health economics textbook expression for health insurance premiums:

$$\text{prem}_f = \text{claims}_f + \text{admin}_f + \text{avgprofit}_f \quad [4]$$

The loading fee, L_f, represents the portion of the total premium above and beyond the actuarially fair value or expected claims to be received from the policy during the coverage period. Typically, the loading fee is modeled as a multiplier to expected claims:

$$\text{prem}_f = (1 + L_f)\text{claims}_f \quad [5]$$

For example, if the premium is \$125 and expected claims total \$100, the loading fee is 0.25 or 25%.

A closely related concept to the loading fee is the MLR. Before the passage of federal health reform, the MLR has been defined as the ratio of expected claims paid by the insurer to the premium. Expressing the loading fee as a multiplier of expected claims, the MLR can be written as follows:

$$\text{MLR}_f = 1/(1 + L_f) \quad [6]$$

A closely related concept to the loading fee is the MLR.

Several factors influence the performance of health insurers. Insurers typically sell multiple products and each product is defined by a set of attributes. Thus, insurance products are often differentiated within and across firms. Common ways in which insurance products differ include their actuarial value and benefit design, the breadth and reputation of their provider network, and the level of customer service provided. These factors contribute to insurers' expected claims and loading fees. Although detailed information on product attributes may be easily observed for a single insurer, no comprehensive data source exists to facilitate analyses for the current population of US health insurers and their products.

Competition is another important factor affecting insurers' performance. Economic theory predicts that stronger insurance market competition among homogenous products should lead to lower premiums, *ceteris paribus*. Also, to the extent that purchasers of insurance have greater market power, this may lead to lower premiums. The structure of upstream markets is important too. Because insurers negotiate with local hospitals and physician practices over reimbursement rates, more competitive provider markets may improve insurers' leverage in negotiations and lead to lower input prices. Furthermore, for the individual and small employer market segments, brokers and agents play an important role in facilitating coverage purchases. Insurers' commission schedules with brokers and agents may be affected by the extent of competition among them as well.

Over time, insurers' premiums have followed a cyclic pattern. Called the underwriting cycle, this pattern reflects fluctuations in premiums and insurer profitability generated by decisions of firms to trade off profits for expanded market share. As noted by Grossman and Ginsburg (2004), several factors have contributed to the historical underwriting cycle, including the timing of forecasted cost trends relative to premium setting, the degree of insurance market competition, and the presence of not-for-profit insurers in the market.

Finally, the regulatory environment can affect insurers' performance. Following a failed attempt to pass federal healthcare reform in 1993–94, many states passed legislation to improve the functioning of the small employer and individual markets for insurance. Prevalent forms of regulation include guaranteed issue, guaranteed renewability, and premium rating limitations (e.g., rate bands), as well as mandated benefits (e.g., mammography screening). Differences in state regulations of insurers have led to variation in many insurance market outcomes, including premiums, administrative expenses, and coverage.

Empirical Evidence on Insurer Performance

Within the empirical literature on health insurance production, many studies have investigated factors that help to explain variation in premiums, although not necessarily focusing on specific components. A smaller body of research has focused on estimating the size of insurers' loading fees and/or MLRs. There is heightened awareness around the latter following implementation of federal minimum MLR regulation in 2011 as part of the ACA. Below, this article summarizes the empirical evidence on the factors that influence premiums as well as insurers' loading fees and/or MLRs for the employer group and individual markets.

What Factors Influence Premiums?

Market structure

Insurance market structure can be defined in a number of ways. Three of the most common measures include the total number of insurers operating in the relevant geographic and product market; a four-firm concentration ratio that provides the percentage of market share captured by the largest four firms in the market; and the Herfindahl–Hirschman Index (HHI), which is the sum of the squared market shares of the firms operating within the market, measured in percentage terms. The HHI has an upper bound of 10 000, corresponding to a monopoly.

Two studies have examined the influence of insurance market structure on premiums. Using a national sample of health maintenance organizations (HMOs) for the period 1988–91, Wholey *et al.* (1995) examined the relationship between premiums and the number of HMOs in the market. They found evidence that premiums were lower as the number of firms increased, providing support for advocates of managed competition. Also examining the effects of changes in

market structure, Dafny *et al.* (2012) investigated whether consolidation in the US health insurance industry, driven by a large merger, led to higher ESI premiums. They found that real premiums have grown by two percentage points in a typical market due to an average market-level change in HHI of 698 points.

Karaca-Mandic *et al.* (2013a) recently investigated the effects of competition in the market for insurance agents and brokers on ESI premiums for small employers. Using the Medical Expenditure Panel Survey – Insurance Component and data from the National Association of Health Underwriters, the authors provide evidence that premiums of policies offered by small employers are lower in markets with stronger competition among insurance agents and brokers.

Effects of regulation

Several actuarial and econometric studies have examined the effects on premiums of state-level insurance regulations, including benefit mandates (e.g., coverage for mammograms, *in vitro* fertilization, or mental health services) and rating regulations. Monheit and Rizzo (2007) summarize this evidence. Overall, there is mixed evidence with respect to the effects of benefit mandates on premiums. Some studies suggest these mandates are associated with modest premium increases, whereas others find no relationship. Work by Kowalski *et al.* (2008) focused on the relationship between state regulations implemented during the 1990s and premiums, including benefit mandates, guaranteed issue, community rating, guaranteed renewability, any-willing-provider laws, and individual market premiums. Using data from eHealthinsurance and Golden Rule, they found evidence that community rating regulations raised premiums and that the rate of increase was substantially higher if guaranteed issue regulations accompanied community rating regulations.

Other factors

Within the literature, a number of studies have documented variation in premiums by state, firm size, and plan type. Some studies have also examined premium variation over time within the context of the underwriting cycle and found evidence that insurers respond to a higher prior-year MLR (higher fraction of claims relative to premiums) by raising premiums in the next year (Born and Santerre, 2008). Using a proprietary data set of large employers, Dafny (2010) examine ESI premium setting and found that insurers engage in 'direct' price discrimination, charging higher premiums to firms with deeper pockets, as measured by operating profits. Finally, Karaca-Mandic *et al.* (2013a,b) use panel data for 2001–09 from the National Association of Insurance Commissioners (NAIC) to analyze the factors explaining variation in premiums per member month (PPMM) of coverage in the individual market. They found that insurers operating in other market segments, including the group and Medigap markets, had higher PPMM, whereas those operating in the Medicaid market had lower PPMM. They also documented differences in premiums by whether the insurer is local, regional, or national; whether the insurer is an HMO; and the size of the insurer as measured by the total number of member months of coverage.

What Is the Evidence on Loading Fees, Medical Loss Ratios, and Their Components?

The health insurance loading fee represents the portion of the premium above the expected claims paid by the insurance company. The loading fee includes general and claims-related administrative expenses, profits, broker commissions, and other sales-related expenses, and corresponds to the cost of transferring part of the risk-bearing from the individual to the insurer. According to the conventional theory of insurance, a risk-averse individual is willing to pay for a premium above the expected claims, and thus the size of the load reflects the value of a certain amount of income over an uncertain one with the same expected magnitude. Therefore, under the conventional theory, one can think of the loading fee as the 'relevant price' of the health insurance policy (Phelps, 2010), and therefore, a key factor when considering the value of coverage. In Nyman's theory of insurance, which does not rely on risk aversion to explain why individuals purchase insurance, premium is a more relevant price of insurance as it embodies the amount of non-health-related goods an individual gives up when healthy to receive an income transfer when sick (Nyman, 2003).

As a crude approximation to capture the extent of administrative costs and other fees associated with private insurance provision, the Centers for Medicare and Medicaid Services' Office of the Actuary estimates the net cost of private health insurance as the difference between the private health insurance premiums paid and benefits received in the NHEA. **Table 1** documents the net cost of private insurance as

Table 1 Private health insurance premiums paid and benefits received (in billions of dollars)

	1997	*1998*	*1999*	*2000*	*2001*	*2002*	*2003*	*2004*	*2005*	*2006*	*2007*	*2008*	*2009*	*2010*
Private health insurance premiums	362.50	388.10	419.90	459.60	503.00	560.50	614.50	658.90	702.90	740.20	776.20	807.60	828.80	848.70

a percentage of private insurance benefits paid. As one can see, this percentage has remained relatively stable in the 12%–16.5% range during the 1997–2010 period. These statistics represent an average measure, without distinguishing among ESI (overall or across employer group sizes), individual market coverage, or supplemental Medicare insurance products.

The NAIC is the organization of insurance regulators from the 50 states, the District of Columbia, and the five US territories. It has one of the world's largest insurance industry databases, which are regularly used by industry leaders to determine market share, conduct market research, and monitor industry trends. The NAIC also publishes aggregate annual data separately by market segment (individual, group, supplemental Medicare, etc). **Table 2** presents data from the Statistical Compilation of Annual Statement Information for Health Insurance Companies published by the NAIC for the aggregate US group market. These statistics also do not distinguish by employer group size, but indicate that overall loading fees for the group market ranged between 11% and 20% for the 1997–2008 period. The MLR, defined as the percentage of premiums spent on clinical services, ranged between 83% and 90% during the same time period.

As noted in the section 'Introduction,' small employers are much less likely to offer health insurance relative to large employers. One explanation for this pattern is that employer groups face different loading fees. Thorpe (1992) posits several reasons why this might occur. Differences in transaction costs are one possible reason. Given the fixed costs of marketing and underwriting (in states where it is allowed), small employer groups are more expensive on a per-employee basis relative to larger ones. Furthermore, because small employers exhibit greater price sensitivity in their demand for insurance, they may be more likely to switch insurers as prices change, leading to additional expenses for marketing and underwriting over time. Third, given the voluntary nature of the market, insurers often express concern about the potential for adverse selection among small employers, and in turn, this may lead to higher risk premia.

The most commonly reported set of loading fee estimates by firm size dates back to two decades when an actuarial study was prepared by the Hay/Huggins Company for the US Congress' House Committee on Education and Labor in 1988. These estimates reflected the underwriting practices of major insurers, and suggested loading fees of approximately 40% for the very smallest firms (1–4 employees), 25% for those slightly larger (20–49 employees), and 18% for those with 50–99 employees. Hay/Huggins also reported that fees decline to 16% for those with 100–499 employees and to 12% for those up to 2500 employees. These estimates from the 1980s are still referenced frequently in the literature, including current health economics and health insurance texts.

In recent work, Karaca-Mandic *et al*. (2011) generated new estimates on the size of loading fees and how they differ across the firm size distribution using data from the confidential MEPS Household Component–Insurance Component Linked File. Overall, they found that firms of up to 100 employees face similar loading fees of approximately 34%. Loads decline with firm size and are estimated to be on average 15% for firms with between 101 and 10 000 employees and 4% for firms with more than 10 000 employees.

Focusing specifically on the individual market, Pauly and Nichols (2002) used NAIC data for the period 1988–99 and reported that expenses related to administration, sales, and risk-bearing represented between 30% and 40% of the premiums for individual market insurance. More recently, Abraham and Karaca-Mandic (2011) examined variation in MLRs among US health insurers in the individual market using NAIC data from 2002, 2005, and 2009. The authors documented large variation in MLRs by state, with enrollment-

Table 2 Health insurance industry aggregates, annual statement data from the NAIC for total US group market

Year	*Premiums earned (thousands)*	*Amount incurred for provision of health-care services (thousands)*	*Loading fee*	*Medical loss ratio (%)*
1997	44 559 067	39 972 761	0.11	90
1998	50 231 225	44 330 794	0.13	88
1999	114 735 686	101 529 936	0.13	88
2000	126 648 010	111 698 125	0.13	88
2001	111 019 585	96 970 954	0.14	87
2002	122 195 391	105 307 633	0.16	86
2003	131 529 713	113 158 119	0.16	86
2004	141 303 514	119 484 906	0.18	85
2005	157 094 448	131 132 072	0.2	83
2006	161 129 572	133 750 007	0.2	83
2007	169 768 926	145 427 131	0.17	86
2008	173 578 348	149 730 464	0.16	86
2009	174 888 283	152 544 111	0.15	87

Notes:

1. 1997, 1998, 1999, and 2000 represent only HMOs.
2. Medicare supplement, Federal Employees Health Benefit Plan, Title XVIII Medicare, and Title XIX Medicaid are not included in statistics reported.
3. Loading fee is calculated as (Premiums Earned/Claims Incurred) − 1.
4. Medical loss ratio is calculated as 100 (Claims Incurred/Premiums Earned).

weighted average MLRs ranging from 0.629 in New Hampshire to values greater than 1 in Alabama, Massachusetts, Michigan, and North Dakota in 2009. Additionally, they estimated that 29% of insurer-state observations in the individual market would have MLRs (based on the historical definition) below the 80% minimum threshold imposed by the new ACA regulations, corresponding to 32% of individual market enrollment.

In 2011, a study by the General Accounting Office (GAO, 2011) analyzed insurers' MLRs in the individual and group markets using 2010 data and employing ACA MLR standards, which include adjustments for quality improvement expenses, federal and state taxes and licensing/regulatory fees, and life-years of enrollment. For the individual market, they found wide variation in MLRs, with only 43% of credible insurers and 48% of covered lives at or above the 2011 standard. For the small and group markets, these percentages were notably higher.

Although these studies provide valuable descriptive information, there is little empirical research to understand the factors that explain variation in insurers' loading fees or MLRs. A study by Karaca-Mandic *et al.* (2013b) investigates the determinants of MLR variation in the individual market over the 2001–09 time period. They evaluated how MLRs are influenced by changes in the composition of insurer and provider markets, the employer size distribution, and the demographic and health status of the population. Results suggest that insurance market structure is inversely related to MLRs. Insurers in markets in which they are the only credible insurer have lower MLRs, on average. This is consistent with such firms having higher market power. Here the classification of being a 'credible' insurer refers to having at least 1000 member-years of coverage as stipulated by federal regulations. Although the predicted average MLR is 77% for an insurer that is the only credible firm in the insurance market, it is 82% for an insurer with 2–4 other credible firms in the market, and 83% for an insurer with 5 or more credible firms in the market.

Conclusion

This article summarizes current evidence on US health insurers' performance in the ESI and individual markets, providing important baseline information about premiums as well as loading fees and MLRs. Dramatic changes to US health insurance markets and insurers' performance are expected as a result of the Patient Protection and ACA of 2010. In 2014, insurance exchanges will be implemented and will serve as organized marketplaces through which individuals and small employers can buy coverage. Exchanges will also be a primary mechanism through which coverage will be expanded to millions of uninsured, lower-income Americans who lack access to affordable ESI options. Finally, insurers are adjusting to a very different regulatory environment created by the ACA, including minimum MLR regulation and premium rate review enacted in 2011, as well as several major changes to benefit designs, the adoption of modified community rating, and the requirement that most individuals obtain health insurance in the United States beginning in 2014.

Personalized Medicine: Pricing and Reimbursement Policies as a Potential Barrier to Development and Adoption, Economics of

LP Garrison, University of Washington, Seattle, WA, USA
A Towse, Office of Health Economics, London, UK

Background: Barriers to Personalized Medicine

More than 10 years have passed since the completion of the first sequencing of the human genome in 2001. Since then, there has been continued and growing interest in the potential to use this new genetic information to better predict patient response to therapy. A variety of terms have been coined to describe this potential: personalized medicine (PM), stratified medicine, tailored medicine, and individualized therapy, among others. This article will adopt PM as the descriptor, more because of its currency and popularity than because of its more accuracy than other terms. PM has been defined many a times as "providing the right treatment to the right patient at the right time." Arguably, that is the aim of all medical therapy: the important difference in PM is the use of a new biomarker-based diagnostic test to further define and identify a subgroup of patients (called 'stratification') for whom the treatment performs better – in terms of either cost-effectiveness or benefit–risk balance. Incentives for the development and use of PM raise a number of interesting economic issues.

In the year 2000, Francis Collins, the current head of the US National Institutes of Health, said: "In the next five to seven years, we should identify the genetic susceptibility factors for virtually all common diseases – cancer, diabetes, heart disease, the major mental illnesses – on down that list." Clearly, this has not come to pass. In 2005, a more guarded assessment in the report 'Personalized Medicine: Hopes and Realities' from The Royal Society cautioned: "Pharmacogenetics is unlikely to revolutionize or personalize medical practice in the immediate future."

Before considering potential reasons for this lack of expected progress, it is useful to define some relevant biological, epidemiological, and clinical concepts and terms:

- Pharmacogenetics versus pharmacogenomics – the former is the study of how people's genetic makeup affects their response to medicines, whereas the latter is the application of genomic concepts to the development and clinical application of pharmaceuticals.
- Genotype versus phenotype – the former represents a person's genetic makeup, as reflected by his or her deoxyribonucleic acid (DNA) sequence, whereas the latter is an observable trait or characteristic of an organism (that may or may not be inherited).
- Germline versus somatic mutations – the former are heritable variations, whereas the latter are acquired (e.g., in cancer).
- Biomarkers – they are a broad array of biological indicators, including genetic variants, proteins, and endogenous metabolites, among others.
- Predictive versus prognostic biomarker – a prognostic biomarker is used to project patient health (e.g., life expectancy) based on patient characteristics, whereas a predictive biomarker predicts response to an intervention (e.g., a drug).

The slower-than-expected progress over the past decade could be for a number of reasons – scientific, regulatory, and economic. It does seem clear that the science is more difficult than first hoped. First, it is always important to remember that the science behind drug development is complex and uncertain. Almost 9 out of 10 new medicines under development fail between Phase 1 and Phase 3. Despite increasing amounts spent on drug development, industry productivity, as measured by approved new molecular entities, has been stagnant in recent years. The most recent estimate from the UK Office of Health Economics is that the average cost of drug development has grown to approximately $1.5 billion US$2011 per new compound. Clearly, the scientific unknowns and challenges are substantial.

Adding the parallel development of a predictive, biomarker-based test may reduce one scientific challenge but adds another that involves its own uncertainties. Furthermore, prediction based on genetic makeup is generally imprecise. Although a small number of single mutations (monogenic diseases) lead to specific health conditions (e.g., Huntington's disease), most complex diseases (such as diabetes) are affected by a large number of genes. Although an entire genome can be sequenced, it is only the beginning of understanding the biological function of most genes. Although some traits, such as height, are highly heritable, others are not: indeed, twin studies indicate that genes account for only approximately a quarter of the variation in lifespan – perhaps the ultimate measure of health. Clearly, gene–environment interaction is a very important influence. Regulation of drugs and devices may also be a barrier: the approval pathway for new pharmacogenomic tests has not been defined until recently and the standards of evidence for clinical utility for combination products (i.e., drug and test) are still being debated. Furthermore, there is not a level playing field between *in vitro* diagnostic tests (IVDs), which need regulatory approval for marketing, and laboratory-developed tests (LDTs) also called in-house tests (IHTs). The evidentiary requirements and quality controls for IVDs are much greater. In Europe, public health providers face a different regulatory regime that does not require each test to be approved. Yet, these different tests and providers compete in some PM applications.

But there are also some potential economic barriers that could increasingly be a factor given growing efforts to control medical spending in most developed countries. The incentive issue for existing marketed drugs is fairly obvious. Once a new, patented medicine is on the market with prices and reimbursement established around the world, the manufacturer has a very limited economic incentive to discover the subset of

 doi:10.1016/B978-0-12-375678-7.01210-4

patients in whom the drug works best if reimbursement will then be restricted to the subset. The problem is that reimbursement prices for drugs – especially outside the US – tend to be rigid and inflexible during the period of the patent. Thus, even if most of the aggregate health benefit – and hence economic value – is concentrated in a subset of patients, the manufacturer will receive or capture a much smaller share of that aggregate value if reimbursement is restricted to that subset but the reimbursed price does not rise to reflect their higher average health gain. From a longer term dynamic perspective, if price inflexibility holds and there is a strong possibility that the targeting test would be forthcoming, then drug manufacturers may have much less incentive to develop the drug in the first place. This has long-term, dynamic implications for the incentives for R&D investments in PMs. However, some targeting using tests might actually facilitate R&D and the demonstration of efficacy and safety, although this is difficult to predict *a priori* unless the mechanism of action of the drug is closely linked to a biomarker, for example, as was the case for imatinib (Gleevec®, Novartis) for chronic myelogenous leukemia (CML).

The rigidity of diagnostic reimbursement could be an even larger economic barrier – especially for companion diagnostics for drugs that are already on the market. In the US and most EU health-care systems, reimbursement for diagnostics is based on an administered pricing system linked imperfectly to the expected marginal cost of production and distribution, meaning that some diagnostics might garner profits, whereas others might just break even or even lose money (but persist for other business reasons). Thus, there is a limited incentive to incur the substantial fixed costs of evidence generation that would be necessary to demonstrate the clinical utility of the biomarker-based test in combination with the drug.

This article focuses on economic issues related to pricing and reimbursement policies as a potential barrier to the development and adoption of new, innovative PM technology. There are other important economic issues in PM, such as the impact on drug development costs, the relation to physician incentives to test and to follow test results, and issues related to targeting as a strategy for late entrants into a drug class. The next section summarizes the key theoretical issues. This is followed by a discussion of some key examples of PMs that are in use. The relevance of literature on the cost-effectiveness of PMs is discussed next. The article ends by identifying six major policy challenges. The general conclusion is that pricing and reimbursement systems will need to implement more flexible value-based rewards for PMs if the appropriate amount of R&D and evidence generation is going to be supported.

Economic Incentives for Personalized Medicine Development: A Framework

To this point, only 10–15 PM tests enjoy a significant volume of use, and the amount of evidence about their health and economic impact is limited. But many have been the subject of a cost-effectiveness analysis (CEA) (Wong *et al.*, 2010), and most are considered cost-effective by usual standards – or they would not be in use in health systems. For the purpose of this article, the more interesting and relevant work is the theoretical analysis of economic incentives and their policy implications for PM R&D.

This work has addressed two major questions. First, is it likely that current market structures for innovative PMs and their companion diagnostics will produce the optimal amount of PM development and use? Second, if the current situation is likely to be suboptimal, what could be done to improve it? It is important to recognize that these two questions include not only short-term questions about static efficiency but also long-term questions about dynamic efficiency that affect the sustainability of both PM and the patented medicines industry as a whole, especially because PM is often cited as the 'new paradigm' for drug development.

In an article published in 2002, Danzon and Towse developed a formal model of pharmacogenetic testing to examine the conditions under which the development of these targeted interventions was likely to be socially optimal. The model uses the common assumption of a societal willingness to pay for health gains (i.e., a threshold amount), as is often used in pharmacoeconomic CEA. However, they let the share of the gain captured by the drug manufacturer vary. The essential elements of their model are intuitively straightforward. Imagine that a diagnostic test can stratify a patient population that has previously received a drug into responders (R), those who benefit from the drug, and nonresponders (N), those who do not benefit. Before the test is available, both responders and nonresponders received the drug at price *P*. In Danzon and Towse's model, testing provides social value in several ways, including (1) avoiding drug spending on the nonresponders and (2) avoiding the costs and adverse health effects of adverse events in nonresponders. Of course, the value of the product among responders exists in either scenario. The key drivers of the social value of testing are the averted costs of adverse events times the share of N, and the cost of testing both R and N groups. Testing will generally be socially beneficial if the aggregate cost of testing is less than costs savings from not using the drug plus avoiding adverse events in N.

Their model identifies the key determinants of the incentives for drug manufacturers and payers to embrace pharmacogenetic testing. They also note implications for test developers and drug development more generally. Clearly, it will be critical for drug manufacturers to be able to capture a large share of the aggregate value created after the test is introduced. This generally means that the price paid for responders in the testing scenario must rise roughly in proportion to the rise in average patient benefit (due to eliminating adverse events and/or nonresponders), compared with the no-testing scenario, and also the price of test must be modest, relative to the cost of treatment. Although payers would generally prefer to pay less, in theory, they would be willing to accept a situation where the total amount paid out is the same if the net health benefits (i.e., among the responders) are the same as long as the costs of testing and the savings from avoiding adverse events in nonresponders are factored in. Danzon and Towse conclude: "The willingness of payers to award higher prices for targeted benefits ... will be essential to retaining neutrality in investment incentives" (p. 10).

Danzon and Towse (2002) also note that it is possible that the testing scenario could produce an eventual market size

that is so small (in terms of total revenues to the drug manufacturer) that it will not be sufficient to justify the costs of drug development if that cost is fixed (that is, independent of the size of the patient population). In practice, however, the US Food and Drug Administration (FDA) permits fewer and much smaller trials for orphan drugs. And government subsidies and other incentives may be needed in these situations for socially optimal investment. They also suggest that with free entry into the business of developing tests, manufacturers – with this new genetic knowledge – will have an incentive to incorporate testing into the drug development paradigm, which might also reduce the costs of that development. This is because in most markets (with the notable exception of the US), it is not possible to increase prices once a drug is launched because of rigid government price regulation. Thus, *ex post* targeting leads to lower volume but does not guarantee an increased price to reflect the greater health gain per patient in the smaller population. To date, although it is clear that manufacturers are increasingly considering testing as part of drug development the aggregate impact has not been large over the past 10 years.

Danzon and Towse assume the price and availability of the test is a given. They focus on the social benefits of health gains and of any reductions in cost. Considering many of these same issues in a less formal analysis, Garrison and Austin (2007) build on this analytical approach by analyzing the incentives for both the diagnostic company and the drug company for the codevelopment of companion diagnostic test (Dx) and a first-in-class drug therapy (Tx). They also explore an additional potential benefit of PM – the 'value of knowing.' They consider six scenarios that represent combinations of the following four factors:

1. whether Tx and Dx pricing reimbursement are value based or cost based, and whether they are flexible over time;
2. timing – whether Tx is already on the market, i.e., *ex post* versus *ex ante*;
3. whether intellectual property protection – to prevent copycats – is a barrier to entry;
4. the competitiveness of insurance market over short versus long term.

Although the overall result in terms of the importance of flexible drug pricing and reimbursement is the same, Garrison and Austin extend the model by adding some value creation for the 'value of knowing,' i.e., that the test–drug combination will be of higher value to the responders as they will know they will benefit. Assuming that they are risk averse, this reduction in uncertainty should give them greater peace of mind. This makes the total pool of value created larger: how this aggregate value is divided among patients, payer/insurers, drug manufacturers, and test developers is an important question. They also emphasize that although pricing and reimbursement for new drugs could be considered 'value-based' in the US and the key markets in the EU during the patent life, reimbursement for diagnostic tests tends to be a more rigid, administered pricing system, which could be called 'cost based.'

Their illustrative model considers a case where 20% of the users are responders and 80% are nonresponders. In the absence of a test, the value created in the 20% is essentially spread over the 100% (subject to adjustment for adverse events in the nonresponders) by setting the price based on the average benefit (including the nonresponders). In their base case scenario, with no Dx available, the (patented) Tx captures all of the value created (given the willingness-to-pay threshold). The five other scenarios explore variations on the four assumptions listed in this article while recognizing that the total value created is now greater due to the value of knowing. It does, then, become *ex post* a different zero-sum game, i.e., after the diagnostic becomes available – there is now a slightly bigger pie to divide up. The implications of the six scenarios are intuitive and straightforward.

If the price of the Tx is fixed, and the Dx enters the market *ex post*, the revenues going to the Tx manufacturer would fall dramatically. The Dx may capture this or not, depending on whether its pricing is regulated and at what level. The Tx manufacturer would suffer a severe revenue loss and has a very limited incentive to encourage Dx entry – unless the value could be recaptured by the Tx manufacturer by owning the Dx. Indeed, this is the circumstance for most drugs already on the market: neither Tx manufacturers nor Dx developers have a strong incentive to develop a test that identifies responders. Oncotype Dx for predicting breast cancer recurrence, which is discussed below, is one exception: the manufacturer avoided the cost-based reimbursement system in the US and charged approximately $3500 for the test. It is true that some panels of diagnostic tests might be lucrative under this system, but this would seem to be less likely true for the novel complex diagnostics needed for PM if their payment is based on the summation of the expected costs of the analytic steps as opposed to a measure of the incremental health gain.

If the Tx manufacturer's drug comes to market in combination with a companion test, then there are several different possibilities. If the Dx is subject to marginal cost-based reimbursement, then the manufacturer will want to capture as much value as possible through the drug price, which has much more flexibility at launch in most countries. If the Tx manufacturer also owns the Dx, then, in theory, the value capture could be split arbitrarily between the two. But, in practice, given administered pricing for the Dx and strong intellectual property protection for the drug, the incentive probably remains to capture as much value through the drug price as possible.

These scenarios illustrate several key points about the economic barriers that companion Dx–Tx products face. First and foremost is that inflexible pricing and reimbursement, which does not adjust to reflect value created, could undermine the rewards for developing PMs. Second, manufacturers would ideally enter the market with a combination product that has been clinically tested and validated *ex ante* as a combination. Flexible, value-based pricing and reimbursement would appear to be a necessary condition for encouraging optimal investments to produce more PM; of course, it cannot guarantee a large volume of PM development because scientific, regulatory, and drug development realities represent constraints.

Personalized Medicine Products

Although some have been disappointed by the slow progress in PM over the past 12 years, there has been a gradual accumulation of PM products, so that now between 10 and 20

Table 1 Companion diagnostic testing in PM

Technology	*Economic and testing features*
HER2 testing for breast cancer	A low-cost immunohistochemistry (IHC) (approx. $100–$200) test for human epidermal growth factor receptor 2 (HER2)-positivity was used in the initial clinical trial program and was provided by diagnostic companies. Subsequently, a higher cost and more accurate test ($300–$500) was developed (called 'FISH') and is in use. Approximately 80% of initial testing is done with IHC, with FISH retesting for patient with equivocal results. The drug manufacturer receives nearly all of the economic value created by the combination from the drug trastuzumab (Herceptin®, Roche)
BCR-ABL testing for chronic myelogenous leukemia (CML)	An example of an *ex ante* test (breakpoint cluster region-Abelson (BCR-ABL) gene) closely tied to the development of the drug: large majority of value capture by the drug imatinib (Gleevec®, Novartis). A second, BCR-ABL test is used to monitor for resistance and assignment to second-line therapies
Oncotype Dx® (Genomic Health) for breast cancer recurrence	An example of a relatively high-cost, value-capturing test aimed at avoiding unproductive chemotherapy
EGFR mutation testing in nonsmall-cell lung cancer (NSCLC)	An example where the stratifying mutation (epidermal growth factor receptor (EGFR)) was identified in trials that also included test-negative patients
HLA-B∗5701 allele testing for abacavir in HIV	Example of a test to identify patients who are more likely to suffer a severe adverse reaction to the HIV drug abacavir (Ziagen®, ViiV Healthcare)
KRAS testing in colorectal cancer	The KRAS mutation predicts which patients will not respond to two different monoclonal antibody treatments for colorectal cancer. The biomarker was identified after the products were on the market
PreDx® (Tethys Biosciences) diabetes risk test	This multimarker test identifies which prediabetic patients are at high risk of progressing to Type 2 diabetes: it indicates whether to begin prophylactic treatment with metformin
ALK mutation testing in NSCLC	Example of the drug crizotonib (Xalkori®, Pfizer) that targets a small subset (approximately 4%) of patients in disease condition with significant unmet medical need. It offers substantial survival gains in the subset, but with high testing cost per identified responder that must be factored in

notable PM products are available. Many of the PM products have been in oncology where it has been possible to link somatic mutations to chemotherapeutic response. **Table 1** presents some examples of PM products that illustrate the range of issues that arise in combining companion diagnostics with drugs to achieve PM. More details on three of these examples are provided in the next three paragraphs.

Trastuzumab (Herceptin®, Roche), a biological compound for the treatment of human epidermal growth factor receptor 2 (HER2)-positive breast cancer, has been called the first 'poster child' for PM. It was first approved in the US for the treatment of metastatic breast cancer (MBC) in 1998. Longer term (3-year follow-up) trials were initiated in early-stage breast cancer (EBC) and marketing approval was received in 2004. It provides a number of useful lessons as a case study in PM. First, these combination products can have a long gestation and life cycle. The potential of the HER mechanism was discovered in the early 1980s, but it took approximately 15 years to yield a viable compound combined with a predictive test. Second, the EBC indication, which was approved 6 years later than the MBC indication, produced much larger per-patient health gains and benefited many more women in the aggregate. Because the initial price of trastuzumab for treatment of MBC was set closer to the implicit willingness-to-pay threshold for cost-effectiveness (>US$100 000 per quality-adjusted life-year (QALY)) in the US, treatment in the EBC indication was much more cost-effective (<US$30 000 per QALY) (Garrison *et al.*, 2007). So what appeared to be high-cost medicine for its initial approved indication can be reasonably cost-effective over the entire product life cycle. The company might well have priced it higher if the favorable results in EBC would have been anticipated. Another complexity of the trastuzumab story is the persistence of basic issues about testing strategy. Two general types of tests are in use – a cheaper immunohistochemistry (IHC) test and a more expensive and more accurate fluorescence *in situ* hybridization test (FISH). IHC is the more common test and is used in 80% of all initial tests in the US. Even after all these years of experience, the optimal companion testing strategy is still under debate due to uncertainty about real-world test performance: approximately 80% of women with breast cancer receive the IHC test initially and some are retested with FISH.

Imatinib (Gleevec®, Novartis) is the unusual example of a PM combination product developed through rational drug design. It has been heralded as a virtual cure for many patients with CML. It has the distinction of having one of the fastest approval times by the FDA. The breakpoint cluster region-Abelson (BCR-ABL) enzyme that promotes cancer cell development appears only in cancer cells, can be identified by a test, and can be blocked. Once again, the large majority of the value created is captured by the drug, which has been estimated to be cost-effective in the US with a cost per QALY of approximately $50 000.

Oncotype Dx® for predicting breast cancer recurrence could be considered the poster child for a value-capturing PM test at approximately $3500 per test in the US. It is based on a '21-gene signature' that was constructed through retrospective analysis of historical tumor samples to generate a patented index to predict the likelihood of recurrence. The major economic benefit is that it avoids chemotherapy costs and side effects (including the risk of death) in women with EBC. The manufacturer was able to circumvent usual coding and pricing practices in obtaining the US Medicare reimbursement. The alternative would have been to use 'code stacking' of analytic steps, such as RNA extraction, reverse transcription, gene amplification, and interpretation and report. But this would have resulted in a payment level of only approximately US$540 (Gustavsen *et al.*, 2010).

Personalized Medicine, Cost-Effectiveness Analysis, and Pharmacoeconomics

In general, the methods of economic evaluations in PM are no different than standard CEA. In the usual case in pharmacoeconomics, the cost-effectiveness of a new medicine is assessed in a population with a particular disease (such as diabetes or rheumatoid arthritis) for the subset of patients who use the drug. A standard pharmaceutical CEA compares the impact of the use of a new medicine on health outcomes (usually measured in terms of QALYs gained) and on medical costs. The impact of PM further segments this subpopulation through the use of the biomarker-based test. The CEA, therefore, changes to the question of the economic impact of the use of the combination of the test and the treatment versus using the drug (or another treatment) without testing in the full population. The test is often called a companion diagnostic, and the pair has been called a 'codependent technology' (e.g., by regulators in Australia). The overall standard analysis in the field of pharmacoeconomics remains 'cost-utility analysis' with the primary metric being the incremental cost-effectiveness ratio (ICER) in terms of cost per QALY gained, although it is not used by payers in all jurisdictions, for example, Germany.

Given the cost of the test and the cost of the treatment, the usual principles of CEA apply, except that the cost of the testing and outcomes for all test recipients must be included in the analysis. It has been argued that the QALY may not capture the utility gain that patients may receive from the value of knowing, i.e., the reduction in uncertainty in terms of whether the medicine will work well for them. From a modeling approach, this reduction amounts to less uncertainty about the value of the drug (assuming the test has high accuracy). If this were to be included, some add-on or adjustment to the QALY gain would be needed: there are various preference elicitation techniques in economics that can be used to elicit willingness to pay for such product attributes.

Besides creating value by reducing uncertainty, a targeted Dx–Tx combination could create further value in a population beyond what is captured in the QALY and ICER in, at least, two other ways. First, suppose that some responders were noncompliant because they were not sure whether or not they were responding. A companion Dx could increase their confidence about response and hence compliance with Tx, producing better outcomes in those patients, and thus creating more value at the aggregate level. Second, in the situation where the Dx is not available, some patients who would be responders might not actually choose to go to the doctor for the broader diagnosis. With an available Dx, however, they might seek this care. Thus, overall uptake would increase. Measuring this aggregate value gain would require a somewhat more sophisticated model than is typically used in CEA for a typical patient: a population-level uptake and use model would be needed, more akin to a budget impact model. But it is feasible to model and estimate these additional sources of value.

Regulatory and Policy Issues and Implications

There are several major scientific challenges in the development of PM, including the low probability that a new mechanism of action will work, the challenge of parallel development of a new companion diagnostic, and the uncertainty of genetic prediction of complex traits. Clearly, the scientific unknowns and challenges are substantial. Nonetheless, it is important to ask what can be done to optimize the economic incentives. The following six potential challenges need to be researched, and, if appropriate, policy changes made.

Flexible Value-Based Pricing for Drugs

Economic theory would suggest that payers and pricing and reimbursement authorities should allow for flexible pricing (both up and down) for drugs at launch and postlaunch if the evidence suggests that they can be targeted in a narrower patient group or used in a number of different indications or subgroups of different value. The UK 2009 Pharmaceutical Price Regulation Scheme, for example, included (1) provisions for 'flexible pricing' that allowed drug developers to seek approval from the National Institute for Health and Clinical Excellence for higher prices when evidence of value increased and (2) provisions for new indications to be launched at different prices (higher or lower) than existing indications. However, neither of these provisions has been used to date in the UK. This may reflect uncertainty on the part of companies as to how the policy would be applied or the linkage of the UK market via parallel trade and reference pricing to other EU markets where such provisions do not apply.

Regulatory Flexibility in Drug–Test Combination Development

Given the evidence on drug development failure rates, pharmaceutical companies can be expected to be resistant to increases in development costs caused by adding a test into the development program (notwithstanding the potential advantages of *ex ante* vs. *ex post* stratification for the ability of the pharmaceutical company to extract rents). In the case of the drug–test companion development, one might, therefore, expect that it is important initially that the delivery of a prototype assay for use in Phase 3 development does not call for significant investment in advance of being in position to recognize the efficacy or otherwise of the drug itself in Phase 2. To achieve this would require flexibility in the regulatory hurdles for tests as part of drug development. (And this links to the importance for achieving socially optimal outcomes of having an environment in which better quality follow-on tests are incentivized to enter the market.) This flexibility in the drug development process may require the payer's pricing and reimbursement arrangements for drug–test combinations to concentrate on the evidence from the Phase 3 drug development trial and not require a patient randomization to use the test (e.g., the 'double randomized trial' proposed in the Australian government's guidelines for codependent technologies.) As the model changes over time, drug developers may not have to codevelop new tests and biomarkers but can draw on existing ones. In this context, the key issue will not be for the drug developer: instead, it will be necessary to ensure that diagnostic developers have an incentive to bring improved

tests to the market and will obtain value-based remuneration for them.

Flexible Value-Based Reimbursement for Diagnostics

Testing that enables better choice of treatment or improved disease management may generate downstream health effects of extended life and/or improved quality of life. In addition, a diagnostic test can enhance the level of information about a specific clinical condition or health state, and so reduce or eliminate uncertainty. This may have value independent of any ability to improve treatment choice – although insurers' willingness to pay for this may be unclear. Historically, pricing and reimbursement systems for diagnostics have been focused on the expected cost of making and conducting the test (which may depend on the technology platform used) and not the value delivered. This has meant that the price of a new diagnostic is often based on the price of existing tests ('cross-walking') with similar clinical use or with similar characteristics or on production cost based on analytic steps. For example, in the US, a number of diagnostics are reimbursed via code stacking by reporting a combination of reimbursement Current Procedural Terminology codes describing laboratory protocol stages. Theory would suggest that both diagnostic-dedicated and drug health technology assessment (HTA) processes should use a common, consistent, and comprehensive approach to assessing value to enable the development of pricing and reimbursement arrangements capturing the full incremental value offered by those technologies. Policymakers also need to consider the incentive for companies to invest in evidence collection to raise the standard of clinical utility data available to support the case for using a companion test. Such incentives might come from rewarding competing tests that supply evidence that they bring improved health gain and information through greater accuracy.

Dividing the Combination Value between the Drug and the Diagnostic

Accepting for now the notion that flexible value-based pricing is desirable for both an innovative PM and an innovative companion diagnostic raises the question, how can the problem of synergistic/codependent technologies noted above be best resolved? As a starting point, it may be easier to start with the case of the *ex post*, 'standalone' test. Recall that the average development cost of a new drug is $1.5 billion US$2011, and the productivity of drug R&D has been declining over time. In contrast, the cost to develop a new biomarker-based assay is in the order of $10 million to $50 million – at the high end if additional clinical trials are needed to validate the biomarker-based test. Consider a hypothetical case where an existing biopharmaceutical is on the market and earning $1 billion in annual revenues despite having only a 50% response rate. Suppose a reliable biomarker-based test is invented that can predict the responders. In theory, the payer would be indifferent to giving them $500 million and perhaps a premium for the value of knowing (i.e., reduced uncertainty for both the payer and the patient). Clearly, if the drug manufacturer thought in advance that this might happen, the prospect of lower revenues would have reduced the likelihood of them making the initial investment. One could argue, however, that it was the drug manufacturer's invention that created the health gain in the responders. Then, the extra value created by the Dx manufacturer consists of (1) avoiding any adverse event treatment costs and any related health losses in the nonresponders plus (2) the 'value-of-knowing premium.' (Note that if the premium were, say, 5% of total health gain, it would be worth $50 million: an amount that could support substantial evidence generation.) With flexible value-based pricing, this logic would argue that the drug innovator's price would be roughly doubled (i.e., to $1 billion in revenues) and the Dx innovator would receive a reward in relation to cost savings and QALY gains in the nonresponders plus a premium for the value of knowing (i.e., $50 million). This split is arbitrary in a static sense, but it can be argued that it reinforces dynamic efficiency by considering the relative size of the investments needed to develop a drug versus a diagnostic. Clearly, this issue deserves further research.

'Follower' Diagnostic Tests 'Piggyback' on Clinical Utility Evidence

Evidence on drug effectiveness and value is generated by the drug developer in order to obtain regulatory and pricing approval. The drug company has a patent (no one can copy the product) and also regulatory exclusivity on the data they generate (no one can reference the data to get regulatory approval by claiming that their product does the same). The situation is more complicated in diagnostics: patents may be less robust, regulatory hurdles are lower, and so it is more difficult to prevent others appropriating the benefits of evidence from studies the diagnostic manufacturer has paid for. As a consequence, there may be underinvestment in evidence generation. Data exclusivity could be given to evidence for diagnostics. This would require 'follow-on' tests to replicate the evidence generated by the 'first-in-class' test (as is the case for drugs). However, under current diagnostic regulations in the US and EU countries, LDTs (and in the EU any tests provided by public health providers) have to meet lower regulatory hurdles and so could not be prevented from piggybacking on clinical utility evidence. In addition to the data exclusivity requirement, there may, therefore, need to be an expectation that payers will pay more for the test with the stronger evidence base (i.e., that they will ignore tests without an evidence base when making HTA). Of course, a balance has to be struck, as with patenting. The objective is not to delay competition to provide innovative tests but to ensure initial providers have the potential to earn a return if they have evidence to support claims of value. Research is clearly needed on both effective incentives to prevent piggybacking for a least a period of time and how long they should be put in place.

Flexibility in Diagnostic Test Evidence for Reimbursement

Given the US and EU regulatory environments, a pragmatic approach could be taken to collecting evidence on the clinical utility of diagnostics, for example, using small randomized

studies (if not built into Phase 3 of drug development), which lead to conditional reimbursement approval and evidence-based reimbursement rate to incentivize manufacturers plus real-world, postlaunch data collection. To facilitate real-world data collection, increased investment in national e-health records would, certainly, help, although the overall investment case for such records is much greater than simply facilitating assessment of the benefits (or otherwise) of developing and validating diagnostic tests.

Conclusion

Although there is a general perception that the growth of PM has been slower than hoped, it is not clear how much of this perceived shortfall is due to scientific and regulatory constraints versus economic incentives. Many of the PM products have been in oncology, where it has been possible to link somatic mutations to drug response. The science is more difficult outside of oncology. There are, clearly, problems with economic incentives in this area as well. However, the empirical evidence on this is limited by the challenge of constructing the counterfactual. These may reflect the scientific challenge: not enough drug-diagnostic combinations have received regulatory approval to allow exploration of the issues around commercial success. However, the relatively small number of regulatory approvals may also reflect perceived commercial limitations as well as scientific challenges.

Over the past dozen years, the thinking about PM predictive tests has evolved from thinking primarily about using genetic mutations or combinations as predictors of clinical response to a wider range of 'biomarkers,' and even to changing the name of the whole area to 'molecular diagnostics.' Owing to the rapidly falling cost of sequencing an individual's entire genome (e.g., projected to be less than $1000 in the near future), a new set of economic issues are arising around the question of how to use this plethora of data from whole genome scans. These new economic issues have not been addressed here but will need to be better understood in future discussions of the economics of PM. In the extreme, the emerging pharmacogenomics diagnostic industry will change drastically, making it possible for a whole genome test to be performed at birth on an individual. Still, testing for somatic mutations would be needed and incentives would be required to invest in providing evidence that a particular set of biomarkers (including genes) is predictive of disease.

GUIDE TO USING THE ENCYCLOPEDIA

Structure of the Encyclopedia

The material in the encyclopedia is arranged as a series of articles in alphabetical order.

There are four features to help you easily find the topic you're interested in: an alphabetical contents list, cross-references to other relevant articles within each article, and a full subject index.

1 Alphabetical Contents List

The alphabetical contents list, which appears at the front of each volume, lists the entries in the order that they appear in the encyclopedia. It includes both the volume number and the page number of each entry.

2 Cross-References

Most of the entries in the encyclopedia have been cross-referenced. The cross-references, which appear at the end of an entry as a See also list, serve four different functions:

i. To draw the reader's attention to related material in other entries.
ii. To indicate material that broadens and extends the scope of the article.
iii. To indicate material that covers a topic in more depth.
iv. To direct readers to other articles by the same author(s).

Example

The following list of cross-references appears at the end of the entry Abortion.

> *See also*: Education and Health in Developing Economies. Fertility and Population in Developing Countries. Global Public Goods and Health. Infectious Disease Externalities. Nutrition, Health, and Economic Performance. Water Supply and Sanitation

3 Index

The index includes page numbers for quick reference to the information you're looking for. The index entries differentiate between references to a whole entry, a part of an entry, and a table or figure.

4 Contributors

At the start of each volume there is list of the authors who contributed to that volume.

SUBJECT CLASSIFICATION

Demand for Health and Health Care

Collective Purchasing of Health Care
Demand Cross Elasticities and 'Offset Effects'
Demand for Insurance That Nudges Demand
Education and Health: Disentangling Causal Relationships from Associations
Health Care Demand, Empirical Determinants of
Medical Decision Making and Demand
Peer Effects, Social Networks, and Healthcare Demand
Physician-Induced Demand

PREFACE

What Do Health Economists Do?

This encyclopedia gives the reader ample opportunity to read about what it is that health economists do and the ways in which they set about doing it. One may suppose that health economics consist of no more than the application of the discipline of economics (that is, economic theory and economic ways of doing empirical work) to the two topics of health and healthcare. However, although that would usefully uncouple 'economics' from an exclusive association with 'the (monetized) economy,' markets, and prices, it would miss out a great deal of what it is that health economists actually do, irrespective of whether they are being descriptive, theoretical, or applied. One distinctive characteristic of health economics is the way in which there has been a process of absorption into it (and, undoubtedly, from it too); in particular, the absorption of ideas and ways of working from biostatistics, clinical subjects, cognitive psychology, decision theory, demography, epidemiology, ethics, political science, public administration, and other disciplines already associated with 'health services research' (HSR) and, although more narrowly, 'health technology assessment' (HTA). But to identify health economics with HSR or HTA would also miss much else that health economists do.

… And How Do They Do It?

As for the ways in which they do it, in practice, the overwhelming majority of health economists use the familiar theoretical tools of neoclassical economics, although by no means all (possibly not even a majority) are committed to the welfarist (specifically the Paretian) approach usually adopted by mainstream economists when addressing normative issues, which actually turns out to have been a territory in which some of the most innovative ideas of health economics have been generated. Health economists are also more guarded than most other economists in their use of the postulates of soi-disant 'rationality' and in their beliefs about what unregulated markets can achieve. To study healthcare markets is emphatically not, of course, necessarily to advocate their use.

A Schematic of Health Economics

To think of health economics merely in these various restricted ways would be indeed to miss a great deal. The broader span of subject matter may be seen from the plumbing diagram, in which I have attempted to illustrate the entire range of topics in health economics. A version of the current schematic first appeared in Williams (1997, p. 46). The content of the encyclopedia follows, broadly, this same structure. The arrows in the diagram indicate a natural logical and empirical order, beginning with **Box A** (Health and its value) (**Figure 1**).

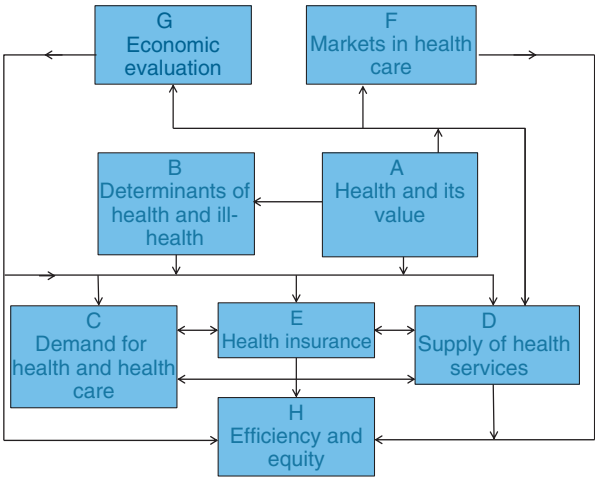

Figure 1 A schematic of health economics.

Box A, in the center-right of the schematic, contains fundamental concepts and measures of population health and health outcomes, along with the normative methods of welfarism and extra-welfarism; measures of utility and health outcomes, including their uses and limitations; and methods of health outcome valuation, such as willingness to pay and experimental methods for revealing such values, and their uses and limitations. It includes macro health economic topics like the global burden of disease, international trade, public and private healthcare expenditures, Gross Domestic Product (GDP) and healthcare expenditure, technological change, and economic growth. Some of the material here is common to epidemiology and bioethics.

Box A Health and its value

Concepts and measures of population health and health outcomes.
Ethical approaches (e.g., welfarism and extrawelfarism).
Measures of utility and the principal health outcome measures, their uses, and limitations.
Health outcome valuation methods, willingness to pay, their uses, and limitations.
Macro health economics: global burdens of disease, international trade, healthcare expenditures, GDP, technological change, and economic growth.

Box B (Determinants of health and ill health) builds on these basics in various 'big-picture' topics, such as the population health perspective for analysis and the determinants of lifetime health, such as genetics, early parenting, and schooling; it embraces occupational health and safety, addiction (especially tobacco, alcohol, and drugs), inequality as a determinant of ill health, poverty and the global burden of disease in low- and middle-income countries, epidemics, prevention, and public health technologies. Here too, much is

Box B Determinants of health and ill health

The population health perspective.
Early determinants of lifetime health (e.g., genetics, parenting, and schooling).
Occupational health and safety.
Addiction: tobacco, alcohol, and drugs.
Inequality as a determinant of ill health.
Poverty and global health (in LMICs).
Epidemics.
Prevention.
Public health technologies.

shared, both empirically and conceptually, with other disciplines.

From this it is a relatively short step into **Box C** (Demand for health and healthcare): here we are concerned with the difference between demand and need; the demand for health as 'human capital'; the demand for healthcare (as compared with health) and its mediation by 'agents' like doctors on behalf of 'principals'; income and price elasticities; information asymmetries (as in the different types of knowledge and understandings by patients and healthcare professionals, respectively) and agency relationships (when one, such as a health professional, acts on behalf of another, such as a patient); externalities or spillovers (when one person's health or behavior directly affects that of another) and publicness (the quality which means that goods or services provided for one are also necessarily provided for others, like proximity to a hospital); and supplier-induced demand (as when a professional recommends and supplies care driven by other interests than the patient's).

Box C Demand for health and healthcare

Demand and need.
The demand for health as human capital.
The demand for healthcare.
Agency relationships in healthcare.
Income and price elasticities.
Information asymmetries and agency relationships.
Externalities and publicness.
Supplier-induced demand.

Then comes **Box D** (Supply of healthcare) covering human resources; the remuneration and behavior of professionals; investment and training of professionals in healthcare; monopoly and competition in healthcare supply; for-profit and nonprofit models of healthcare institutions like hospitals and clinics; health production functions; healthcare cost and production functions that explore the links between 'what goes in' and 'what comes out;' economies of scale and scope; quality of care and service; and the safety of interventions and modes of delivery. It includes the estimation of cost functions and the economics of the pharmaceutical and medical equipment industries. A distinctive difference in this territory from many other areas of application is the need to drop the assumption

Box D Supply of health services

Human resources, remuneration, and the behavior of professionals.
Investment and training of professionals in healthcare.
Monopoly and competition in healthcare supply.
Models of healthcare institutions (for-profit and nonprofit).
Health production functions.
Healthcare cost and production functions.
Economies of scale and scope.
Quality and safety.
The pharmaceutical and medical equipment industries.

of profit-maximizing as a common approach to institutional behavior and to incorporate the idea of 'professionalism' when explaining or predicting the responses of healthcare professionals to changes in their environment.

Supply and demand are mediated (at least in the high-income world) by insurance: the major topic of **Box E** and a large part of health economics as practiced in the US. This covers the demand for insurance; the supply of insurance services and the motivations and regulations of insurance as an industry; moral hazard (the effect of insurance on utilization); adverse selection (the effect of insurance on who is insured); equity and health insurance; private and public systems of insurance; the welfare effects of soi-disant 'excess' insurance; effects of insurance on healthcare providers; and various specific issues in coverage, such as services to be covered in an insured bundle and individual eligibility to receive care. Although the health insurance industry occupies a smaller place in most countries outside the US, the issues invariably crop up in a different guise and require different regulatory and other responses.

Box E Health insurance

The demand for insurance.
The supply of insurance services.
Moral hazard.
Adverse selection.
Equity and health insurance.
Private and public systems.
Welfare effects of 'excess' insurance.
Effects of insurance on healthcare providers.
Issues in coverage: services covered and individual eligibility.
Coverage in LMICs.

Then, in **Box F**, comes a major area of applied health economics: markets in healthcare and the balance between private and public provision, the roles of regulation and subsidy, and the mostly highly politicized topics in health policy. This box includes information and how its absence or distortion corrupts markets; other forms of market failure due to externalities; monopolies and a catalog of practical difficulties both for the market and for more centrally planned systems; labor markets in healthcare (physicians, nurses, managers, and allied professions), internal markets (as when the public sector of healthcare is divided into agencies that commission care on behalf of populations and those that

Box F Markets in healthcare

Information and markets and market failure.
Labor markets in healthcare: physicians, nurses, managers, and allied professions.
Internal markets in the healthcare sector.
Rationing and prioritization.
Welfare economics and system evaluation.
Comparative systems.
Waiting times and lists.
Discrimination.
Public goods and externalities.
Regulation and subsidy.

provide it); rationing and the various forms it can take; welfare economics and system evaluation; waiting times and lists; and discrimination. It is here that many of the features that make healthcare 'different' from other goods and services become prominent.

Box G is about evaluation and healthcare investment, a field in which the applied literature is huge. It includes cost-benefit analysis, cost-utility analysis, cost-effectiveness analysis, and cost-consequences analysis; their application in rich and poor countries; the use of economics in medical decision making (such as the creation of clinical guidelines); discounting and interest rates; sensitivity analysis as a means of testing how dependent one's results are on assumptions; the use of evidence, efficacy, and effectiveness; HTA, study design, and decision process design in agencies with formulary-type decisions to make; the treatment of risk and uncertainty; modeling made necessary by the absence of data generated in trials; and systematic reviews and meta-analyses of existing literature. This territory has burgeoned especially, thanks to the rise of 'evidence-based' decision making and the demand from regulators for decision rules in determining the composition of insured bundles and the setting of pharmaceutical prices.

Box G Economic evaluation

Decision rules in healthcare investment.
Techniques of cost-benefit analysis in health and healthcare.
Techniques of cost-utility analysis and cost-effectiveness analysis in health and healthcare in rich and poor countries.
Techniques of cost-consequences analysis.
Decision theoretical approaches.
Outcome measures and their interpretation.
Discounting.
Sensitivity analysis.
Evidence, efficacy, and effectiveness.
Economics and health technology assessment.
Study design.
Risk and uncertainty.
Modeling.
Systematic reviews and meta-analyses.

The final Box, H, draws on all the preceding theoretical and empirical work: concepts of efficiency, equity, and possible conflicts between them; inequality and the socioeconomic 'gradient;' techniques for measuring equity and inequity; evaluating efficiency at the system level; evaluating equity at system level: financing arrangements; evaluating equity at system level: service access and delivery; institutional arrangements for efficiency and equity; policies against global poverty and for health; universality and comprehensiveness as global objectives of healthcare; and healthcare financing and delivery systems in low- and middle-income countries (LMICs). This is the most overtly 'political' and policy-oriented territory.

Box H Efficiency and equity

Concepts of efficiency, equity, and possible conflicts.
Inequality and the socioeconomic 'gradient.'
Evaluating efficiency: international comparisons.
Techniques for measuring equity and inequity.
Evaluating equity at system level: financing arrangements.
Evaluating equity at system level: service access and delivery.
Institutional arrangements for efficiency and equity.
Global poverty and health.
Universality and comprehensiveness.
Healthcare financing and delivery systems in LMICs.

A Word on Textbooks

The scope of a subject is often revealed by the contents of its textbooks. There are now many textbooks in health economics, having various degrees of sophistication, breadth of coverage, balance of description, theory and application, and political sympathies. They are not reviewed here but I have tried to make the (English language) list in the Further Reading as complete as possible. Because the assumptions that textbook writers make about the preexisting experience of readers and about their professional backgrounds vary, not every text listed here will suit every potential reader. Moreover, a few have the breadth of coverage indicated in the schematic here. Those interested in learning more about the subject to supplement what is to be gleaned from the pages of this encyclopedia are, therefore, urged to sample what is on offer before purchase.

Acknowledgments

My debts of gratitude are owed to many people. I must particularly thank Richard Berryman (Senior Project Manager), at Elsevier, who oversaw the inception of the project, and Gemma Taft (Project Manager) and Joanne Williams (Associate Project Manager), who gave me the most marvelous advice and support throughout. The editorial heavy lifting was done by Billy Jack and Karen Grépin (Global Health); Aki Tsuchiya and John Wildman (Efficiency and Equity); John Cawley and Kosali Simon (Determinants of Health and Ill health); Richard Cookson and Mark Suhrcke (Public Health); Erik Nord (Health and its Value); Richard Smith (Health and the

Macroeconomy); John Mullahy and Anirban Basu (Health Econometrics); Tom McGuire (Demand for Health and Healthcare); John Nyman (Health Insurance); Jim Burgess (Supply of Health Services); Martin Gaynor and Sean Nicholson (Human Resources); Patricia Danzon (Pharmaceutical and Medical Equipment Industries); Pau Olivella and Pedro Pita Barros (Markets in Healthcare); and John Brazier, Mark Sculpher, and Anirban Basu (Economic Evaluation). Finally, my thanks to the Advisory Board: Ron Akehurst, Andy Briggs, Martin Buxton, May Cheng, Mike Drummond, Tom Getzen, Jane Hall, Andrew Jones, Bengt Jonsson, Di McIntyre, David Madden, Jo Mauskopf, Alan Maynard, Anne Mills, the late Gavin Mooney, Jo Newhouse, Carol Propper, Ravindra Rannan-Eliya, Jeff Richardson, Lise Rochaix, Louise Russell, Peter Smith, Adrian Towse, Wynand Van de Ven, Bobbi Wolfe, and Peter Zweifel. Although the Board was not called on for frequent help, their strategic advice and willingness to be available when I needed them was a great comfort.

Pharmaceutical Company Strategies and Distribution Systems in Emerging Markets

P Yadav and L Smith, University of Michigan, Ann Arbor, MI, USA

Background

Decline in research productivity, slow growth in mature markets, a massive number of patent expirations, and pressures for cost containment from major payers together are forcing leading pharmaceutical companies to rethink their strategies for growth in emerging markets. According to Intercontinental Marketing Services (IMS) Health, by 2014 50% of market growth in pharmaceutical industry will come from 17 countries in emerging markets. With emerging economies representing close to 55% of the world's gross domestic product, pharmaceutical companies have identified new opportunities and markets for investment in these contexts. Rapid economic growth combined with continued population increases in countries like India, China, and Brazil offer new business opportunities for pharmaceutical companies. Additionally, improved technological capabilities and industrial development as a result of economic growth create improved methods for engaging in these developing markets.

In low- and middle-income countries, national growth requires health distribution systems that respond to the population's diverse range of health conditions including assured access to appropriate products, medicines, and vaccines to treat and manage those conditions. More specifically, many developing countries require health products, medicines, and vaccines that can address a double burden of disease; one of both communicable diseases (CDs), infectious diseases as well as noncommunicable diseases (NCDs), chronic diseases. In 2002, approximately 46% of the global burden of disease was attributable to NCDs (Young *et al.*, 2009). The resulting interaction between NCDs and CDs may increase susceptibility of individual health. A synergistic negative interaction of disease types also appears prevalent among individuals in low- and middle-income countries. For example, individuals with diabetes may struggle to manage their health with regard to exposure to infection, particularly to the eyes and feet. Likewise, close to a quarter of cancers in developing countries may be attributed to infectious agents. As a result of these and other interactions, individuals require treatment for single disease areas, as well as increasingly for multiple conditions, some of which may be more chronic in nature.

The challenges in managing pharmaceuticals in emerging countries are very different from those in advanced economies. In developed countries, the challenge is to enhance the efficiency of spending on pharmaceuticals. In most of the emerging markets, the main challenge is how to expand the pharmaceutical market to include a larger share of the population. In these economies, increased spending on pharmaceuticals could lead to higher benefits in health outcomes and in some cases could also catalyze economic growth. As social health insurance plans in some of the emerging countries expand in terms of their population coverage and the range of services that are included, many are being cautious not to generate fiscal pressures at an early stage that may hamper their sustainability. The governments of many emerging market countries are attempting to expand the reach and coverage of their pharmaceutical systems in a way that avoids the high costs observed in the health systems of more developed economies.

The Unique Characteristics of Emerging Markets

For pharmaceutical manufacturers participating in pharmaceutical market growth in emerging markets, careful analysis of the structural differences in emerging market pharmaceutical systems is required. For many governments, strategies to ensure consistent access to medicines, vaccines, and health technologies in emerging markets are necessary. To ensure market growth in these countries, manufacturers often align their strategies with government strategies for improving access through innovative mechanisms like differential pricing schemes or local marketing and health education campaigns for high burden disease areas.

There are significant differences among developing countries in terms of total health expenditures, total pharmaceutical expenditures, strength of drug regulatory authorities, social health insurance, and relative division of distribution between public and private sector for pharmaceuticals. Distribution strategies will vary according to the exact set of factors present in a country. Main factors, which hold across most developing countries, are discussed below.

In mature developed markets, some form of health insurance usually reimburses pharmaceutical purchases in whole or in part. Large fractions of these populations are insured through state, employer, or private insurance. In contrast, many developing countries do not have a national health insurance system in place to ensure affordable access to services and health products for the population. Public or private health insurance is limited mainly to those with high expendable income or those employed in the formal sector. As such, the market for medicines is largely dependent on ability and willingness to pay for products. In low- or middle-income countries, purchasing of pharmaceuticals accounts for up to 40% of the total healthcare expenditure whereas in many established market economies, only 20% of costs are attributed to pharmaceutical drugs. Furthermore, in low-income countries approximately 80% of total pharmaceutical expenditures are out of pocket (**Figures 1** and **2**).

In countries like Brazil and China, newer programs of social insurance have created alternative methods to help ensure individual access to medicines through subsidies and/or targeted retail pharmacy programs for the rural poor. China has expanded its public health insurance system to cover almost

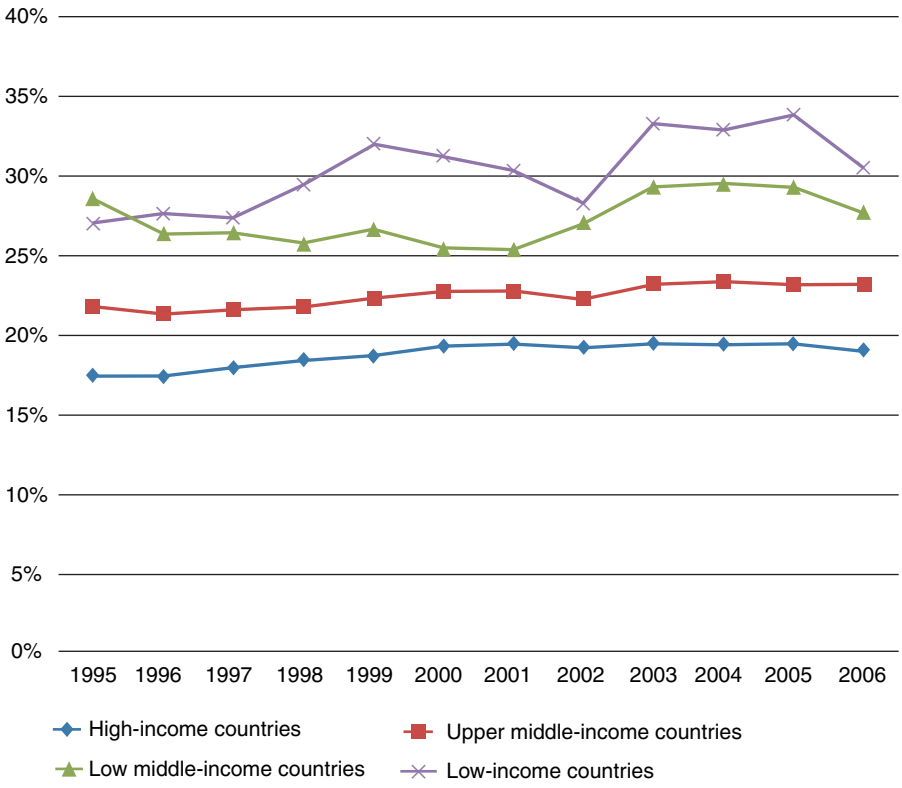

Figure 1 Average total pharmaceutical expenditure as a percent of the total health expenditure (1995–2006). Reproduced from Global Health Expenditure Database (1995–2006). National health accounts, World Health Organization. Available at: http://www.who.int/nha/en/ (accessed 03.10.13).

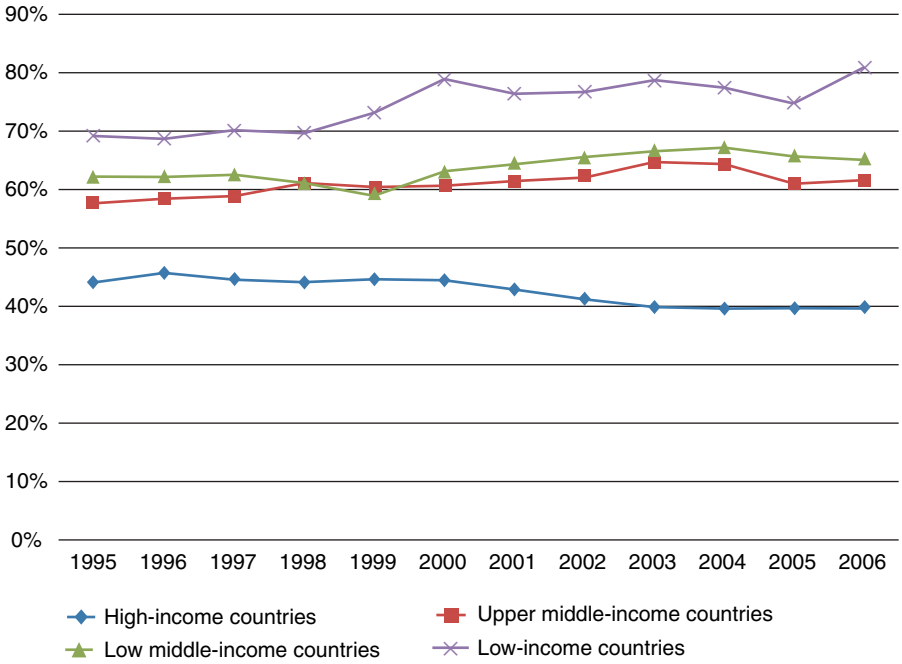

Figure 2 Average percent of total pharmaceutical expenditures that are out of pocket (1995–2006). Reproduced from Global Health Expenditure Database. National health accounts, World Health Organization. Available at: http://www.who.int/nha/en/ (accessed 18.07.13).

Table 1 Differences in overall structure of pharmaceutical market in developed and developing countries

Factor	*Developed countries*	*Developing countries*
Payer/reimbursement	Strong presence of public or private insurance companies and limited out-of-pocket expenditure	Mostly payments are made out of pocket. Social health insurance systems are expanding in many emerging markets. Private insurance plans are also growing in some emerging market countries
Regulatory structure	Strong well-defined laws and overall good ability to enforce regulations	Weak fragmented regulatory structures, ill-defined laws in some instances, and poor ability to enforce regulations
Patented generic versus branded generic	The market for prescription drugs consists of patented drugs and generics	Poor regulatory structure creates a strong market for branded generics (brand is used a signal of quality by the patient)
Prescription adherence	Prescription drugs can only be dispensed with a formal prescription	Retail pharmacies often dispense medicines and also act as the first point of healthcare contact for many patients
Balance of power in the system	Buyer (insurance companies or national health system) monopsony creates good balance of power between the manufacturer and the patients. In the US pharmacy benefit managers (PBM) and drug formularies are commonly used as a means to ensure further balance of power	Balance of power is tilted toward the manufacturer and the distribution channel. A large fraction of patients purchase using out-of-pocket funds and have little bargaining power
Price sensitivity	Pricing is crucial to gaining formulary or national reimbursement acceptance, but price sensitivity within bands is lower	Out-of-pocket payments lead to high price elasticity. Pricing is a key strategic differentiator

95% of the population. Since the early 1990s, Brazil has begun a social health insurance program called the Single Unified System (SUS) on which more than 75% of the population relies on exclusively for care. Approximately 20% of the population (wealthier socioeconomic strata and employees of certain businesses) purchases health insurance from private insurers who are regulated by the National Supplementary Health Agency. People who purchase private insurance receive a tax rebate, however, they still are required to contribute to the SUS through their income taxes. Lower-income groups tend to spend more out of pocket on medicines than higher-income groups in Brazil as higher-income groups typically purchase separate private insurance. Private sources of finance, such as out-of-pocket spending by families and companies with some direct and indirect government subsidies, fund most medicines in the Brazilian health system. Other developing countries such as Malaysia and Thailand have public health insurance plans with very high degrees of coverage. However, in most cases the breadth of services covered under the plans remains limited to catastrophic healthcare needs or very basic services such as immunization. Patients usually have to pay out of pocket for other outpatient or inpatient services and for purchasing medicines.

Also, in developed countries most pharmaceuticals are only obtained using a prescription provided by a physician and consumers purchase drugs from retail pharmacies. In many developing countries, adherence to prescription requirements is poor and patients may often obtain medicines at retail pharmacies without a formal prescription. Most developed countries have well-developed regulatory institutions to ensure the safety and efficacy of drugs. Regulatory agencies in low- and middle-income countries are weak and have very limited capacity to enforce rules. As a result, the task of ensuring quality of medicines is placed on the patients. This creates a stronger market for branded generics in developing countries than in developed countries as branded medicines are used as a signal to patients for quality products.

In low-income countries, especially in Africa, direct purchasing and distribution of medicines by the government (Ministries of Health) represents a significant portion of overall market for pharmaceuticals (Table 1).

Pharmaceutical Distribution Systems in Developed Markets

In both developed and developing countries, given the large number of medicines and packaging variants, it is difficult for retail pharmacies to purchase all of these products directly from the manufacturer and stock them in their retail stores. If all retail pharmacies and hospitals ordered all their medicines from the hundreds of different manufacturers, the number of transactions would be exponentially large and inhibit a working system. Retail pharmacies therefore depend on a well-functioning distribution system consisting of distributors, wholesalers, and prewholesalers. Distributors typically store and distribute a manufacturer's product for a fee; however, they do not own the inventory they distribute. Wholesalers are intermediaries that purchase medicines from manufacturers or prewholesalers. Wholesalers store and distribute supplies while also managing the risks associated with purchased inventory.

In most developed countries a large fraction of the pharmaceuticals used are prescribed by clinical or hospital physicians, which patients obtain at retail pharmacies. In the US, for example, almost 75% of the pharmaceutical sales are covered by retail pharmacies. There are more than 57 000 pharmacies in the US and almost 50% of the retail pharmacy market consists of chain pharmacies including food stores with pharmacies (Yadav *et al.*, 2012). In contrast, many countries in Europe do not allow chain pharmacies. Some large chain pharmacies and hospitals purchase their drugs directly from manufacturers and run their own distribution networks. Some manufacturers also ship certain specialty products directly to retail pharmacies through a specialized logistics service provider. Even with these alternatives, the greater portion of distribution occurs through wholesalers and distributors.

In Europe the manufacturer frequently sends the product from production to a prewholesaler first who then ships the product to wholesalers or large hospitals. Wholesalers then distribute the product to retail pharmacies with an average delivery frequency of twice daily. Most wholesalers stock and distribute products from a number of different manufacturers and often multiple wholesalers operate in a particular region offering competition and choice to the pharmacies. In the US manufacturers ship their product to distributors who then distribute the product to the retail pharmacies several times a week. The lower delivery frequency to retail pharmacies in the US implies that on average pharmacies in the US carry more inventory than pharmacies in Europe, although this is not always true.

In most developed regions of the world the wholesaling and distribution segment of the distribution system is concentrated amongst a few players. The three largest US wholesalers, Cardinal Health, McKesson, and AmerisourceBergen, distribute more than 90% of all pharmaceuticals sold in the US. Increasingly, these companies behave more like distributors in that they have inventory management agreements with manufacturers under which they do not necessarily own stock or carry the associated inventory risk but instead receive a fee from the manufacturers. Similar to the US, in Europe, Japan and other developed regions of the world four to five major distributors with national coverage account for 90% of the market. This is due to the underlying economies of scale in the pharmaceutical distribution business.

Financial flows within developed market distribution chains are somewhat complicated. Although money flows from health plans/insurers to manufacturers with the retail pharmacy in between may seem straightforward, the nature of price negotiations and discounting makes this system more complex. In the US, for example, insurers may negotiate prices with manufacturers. Alternatively, health plans may create or contract specialized agencies called pharmacy benefit managers (PBMs) to obtain discounted prices from manufacturers for exclusiveness on formulary or volume-based discounts. Hospitals and other providers work through Group Purchasing Organizations (GPOs) for negotiating these discounts. The discounts obtained are then shared with health plans. Similar arrangements also exist in the UK.

Order information flows from the healthcare provider to the pharmacy when a prescription is 'called in.' Pharmacies and hospitals replenish their inventories by ordering from the distributors or wholesalers. The distributors and wholesalers in turn order from the manufacturer when their stock needs replenishment. In addition, retail sales information and distributor sales information are collected by private third parties like IMS Health, which allow payers, manufacturers, and regulators to access information from each point in the supply chain. Owing to the nature of the financial flows and contracting with GPOs and PBMs, the distributor and the retail pharmacy also provide product sales information to the GPO and PBM.

Pharmaceutical Distribution Systems in Emerging Markets

Similar to the developed countries, in most emerging markets medicines in the private sector are distributed through a network of importers, wholesalers, subwholesalers, pharmacies, and drug stores (Pharmacies included a trained and certified pharmacist. Drug stores, often also referred to as chemists, are additional informal or formal retail distribution points for medicines typically without a trained/registered pharmacist. Many countries have formal regulatory mechanisms to allow for legal distribution of medicines through drug shops.) National importers and wholesalers create the link between pharmaceutical manufacturers and retail pharmacies, private clinics, hospitals, and other informal drug shops. However, for historical reasons, the pharmaceutical distribution system in most emerging markets has a different market structure compared to developed countries. The main differences include a lack of distribution networks with national reach; excessive fragmentation and too many small players; too many intermediaries between the manufacturer and the patient; poor IT and communication flow systems resulting in poor coordination across actors in the distribution channel.

For example, in 2007 the total number of retail pharmaceutical dispensing points in China was approximately five times that of the US (approximately 50 000 in the US and 140 000 in China) and the total number of wholesalers and distributors in China was close to 16 500 (Zhou, 2007). The total market share held by the top-three largest Chinese pharmaceutical distributors was only 42% as compared with that of the three leading distributors in the US, which account for 90% of the market share. Fragmentation of the wholesale market is commonly observed in most emerging markets with trends similar to that of China observed in India, Brazil, and other developing regions with large private sector markets for pharmaceuticals. Capital constraints faced by wholesalers coupled with corruption that favors certain wholesalers in purchasing by hospitals prevents large-scale consolidation in the industry. These factors do not allow scale economies to have their full effect and a fragmented wholesaling and distribution sector continues to exist.

Owing to the relative lack of distributors/wholesalers with nationwide coverage and reach, wholesalers often have to rely on regional subwholesalers or stockists, which adds another layer to the supply chain. High markups between multiple intermediaries in the distribution chain result in poor affordability and inability of the manufacturer to pursue growth strategies that rely on reaching larger proportions of the population at lower price points. Lack of information flows

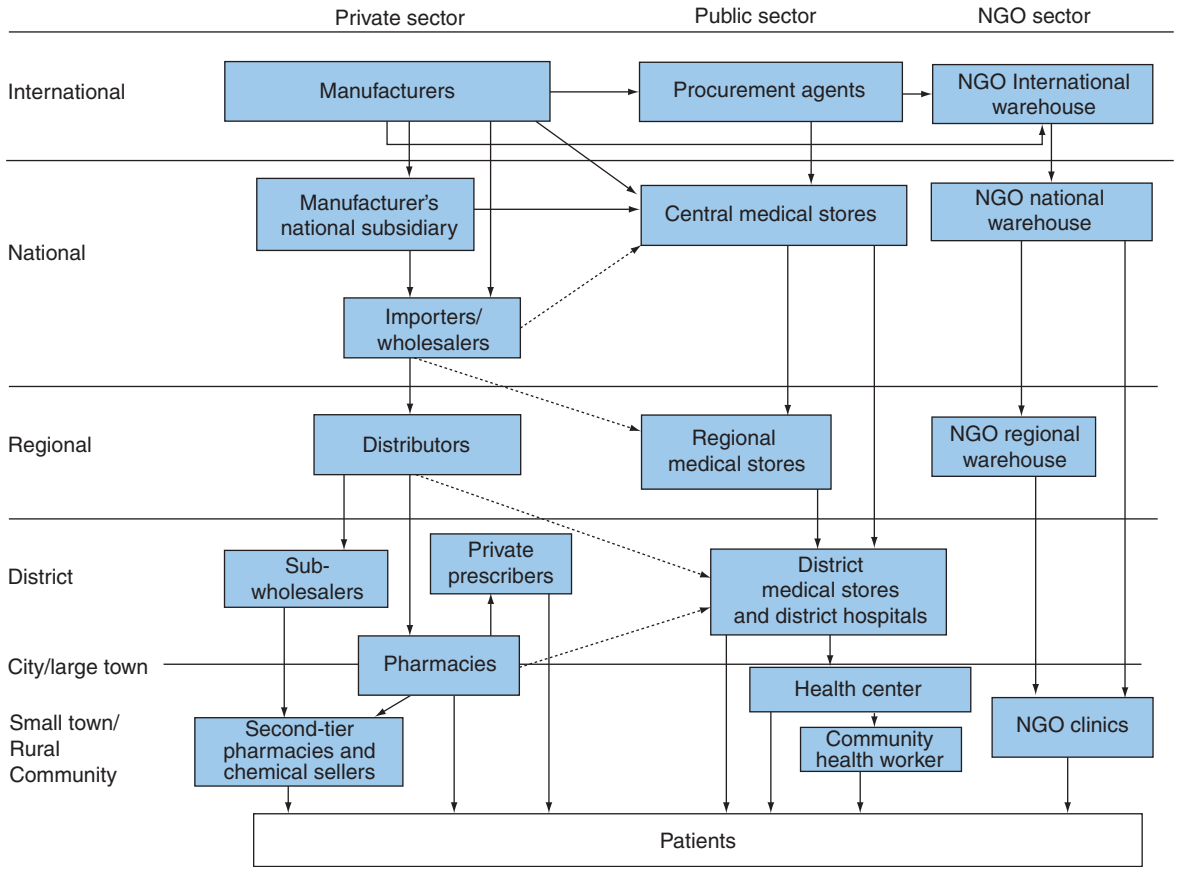

Figure 3 Distribution network for essential medicines in the public, private, and NGO channels in developing countries. Reproduced from Yadav, P., Tata, H. and Babaley, M. (2012). *The World Medicines Situation 2011: Storage and supply chain management*. Geneva: World Health Organization.

and opacity of information at different nodes in the system worsens the problem.

Apart from the private sector, in many low- and lower middle-income countries distribution of medicines also takes place in the public and nongovernmental organization (NGO)/faith-based sector (Figure 3).

In sub-Saharan Africa the predominant model is public sector distribution of medicines through a central medical store (CMS) which coordinates directly with regional or district stores. Transportation of goods is managed by a government/CMS owned and managed fleet. In addition to the CMS and regional or district stores, there are a number of primary and secondary distribution locations. These additional locations are present because of product- or program-specific supply chains setup by funding partners of the public sector. Increased availability of funding for the procurement of medicines over the past 5–10 years has highlighted weaknesses in the public sector medicine supply systems in some emerging markets.

Country case studies of Zambia and Jordan provide specific examples of distribution systems. The Zambian system represents a predominantly public sector medicine supply system. Jordan, by contrast, provides a private sector example. Each case outlines opportunities and challenges relevant to the previous distribution system review. The case study in Zambia outlines the difficulty the public sector has ensuring reliable supply and availability. In comparison the private sector in Jordan has difficulty in ensuring quality and price of medicines (Tables 2 and 3).

Distribution and delivery systems may also depend on the involvement of NGOs or faith-based organizations. Pharmaceutical delivery in this context is typically arranged according to the customer's own prearrangement, courier services, drug supply organization delivery services, or direct delivery services. Variations in the distribution structures for this specific channel are considerable across countries.

Generally, procurement, distribution, and the overarching provision of pharmaceutical goods within a particular country are disaggregated across groups with limited information sharing between public sector, private sector, and NGO/donor groups. As a result, pharmaceutical procurement and distribution strategies lack the coordination and efficiency to ensure optimal market function. High transaction costs and opacity in the market due to excess fragmentation leads to higher retail prices of pharmaceutical products. Although coordination and information sharing is a problem in developed countries too, a wider use of information technology and the presence of information consolidators such as IMS Health makes it somewhat easier.

Price is a key strategic differentiator between distribution chains in developed markets compared to those in emerging markets. Emerging market distribution chains often involve high markups between multiple intermediaries, thus making it

Table 2 Case study – Zambia

Public sector medicine supply distribution	*Distribution opportunities and challenges*
Government of Zambia stores and distributes medicines through a national medical store, Medical Stores Limited (MSL). Additional management support is contracted through Crown Agents	The MSL is engaged with typical demand expectations at each district. Such engagement enables the MSL to make discretionary decisions related to overestimated demand expectations after a period of product stockout. Although the MSL discretionary decision making may prevent a flood of stock from reaching the district level and expiry before potential use, it does not encourage transparent information flows
Districts are distributed medicines on a monthly basis by the MSL according to preset allocations of medicines. Allocations are based on reported demand at the district level, of medicines. Districts send orders directly to the MSL utilizing information on their current stock levels as well as a review the monthly stock availability report provided by the MSL	Additionally, districts often order according to the stock availability report provided monthly by the MSL. If district level representatives know an item is out of stock, their orders to the MSL will reflect what they expect to be able to receive, not necessarily the true demand. The MSL in turn, overtime, operates on accurate demand information
In addition to the demand information, all districts receive a standard, predetermined number of medicine kits every month

Table 3 Case study – Jordan

Private sector medicine supply distribution	*Distribution opportunities and challenges*
The private sector supply chain in Jordan consists of several large importers and wholesalers from international manufacturers/ suppliers. There are also a number of local manufacturers that produce generic medications, primarily for export to other countries. Medicines are sold within the country to private hospitals, retail pharmacies, and drug outlets	National regulation of all importers and wholesalers ensures that pharmaceutical products have the required quality storage facilities. The local manufacturing groups have improved lead times as well as higher overall responsiveness for distribution of medicines within the country; however, their larger market is in exporting medicines to other countries
Importers and wholesalers are often granted lines of credit from suppliers and manufacturers that vary in length based on the volume of orders. The longer the period of credit requested, the larger the order required per time period. As a result, importers and wholesalers are often responsible for the larger sized order, the interest on a line of credit as well as typical, distribution and related transportation costs of their goods within the country	Prices in the private sector tend to be high. Given the relatively small market for medicines in Jordan, it is often difficult for suppliers to reach economies of scale unless they tender to public and private sector facilities. The importers and wholesalers carry additional costs resulting from poor credit provisioning in the system and the high costs of credit

difficult to ensure affordability. Reaching a larger portion of rural segments of a population with alternative pricing models can be a successful growth and pricing strategy, however, without an organized and efficient distribution system, high costs and multiple sources of uncertainty prohibit the widespread use of such approaches. Poor coordination between retail pharmacies, drug shops, private clinics, and other informal service channels precludes a systematic method for targeting inexpensively priced medicines specifically to the poor. It may also preclude increasing revenue for manufacturers at the time as improving access. Newer distribution strategies that ensure better flow tracking will enable strategies for high sales volumes (a benefit to manufacturers) with lower margins (a benefit to the general population) rather than the current model of high margin, low volume.

Strategy for Emerging Markets

Success in emerging markets requires selecting prices that lead to high affordability by the population and revenue growth for the pharmaceutical company. In some cases partnerships or equity ownership in local companies helps achieve some of these objectives.

Differential Pricing in Emerging Markets

Pharmaceutical companies have used alternative pricing models to target emerging markets. Differential pricing is based on the economic principle that the greatest profit may be derived from pricing products closest to a consumer's maximum willingness and ability to pay for that product. Typically, consumers are placed within groups according to their wealth and products are distributed at different pricing tiers to the different groups. When well designed, differential pricing for pharmaceuticals can increase affordability for patients and increase profits for the pharmaceutical company. Many pharmaceutical companies have developed and implemented differential pricing schemes with success. GlaxoSmithKline (GSK) sells a portfolio of 25 medicines targeted at both CD and NCD areas at significantly lowered prices in

low-income countries. Merck also runs a differential pricing scheme for their diabetes medication Januvia. Novartis has developed a differential pricing scheme for insulin in developing countries. A distribution system with flow tracking and information sharing is essential to ensure medicines reach those communities most in need of preferential pricing.

Manufacturing Partnerships and Acquisitions in Developing Countries

Some pharmaceutical companies use joint ventures and acquisitions of local manufacturing companies as a strategy to achieve growth in emerging markets. This allows selecting prices more appropriate to the emerging markets without the risks of developed countries asking for the same prices as different companies manufacture the products. It also allows leveraging the marketing and distribution strengths of the local company. GSK has created a strategic partnership with Aspen Pharma, a South African generics manufacturer under which Aspen manufactures and distributes many of GSK's products in the region. GSK owns 18.5% equity stake in Aspen. Abbott Laboratories, another large multinational pharmaceutical company recently acquired Indian manufacturer Piramal Healthcare Limited to accelerate its growth in emerging markets.

Distribution Strategy for Emerging Markets

Apart from differential pricing, success in emerging markets will require distribution networks to reach areas, which the current distribution model does not reach. This may require major adjustments to current business models. Improving supply chain reach and efficiency will serve as the foundation of such a strategy. Although public investments in infrastructure will automatically increase supply chain reach and efficiency, it is unclear whether infrastructure growth will be able to match the needs to enable growth and coverage in a timely fashion.

Regional or Country-Level Prewholesaling Operations

The current structure of multiple wholesalers/importers purchasing directly from the manufacturer often creates supply chain inefficiencies. Manufacturers often sell to and invest in a single wholesaler to save on transaction costs. Selling to one wholesaler limits sales volumes and geographical reach. Given the large number of wholesalers this leads to the practice of horizontal selling where the single wholesaler then sells the manufacturer's products to other wholesalers and then on to subwholesalers and retailers. Sales between wholesalers at the national level often add an additional transaction cost and mark-up to the final retail price.

Even though having additional intermediaries usually leads to higher markups, introducing a prewholesaling operation may help aggregate and organize a highly fragmented wholesaler base. Prewholesalers allow manufacturers to distribute their product to multiple wholesalers and achieve higher volumes of sales, product reach, and market penetration without necessarily adding to the costs of creating a company-owned distribution or commercial entity. A prewholesaler could also reduce markups between national wholesalers as well as reduce long lead times for orders improving the efficiency and financial stability of wholesalers who often have to find expensive working capital credit to cover lead times. In many instances the benefits (i.e., economies of scale and reduced transaction costs) outweigh the costs (i.e., increased margins) and a prewholesaler model helps improve overall supply chain efficiency.

New Retail Pharmacy Formats

Enhanced supply chain reach would require working with newer retail pharmacy formats. Instead of concentrating on a few hospitals and large pharmacies, growth will come from increasing points of sale. This would require accepting that not all retail points of sale for medicines will have the form, shape, and structure of a developed-country pharmacy. Regulatory hurdles will have to be carefully negotiated in making this change. Also cost for transit will have to be reduced significantly to reach a larger number of outlets without compromising margins. Health microfranchises represent a specific network of retail points of sale, which may be employed in the development of an optimum distribution network. These microfranchises are often developed as a means to improve access and quality of medicines and prescribing practices within emerging markets. Microfranchises are technically a part of the private sector, however, they are often accredited and maintain a certain quality standard regulated by the public sector. Accredited Drug Dispensing Outlets (ADDOs) in Tanzania, CARE shops in Ghana, and Child and Family Wellness (CFW) Shops in Kenya represent three similar microfranchise models that provide extensive sales networks, with a specific emphasis on serving remote communities.

New Models for Supply Chain Information Collection

Information flows in the supply chain where a third party information broker collects information about sales from each point in the supply chain may take years before it develops in many of the emerging markets. New models for collecting supply chain information should be examined for their feasibility. There are many new models that utilize technology to share real-time information throughout distribution networks. Logistimo, a web service run on mobile phones and Internet browsers, offers supply chain management tools specific to emerging markets. Similarly, All Indian Origin Chemists and Distributors Limited (AOICD) offers technology-based logistics services to pharmaceutical companies to improve supply chain and distribution network visibility and efficiency. SMS-for-Life is another example of technology (using SMS text and electronic mapping) that has effectively facilitated comprehensive and accurate stock counts of medicines at health facilities by district-level staff. SMS-for-life is a public–private partnership between Novartis, Vodafone, IBM, Ministry for Health of Tanzania, and the Roll Back Malaria Partnership.

Partnerships with Governments and Other Agencies

Leveraging public-sector resources to reach areas that a company cannot directly influence is another method for

improving reach. The resources required for expanding supply chain reach often are beyond the means of a single firm. Poor infrastructure in rural markets, such as roads, electricity, and telecommunications, create barriers to entry for many large manufacturers. The absence of mass media and communication platforms makes demand creation and awareness building among patients and community members very expensive, and inhibits the growth that can be achieved in rural markets. Partnerships should be formed with the government (at federal, state, and local levels) where common goals can be met through public–private partnerships.

Note that civil society and consumer groups often view new business models with mistrust. Partnering with organizations that have higher trust and confidence of the community ensures that the innovative distribution model can survive the early days of infancy without backlash from the civil society organizations and community groups because of misconceptions about the objectives of the model, etc.

Distribution Strategies of the Generics

Many small and large generic companies have achieved significant rural penetration in emerging markets. Carefully examining their distribution strategies can be a useful exercise while formulating a new distribution strategy. Many generic companies have set up rural-focused distribution channels and developed rural sales forces with locally trained staff. Mankind Pharmaceuticals and Cipla represent two such companies that have increased their product reach both domestically and within other countries through targeted distribution channels. This has given them stronger reach into both rural healthcare providers and rural pharmacies and drug shops. Some innovative pharmaceutical companies have also focused on the rural markets through patient education. The Arogya Parivar program from Novartis involves health educators, usually local women, who are recruited and trained to raise awareness about specific diseases. The initiative utilizes a special sales force to ensure that medicines are available in the most remote locations. The above strategies may not be sustainable for all companies, especially for companies with fewer and more costly products in their portfolio.

Conclusions

Emerging markets now represent a significant portion of the global pharmaceutical market and are growing at much faster rates than the more mature developed-country pharmaceutical markets. Pharmaceutical markets in emerging markets tend to be very different than developed markets with private sector out-of-pocket expenditures leading financing in Asia, some parts of Africa, and Latin America. Additionally, publicly funded medicines tend to be more prominent in other emerging market regions, especially within the African context. The nature of the distribution system used for pharmaceuticals in emerging markets is different from developed-country pharmaceutical markets in several ways. Successful growth strategies for emerging markets will depend on expanding the reach of supply chains as well as increasing its overall efficiency. This article presents strategies used for achieving those goals.

Pharmaceutical Marketing and Promotion

DM Dave, Bentley University, Waltham, MA, USA

Introduction

Between 1980 and 2010, expenditures on prescription (Rx) drugs in the US increased almost 1500%, from $53 to $831 per person (see Figure 1). Spending on Rx drugs has generally outpaced the growth in national health expenditures, doubling its share to 10%, and making it one of the fastest growing components of health care costs (see Figure 2). The growth in the share of prescription drug expenditures has coincided with the growth in pharmaceutical promotion, which increased from $11.4 billion in 1996 to $29.9 billion in 2005 (Donohue *et al.*, 2007) and $32.3 billion in 2008 (SK&A, 2011). In recent years, both Rx drug spending and promotional spending have leveled off, however, due to patent expiration on certain major drugs (such as Advair, Prevacid, and Lipitor) that are not replaced by new on-patent drugs.

Promotion of prescription drugs is generally limited to drugs on patent. It includes direct-to-consumer advertising (DTCA) on broadcast and print media as well as direct-to-physician promotion (DTPP) through visits by company representatives to providers (known as detailing), free samples provided to physicians, and advertising in professional journals. Although DTPP still comprises most of the promotional budget (approximately 83% in 2011; SK&A, 2011), the largest relative increase in promotion between 1995 and 2005 resulted from the expansion of DTCA into broadcast media. The share of total promotional spending allocated to DTCA increased from less than 1% in the early 1990s to 8.6% in 1996 and 14.5% in 2003 (see Figure 3), and has remained relatively stable since.

Pharmaceutical promotion remains controversial and is facing increased public scrutiny. At the heart of the debate is whether such marketing is welfare-enhancing. The pharmaceutical industry claims that both consumer-directed and physician-directed advertising educates patients and providers on potential treatment options, opens up lines of communication between the patient and the physician, and can even increase patient–physician contact or expand appropriate treatment for undertreated conditions, consistent with an 'informative view' of advertising. Congressional leaders and consumer groups have contended that such promotion may raise prescription drug costs. Providers may be induced into prescribing more expensive (and/or possibly inappropriate) drugs in the presence of cheaper and equally effective alternatives, consistent with brand differentiation and a 'persuasive view' of advertising.

Growth in prescription drug spending is broadly driven by increases in utilization and price, and shifts in the composition of drugs being used, all of which may be impacted by marketing. A comprehensive assessment regarding the welfare effects of pharmaceutical advertising and promotion requires information on three broad but related issues: (1) effects on primary industry-wide versus selective brand-specific demand; (2) effects on price; and (3) effects on competition. The next section briefly discusses the historical background on pharmaceutical promotion followed by a conceptual framework of advertising to help guide welfare implications, before turning to the empirical evidence with respect to each of the three issues noted above.

Background

The 1962 Kefauver–Harris Amendments to the 1938 Federal Food, Drug and Cosmetic Act shifted jurisdiction on regulating drug promotion from the Federal Trade Commission to the Food and Drug Administration (FDA) and outlined the

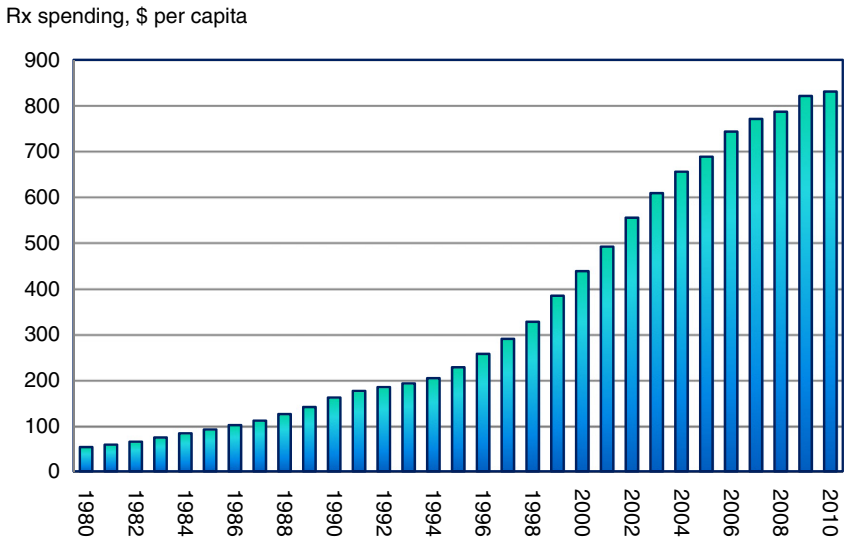

Figure 1 Prescription drug spending in the US. Data from Centers for Medicare and Medicaid Services (CMS).

basic requirements for acceptable prescription drug marketing (see Berndt, 2006; Dave and Saffer, 2012). Prescription drug promotional materials cannot be false or misleading, must provide 'fair balance' coverage of risks and benefits of using the drug, must provide a 'brief summary' of contraindications and effectiveness, and must also meet specific guidelines for readability and size of print. For a number of years, the FDA interpreted the 'brief summary' provision as requiring the advertiser to provide the detailed information contained in the drug's FDA-approved product labeling, thereby confining consumer-directed advertising to newspapers and magazines. There were two conditions under which firms could bypass the

'brief summary' provision: (1) if the advertising were 'help-seeking' and mentioned only disease symptoms and not any drug name, or (2) if the advertisement is a 'reminder' and mentions the drug name or its dosage without specifying what the drug is intended to treat.

Expansion of advertising into broadcast media was precipitated by the FDA's clarification of its regulation of consumer-directed advertising, particularly for broadcast advertisements. After a test period and request for public comment starting in 1995, the FDA approved the broadcast DTCA draft guidance in August 1997, eliminating the requirement that advertisements present the entire 'brief summary' taken from the product label insert. In August of 1999, the FDA further clarified the risk information requirements. Advertisements needed only to include 'major statements' of the risks and benefits of the drug, along with directions to information sources in addition to a physician, such as a toll-free phone number, a website, or a print advertisement. This shift removed a major barrier that had initially made television and radio advertising infeasible and had initially relegated consumer-directed advertising to print media only.

Between 1996 and 2000, DTCA was the fastest growing component of pharmaceutical promotion, growing at an average annual rate of 33% for gastrointestinal, cholesterol, insomnia, and antiarthritic/analgesic drugs. In comparison, detailing and sampling grew at annual rates of 12–13%, whereas professional journal advertising remained virtually unchanged (Dave and Saffer, 2012). Though the FDA's shift in guidelines specifically applied to broadcast advertising, there was also an increase in nonbroadcast advertising starting in 2000. This may be indirectly related to the FDA's new guidelines which required only 'major statements' of the drug's risks and benefits along with directions to alternate sources for more complete information. The feasibility of using television and radio advertisements may have raised the marginal product of other nonbroadcast forms. Indeed, broadcast advertisements often direct consumers to concurrent advertisements in magazines or newspapers for further information on the drug's usage and side effects.

Drugs intended to treat chronic conditions such as cardiovascular, mental health, respiratory, and erectile dysfunction conditions tend to be among the most heavily advertised. For instance, the top 5 advertised drugs in 2010 were Lipitor (indicated for high cholesterol), Cialis (erectile dysfunction), Cymbalta (mental health), Advair (asthma), and Abilify (mental health) (Bulik, 2011). The top 25 advertised drugs in 2010 (noted in Bulik, 2011) accounted for about $2.8 billion in consumer advertising expenditures or approximately two-thirds of total DTCA – suggesting a highly skewed distribution in consumer ad spending.

Recent years have witnessed a downturn in DTCA (see **Figure 2**), and total pharmaceutical sales force in the US has been cut by approximately 30% from its peak. These cuts partly reflect fewer drug launches compared to the late 1990s, and an increasing share of new drugs that are targeted at specialist physicians (for instance, cancer and orphan drugs developed specifically to treat rare conditions). Optimal promotion of such drugs may not include DTCA and, by definition, needs fewer sales representatives than the major primary-care drugs of the 1990s.

Conceptual Framework

This section draws on Bagwell (2007), which provides a comprehensive review of the economics of advertising. It is often presumed that the average consumer is responsive to advertising and promotion. However, one of the key questions in markets for healthcare inputs is whether advertising raises 'selective' or brand-specific demand versus 'primary' or industry-wide demand. The answer to this question has normative implications and relevance for public health. For instance, is advertising by the pharmaceutical industry combative and solely reflective of a market-share transfer or does it also convey information and lead to an overall expansion of the market? As a starting point, it is helpful to draw upon three principal views that have emerged with respect to why consumers may respond to advertising: (1) persuasive, (2) informative, and (3) complementary.

For firms operating under a hybrid market structure such as monopolistic competition, advertising can help them to differentiate their products and alter consumers' tastes and preferences. Under this 'persuasion' hypothesis, brand-level demand would not only shift outward in response but also become relatively less elastic, possibly leading to higher prices. Advertising-induced product differentiation and creation of brand capital may deter entry and enhance the monopolistic power of incumbent firms, especially if these established firms also enjoy scale economies in advertising and production. Thus, advertising can have anticompetitive effects under the persuasion view.

Consumers may also respond to the potential information content communicated through advertising. For instance, in markets characterized by imperfect information, advertising can effectively reduce search costs by conveying direct or indirect information regarding the existence, quality, price, and other attributes of products. With respect to pharmaceuticals, for instance, consumer advertisements may inform individuals of treatment options that they did not know existed, help them to diagnose their symptoms and seek out medical care, and remind patients to take their medications as prescribed. Similarly, detailing may provide valuable information to physicians concerning the drug's indications and contraindications allowing them to make better-informed choices. In such markets, advertising emerges as an endogenous response and solution to the information asymmetry.

There is also a distinction between search goods, wherein the consumer can determine quality before purchase though perhaps after incurring some search costs, and experience goods, wherein the consumer can assess quality only after consumption. Advertising intensity is predicted to be higher for experience goods because it can signal product quality and address the informational imbalance. The information content can also enhance the match between products and buyers in markets where consumers have heterogeneous valuations.

In contrast to the persuasive view, advertising plays a more constructive role under the informative view, and may also have pro-competitive effects. The firm's demand becomes relatively more elastic and price dispersion in the market is reduced. Advertising can thus promote competition among incumbent firms and facilitate the entry of new firms as well as new products.

The third view of advertising provides a framework under which advertising is complementary to the advertised product, and also bridges back to the informative view. For instance, if advertising enables consumers to produce information at lower cost, then consumers can more efficiently convert market goods into valued final commodities. Under this framework, a higher level of Rx drugs advertising can raise demand because the consumer now believes that he/she can obtain a greater output of the final commodity (health) from a given input of the advertised good. And, even if advertising is uninformative, it may still play a constructive role because consumers may value it directly.

The upshot of this discussion is that no single view of advertising is applicable in every setting. Furthermore, from a public health standpoint, the debate centers on whether advertising reflects a brand-switching process or a market expansion process, especially in relation to the market for health inputs. Although this is not to suggest that all brand-switching advertisements are socially wasteful (because some brand-switching may represent a better match of product attributes and consumer demand) and all market expanding advertisements are good (especially because advertisements that expand the market for unhealthy inputs may have adverse internalities as well as externalities), this dichotomy presents a useful starting point to frame some of the effects of advertising. Because advertising can affect both selective (brand-centric) as well as primary (market) demand under all three views, the question cannot be resolved based on theory alone and empirical evidence needs to bear upon the specific demand effects of advertising.

With that said, markets for over-the-counter (OTC) and prescription (Rx) medications have some predominant experience attributes. Thus, advertising intensity for the pharmaceutical industry (approximately 20% of sales) tends to be higher relative to the average industry (4–5%). These views of advertising also highlight potential effects on price, which depend on the extent to which advertising expenditures raise operating costs, affect price elasticity of demand, and allow firms to take advantage of scale economies. The concentration effects of advertising – that is, whether it facilitates entry or whether it augments the monopolistic power of established firms – depends on whether advertising is purely persuasive in nature and leads to spurious brand differentiation or whether it redresses imperfect information and makes demand more elastic.

It should also be noted that these different views of advertising may fit different forms of promotion, and are not necessarily mutually exclusive. For instance, detailing plays a role in educating providers about newer drugs and may have information value early in a product's life cycle, whereas later in the life cycle its role is predominantly persuasive, chiefly relegated to delivering samples and reminders. DTCA and detailing, by differentially targeting consumers versus providers, may also inherently play different roles in affecting primary versus selective demand. Thus, there may be a great deal of heterogeneity with respect to how consumer- and physician-directed promotion affects demand, with possible interactions with each other as well as with competition and drug characteristics. Because DTCA (and to some extent detailing) can potentially increase sales without the company having to offer a lower price or superior quality in trying to get their drug onto a preferential position with the insurer, DTCA may have the ability to undermine the insurer's formulary (Wosińska, 2002). Thus, interactions between DTCA effects and the drug's formulary position as well as between DTCA and price are also possible.

Empirical Evidence

Econometric studies have estimated the effects of DTCA and DTPP on pharmaceutical sales, patient adherence, demand for primary care, and, in a few instances, on pharmaceutical prices. Most studies have estimated an 'average' response to promotion, and very few studies have considered heterogeneity in the effects with respect to formulary placement, drug characteristics, or advertising medium. Estimating causal effects of promotion on sales and price is further complicated by potential bias due to structural endogeneity or reverse causality; promotion may affect demand, but promotional spending may also be a function of revenues.

In addition, there is potential bias from statistical endogeneity or nonrandom selection; observed and unobserved heterogeneity across Rx drugs may be driving promotion as well as sales, and prices. In the multiperiod optimization framework considered by Bhattacharya and Vogt (2003), the dynamic profit-maximizing strategy for a firm is to initially employ a relatively high level of promotion and set a relatively low price to increase current demand by raising consumers' and physicians' stock of knowledge regarding the drug. As knowledge is costly to acquire, physicians' prescribing patterns tend to be sticky and consumer use may also be sticky especially for chronic conditions. Thus, in addition to sales, price, and promotion affecting each other, they are also partly governed by the drug's life cycle and by other drug-specific unobservables, including formulary placement and implied consumer cost-sharing.

Alluding to such potential selection effects, Iizuka (2004) studies 169 brand-name drugs over 1996–99, and finds evidence that higher quality drugs (as measured by the FDA's priority rating) are more likely to engage in DTCA as are drugs with a larger potential market size (measured by the prevalence rate of certain chronic conditions from the National Health Interview Surveys). DTCA spending tends to be lower when there is a generic competitor on the market. Thus, advertised drugs are systematically different from non-advertised ones, and these differences may confound the causal relationship between promotion and demand. The more sophisticated of the studies address these concerns through instrumental variables and fixed effects.

Demand Effects

Market expansion versus product-level effects of DTCA

Rosenthal *et al.* (2003) study brands in five therapeutic classes using an aggregated US monthly time series from August 1996 to December 1999. Their results indicate that the primary impact of DTCA lies in expanding the total market size rather than affecting product market share. Specifically, at the level of

the therapeutic class, DTCA spending positively impacts sales with an estimated elasticity of 0.10. Although they do not report any significant effects of brand-specific DTCA (or detailing) on brand-specific market shares, they do caution that it may be "premature to conclude that DTCA only affects class level sales, and not individual product sales." The models estimate only a contemporaneous effect owing to the short span of the time series. This is likely to be a lower-bound estimate because advertising effects in the prescription drug market may be especially prolonged due to the multistage process, with time lags between ad exposure, scheduling a physician visit, and obtaining and filling the prescription. Wosińska (2002) shows the importance of the drug formulary in driving DTCA effects (with advertising having a greater effect on demand for drugs that have a preferential position on the insurer's formulary), and notes that the inability to differentiate across the formulary status may also explain why Rosenthal *et al.* (2003) do not find a market share effect of DTCA.

The specifications in Rosenthal *et al.* (2003) include class fixed effects, but do not control for unobserved heterogeneity across drugs within a class through drug-specific fixed effects. The study uses time to patent expiration, an indicator for 1997 (reflecting the FDA's change in policy), and interpolated monthly television advertising costs per minute as IVs that can plausibly be excluded from the sales equation. Some studies, however, have shown that the drug's life cycle is an important determinant of sales, which suggests that the product's life cycle may not be an appropriate instrument for advertising and promotion (Bhattacharya and Vogt, 2003; Dave and Saffer, 2012). Nevertheless, Rosenthal *et al.* (2003) provide one of the earliest and seminal analyses of DTCA following its resurgence in the late 1990s, and several subsequent studies confirm their market-expansion effect of DTCA.

Iizuka and Jin (2005) merge individual-level data from the National Ambulatory Medical Care Surveys over 1995–2000 with monthly DTCA. Similar to Rosenthal *et al.* (2003), their effect is identified from variation in DTCA across drugs within a given class (and over time). They also utilize an IV procedure, employing the same drug company's DTCA expenditures in other unrelated drug classes as an instrument for DTCA in a particular drug class. Consistent with a market-expansion effect, they find that each $28 increase in DTCA (which includes current advertising and a depreciated sum of past advertising) leads to an additional physician visit within a year where an Rx drug from the class is prescribed.

The market expansion effect suggests that some consumers, whose medical conditions were previously undiagnosed or undertreated, may benefit from the information provided by DTCA. Consumers, becoming aware of new treatments, may be incentivized to seek out physician care. However, the market expansion effect may also partly reflect inappropriate care, if advertising increases the use of drugs with uncertain safety profiles. Pointing to perhaps such an increase in misuse, David *et al.* (2010) find that higher levels of DTCA lead to increased reporting of adverse medical events for drugs related to certain conditions such as arthritis and depression, whereas detailing reduces the adverse event rate for high cholesterol and allergy drugs. They conclude that the effect of promotion and advertising in improving communication between patients and physicians may be welfare-enhancing if physicians can identify who is the best match for treatment. This is feasible in the case of cholesterol and allergy medications by the existence of simple diagnostic tests. In cases where there is greater uncertainty regarding diagnosis or acceptable standards for care, advertising and promotion may hinder the role of the physician as a mediator between consumer-directed promotion and proper use.

In addition to a market expansion effect, few studies do find evidence of some DTCA-induced brand-switching. Wosińska (2002), in a study of prescription claims for cholesterol drugs for Blue Shield of California over the period 1996–99, finds that current DTCA raises market share though this effect is limited to drugs that have preferential status on the insurer's formulary. Thus, it is possible that physicians suggest and prescribe advertised formulary drugs when patients inquire about advertisements for drugs that are not on the formulary. Dave and Saffer (2012) utilize monthly data on all prescription drugs in four major therapeutic classes from 1994 to 2005, exploiting the period enveloping the FDA's shift in regulations as a natural experiment and exogenous shock to DTCA. Similar to Iizuka and Jin (2005), they construct a stock of depreciated DTCA spending over the past year. Models account for unobserved heterogeneity across drugs and potential selection into DTCA by including drug-level fixed effects and various time-varying confounders including physician detailing and sampling, the drug's life cycle, competitors' advertising, generic competition, and FDA approval of new indications for the drug and labeling/marketing warnings. This study underscores the point that it is important to separately assess broadcast and nonbroadcast DTCA due to differences in their content, growth trends (because the FDA's policy change specifically affected broadcast DTCA), and their marginal impacts. They find that broadcast DTCA does significantly impact own-sales and market share with a relatively small elasticity of 0.10, though this response is higher relative to nonbroadcast DTCA. There is also some evidence that class-level DTCA may raise sales for the nonadvertised drugs. Assuming that physicians are prescribing an equally effective drug, this may be a spillover benefit of DTCA in some cases because nonadvertised drugs tend to be older and also cost less.

Prior studies, which at times found conflicting evidence on the impact of own-DTCA on own-sales, may have been confounded by aggregating broadcast and nonbroadcast forms. In periods predating the FDA's policy shift, virtually all DTCA was relegated to nonbroadcast media, whereas starting in 1998 and 1999 advertisements in broadcast media became the primary form of DTCA. Therefore, the effect of total DTCA, being a weighted average of the effect of the two separate forms, would be expected to vary depending on the time period under study and the relative composition of total DTCA between nonbroadcast and broadcast media.

Directly bypassing the potential endogeneity of advertising, Kravitz *et al.* (2005) examine how DTCA impacts the prescribing behavior of antidepressants in a randomized control trial (RCT) setting. Standardized patients, mostly professional actors, were randomly assigned to make 298 unannounced visits to family physicians and general internists. The patients made a specific brand request (referring to a DTC advertisement), a general drug request, or no request. Physicians

prescribed antidepressants for the patients portraying general depression in 54% of the visits, including 76% of visits where the patients made a general request for a drug, 53% of visits where a specific drug was mentioned, and 31% where no drug was mentioned by the patient. Patients were prescribed Paxil in 27% of the visits where they explicitly mentioned the drug, compared to 4% where there was no request for a drug and 2% where the patients made a general request for a drug. For patients portraying adjustment disorder, where antidepressants confer little or no benefits, 37% of patients requesting Paxil received a prescription for the drug, compared to 10% of patients who made a general drug request and none for patients who did not request any drugs. This study points to the role of brand-specific DTCA in raising own-demand by leading to a prescription for that brand, as well as in raising overall demand for drugs in the therapeutic class. The authors note that DTCA "may have competing effects on quality, potentially averting underuse and promoting overuse."

Observational and survey-based studies suggest that DTCA can educate consumers about health conditions and available treatments, though it may also have the potential to be misleading or uninformative. Hollon (2005) summarizes some of the survey-based evidence and notes that between 25% and 33% of adults annually have had a discussion with their physician regarding a health issue after having seen an advertisement. Although DTCA can stimulate a new diagnosis (approximately 25% of patients with DTCA visits), potentially leading to treatment of previously undertreated conditions, almost 80% of physicians report that DTCA encourages patients to seek treatments that they may not need. Thus, DTCA can mediate the patient–physician relationship through reeducation and informative discussions as well as through a likely fulfillment of the patient's request for a specific drug.

Additional evidence on the demand effects of DTCA is provided by econometric studies that examine patient adherence. Consistent with the informative view of advertising, these studies underscore an important health-promoting benefit of DTCA in reminding patients to adhere to their drug therapy as prescribed. For instance, Calfee *et al.* (2002) utilize a national monthly time series of statin prescriptions, between 1995 and 2000, and find television advertising expenditures on statins are associated with an increased proportion of existing patients who were successfully treated (existing patients with a high-cholesterol diagnosis whose total cholesterol fell below 200 mg dl^{-1}). This effect combines both a compliance effect and also a market expansion effect as successfully treated patients spread the word about the effectiveness of statin drugs and raise demand among untreated or undertreated patients.

Effects of physician-directed promotion

In addition to consumer advertising, studies have also examined the impact of promotion aimed at healthcare providers, which historically has been the primary form of promotion used by the pharmaceutical industry. As uncertainty regarding the efficacy of the drug and its safety profile tends to be high in the early stages of the drug's life cycle, DTPP can play an informative role following a drug's launch. After some point, DTPP largely takes on a persuasive role by providing samples and reminders.

Studies have generally found that the marginal impact of detailing on market share is significantly larger relative to that for consumer-directed advertising. For instance, Dave and Saffer (2012) find significantly larger sales-DTPP elasticities (0.51 for detailing and 0.34 for sampling) compared to the sales-DTCA elasticity (0.13). Wosińska (2002) also reports that the effect of detailing on market share is approximately five times higher relative to the effect of DTCA.

Beyond estimating mean effects of DTPP, some studies further assess interactions between the various marketing elements and also consider differential effects across various market, physician, and product-level characteristics. Narayanan *et al.* (2004) utilize monthly data on three branded second-generation antihistamines (and one aggregated measure of all other first-generation and other antihistamines) spanning April 1993 through March 2002. They find that detailing primarily and positively affects brand share, whereas DTCA has a significant positive effect on both brand shares and class sales. The return on investment is much larger for detailing than for DTCA, a feature that they attribute to the fact that detailing allows for a much more targeted promotional effort relative to DTCA. They also find evidence of synergy between the two forms of promotion. For instance, a sales call to a physician's office has a higher marginal impact on brand share when combined with DTCA. Studies also find that sampling and detailing are highly complementary, and that sampling can raise the effectiveness of detailing; detailing is also found to be generally more effective when targeted towards specialists followed by primary-care physicians.

International evidence

Similar to all industrialized nations except for the US and New Zealand, Canada prohibits DTCA for prescription medications. However, approximately 30% of the television viewing of Canadians in English-speaking provinces consists of US satellite and cable TV, which carries consumer-directed Rx drug advertisements (Mintzes *et al.*, 2009). Law *et al.* (2008) study the impact of such US-based advertisements on Canadian prescribing rates for three drugs (Enbrel for rheumatoid arthritis, Nasonex for allergy symptoms, and Zelnorm for irritable bowel syndrome (IBS) in women) in English-speaking provinces relative to French-speaking Quebec. The study finds only short-lived positive effects for Zelnorm, and no significant effects for the other two drugs. Zelnorm is the only drug approved for its indication in Canada, whereas the other two drugs had competitors. IBS is also underdiagnosed and undertreated, in which case DTCA can be informative. However, Zelnorm tends to be measurably effective in only approximately 1 out of 17 patients, which may explain why the effects of DTCA are short lived. Insignificant effects of DTCA on the prescribing rates for Enbrel may be because the drug requires a specialist referral and subcutaneous injection. Thus, similar to studies from the US, the impact of DTCA on drug use appears to be variable and dependent on the characteristics of the advertised drug and the medical environment.

Two major shifts in DTCA-related administrative policy occurred in Canada. In 1996, a redefinition of the boundary between 'information dissemination' and 'advertising' by Health Canada provided tacit approval for unbranded disease-oriented 'ask your doctor about available treatments'

advertisements. In 2000, manufacturers were allowed to use 'reminder advertisements' that state a brand-name but do not mention any indications, or make any therapeutic claims. Though it is not meant to imply a causal effect of this shift in policy (because many new drugs were also launched over this period), total inflation-adjusted DTCA in Canada increased from under $1.6 million (Canadian $) in 1995 to more than $22 million in 2006 (Mintzes *et al.*, 2009). Similar to the US, consumer advertisements in Canada are highly concentrated on relatively few products for treating chronic conditions. Although there has been no rigorous study on how such advertisements have impacted demand and related outcomes to inform on welfare effects, many of the heavily advertised drugs in Canada have US 'black box' warnings and have been subject to Health Canada safety advisories (Mintzes *et al.*, 2009). Thus the safety profile of some of the highly consumer-promoted drugs is questionable.

Unlike most other developed countries, New Zealand had never enacted preemptive legislation to preclude pharmaceutical DTCA, and such advertisements are implicitly permitted under conditions set by the Medicines Act and the Medicines Regulations. As in the US, consumer-directed advertising grew tremendously in New Zealand during the late 1990s. Toop *et al.* (2003) conducted a survey of 1611 general practitioners (GP) in New Zealand, with results qualitatively similar to survey-based evidence from the US. They find that 90% had experienced DTCA-generated consultations. Furthermore, 79% reported that patients frequently inquired about DTC-advertised medications, and 44% noted that they had switched to or started treatment with medicines they felt offered little added benefit over drugs they would normally use as a result of DTCA. Approximately 12% of the respondents believed that DTCA is a useful means of educating consumers about the drugs' risks and benefits, 16% felt that DTCA helped their patients get necessary medical care at an earlier stage, and 13% reported DTCA improved adherence.

Chintagunta and Desiraju (2005) report sales elasticities with respect to detailing and price for three selective serotonin reuptake inhibitor (SSRI) antidepressants (Prozac, Zoloft, and Paxil) across five markets (US, UK, Germany, Italy, and France), based on quarterly data from 1988 to 1999. The authors estimate IV models, instrumenting price with current and lagged values of the producer price index for preparations and psychotherapeutics and cost measures from the companies' balance sheets, and instrumenting detailing with the current and lagged values of wage index. Own-detailing is found to have a significant and positive impact on own sales for all three drugs in all markets. The elasticity magnitudes are generally similar for the other four countries, ranging from 0.17 to 0.59, though several orders of magnitude higher for France (2.32–2.43). The authors note that this may be due to a large marginal benefit of SSRI-related detailing in France, because pre-SSRI antidepressants had not been actively detailed. Cross-detailing elasticities are generally negative and smaller in magnitude, which is consistent with the persuasive view of advertising; detailing primarily affects selective demand and leads to brand-switching.

Berndt *et al.* (2007) present a study of the rate at which new drugs are promoted and diffused, across three therapeutic classes (antihypertensives, antidepressants, and antiepileptics) and ten countries. They find that the largest level of detailing occurs for antihypertensives, followed by antidepressants and then by antiepileptics. Spain has the highest rate of detailing for all three classes, consistent with its high rate of utilization growth of these drugs. US detail counts per capita are close to the median in their sample. Cross-national differences further indicate that it is not necessarily the case that new drugs in the US are intensely detailed over older drugs. The authors further model the diffusion process through two separate components, including the total drug therapy days per capita and the new-drug expenditure share, and estimate this framework via the Almost Ideal Demand system for the three drug classes. They generally find insignificant or very small detailing elasticities with respect to aggregate utilization for all three classes. This is consistent with the US-based studies, which generally find that detailing impacts selective brand-specific demand rather than primary market demand. However, with respect to the new-drug expenditure shares, the results show positive and significant new-detailing elasticities. The cross effect of detailing on older drugs is negative. Although the authors caution that the promotion intensity is endogenous, their results suggest that detailing can promote the diffusion of newer drugs.

Summary: Demand effects

A number of robust empirical findings emerge from these studies on the demand effects of pharmaceutical promotion. First, both the econometric as well as survey results indicate positive demand effects of DTCA. Survey results (for instance, Hollon, 2005) indicate that physicians do consider specific drug requests initiated by the patient. Although in many cases physicians appear to fulfill these requests, in other cases they take into account acceptable standards of care in prescribing an alternative drug or not prescribing at all (Kravitz *et al.*, 2005). These results are consistent with DTCA having both primary market-expansion effects and also selective brand-specific effects.

The econometric literature is able to further pinpoint the relative strength of these two effects. Studies find consistent evidence of a significant class-level market expansion effect of DTCA. Dave and Saffer (2012), for instance, find that class-level DTCA may raise the sales for lower cost, nonadvertised drugs. Thus, DTCA may bring a patient to the doctor's office, but in some cases the doctor is prescribing a lower-cost alternative. Consumer-directed promotion raises class-level sales, by encouraging patients to seek medical help, encouraging patient–physician contact, and promoting compliance with Rx drug therapy. This is reflective of the informative view of advertising, wherein DTCA plays at least some role in educating consumers and expanding treatment among those previously under-treated. However, at the same time, there is some evidence (Kravitz *et al.*, 2005; David *et al.*, 2010) that the increase in primary demand may partially reflect overtreatment or possibly inappropriate care, especially for conditions where greater uncertainty exists regarding diagnosis and acceptable standards for care. The evidence relating to the effects of own-DTCA on the specific drug's market share is mixed, though some recent studies (Dave and Saffer, 2012; Wosińska, 2002) suggest significant but relatively small

elasticity magnitudes. These studies also point to considerable heterogeneity in these own-DTCA effects, depending on the drug's formulary position, level of DTPP, other competitors in the therapeutic class, characteristics, and the composition of its DTCA. The literature frequently views such 'business-stealing' advertising as less benign, though to the extent that it results in a better match between the consumer and the product it may also confer some welfare benefits (Berndt, 2006). However, because higher-advertised drugs tend to cost more on average and to the extent that such advertising results in a higher-priced product capturing market share, it may raise healthcare costs and confer negative spillover effects. Though, here too, the effect is ambiguous if price and quality are positively correlated. Overall, stronger market expansion effects combined with weaker and mixed evidence on selective brand-specific demand effects of DTCA suggest that consumer-directed advertising is perhaps more reflective of the informative view of advertising over the persuasive view.

This literature also consistently finds that the effects of physician-directed promotion, such as detailing and sampling, on own-demand are significantly larger relative to consumer-directed promotion. This is consistent with detailing primarily driving market share, as against DTCA driving class expansion. Detailing, sampling, and medical journal advertising can shift treatment away from nondrug therapy toward the promoted drug, and can raise the number of patients treated with drug therapy, but cannot induce untreated consumers to visit the doctor. DTCA, however, can stimulate contact between untreated patients and physicians (market expansion), and can also perhaps impact prescription choice (brand demand). Thus, DTPP is relatively more reflective of the persuasive view of advertising, at least during the later stages of the drug's life cycle. During the early stages when there is greater uncertainty regarding a newer drug's attributes, DTPP may bridge an informational gap and educate physicians regarding the drug's availability, effectiveness, and safety profile.

Price effects

Advertising by pharmaceutical manufacturers does not contain price information. Because patients only pay the pharmacy their copayment, which differs across health plans, pharmacies also have no incentives to advertise prices for Rx drugs (though they do advertise price information regarding OTC drugs and sometimes their waiving of patient copays for generic drugs). In the context of manufacturer non-price advertising, promotion may nevertheless affect price through various processes. First, the increase in operating costs due to higher promotional spending may be shifted to consumers in the form of higher prices. Second, promotion may increase demand and/or reduce the absolute magnitude of the demand-price elasticity, in turn raising price. This is consistent with the persuasive view of advertising, wherein advertising-induced product differentiation and creation of brand capital may enhance firms' monopolistic power. For instance, in an oligopolistic situation advertising will raise prices if it raises product demand, makes demand less elastic, and does not substantially lower marginal costs. Detailing, DTCA, and price are also complementary strategies for the firm.

In contrast to the persuasive view, manufacturers' advertising targeted toward consumers (and physicians) may lower price if such promotion reduces search costs for consumers (and physicians) by communicating direct or indirect information regarding the existence, quality, price and other product attributes, and subsequently makes demand more elastic (Encinosa *et al.*, 2011). With respect to the pharmaceutical marketplace, the 'consumer' can also be interpreted as the pharmacy benefit managers (PBM) who negotiate discounts and rebates with drug manufacturers on behalf of the insurers. Steiner (1973) presents a dual-stage model wherein consumer advertising can affect both the manufacturer's and the retailer's margin. Manufacturers' consumer-directed advertising provides information and raises consumer demand for the brand, which may facilitate competition between retailers on the advertised brand and subsequently lower retail margins although raising manufacturer prices. It should be noted, however, that lower retail margins combined with higher manufacturer prices does not necessarily imply lower retail prices. If the increase in manufacturer prices is not large enough, and consumer price sensitivity increases sufficiently, then retail prices may fall.

The empirical evidence on the effects of advertising and promotion on price is more limited relative to the evidence on demand. This paucity of research partly derives from the difficulty in obtaining measures of net Rx drug prices due to the presence of third-party payers and unobserved rebates from drug manufacturers to third-party payers.

Kopp and Sheffet (1997) provide an early study of the effects of DTCA on retail gross margins, testing the dual-stage theory of Steiner (1973). They construct the brand gross margin ratio, which measures the percentage by which a particular drug's retail margin is higher or lower relative to the class average, based on the average wholesale price – AWP (prices paid by pharmacies) and a pharmacy survey of retail prices. They then compare this brand gross margin ratio for 13 DTC-advertised brands with the remainder of 120 top-selling drugs that were not DTC-advertised over 1986–92 (control group). Because non-DTC advertised drugs are systematically different from those that are advertised, trends in the control group may not be a valid counterfactual. DTCA during this period, which predated the FDA's policy shift, was also relatively small and confined to print media. In support of Steiner's model, the study finds that retail margins for the advertised drugs fell relative to the nonadvertised drugs.

Rizzo (1999) studies 46 antihypertensive drugs and, based on drug-specific fixed effects models, finds that increased current and past detailing efforts reduce the price elasticity. The price measure reflects the wholesale price of the drug to drug stores and hospitals. The reduction in the price elasticity may consequently result in higher prices, though Rizzo does not examine the direct link between detailing and price. He concludes that pharmaceutical promotion differentiates products, increases brand loyalty, and inhibits price competition in the pharmaceutical industry. The study is based on pooled annual data from 1988 to 1993, which predate the DTCA policy shift, and only considers promotion to physicians. Rizzo's results contrast with Narayanan *et al.* (2004) who find a negative interaction between detailing and price suggesting that detailing may raise the price elasticity, albeit for a different sample of drugs (antihistamines) and a more recent time period (1993–2002).

Law *et al.* (2009) examine quarterly level pharmacy data for Plavix (an antiplatelet drug used to prevent stroke and heart attack in at-risk patients) from 27 Medicaid programs over 1999–2005. Plavix initiated DTCA in 2001. Based on an interrupted time-series design, the study finds that, although there was no change in the preexisting trend in demand, there was a sustained increase in total Medicaid-reimbursed pharmacy cost per unit of $0.40 (11.8%) after the expansion in DTCA. They note that the extra reimbursement from Medicaid likely reflects an increase in the manufacturer's price.

Dave and Saffer (2012), discussed earlier, utilizing a larger sample of all Rx drugs in four therapeutic classes, also find that DTCA raises the AWP, though the estimated elasticity is of a relatively small magnitude (0.04). Consistent with this positive impact on price, they also find suggestive evidence that the consumer price response became relatively more inelastic during the period when DTCA was expanding. Simulations indicate that expansions in broadcast DTCA over 1994–2005 accounted for 19% of the overall growth in prescription drug spending (assuming that movements in the AWP and retail prices are proportional), with less than a third of this impact being driven by higher prices and the remainder due to higher demand.

Encinosa *et al.* (2011) examine 17 million claims for 177 Rx drugs in 19 therapeutic classes, between 2001 and 2002. They study both the AWP and the transacted retail price, which is the total reimbursement that the pharmacy receives from the insurers plus any patient copayment. The authors estimate drug-level fixed effects models and find that an increase in DTCA (from 0 to the sample mean) reduced average transacted prices by 1.8%, decreased price dispersion by 3.7%, and reduced pharmacy profit margins by 1.5% (consistent with Kopp and Sheffet, 1997). The reduced price dispersion and lower retail profit margins are interpreted as a sign of increased price shopping by the insurers' PBM. However, similar to Dave and Saffer (2012), they also find positive effects on the AWP though this effect becomes insignificant once they control for market fixed effects. The study does not assess effects of DTPP.

Limitations

One challenge faced by all of these empirical studies concerns the simultaneity between advertising and pricing decisions. For instance, as noted earlier, in the model developed by Bhattacharya and Vogt (2003), price and promotion are jointly determined over the drug's life cycle. This trajectory of higher prices and lower advertising over the drug's life cycle is also consistent with the Dorfman–Steiner (Dorfman and Steiner, 1954) condition for optimal advertising:

$$\text{Advertising/Sales} = \varepsilon_{QA}/\varepsilon_{QP}$$

The optimal advertising-to-sales ratio is a positive function of the elasticity of sales with respect to advertising (ε_{QA}) and is inversely related to the elasticity of sales with respect to price (ε_{QP}), both expressed in absolute magnitudes. Thus, the decline in advertising over the drug's life cycle is consistent with an age-related decline in the sales-advertising elasticity (Berndt, 2006). It is also consistent with an increase in the price elasticity as the drug ages and newer drugs enter. A positive association between advertising and price inelasticity may thus reflect causality in both directions – if persuasive in nature, advertising may make demand more inelastic, but *ceteris paribus* more inelastic demand also leads to a higher optimal level of advertising. Although many of these studies attempt to address this simultaneity through additional controls for the drug's life cycle, drug-level fixed effects, and exploiting the exogenous shift in FDA regulations, the results should be interpreted in the context of the limitations noted.

Another limitation relates to the measurement of drug prices. None of the price measures include rebates negotiated between PBM and other payers (for instance, state Medicaid agencies) from the drug manufacturers, because information on these rebate arrangements is confidential. Sources estimate these rebates at between 2% and 35% of drug sale prices (Dave and Saffer, 2012). This rebate does not affect the price paid by a retail pharmacy to the wholesaler, or the price paid by the PBM to the pharmacy. It is a separate transaction between the PBM and the manufacturer, and affects the net transaction price. Manufacturers of brand-name drugs that treat conditions for which alternative drugs are available have a strong incentive to grant discounts to the PBM in return for preferential positioning of their drug on the formulary. If generic equivalents are available, the manufacturer may also grant a discount to make the price of its brand-name product more competitive. Movements in the list AWP or the observed transacted retail price therefore may not be reflective of movements in the net transaction price. The growth in restrictive formularies over the period when DTCA was expanding suggests that the size of the negotiated rebates may also have expanded, leading to a decrease in the net transaction price. However, the key issue concerns the extent to which the size of the rebate is correlated with DTCA. If DTCA is targeted to raise consumer demand, provide information, and push for better positioning on the formulary, then DTCA may be associated with higher rebates leading to an overestimate of the positive effects of DTCA on the net transaction price. In this case, given that the estimated price elasticity is low, it is possible that transaction prices net of rebates may have remained unchanged or even declined. If DTCA raises market power, and reduces the rebates to PBMs, then the estimated elasticity of the net transaction price with respect to DTCA is biased downward.

Summary: Price effects

These limitations notwithstanding, the above studies do point to a few relatively consistent findings. First, DTCA may have a positive though small effect on AWP (Dave and Saffer, 2012; Encinosa *et al.*, 2011; Law *et al.*, 2009), consistent with DTCA-induced market power. Second, there is suggestive evidence that DTCA may have also reduced pharmacy retail margins (Encinosa *et al.*, 2011; Kopp and Sheffet, 1997). Both of these findings are also consistent with Steiner's (1973) dual-stage model, wherein manufacturer advertising provides information, helps differentiate brands, raises consumer demand, facilitates price-based competition (and price negotiations in the case of Rx drugs), and subsequently lowers retail margins although raising manufacturer prices. Evidence is weakly indicative that certain forms of promotion may lower the price elasticity (Dave and Saffer, 2012; Rizzo, 1999). Even then there is no strong evidence that promotion causes substantially higher retail-level prices.

Effects on entry and innovation

The above studies suggest that consumer-directed pharmaceutical promotion has information content, conveying potential treatment options to consumers and expanding the market for drug therapy, at least for certain conditions. To some extent, this also applies to DTPP, which can be educational during the early phases of the drug's life cycle. As consumers (and insurer representatives – PBMs) receive low-cost (relative to incurring search costs) information, demand can become relatively more elastic and price dispersion in the market is reduced. Under this informative view, advertising can thus promote competition among incumbent firms and facilitate the entry of new firms and new products. At the same time, some studies also point to persuasive effects of DTCA and DTPP. Such promotion-induced product differentiation may have anticompetitive effects by enhancing the monopolistic power of firms and deterring entry. Anticompetitive effects on generics, however, at least in the US market, may be muted because pharmacists can substitute generics even if the physician writes a script for the branded drug. For this reason, promotion slows as patent expiry approaches and ceases almost entirely once generics enter.

Some evidence can be gleaned from direct studies of the effects on the entry of generic and branded substitutes. Scott Morton (2000), for instance, investigates the role of prepatent expiry brand-level DTPP in impacting postexpiry generic entry. Promotion is likely to be endogenous, reflecting the same market conditions that affect entry; strong markets attract both more advertising and more entrants. Thus, the study estimates IV-based models, using as instruments the drug's life cycle, an indicator for whether the firm has other forms of the same drug still under patent, and the number of physicians expected to prescribe the drug. These IV estimates do not show any significant or substantial barrier to entry by generic firms associated with brand advertising.

Kwong and Norton (2007) study the lagged effects of promotion on pharmaceutical innovation in eight drug markets, as measured by the total number of investigational products entering clinical development in a given market, over 1995–2001. They find that detailing may have a significant positive effect on the number of new products entering into clinical development, with markets for chronic disease with high levels of detailing being more attractive to pharmaceutical firms. Other types of advertising were not found to impact product entry, however. They note that this may be due to the unique role of detailing in affecting brand-specific demand and enhancing product differentiation. As the study is unable to implement IV-based corrections or control for drug-class fixed effects due to the limited sample size, the authors acknowledge that the results may be subject to endogeneity and omitted variables bias.

Conclusion

Pharmaceutical promotion, and in particular DTCA, has emerged as a marketing force in the US healthcare system. Although the debate surrounding such promotion is unlikely to be resolved anytime soon, pharmaceutical promotion should be evaluated both in terms of its costs as well as its benefits. Welfare implications can be indirectly gleaned from the extent to which such promotion affects demand, competition, and prices.

Several studies have suggested that consumer-directed advertising provides information content regarding treatment options, induces physician contact, and expands treatment, at least for certain undertreated or chronic conditions such as depression and high cholesterol. The benefits of DTCA derive from improved health due to increases in the initiation of drug therapy and adherence with drug therapy. Detecting and treating health conditions at an earlier stage, through primary care, may also be cost-effective relative to treatment at a later stage through acute care. Many health conditions are especially undertreated for disadvantaged groups; for instance, Blacks are significantly less likely to receive Rx drug treatment for high cholesterol. Thus, if DTC advertisements provide useful information and induce patients to visit their doctors, then their potential educational benefits may help reduce health-related disparities.

There is limited direct evidence on the competitive effects of pharmaceutical promotion. Though, the few studies that have been conducted seem to indicate that, if anything, promotion may be pro-competitive. Promotion aimed at providers can facilitate entry of other products in the drug class and also positively impact the number of new products entering into clinical development. There do not appear to be strong deterrent effects on generic entry. These results are consistent with the informative-view of advertising, and studies that find advertising-induced market expansion effects generally interpret these findings as welfare improving.

One of the costs of DTCA and DTPP includes potentially higher drug prices and increased use of more expensive drugs in place of equally effective lower-priced drugs. Although there is no direct study of this latter effect, Kravitz *et al.* (2005), in a randomized setting, find that for actors portraying adjustment disorder where antidepressants confer little or no benefits, 37% of actor-patients requesting Paxil received a prescription for the drug, compared to 10% of those who made a general drug request and none for those who made no request. Higher drug and healthcare expenditures can raise insurance premiums, increasing taxpayer and individual costs, and lead to a larger prevalence of the uninsured. Cost-ineffective treatments also impose opportunity costs for public and private resources. Here too, the evidence is limited and hampered by measurement error in drug prices. However, the few studies in this area suggest that promotion may have a small positive effect on the AWP and reduce retail pharmacy margins. There is no strong evidence that DTCA or other promotion substantially raises retail-level drug prices.

Evidence from physician surveys and a randomized control study (Kravitz *et al.*, 2005) does suggest that there may be some DTCA-induced overuse and overtreatment, particularly in cases where there are no structured clinical guidelines for treatment. That physicians prescribe a certain drug in response to patients' request suggests a persuasive brand-switching response to DTCA in addition to a market-expansion component. Some econometric studies confirm that DTCA affects selective demand, which is often viewed as less benign relative to promotion that affects primary demand. However, these brand-specific effects generally tend to be small in magnitude.

In contrast, both the US-based and international studies consistently find that the brand-switching effects are far stronger for physician-aimed promotion.

Market expansion and shifting brands for nontherapeutic reasons also raise the concern of a suboptimal patient–drug match for marginal patients, carrying the risk that the drug is prescribed inappropriately and leading to a worsening of the drug's average safety profile. As shown in David *et al.* (2010), increased levels of DTCA are associated with increased reporting of adverse medical events for certain conditions. Because newer drugs generally tend to be more heavily promoted, especially with consumer-directed advertisements, a popular proposal among critics of DTCA in Congress is to impose a moratorium on such advertisements during the first 2 years of a drug's launch. In response, a group of leading pharmaceutical firms (Merck, Schering-Plough, Johnson & Johnson, and Pfizer) have agreed to a voluntary 6-month moratorium on DTCA for new drugs. This would give the FDA, providers, and patients time to learn about new safety issues for new entrants. The benefits of such a proposal also need to be balanced against the need to convey information regarding new drug therapies, which may be especially important in the early stages of a drug's launch. Optimal use of DTCA may therefore require further structured guidelines.

In summary, pharmaceutical promotion has effects which can be strongly health-promoting and welfare-enhancing, but may also have adverse effects through potential overtreatment, cost-ineffective substitutions, and potential misuse. In cases where physicians can effectively perform their role as mediators, the concern about promotion-induced inappropriate use is mitigated. However, for conditions where the diagnosis or risks may be difficult to assess, there may be a need for greater oversight and investment in postmarketing surveillance by pharmaceutical firms.

Pharmaceutical Parallel Trade: Legal, Policy, and Economic Issues

P Kanavos and O Wouters, London School of Economics, London, UK

Glossary

Arbitrage A trading strategy that exploits profit opportunities arising from price differences across jurisdictions.

Commercial drug importation or pharmaceutical parallel trade The legal movement of a drug between countries by a third party without the authorization of the originator manufacturer.

Direct to pharmacy distribution (DTP) In the DTP model, pharmaceutical manufacturers bypass wholesalers to deliver drugs directly to pharmacies; wholesalers only provide logistic support and do not own the stock.

Exhaustion of intellectual property rights The exhaustion doctrine in intellectual property law mandates that once a product has been legitimately marketed, the patent holder exhausts their control over the product in that market. The type of exhaustion regime (i.e., national, regional, or international) corresponds to the patent holder's level of control of the product in foreign markets.

External price referencing (EPR) A country compares pharmaceutical prices in a basket of countries to establish a domestic reference price. The purpose of EPR may be to (1) negotiate or set prices within a country, (2) negotiate coverage and reimbursement levels, or (3) authorize product marketing.

Price discrimination The sale of goods or services to different individuals at different prices.

Ramsey pricing A linear pricing scheme in which a natural monopoly sets prices as a function of consumers' inverse demand elasticities. In the context of pharmaceuticals, this allows drug manufacturers to recover their sunk R&D costs and establishes prices based on patients' price sensitivity.

Reduced wholesaler model (RWM) In the RWM, pharmaceutical manufacturers only contract with a small number of wholesalers whose distribution behavior they can monitor more effectively; the traditional principles of wholesaling apply for RWMs.

TRIPS Agreement The World Trade Organization (WTO) Agreement on Trade-Related Aspects of Intellectual Property Rights, more commonly known as the TRIPS Agreement, is a comprehensive multilateral agreement on intellectual property. It provides the legal framework for pharmaceutical parallel trade.

Welfare A measure of an individual's or society's level of well-being.

Background

Pharmaceutical parallel trade, also called commercial drug importation, is the legal movement of a product between countries by a third party (usually a wholesaler or a distributor) without the authorization of the originator manufacturer (who is often also the patent holder). The potential for pharmaceutical parallel trade may arise given three conditions. First, price differences across jurisdictions for the same product must exist due to variation in price regulation, discordant willingness to pay, exchange rate fluctuations or other factors influencing drug prices. Second, manufacturers retain weak vertical control over the supply chain once they sell a product to wholesalers or distributors. Third, some countries adopt regimes of international or regional exhaustion of intellectual property rights (IPRs) that limit the patent holder's ability to block trade once they have marketed a product. Under these conditions, arbitrage opportunities should stimulate the export of medicines from low- to high-price countries.

Parallel trade is particularly prevalent in the European Union (EU), where it accounts for up to 20% of retail prescription drug spending in some countries. The legalization of commercial drug importation has also been proposed in the US and it remains a highly controversial issue in countries around the world. Proponents of parallel trade, including some public health authorities, argue that it increases affordability of medicines and generates health system savings. Theoretically, the mere threat of parallel trade (whether or not it actually occurs) should lead manufacturers to reduce prices. Critics, however, question its long-term effects on drug prices. They also claim that parallel distributors free ride on the marketing and service investments of authorized wholesalers and that widespread parallel trade would decrease profits for pharmaceutical manufacturers; ultimately, it would reduce pharmaceutical investment in research and development (R&D) and harm innovation. This article outlines the legal, policy, and economic issues surrounding pharmaceutical parallel trade. As it has been most common in the EU, much of this article focuses on this region.

The Legal Debate

At the international level, the legal framework governing pharmaceutical parallel trade is provided by the World Trade Organization (WTO) Agreement on Trade-Related Aspects of Intellectual Property Rights, more commonly known as the TRIPS Agreement. There have been recent amendments and additions to the TRIPS Agreement that facilitate the parallel trade of medicines (e.g., the Doha Declaration), as well as bilateral agreements that restrict it (e.g., TRIPS-plus). Regional and national legislation also affects trade and competition

 doi:10.1016/B978-0-12-375678-7.01213-X

(see Kyle (2009) for an in-depth analysis of the legal aspects of pharmaceutical parallel trade).

Intellectual Property Provisions and Parallel Trade

The TRIPS Agreement requires that WTO member states adopt minimum standards of IP protection and enforcement of IPRs. However, Article 6 of TRIPS leaves to the discretion of individual countries whether they choose to adopt a regime of national, regional, or international exhaustion of IPRs. The exhaustion doctrine in intellectual property law mandates that once a product has been legitimately marketed, the patent holder exhausts their control over the product in that market. The type of exhaustion regime corresponds to the patent holder's level of control of the product in foreign markets. Under a regime of national exhaustion, the patent holder can block the parallel import of the product from a foreign market, whereas the parallel import is legal under a regime of international exhaustion. Regional exhaustion permits parallel trade within the region, but not from nonmember countries. Frequently cited examples of national, regional, and international exhaustion regimes are the United States (US), the EU, and Kenya, respectively. The Doha Declaration on the TRIPS Agreement clarifies that members can implement the exhaustion regime that supports their domestic policy goals.

Within the EU, rules governing the single market prevent member states from imposing trade barriers on imports from other member states and mandate a regional, or community, exhaustion of IPRs. The European Court of Justice (ECJ) has taken the view that once a product is sold in one member state, it is a breach of Article 28 of the EC Treaty to prevent the product from being resold in another member state even if it is protected by a patent or other forms of IPRs. This is consistent with the principle of free trade of goods between EU members, although the regional exhaustion regime still prevents the parallel importation of a product that was first sold outside of the EU. The ECJ has upheld the legitimacy of parallel trade in numerous cases (e.g., Bristol-Myers Squibb vs. Paranova A/S, 1996, ECJ Case 427/93).

Parallel distributors must often repackage a drug to comply with the labeling and package criteria of the importing country. Manufacturers have legally challenged repackaging and claimed that it may adversely affect the consumer perception of the quality of the drug and harm the manufacturer's reputation. The ECJ, however, has generally ruled in favor of parallel traders.

Competition and Trade Policy

European Union

In response to parallel trade in the EU, several drug manufacturers have attempted various practices to discourage parallel trade, including restricting supply to exporting countries, price discriminating based on whether the drugs are meant for domestic or foreign consumption (i.e., exported) or only selling to a distributor if they agree to not engage in parallel trade. Owing to the single market in the EU, however, restrictions on parallel trade may violate clauses of the EC Treaty that pertain to collusive behavior and cartels (Article 81) and abuse of dominant position (Article 82); such practices could therefore be deemed anticompetitive.

EU courts have ruled that any implicit or explicit decision between the manufacturer and the distributor that limits the extent of parallel trade violates Article 81 (e.g., Sandoz Prodotti Farmaceutici vs. Comm'n, 1990, ECJ Case C-277/87). However, pharmaceutical manufacturers have occasionally been allowed to restrict supply to a quantity sufficient only for domestic consumption. In the case Bayer vs. Commission (2000, ECJ Case T41/96), the court ruled that Bayer was allowed to limit the supply of the drug Adalat to the Spanish and French markets to prevent outside consumption of the drug. As the domestic demand must first be satisfied before a drug can be exported (i.e., parallel trade can be banned if it induces a shortage in the exporting country), the court found that the arrangement did not violate Article 81 and ruled in favor of Bayer.

Even if draining the domestic market is subject to interpretation under Article 81, it may still constitute an abuse of a pharmaceutical manufacturer's dominant position (Article 82). In a different case (Syfait vs. GlaxoSmithKline, 2008, ECJ Cases C-53/03, C-468/06 and C-478/06), the ECJ found that GlaxoSmithKline, which was limiting supply to Greek distributors, held a dominant position but did not necessarily violate Article 82. The main reasoning behind the decision was that, unlike in other industries, intercountry differences in drug prices are often the result of discordant national regulatory environments and are only weakly influenced by manufacturers. However, the court later reversed its opinion that pharmaceutical manufacturers are not largely involved in the pricing process and found that GlaxoSmithKline violated Article 82 (Sot. Lelos kai Sia EE vs. GlaxoSmithKline AEVE, 2008, ECJ Cases C-468/06 and C-478/06).

Disputes have also arisen over whether pharmaceutical manufacturers can charge different prices based on if a drug will be consumed in the home or foreign country or selectively withdraw a product from a market to curb the volume of parallel trade. Although explicit price discrimination would violate Article 81, pharmaceutical manufacturers have again claimed that the pricing outcome was the result of regulatory pressures, not a manufacturer decision. The EU courts have offered mixed rulings on this issue depending on the circumstances of individual cases. The courts have also ruled that Article 81 prevents manufacturers from ceasing to supply a market due to the threat of parallel trade, as some theoretical models have suggested would occur; manufacturers must guarantee adequate access to needed drugs.

Overall, despite innovative attempts by pharmaceutical manufacturers to hinder parallel trade, the European courts have generally ruled in favor of parallel trade and supported the free movement of products within the EU. The current policy imperative is how to prevent the parallel distributors from capturing all of the transaction profits, in order to transfer the savings to consumers and purchasers.

United States

Parallel trade has received extensive policy attention in the US, where pharmaceutical prices have historically been higher than in other countries (e.g., Canada). Some US policymakers have championed parallel trade as a viable option to curtail pharmaceutical spending. Advocates of parallel trade argue

that drug importation can reduce US drug prices without direct price regulation; critics argue that it would introduce significant safety risks due to the potentially less stringent quality assurance of foreign regulatory bodies, would not necessarily reduce prices to US consumers, and could ultimately harm pharmaceutical innovation and threaten the competitive advantage of US firms. Although legislation authorizing parallel trade was passed by the US Congress and signed into law in 2000, it was never implemented due to the aforementioned concerns. In the last decade, several other congressional bills have been introduced, but all have ultimately been defeated.

Despite the illegality of commercial drug importation, the existence of a small but steady flow has induced various responses by pharmaceutical manufacturers. Certain manufacturers have limited Canadian supply and have even circumvented distributors and supplied retail pharmacies directly to mitigate the risk of parallel trade. This has led to investigations by US antitrust authorities into possible collusive or anticompetitive behavior among manufacturers in violation of the Sherman Antitrust Act of 1890. Parallel exportation has also been opposed by the Canadian authorities, which have raised concerns about the possibility of supply shortages.

The US experience suggests that a single market may be a prerequisite for the successful introduction of parallel trade. The special regulation of pharmaceutical products under the Federal Food, Drug, and Cosmetic Act (1938) and the Prescription Drug Marketing Act (1987) also means that even if parallel trade were authorized for other goods, it would not necessarily extend to pharmaceuticals.

Conceptual Frameworks for Evaluating Parallel Trade

Several models have been proposed to explain the behavior of pharmaceutical manufacturers, payers, and regulatory agencies in the presence of parallel trade opportunities. Most studies employ a variety of theoretical approaches to explore the effects of pharmaceutical parallel trade on price competition, social welfare, and innovation; key studies are summarized in Table 1.

Price Discrimination, Innovation, and Welfare Effects

The evidence suggests that the effect of parallel trade on social welfare is an empirical issue that depends on parameters such as demand and demand-side policies, regulation, patient preferences, market structure, and innovation. The social welfare effects of pharmaceutical parallel trade are ambiguous: in the short term, lower prices may contain growth in pharmaceutical expenditure and improve patient access to medicines, whereas profit reductions to originator manufacturers may discourage pharmaceutical investment in R&D and thus harm the long-term prospects of innovative drug discovery.

Traditionally, economic analyses of parallel trade have considered it as a channel for undermining third-degree price discrimination. Without considering distribution issues and differing demand elasticities across countries for homogeneous goods, parallel trade could lead to uniform international prices. Economic theory predicts that in unregulated markets and in the absence of product differentiation, arbitrage induces price competition and stimulates downward price convergence. Nevertheless, the static welfare effects of third-degree price discrimination compared with a single price monopoly are likely to be positive if price discrimination leads to higher output and consumption, which seems plausible for pharmaceuticals.

Theoretical studies have generated opposing conclusions on the effect of parallel trade on innovation. Most studies have assumed that price regulations are fixed across countries and have shown that parallel trade may disincentivize R&D investment. In a research-intensive industry, parallel trade may threaten the ability of manufacturers to recoup their R&D investment costs. Assuming that parallel trade does not affect the total volume of consumption across all countries, parallel trade satisfies part of the demand in the importing country at a lower price. The overall profit to the manufacturer is therefore reduced. Whereas free trade is often promoted to allow all consumers to benefit from more efficient production functions, this stance may not be appropriate for the in-patent pharmaceutical market, where lower drug prices are often the outcome of more stringent regulatory regimes, not lower production costs. In this context, the use of Ramsey pricing, or a markup based on inverse demand elasticities, may maximize global social welfare and is preferable to international (or even regional) exhaustion of rights.

Other models considered a situation where the assumption of fixed pricing environments does not hold, in which case parallel trade may instead stimulate the convergence of price

regulations to those of the exporting nation and encourage R&D investment. In other words, when IPRs are exhausted internationally and different prices exist across countries, parallel trade may stimulate an international harmonization of price regulations and support innovation. The ex-post allocation of resources should motivate the importing country to provide a trade friendly environment for the firms. These theoretical findings are supported by evidence of more relaxed pricing regimes in Portugal, Italy, and France following the growth of parallel exports in those countries.

Some models have even found that parallel trade should increase the profits of the originator manufacturer in the context of a Nash bargaining game. Although such a finding is counterintuitive when one considers the opposition of pharmaceutical manufacturers to parallel trade, certain variables are absent in these models that may limit their practical application. For example, they may not consider the possibly detrimental impact of parallel trade on the ability of manufacturers to price discriminate in markets other than the ones considered in the model.

In general, the theoretical conclusions differ significantly depending on the model assumptions (Table 1). These assumptions include (1) the type of regulation in place (e.g., fixed vs. variable regulatory regimes, the threat of compulsory licensing, price caps, etc.); (2) the ability of manufacturers to discriminate based on quality (i.e., produce high- and low-quality products) or decide not to serve a particular market; and (3) the manufacturer's level of control over prices in the exporting and importing markets (to incorporate parallel trade into cost functions), among other factors.

Impact on Competition and Prices

Standard microeconomic theory predicts that parallel trade catalyzes price competition. This anticipated price outcome was supported by evidence from Sweden between 1994 and 1999, which showed that prices of drugs exposed to parallel competition dropped by 12–19%. Other studies, however, have found that the distribution chain collects most of the economic gains from pharmaceutical parallel trade and that prices remain stable at their initial level in destination countries. Due to universal health insurance coverage and low copays or copay exemptions, patients and payers (i.e., governments and health insurers) rarely benefit directly from pharmaceutical price differences. Instead, parallel distributors obtain the majority of available rents, as purchasers have limited incentives to respond to price differentials.

The volume of parallel trade does not necessarily put downward pressure on prices in destination countries. Several studies have found little evidence of sustainable price competition, even when parallel trade is actively promoted. Exchange rate fluctuations, purchasing power parities and generic penetration may be responsible for any price decreases. The pricing strategies of parallel distributors rarely deviate from those of local manufacturers in destination countries, despite discordant cost functions. Assuming both parallel distributors and originator drug manufacturers are profit maximizers and that the former face negligible marginal production costs, game theory models predict upward price convergence which minimizes the opportunity for welfare gains.

Overall, the accuracy and validity of the various theoretical models depend primarily on the respective assumptions about the behavior of originator manufacturers, parallel traders and regulatory authorities in the home and foreign markets in the presence of arbitrage opportunities. Given discordant assumptions across models (e.g., outturn of pricing negotiations, manufacturer R&D strategies or patient copayment levels), it is expected that different theoretical conclusions will be derived.

Determinants of Parallel Trade

Barriers to Entry

Despite the rapid growth of pharmaceutical parallel trade in recent years and the adoption of policies encouraging its use, this has not been without barriers. First, a parallel traded product needs to be approved and licensed by national regulatory agencies to ensure product safety. However, the ECJ and the associated jurisprudence have simplified these procedures and parallel importation can be approved quickly. Second, the nature of the pharmaceutical distribution chain suggests that obtaining market share requires a minimum scale of operations: parallel distributors must be in a position to sustainably supply a significant number of products to local retailers, otherwise they risk not becoming a preferred wholesaler and increasing retailers' costs of compliance. Third, given the fragmented structure of European wholesaling, parallel distribution requires large networks of national wholesalers from whom medicines can be purchased at favorably low prices and exported to high-price countries. Fourth, manufacturers are increasingly in a position to exercise some vertical control over the supply chain in all countries where they operate – provided this is not explicit – and this means that extra quantities for parallel exportation are difficult to obtain. Fifth, other barriers to entry may relate to the negative perception of parallel traded products among consumers in that the packaging, language, and presentation may be different to what consumers are accustomed to. Sixth, consumers may negatively perceive parallel traded products if the packaging, language, and presentation are different to what they are accustomed to. Finally, other barriers to entry include: (1) small license fees, (2) the requirement to insert a patient leaflet in the destination country's language, and (3) moderate transport costs.

Pricing Strategies across Countries

Perhaps, the greatest determinant of parallel trade is the wholesale price difference between the importing and the exporting country. This price difference provides the initial signal for parallel trade, taking transport and regulatory complicance costs into consideration. The magnitude of the price difference will determine whether parallel trade is likely to be profitable for those who exercise it. Empirical evidence finds a positive and statistically significant relationship

between the magnitude of the price gap and market entry and penetration of parallel traded products.

Drug manufacturers may attempt to limit the impact of parallel trade. Whether or not manufacturers are successful at discouraging parallel trade depends on two key parameters. First, the control that manufacturers exercise over the distribution chain (see Section Fragmentation of the distribution chain and vertical control). Second, the types of price regulation applied across countries. The widespread implementation of external price referencing (EPR) in the EU has indirectly enabled manufacturers to adopt various strategies to mitigate the impact of parallel trade. One of these is entry or launch sequencing, whereby a product is launched in countries where prices are higher to influence prices in other countries that use the launch country as a reference. Another strategy is launch delay, especially if expected prices in a country are below a certain threshold and may induce parallel trade or influence prices downwards elsewhere. A third strategy is to either not launch or withdraw from a market given the level of expected prices. This can take place at any time, especially if EPR is used repeatedly to take advantage of price changes in a country's reference basket.

Product Availability

If parallel distributors are not able to acquire sufficently large product stocks in export countries, parallel trade cannot occur. Importantly, pharmaceutical manufacturers have little, if any, interest to promote parallel trade between markets by diverting sales of their own product from high- to low-price countries. On the contrary, the ability of parallel distributors to identify sources of product is a key driver to the conduct of parallel trade and requires knowledge of price levels across jurisdictions. Sources of product can be wholesalers (for larger quantities) or retailers (for smaller quantities) in export countries. The source of parallel traded products is not always exclusively the lowest price jurisdiction, but a range of jurisdictions depending on the availability, proximity, and price difference to the destination country. The security of supply affects the capacity of parallel distributors to offer competitive prices and the long-term sustainability of parallel trade in a particular product market.

Administrative Measures and Incentives

Governments and health insurers often promote the use of parallel imported products to encourage price competition and to achieve efficiency savings. The experience of European countries is considerable in this regard and has involved both direct and indirect financial incentives and penalties to individual stakeholders; these policies are country-specific and focus primarily on the incentive structure at the retail level. The most prevalent policies are summarized in Table 2 and relate to:

- First, the award of positive financial incentives for pharmacies to actively procure and distribute parallel imported pharmaceuticals. Pharmacies can retain a proportion of the price difference between the originator and the parallel imported medicine (e.g., 33% of that difference in the Netherlands and 50% in Norway).
- Second, the presence of negative incentives, whereby pharmacies are penalized if they do not dispense a parallel traded product. In Germany, sickness funds and pharmacy associations have agreed on a parallel import quota for the latter to dispense in a given year, which is based on pharmacies' overall turnover with the sickness funds (e.g., 7% in 2003). Sickness funds receive all the financial benefits from price differences. The reimbursement for pharmacies that fail to comply with the quota is reduced accordingly. In the opposite case, pharmacies receive a credit to settle bills when the import quota is surpassed, although there is no cash benefit.
- Third, the mandatory provision of information, whereby pharmacies are legally bound to inform patients on the availability of a cheaper parallel imported drug if savings reach up to 5% on a prescribed product (e.g., Denmark). No financial benefits are envisaged for pharmacies.
- Fourth, financial incentives by means of additional lump sum payments (e.g., Sweden) and in connection with national substitution policies to enhance the use of generic and parallel traded medicines.
- Finally, discounting practices for the procurement of medicines exist in many countries (e.g., the Netherlands and the UK). Pharmacy savings on procurement prices of medicines (including parallel traded medicines) compared with list prices form part of their remuneration; regulators

Table 2 Policy measures encouraging the dispensing and use of parallel traded pharmaceuticals in Europe

Type of measure[a]	*Evidence of application*	*How it works in practice*
1. Positive financial incentive	The Netherlands and Norway	Pharmacies retain part of the price difference between parallel traded and locally sourced drugs (33% in the Netherlands, 50% in Norway)
2. Penalty	Germany	Penalties to pharmacies if they do not dispense a certain proportion of parallel traded drugs (i.e., quota system)
3. Compulsory information	Denmark	Pharmacists are required to provide information to patients about a parallel traded drug if the price difference exceeds 5% of prescription cost
4. Lump sum payments	Sweden	Payments to pharmacies for their promotion of generic and parallel traded drugs
5. Discount and clawback	The Netherlands and the UK	Discounting allowed, but a proportion of that discount to pharmacy is retained via the clawback

[a]Measures reported in this table have been implemented in the cited countries at particular points in time and may be of transient nature or subject to changes.
Source: The authors based on the literature.

can retain part of that discount by implementing a clawback when reimbursing pharmacies.

Other Factors Influencing the Extent of Parallel Trade

Several other factors are likely to influence the amplitude of parallel trade. These are discussed below.

Fragmentation of the distribution chain and vertical control

The fragmentation of the distribution chain in exporting countries is positively associated with parallel trade; the more fragmented it is, the more likely wholesalers – and possibly retailers – are to parallel export part of their stock. For wholesalers, the financial incentive to engage in parallel exporting can be greater than distributing products to the domestic retail chain. To counteract this incentive, regulators in some European countries require wholesalers to register and report the destination of their products (Spain) or to keep a stock at 25% more than historical demand (Greece). Recently, pharmaceutical manufacturers have sought to increase their control of the distribution chain, either by bypassing wholesalers and delivering directly to pharmacy (direct-to-pharmacy (DTP) model) or contracting with a small number of wholesalers (reduced wholesaler model (RWM)), typically two or three, whose distribution behavior they can monitor more effectively. In the DTP model, wholesalers only provide logistical support and do not own the stock, whereas the traditional principles of wholesaling apply for RWMs. In practice, however, the 'public service obligation,' requiring all registered wholesalers to be sufficently stocked to further supply the product to the retail distribution chain, is a significant barrier to the wider implementation of either model.

Market size and geographical proximity

One of the likely indicators of the potential for parallel trade in individual countries is the country's 'economic size.' The larger a particular market, the more attractive it is for both manufacturers and distributors to undertake production and parallel trade, respectively. The gravity model of international trade predicts that the flow of goods between two locations is positively related to their size (or income levels) and negatively related to the distance between them, after controlling for factors that may affect trade (e.g., price differences and differences in the salient features of regulatory frameworks). Empirical evidence suggests that distance appears to reduce the total volume of parallel trade into a country; however, a gravity specification exhibits an opposite effect for volume (as a proxy for market penetration). This may be because once parallel distributors have established contact with a potential source, distance does not become a significant barrier and geographically distant sources may have incentives to become better connected.

Patent expiry and genericization

The effect of generic entry on the extent of parallel trade has not been studied in a systematic way. Genericization leads to competition between originator and generics, which may result in the price of the originator declining. If this is combined with administrative policies (e.g., compulsory generic substitution), the market share of originators (locally sourced or parallel imported) is likely to be small. The only reason why genericization might enhance parallel trade is if there is differential patent expiry among jurisdictions, in which case, patent-expired originators in one jurisdiction may be acquired at a significant discount and resold in jurisdictions where the same product remains patent protected.

Exchange rate fluctuations

Exchange rate fluctuations can indirectly influence the extent of parallel trade, insofar as currency appreciations or depreciations affect relative prices of pharmaceutical products across countries. *Ceteris paribus*, currency depreciation could make exportation more attractive, or could even reverse the flow of trade, if price differences between the export and the import country are small. In the UK, moderate average price reductions in the context of the Pharmaceutical Price Regulation Scheme (PPRS), along with the depreciation of sterling *vis-à-vis* the Euro, reversed the flow of trade in 2007. Since then, the UK has been a net exporter of pharmaceutical products, compared with the opposite situation until that point; parallel imports accounted for approximately 20% of the UK prescription in-patent market in 2002.

Parallel Trade and Its Economic Impact

Stakeholder Positions

The economic and noneconomic impact of parallel trade on health systems is heavily debated by the key stakeholders in both exporting and importing countries, including parallel distributors, drug manufacturers, health insurers, distribution chain actors and patients. To understand the position of different stakeholders on the subject, it is important to evaluate the incentive structure that motivates them. The available evidence from the EU, where the subject has been studied at some length, is important in this context.

Parallel distributors argue that pharmaceutical parallel trade promotes competition by forcing down the prices of their domestically sourced counterparts and enhances access to medicines; this should contribute to a lower public pharmaceutical expenditure and result in direct and indirect health care savings. Parallel distributors are motivated by the private pecuniary benefits of arbitrage, as the potential for price equalization in regulated pharmaceutical markets is low and price differences are sustained over time. The key issue that affects the volume of parallel trade is the sustainability of supply in potential export markets.

Pharmaceutical manufacturers oppose parallel trade. They argue that it undermines the profitability and ability of manufacturers to recoup R&D investment costs; it therefore harms future investment in R&D and the potential for discovering new treatments. Pharmaceutical parallel trade may provide an unfair playing field, as manufacturers take all the risk in developing drugs and parallel distributors profit from the R&D of manufacturers. As a result, areas where parallel trade takes place or is encouraged may become increasingly unattractive for conducting business, which could cause job losses, cutbacks, and industry relocation in the long term.

Statutory health insurance organizations in exporting (source) countries are not in a position to realize any pecuniary benefits, as products that are meant for the treatment of patients under their jurisdiction are parallel exported to other markets. Instead, parallel exportation can result in product shortages in exporting countries and limit patient access to medicines.

Statutory health insurance organizations in importing (destination) countries, however, may benefit in three ways from a conceptual standpoint. First, savings from parallel trade could accrue partly or entirely to them. In the Netherlands and Norway, the government maximizes its financial benefits by surrendering part of the price difference to pharmacists (see Table 2). Second, health insurance organizations can implement 'clawback' arrangements to ensure that part of the pecuniary benefits accruing to retailers from more competitive purchasing are accounted for through lower reimbursement. Third, price competition may lower pharmaceutical expenditure in destination countries; however, it is difficult to determine the extent to which this is occurring, which is likely to be product-specific. These benefits are static and need to be balanced against the countries becoming less attractive R&D investment locations due to parallel trade.

The retail distribution chain can also benefit in countries where pharmacy margins are not determined by regulation, or where pharmacies are explicitly financially incentivized to dispense a parallel imported product. In this case, pharmacies can negotiate discounts with distributors and parallel distributors, making it profitable to stock and dispense parallel imported medicines that may carry the same reimbursement price as a locally sourced equivalent.

The benefits to patients in destination countries theoretically result from the lower prices of parallel imported drugs, which may reduce patients' overall medication costs and improve their access to medicines. This also assumes that patients pay a significant proportion of their medication out-of-pocket. Such benefits, however, may be transient unless parallel trade can be a sustainable source of cheaper products. The above arguments have little applicability in health systems offering comprehensive prescription drug insurance coverage, however, where patients contribute modestly to the cost of their medicines. The type of cost sharing also plays a role: fixed prescription charges do not offer any financial benefits to patients, whereas a coinsurance might.

Evidence of Economic Impact and Welfare Implications

Parallel trade has generated considerable interest about its economic impact, welfare implications, and effects on the stakeholder community. Few empirical studies have examined its impact on stakeholders and price competition and all focus on the EU experience.

Static gains from parallel trade

Direct benefits from parallel trade can be significant, are static in nature, and arise because of the price differences between exporting and importing countries resulting in a redistribution of revenue from pharmaceutical manufacturers to a variety of stakeholders.

Financial gains to health insurers are modest both in absolute terms and as a share of total prescription drug spending; evidence from six European countries suggests that on average they are less than 2% of the inpatient–outpatient prescription drug market (ranging from 0.3% in Norway to 3.6% in the Netherlands). It has been found that the cumulative financial gain to parallel distributors is much greater than the gain to health insurers. The retail distribution chain also profits directly from the conduct of parallel trade.

Market entry, penetration, and competition

Much of the debate on pharmaceutical parallel trade has focused on its indirect benefits and whether it creates sustainable price competition in the long run. Empirical observations suggest that in importing countries where parallel traded products occupy a significant market share, the difference between the highest and lowest parallel distributors' price rarely exceeds 7%. The distributors with the largest market share are those with prices toward the lower end of the spectrum or those with the lowest price in the range. This indicates that payers and retailers exhibit some price sensitivity to parallel import prices. Still, prices of locally sourced equivalent products do not seem to be influenced by the extent of parallel trade. In several cases, they have actually increased over time, despite seeing their domestic market share declining in the presence of parallel imports. The price spread between parallel traded and locally sourced drugs can vary significantly from shipment to shipment, and from destination to destination, depending on (a) the acquisition price in a source country and (b) the incentives associated with the distribution and sale of parallel imported products in a destination country. In the UK, for example, this difference can be zero as parallel distributors may choose to have a list price at parity with the locally sourced equivalent, enabling them to offer further discounts to retailers.

Few studies, however, have analyzed whether price competition is sustained over time. Empirical evidence from several countries suggests a commensurate average price change of parallel imported and locally sourced products over time; this indicates that there is a co-movement in prices in the presence of parallel trade. The prices of locally sourced and parallel traded products appear to converge upwards rather than downwards. These results are sensitive to the product mix they refer to, the country settings where they are derived from and the time period studied.

The absence of a strong and sustainable price effect is likely due to a number of reasons. First, the fragmentation in the supply chain generates an environment where price differentials between exporting and importing countries are typically divided among several rent-seeking agents. Second, the lack of security in procuring the necessary quantities of product from potential export countries in a sustainable manner undermines downward price convergence. Third, parallel distributors may not always import from the lowest price countries for a variety of reasons (e.g., quantity available at a particular time or geographic proximity to the destination country). Finally, the regulatory and operating environment in importing countries may not be conducive to parallel distributors offering health insurers any price advantage to locally sourced products.

Safety and quality of parallel traded products

The need to repackage some parallel traded medicines increases the risk of counterfeiting. From a regulatory perspective, parallel distributors are obliged to notify the drug regulator in the destination country, as well as the originator manufacturer, of any changes made to the relevant product to obtain an import license for a particular shipment of the product; this makes them liable in case there is tampering with the medicines and counterfeits enter the distribution chain. For example, thousands of packs of three parallel traded counterfeit medicines entering the UK supply chain were recently recalled. The counterfeit medicines were manufactured in China and entered the EU in Luxembourg, where they were resold, without being checked, to UK and Belgian wholesalers. As the drugs entered Luxembourg as 'transit' goods, they were exempt from the checks that would otherwise apply.

Impact on exporting countries

Even if the impact of parallel trade on patients is neutral in the destination country, it is important to evaluate its impact on drug availability in the source country. Arbitrage incentivizes parallel distributors to maximize the quantities they acquire in the exporting country for resale elsewhere. Wholesalers in the source country may also have an incentive to supply parallel distributors with maximum quantities (and provide them with a discount), rather than supply their own market, because they reduce their overall distribution costs when they sell to a single buyer rather than to several buyers (e.g., pharmacies). Consequently, while the distribution system in the export country favors parallel trade, or has few available limits to prevent its extent, this may have an adverse effect on the availability of medicines in that country and thus harm the health of the patients.

Evidence suggests that parallel trade can induce shortages in drugs that are exported intensively. This has been documented in Greece, Spain and, more recently, the UK. The governments of all three countries now require wholesalers to ensure that local demand is first satisfied. Greece implemented short-lived parallel export bans in 2011, 2012, and 2013. In the UK, many products were officially listed in short supply and government authorities threatened to punish manufacturers, wholesalers, pharmacists, and doctors who breached duties to supply medicines to the local market. One could claim that drug manufacturers should increase production in exporting countries to meet demand, but, given the incentives to domestic wholesalers discussed above, it is not guaranteed that increased production will satisfy this demand.

Impact on R&D and innovation

It is further argued that parallel trade has a deleterious effect on R&D and innovation due to the eroded profitability of innovator manufacturers. If a strong research-based industry that invests in R&D and discovers new molecules is a health (and industrial) policy objective in both exporting and importing countries, then profit erosion through parallel trade would provide an obstacle to achieving this goal. If nations compete on the basis of comparative advantages, parallel trade may discourage research-based manufacturers from locating in areas where it is widely practiced or is actively promoted. The encouragement of parallel trade by destination countries constitutes a beggar-thy-neighbor practice whereby higher-price countries borrow regulatory practices from lower-price countries.

Parallel trade and overall welfare implications

Given a range of stakeholder considerations and the available empirical evidence on welfare implications, the overall welfare effects of parallel trade are likely negative. The potential short-term benefit of parallel trade is cost containment in importing countries; if savings are sustained through price competition between locally sourced and parallel imported medicines, parallel trade may stimulate welfare gains. However, such gains are likely to be transient and negated by the adverse long-term effects of parallel trade. First, despite the perceived benefits from increased affordability, the empirical evidence suggests that parallel trade does not lead to sustainable price reductions in destination countries. Instead, price reductions occur in an opportunistic way, reflecting the availability of surplus product stock in source countries. Second, parallel exportation often leads to shortages in source countries, resulting in access problems for patients. Third, a reduction in manufacturers' profitability could lower R&D investment and levels of future innovation. Fourth, global welfare is also likely to suffer, as manufacturers are, in principle, disinterested in launching new products and in supplying countries with low-priced drugs.

Conclusions

Pharmaceutical parallel trade is a form of arbitrage caused by intercountry price differentials, which are in most cases generated by national regulatory practices. Depending on how the principle of exhaustion of IPRs is applied, the same product can be made available in different jurisdictions without the authorization of the rights holder. The practice of parallel trade has found wide applicability in the EU single market, where it accounts for a significant share of the retail prescription drug market. From a global perspective, the Doha Declaration leaves it up to the WTO members to handle it in a way that protects their national interests. Overall, the key determinants of parallel trade penetration are the price difference between the importing and the exporting country, the overall pharmaceutical market size of a country, and the fragmentation of the distribution chain.

The available evidence on the impact of parallel trade highlights three key conclusions. First, parallel trade does not seem to promote price competition. Instead, the prices of parallel traded and locally sourced products usually converge upwards; prices are more likely to be guided by domestic drug policy measures (e.g., regulatory and generic policies) than by parallel trade. Therefore, although the pharmaceutical market ostensibly offers a suitable environment for arbitrage, the expected price outcomes may be illusory. If national governments wish to further control their drug spending through supply-side measures (focusing on prices), parallel trade is probably a weak policy option. Second, the pecuniary and welfare gains from parallel trade in destination countries have proved to be at best modest; by contrast, exporting countries have suffered significant shortages, which negatively affect

access to treatments and social welfare. Third, there is an evolving jurisprudence that acknowledges the potential value of competition where parallel trade is permitted, but also recognizes the importance of protecting the commercial interests of originator manufacturers.

In the future, several important operational developments may mitigate the extent of pharmaceutical parallel trade. First, the widespread application of EPR enables manufacturers to streamline their launch sequences and opt to not launch if the expected prices would initiate parallel trade. Second, product shortages in export markets are likely to increase resistance to parallel trade. Finally, changing distribution practices (e.g., DTP distribution and RWM) allow manufacturers to exercise greater vertical control over their stock and its destination.

Pharmaceutical Pricing and Reimbursement Regulation in Europe

T Stargardt, University of Hamburg, Hamburg, Germany
S Vandoros, London School of Economics, London, UK

Introduction

Although the presence of a European single market has led to price convergence for many products, pharmaceutical markets still remain very fragmented, with the 27 European Union (EU) countries following different pricing and reimbursement policies. The level of pharmaceutical spending and the willingness to pay for innovation differs between and within EU countries as discussed by Drummond and Towse (2012), whereas the regulatory approaches dealing with the increase in pharmaceutical spending are fairly similar across countries and can be standardized, for example, see Vogler *et al.* (2008). Thus, this article will focus on the most common regulatory instruments used in the EU countries.

The Concept of Pricing and Reimbursement in the EU

In the EU, pricing and reimbursement of pharmaceuticals are closely related and interdependent, with the two terms often becoming mixed-up. As a result, 'pricing' and 'reimbursement' are frequently used as synonyms, but in reality they are not. Although the term 'reimbursement,' i.e., the amount or the percentage of the price of a pharmaceutical paid by a (public) payer for a predefined population or indication can easily be defined, it is much more difficult to explain the term 'price' in the EU context.

There are multiple numeric figures throughout the supply chain of pharmaceuticals that qualify for the term 'price.' The manufacturer's price refers to the price of a pharmaceutical set by the manufacturer, which may include value added tax (VAT). The wholesale price, which is defined as the price at which the wholesaler sells the medicine to the pharmacy, includes a mark-up for the wholesaler (in the EU countries usually defined by law) on the manufacturer's price and VAT. The pharmacy price – also known as retail price – defined as the price at which the pharmacy sells the pharmaceutical includes a mark-up for the pharmacy (in the EU countries usually – again – defined by law) on the wholesaler's price and VAT (Figure 1). Prices are called 'list prices' if they are published and do not include any rebates.

The term 'price' may not be defined only for whom it is set, but also to whom it is charged. When the price of a pharmaceutical refers to what is paid by the consumer, it is usually called 'copayment' or 'out-of-pocket payment' instead of 'price' and when the price of a pharmaceutical refers to what is paid by the (public) payer, it is usually called 'reimbursement' or 'reimbursement price,' i.e., the list price net of any copayments and rebates.

Pharmacy and wholesaler mark-ups differ from country to country, as does the VAT on pharmaceuticals. In their comparison on pharmaceutical regulation in the EU, Vogler *et al.* (2008) have found that wholesaler and pharmacy mark-ups are usually a linear or regressive (i.e., decreasing) function of the price. For example, in Germany, both mark-ups are regressive: the wholesaler mark-up on manufacturer prices is between 6% and 12% of the manufacturer's price, whereas the mark-up of the pharmacy consists of a fixed component, i.e., €8.10 per package, plus a linear mark-up of 3% on the wholesaler's price.

VAT differs even more drastically among the EU countries. According to the data of the Federal Union of German Associations of Pharmacists (2012), a small number of countries, i.e., Denmark, Bulgaria, and Germany charge their full VAT to pharmaceuticals, i.e., 25%, 20%, and 19%, respectively, whereas the majority of countries apply a reduced VAT between 2.1% (France) and 12% (Latvia) or do not apply VAT for outpatient prescription drugs at all (Ireland, Malta, Sweden, and the UK). These differences in mark-ups and VAT make price comparisons of list prices at the pharmacy level among the EU countries very difficult to interpret. Nevertheless, in most EU countries, these rules are applied only for prescription drugs to ensure that a pharmaceutical has the same retail price in all pharmacies in a country, regardless of whether the pharmacy is in an urban or rural area or whether the pharmacy faces competition or not.

The Process of a Price and Reimbursement Decision in the EU

Similar to multitiered reimbursement lists (formularies) in the US, many European countries operate so-called positive lists,

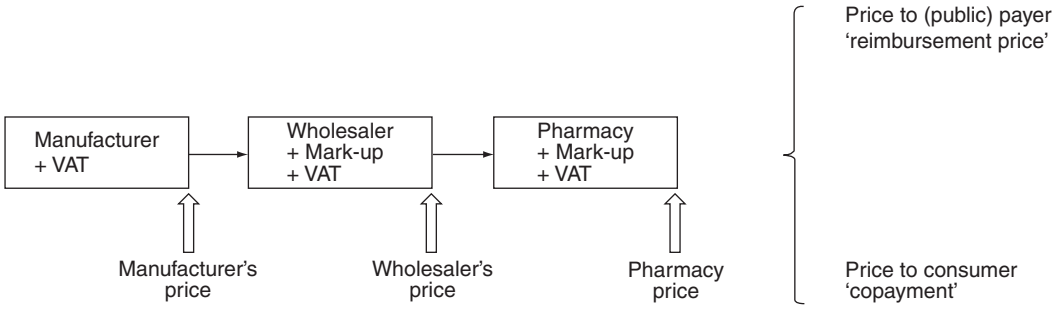

Figure 1 Various levels of 'price' in the pharmaceutical market.

i.e., lists containing all pharmaceuticals that are reimbursed up to a certain amount or for a certain percentage of the pharmaceutical price. The main difference as compared with the US is, however, the scope of a reimbursement/coverage decision. Although a negative decision by one health plan in the US affects only coverage of a drug for patients in that one (regional) plan among many, a negative decision in a European country usually applies for the whole public system, i.e., it excludes that pharmaceutical from reimbursement for the entire population; except for those few with private health insurance. However, there are exceptions in decentralized healthcare systems in Europe, such as in Spain and Italy, where a decision is only valid for a region or where a centralized decision may be overruled by a region.

Some countries, for example, the UK and until recently Germany do not regulate the manufacturer prices directly and only exert influence on the reimbursement price by means of health technology assessment, negotiated rebates, or reference pricing. Other countries, however, combine the reimbursement decision with statutory pricing or price negotiations, for example, France, Italy, and Spain. For those countries that regulate prices of pharmaceuticals, it is common to only regulate prices if manufacturers apply for reimbursement. Also, if a country operates public and private healthcare systems side by side like in Germany, regulation of prices may refer to both systems, whereas reimbursement regulation usually refers to only public health insurance.

The reimbursement process usually starts with the manufacturer applying for reimbursement before the launch of their product (e.g., France, Italy, and Spain). Exceptions apply, as products may already be sold while the application is being submitted or evaluated (e.g., Germany and Austria). In some countries, the decision-making procedure is not linked to market launch directly but may be initiated at any point of time by the regulator (UK: England). The process itself may include two components (**Figure 2**):

1. A pricing decision by the regulator. Either by (a) an agency/authority that sets list prices, i.e., statutory pricing or (b) by negotiation of list prices between the manufacturer and an agency/authority.
2. The reimbursement/coverage decision, i.e., the decision on who will get access to the pharmaceutical (patient population and conditions) and on the amount of reimbursement or the percentage of the list price being reimbursed. Again, the decision may include negotiable (e.g.,

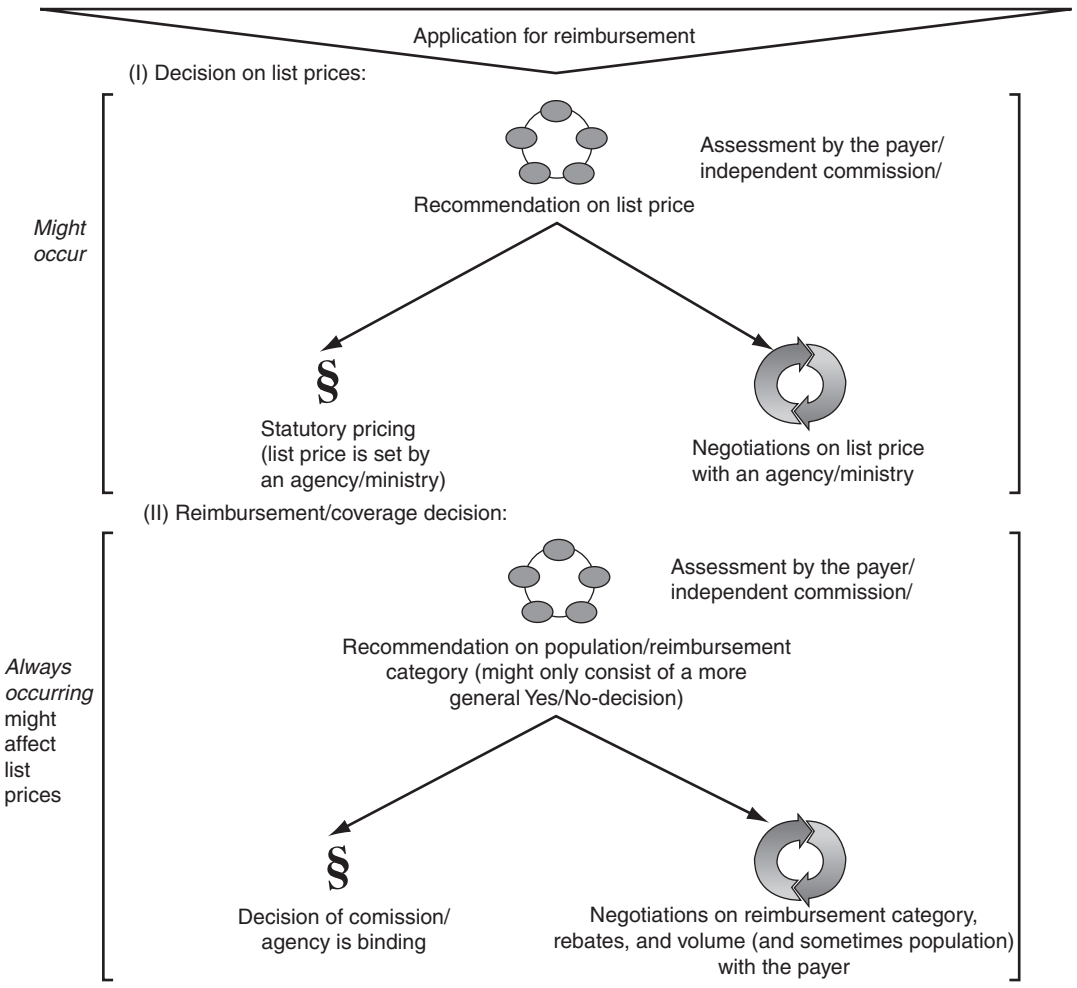

Figure 2 The process of a reimbursement decision.

negotiations on a rebate between the manufacturer and an agency/authority on list prices) or nonnegotiable elements.

Both decisions are usually based on some kind of benefit assessment of the pharmaceutical in question. Sorenson (2010) has found in her comparison that nearly all the EU countries apply health technology assessment to some degree to classify pharmaceuticals according to the therapeutic improvement they deliver. Although the UK applies cost-effectiveness analysis directly that results in a Yes/No decision on the reimbursement status of a pharmaceutical for a particular indication, countries such as France and Germany determine therapeutic improvement (added medical benefit compared with existing therapies) and later on negotiate rebates or prices in order to guarantee value for money. According to a systematic literature review by Erntoft (2011) and comparisons of reimbursement decisions by Blankart *et al.* (2011), other criteria such as budget impact and type of disease (acute vs. chronic and common vs. orphan) may also play an important role when making reimbursement decisions, especially when deciding on the percentage of list price that is to be reimbursed. Sometimes, the therapeutic value of a pharmaceutical itself (not in comparison to existing therapies) or the underlying product properties, i.e., whether a drug prolongs life, whether it improves, or whether it only maintains the patient's condition are used as well.

Demand- and Supply-Side Regulation Structure

Apart from the initial reimbursement decision and classification into a reimbursement category, additional reimbursement regulation exists in all EU countries to influence price, prescription volume, quality of prescribing, or total spending. These approaches are often categorized as demand-side interventions, i.e., interventions that target pharmaceutical consumption at the point of utilization (patients, physicians, and hospitals), and supply-side interventions, i.e., interventions that target pharmaceutical consumption at the point of production or service delivery (manufacturers, wholesalers, and pharmacies) (**Table 1**).

Table 1 Overview of the regulation on the demand and supply-side

Supply-side (industry, wholesalers, and pharmacies)	*Demand-side (patients, physicians, and hospitals)*
Price controls	*Price controls*
Based on clinical performance	Copayments
Based on economic performance	(Enforcement of) generic substitution
Costs of existing treatments	(Enforcement of) parallel trade
Costs (cost-plus regulation)	
Price in neighboring countries (external reference pricing)	*Volume controls/quality of prescribing*
Prices of comparable products (internal reference pricing)	Patient education/information
Temporary price freezes	Prescriber education/ information
(forced) rebates on price/ tendering	Prescription guidelines
Regulation of pharmacy/ wholesaler margins	Prescription monitoring/ auditing
	Prescribing targets (with monetary incentives)
	Classification of products as Rx or OTC negative lists
Spending controls	
Payback/clawback mechanisms	*Spending controls*
Price-volume agreements	Drug budgets
Rebates/discounts	Payback/clawback mechanisms
Risk-sharing agreements	
Industrial regulation	
Profit controls/rate of return	
Tax benefits

Internal Reference Pricing

Reference pricing is one of the most common supply-side measures used in many European countries. The measure refers to reimbursing the same amount for a group of comparable pharmaceuticals (so-called reference pricing cluster), i.e., the difference between the list price and the reference price is borne by consumers as a copayment. Manufacturers whose products are priced above the reference price will usually lower their list prices to the reference price (**Figure 3**). In this case, the consumer is not affected by reference pricing at all as all drugs in a reference pricing cluster are available without an additional copayment.

Although the basic idea behind reference pricing – paying the same amount of money for the same therapeutic value being delivered – sounds reasonable, whether all pharmaceuticals put into one reference pricing cluster are therapeutically equivalent remains a highly debated question.

Generally, it is important to differentiate between (1) therapeutic reference pricing and (2) generic reference pricing. Although in generic reference pricing a common reimbursement limit is established for the off-patent originator and its generics (same active ingredient), therapeutic reference pricing includes all pharmaceuticals deemed to be comparable by the regulator, usually based on mechanism of action, pharmacological properties such as duration of action and form of administration, and/or indication. Depending on the design of the reference pricing scheme, it is possible that a group includes several originator drugs in the same therapeutic category and their generic versions if available. Although generic reference pricing is usually limited to the off-patent market, therapeutic reference pricing may also include pharmaceuticals still on patent.

The method of determining reference prices varies between countries. Countries use the lowest or average of the few lowest prices in a group of pharmaceuticals or define the reference price to ensure that a certain number of products is available at or below the reference price. Depending on the method used, freedom of choice for physicians among fully reimbursed pharmaceuticals is being more or less limited. For example, in Germany, the reference price is set in such a way

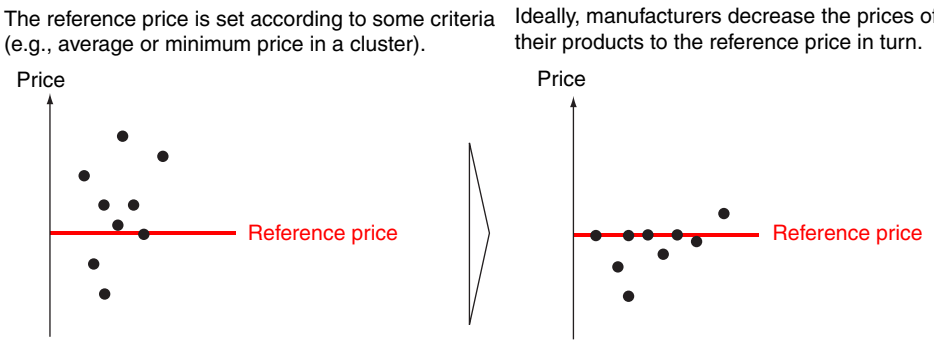

Figure 3 The basic concept of reference pricing within a group of comparable pharmaceuticals.

that roughly one-third of all packages in one group are available at or below the reference price. Although some countries use complex mathematical formulas to determine a reference price per package, others, for example, Hungary, determine the reference price as the lowest price per defined daily dose.

Galizzi *et al.* (2011) have found in their systematic review on reference pricing that the result of generic reference pricing has been consumers switching to less costly products of the same active ingredient, which usually also leads to increases in the market share of generics in general as well as a decrease in drug expenditure. In the case of therapeutic reference pricing, switching may not always occur to less costly drugs within a group of pharmaceuticals but also to close substitutes that are not subject to reference pricing. Schneeweiss *et al.* (2003, 2004) found a decrease in expenditure of CAD$ 6.7 million for angiotensin converting enzyme inhibitors (i.e., 6% of total expenditure for all cardiovascular drugs before the policy change) and CAD$ 1.6 for calcium channel blockers (CCBs) (i.e., 12% below projected expenditure for CCBs from the prepolicy trend) in the first 12 months for the Canadian province Ontario, respectively, whereas Stargardt (2010) found net savings after considering costs due to switching between €94 million and €108 million in the first 12 months for statins in Germany (i.e., between 7.7% and 8.8% of prepolicy expenditure for statins).

Although the majority of studies, for example Schneeweiss *et al.* (2003), do not find evidence of patient's health being affected by policy-induced drug switching, there is also some evidence of increased health-care utilization that points in the opposite direction. Stargardt (2010) found more hospital visits, especially due to cardiovascular disease, for the subgroup of patients that switched their medication more than once following the introduction of reference pricing for statins. However, given the different designs of reference pricing schemes, the variability of manufacturers' reactions to regulation and differences in the study design with regard to measuring the impact of reference pricing, a final drawn conclusion is perhaps unwarranted by the few Canadian and the one German study that use patient-level data to measure healthcare utilization after the application of reference pricing to a drug class.

Regarding the effect of reference pricing on drug prices, Galizzi *et al.* (2011) have found evidence in support of a reduction in prices in the first instance of forming a reference pricing cluster to be dominant in the literature. The long-term results of reference pricing on drug prices, however, are not very clear. Stargardt (2011) provides evidence from Germany that suggests that reference pricing also generates a long-term downward trend in prices, whereas other studies, such as Kanavos *et al.* (2009), argue that the reference price also works as a price floor, below which no producer has an incentive to decrease their price. Again, these differing results are unsurprising, given differences in design of reference pricing systems. In general, however, there is evidence of increased generic competition under reference pricing.

External Reference Pricing

In addition to internal reference pricing, i.e., referencing to prices of other pharmaceuticals within a country, the majority of EU countries also applies external reference pricing, i.e., referencing to prices of the same pharmaceutical in other countries. According to a review article on external reference pricing by Leopold *et al.* (2012), 25 countries, nearly all except for Denmark, Sweden, and the UK, make use of this instrument to some extent. The degree to which information on foreign countries' prices is used differs: It can be used either as the main criterion or only as supportive information in pricing and reimbursement decisions. Also, external reference pricing may be applied either to newly launched pharmaceuticals until the completion of Health Technology Assessment only (e.g., Austria) or to all pharmaceuticals on the market.

The design of external reference pricing varies greatly among the EU countries: some countries define the lowest price (e.g., Hungary and Poland), the third lowest price (e.g., Greece and Bulgaria), or an average of the six lowest prices (e.g., Slovakia) of a basket of foreign prices – as their reimbursement limit – whereas others use an average of all foreign countries' prices included in the basket (e.g., Austria and Ireland), or the price of the country from which the drug has been imported (Luxembourg). Furthermore, according to Leopold *et al.* (2012), the number of countries included in the index varies considerably between 2 (Latvia) and 26 (Slovakia). Portugal, Ireland, and the Netherlands reference only neighboring countries, whereas Austria, Greece, and Slovakia do so to almost all of the EU-25 nations. Generally, however, basket composition seems to be in accordance with the rank of each country according to gross domestic product

(GDP), i.e., countries seem to reference countries with similar levels of GDP.

The extensive use of external reference pricing may, on one hand, create cross-border spill-over effects of price reductions that are welcomed by policy makers and may reduce health-care costs in general. On the other hand, Stargardt and Schreyögg (2006) and Richter (2008) argue that cross-border spillover effects also provide strong incentives for strategic product launches as well as for launching delays and lobbying activities and can affect the effectiveness of regulation or the final decision of a manufacturer to launch pharmaceuticals at all. In particular, Danzon and Epstein (2009) show that external referencing can lead to both reduced access to new drugs and higher prices in lower income countries in the EU.

Sometimes, both types of reference pricing are applied simultaneously or in different instances, for example, external reference pricing is used before or while a reimbursement decision is being taken, whereas internal reference pricing is applied if the molecule loses patent protection. Eventually, the increased use of external reference pricing may contribute to convergence of prices within Europe. Whether this increases or decreases social welfare remains a subject for future research, given the differences between European countries in both consumer preferences and willingness to pay.

Copayments

Compared with the US, copayments in Europe are of minor importance. Historically, copayments were initially introduced as a prescription fee that restricts pharmaceutical consumption, i.e., volume, and does not exert influence on price. Later on, the instrument evolved, as it became partly dependent on prices. Today, many EU countries operate a system of multiple reimbursement categories (positive lists), each of which is subject to a different level of reimbursement, i.e., 90%, 80%, 70%, etc. It is part of the initial coverage decision taken at launch in each market, and thereby also determines copayments. Unlike the US system, there are typically no differences between 'preferred' and 'nonpreferred' brands within a therapeutic category. For example, although one or two of the eight statins may be in the preferred brand tier of a US drug plan (with the others being in the nonpreferred tier or the tier for generics), the same reimbursement category would be valid for all statins reimbursed in nearly all healthcare system in Europe. Thus, the same percentage of reimbursement prices will be reimbursed whether it is branded or generic.

In countries that apply internal reference pricing there might be two types of copayments: (a) prescription fees or price-dependent copayments as defined by the reimbursement category and (b) additional copayments, if the list price of a pharmaceutical is above the reference price, i.e., the difference between the list price and the reference price, regardless of the reimbursement category.

As many studies have found that copayments impact adherence, European healthcare systems usually limit the total annual copayments for (a)-type-copayments to a fixed percentage of the individual's annual income, or exclude vulnerable groups such as severely diseased, retired, or children from copayment on general principle. However, when patients do anticipate that they will be spending more than their annual deductible, the marginal costs of pharmaceutical consumption are reduced to zero and patients will be price-insensitive. This makes those who consume the most nearly price inelastic as they are either generally exempted or can expect to hit the maximum annual copayment threshold anyway. Thus, besides their contribution to financing pharmaceutical care – with the exception of some of the eastern European countries – the impact of (a)-type-copayments on consumption behavior is in those subgroups that consume pharmaceutical the most, rather small. Also, individuals may adapt to the level of copayment after sometime. Lessons from behavioral science and psychology, for example, adaption-level theory have shown the tendency of people to adapt to stimuli over time. Thus, there may be decreased effectiveness of copayments in reducing demand over time.

In contrast to (a)-type-copayments, (b)-type-copayments are seen more as the result of private luxury, i.e., the consumption of a health-care product is considered nonessential as there are always other comparable alternatives with no (b)-type-copayments available. Consequently, such surcharges are not included within annual limits. Thus, this clearly impacts choices of all consumers. For example, when reference pricing was applied to statins in Germany in 2005, this resulted in (b)-type-copayments for atorvastatin whose manufacturer kept the list price above the reference price between €18 and €109 per package (in addition to the 'regular' (a)-type-copayments of €5 per package). As a result, the market share of atorvastatin among all statins fell from 33.2% to 6% within 1 year according to Stargardt (2010).

Spending Caps, Drug Budgets, Prescribing Targets, and Prescription Guidelines

Supply-side regulation also includes measures to contain the volume of prescribing and – as regulators would call it – measures to influence quality of prescribing. Prescription guidelines aim to influence the choice between different active ingredients, clearly differentiating first- and second-line treatment options. This is related to the concept of a preferred product within a group of comparable pharmaceuticals, albeit not being connected to financial incentives. The use of the instruments ranges from nonbinding guidance for therapy choice, to enforceable rules as laid down in national law with electronic prescription monitoring being employed.

As a result of a systematic review of studies by Sturm *et al.* (2011), drug budgets that affect physicians have been found to decrease drug expenditure per prescription, to decrease expenditure per patient, and to decrease prescribed volume. Also, in order to prevent under prescribing in regions where there is a larger concentration of elderly or severely diseased, budgets need to take into account various demographic and epidemiological factors. Andersson *et al.* (2009) have found decentralized drug budgets to result in a higher degree of cost awareness by physicians as compared with a more centralized approach. Germany, for example, employs drug budgets at the physician level. The so-called practice-specific targets of cost control and appropriate prescriptions have been implemented since 2002.

Physicians exceeding 125% of the prescription target are required to compensate the sickness funds, unless they prove the necessity of their prescriptions from a medical viewpoint.

In the UK, physicians' individual prescribing behavior is being compared with national and regional levels. Specifically, data on prescription volume and costs of individual GP practices is collected and statistics are disseminated quarterly to encourage awareness of prescription volume and costs. Monitoring activity results in physicians being notified if they exceed regional averages. Similar systems exist, according to Vogler *et al.* (2008), for example, in France, Germany, the Netherlands, Sweden, and Italy. Sometimes, financial incentives, i.e., bonuses or penalties, are connected to prescribing targets in order to influence regulatory compliance of physicians. If electronic, auditing allows physicians to be constantly aware of their prescribing patterns. However, it also permits authorities to follow-up or intervene in cases of overprescription or underprescription. In any case, prescription monitoring systems rely on comprehensive electronic medical records that allow for comparisons at the regional level.

As continuous physician education and information by health authorities is also vital, prescription guidelines are an important tool to assist physicians with the appropriate/efficient choice of treatment in all countries. By excluding treatments or differentiating between first-line and second-line use of medication, differences in cost effectiveness are accounted for. If compliance with prescription guidelines becomes mandatory, then the use of a drug shall be limited to cases in which its utmost value is delivered according to the decision makers.

Parallel Trade and Promotion of Generic Competition and Substitution

Price regulation at the national level has generated differences in pharmaceutical prices across EU member states. In the presence of a Single European Market, within which circulation of goods is free, arbitrage opportunities occur. As the free movement of goods cannot be restricted, agents can capture economic rents by buying products in low-price countries and selling in other EU countries where prices are higher. Although the parallel traded products are the same as locally sourced ones and produced by the same manufacturers, parallel trade makes the pharmaceutical industry lose the difference between the local price in the importing country and the price in the exporting country, which is captured by parallel traders minus any transportation and (possibly) repackaging costs. Parallel trade may thus reduce the ability of manufacturers to price-differentiate across EU markets.

Parallel trade may lead to savings for health insurances in destination countries in the short run. The long-term effects are, however, debatable: Although some of the previous studies, for example, Ganslandt and Maskus (2004), have shown parallel trade to encourage competition besides significant reduction of manufacturers prices, others have shown that parallel traded products are usually sold at the same level as that of locally sourced ones or just below. Kanavos and Vandoros (2010) have found evidence that manufacturers use nonpricing strategies to respond to parallel trade and that the induction of price convergence by parallel trade seems to be upward rather than downward. Also, there is a discussion on whether parallel trade may lead to welfare losses because of a reduced incentive toward innovation.

For the low-price EU countries, parallel trade may lead to supply problems in the local market due to manufacturers' strong incentive to restrict and/or control volume of sale to local wholesalers. For example, after price cuts following the financial crises in Greece, parallel exports have led to local shortages of some drugs, resulting in a ban on exports of particular products. Such bans may swiftly resolve such problems, but authorities have to ensure that the policy measure is enacted early enough, before shortages are actually observed.

Some EU countries encourage parallel trade by sharing savings from lower prices with the distributional chain or by obliging pharmacies to dispense parallel imports, if available and cheaper by law. For example, in the Netherlands, health insurance shares any price differences between locally sourced products and parallel imported ones with the pharmacies. Thus, some of the savings resulting from increased competition are being transferred to the distribution chain. In Germany, pharmacies and the Federal Association of Sickness Funds even negotiate a minimum parallel import quota in order to exploit the full gains to the public payer.

Although parallel trade refers to exploiting price differences of an active ingredient by a manufacture across markets, generic competition exploits price differences between multiple producers of the same active ingredient within a country. At least for compounds with a large market size, alternative producers of the same active ingredient (generic manufacturers) enter the market on patent expiry. Sometimes, a so-called 'authorized generic' may enter 3–6 months before patent expiry through licensed production by the former innovator. This way, a generic manufacturer may exploit a first-mover advantage whereas the former innovator will extract some of the rents generated by the generic competitor.

In a study on pricing in the US, the UK, France, and Germany, Magazzini *et al.* (2004) have found a tendency for prices of branded products to decrease over time after generic entry in the highly regulated European markets whereas a recent study by Vandoros and Kanavos (2013) has shown opposite effects. Lu and Comanor (1998) have found the intensity of price competition to depend on the therapeutic area, type of disease (e.g., acute vs. chronic), and the launch price. In the US, however, according to Grabowski and Vernon (1996) and Frank and Salkever (1997), the prices of branded drugs have increased after generic entry, whereas the prices of generic drugs have decreased over time.

Generic penetration varies widely in EU countries as do policies to stimulate generic competition. Uptake seems to depend on (1) the price of the branded original and the difference between the price of the branded original and the price of generics that also determines the number of generic competitors in a market, (2) regulation that encourages or discourages the use of generics, for example, whether prescribing by international nonproprietary name(s) rather than brand name being mandatory or by the degree of generic substitution being mandatory at the pharmacy level, (3) the type of drug, i.e., when brand loyalty appears to be larger for some

disease area than for others, and (4) the enforcement of generic policies.

Rebates, Price-Freezes, Price-Volume Agreements, Tendering, and Risk-Sharing Agreements

Rebates or discounts on pharmaceutical prices are also commonly used instruments in EU countries. They can be imposed (1) on the national level by law (also known as price cuts or forced rebates) or (2) by following negotiations between manufacturers and payers at various levels, i.e., at the federal level, the regional level, or for each sickness fund. For example, in response to the financial crisis, Greece has commissioned two rounds of price cuts with a weighted average of 21.5% and 10.2%, according to Vandoros and Stargardt (2013). Germany too applies forced rebates for generics or pharmaceuticals not subject to reference pricing. The so-called price-freezes, i.e., the obligation of a manufacturer not to increase prices for a predefined time period, or the so-called price-volume agreements have been used in combination with price cuts and forced rebates. For example, in France, price-volume agreements on therapeutic drug classes are used to impose spending caps on pharmaceutical expenditure. Compliance with budget constraints is guaranteed by a clawback mechanism in case of overspending.

Competitive tendering has been extensively used for the procurement of drugs in inpatient markets of EU countries. In European outpatient drug markets, according to Kanavos *et al.* (2009), this policy tool is being implemented in Germany and the Netherlands only. In generic tendering, producers submit their bids (prices); one or more of the cheapest product(s) gain reimbursement status or at least some kind of preferred supplier status in return. The policy creates conditions of extreme competition between manufacturers, as only the cheapest product(s) is reimbursed by health insurance in that particular (reimbursed) segment of the market. Therefore, tendering can lead to very aggressive price competition, leading to prices close to the per-unit cost of production.

In the Netherlands, tendering was initially only used for three off-patent products (omeprazole, pravastatin, and simvastatin) in 2005. According to Kanavos *et al.* (2009), price reductions were in the range of 88% (omeprazole), 84% (simvastatin), 85% (amplodipine), 88% (citalopram), and 93% (alendroninezuur) of wholesaler prices. Consequently, the number of products subject to tendering was expanded. In the long run, however, there is a threat that winner-take-all tendering may eventually reduce generic competition: Manufacturers who systematically fail to win any bids may go out of business. If this happens, prices may experience an increase later on, although they are unlikely to reach their initial level. In addition, as pharmacies are remunerated on the basis of a markup of the manufacturer price, pharmacists' income may experience a significant decrease following the implementation of tendering.

One of the more recent forms of agreement between payers and pharmaceutical manufacturers is risk-sharing agreements. In these types of pay-for-performance arrangements, prices, and/or reimbursement are linked to patient outcomes, i.e., manufacturers have to refund a negotiated percentage of prices if predefined treatment goals are not met. This may be related to disease progression, progression-related death, or unacceptable toxicity of a drug.

On the one hand, Cook *et al.* (2008) argue that risk-sharing is a way to increase the confidence of payers in higher prices of innovative drugs. It thus provides an additional option in negotiations for manufacturers and payers that can increase overall efficiency by overcoming risk aversion of payers. On the other hand, this may involve high implementation costs. Barros (2011) argues that the monitoring of a drug's effectiveness will sometimes require special documentation by the treating physician or the dispensing pharmacist, and a suitable data infrastructure. Also, pharmaceutical companies are most likely to adjust prices upwards before negotiation in order to cover cost of failure in some of the patients. They thus see risk-sharing as a means to expand treatment to groups, which do not benefit as much from an innovation as requested by the regulator. Overall, there is still little proof of their long-term performance available.

Concluding Remarks

Owing to the need to limit pharmaceutical expenditure growth for public health insurance in European countries, the regulatory environment of pharmaceutical markets is constantly changing. In many European countries, a 'major reform' of pharmaceutical policy takes place almost on an annual basis. Given the costs of adapting to regulatory interventions by patients, physicians, and the pharmaceutical industry, the evaluation of goal attainment of policy measures in terms of cost containment, budget impact, effects on the provision of health services, and effects on the health of affected individuals, all are of great importance. Often, short-run effects of a policy such as cost-saving may be accompanied by unwanted long-run implications, for example, the worsening medication compliance or lower incentives for R&D. If not evaluated on a regular basis, the design of future measures cannot be based on past experience, which may – unnecessarily – waste scarce resources and harm patients.

Pharmaceuticals and National Health Systems

P Yadav and L Smith, University of Michigan, Ann Arbor, MI, USA

Background

Pharmaceuticals used to treat a variety of health conditions continue to be a critical aspect of quality healthcare. However, consistent access to medicines in many low- and lower-middle income countries persists as a major challenge. Although there has been a global increase in proportion of gross domestic product (GDP) spent on health, there are significant inequalities in the spending on pharmaceuticals across countries. When looking at the share of pharmaceutical expenditures to total health expenditure (THE) by country income group, one can see large differences between the mean spending in high-income countries, compared to low-income countries. This may be reflective of multiple factors including disease burden, health system infrastructure, differences in cost of service delivery and health policies (Table 1).

In 2006, 1.5% of the global GDP represented pharmaceutical spending. Pharmaceutical expenditures are negatively associated to GDP by income group with total pharmaceutical expenditure (TPE) as a share of THEs ranging from a mean of 1.41% in high-income countries to a mean of 1.62% in low-income countries. Lower-income countries spend a greater percentage of their total health costs on pharmaceuticals relative to their GDP (Table 2).

Further, among lower-middle and low-income countries, the private sector is where a large share of pharmaceutical expenditures are made. A considerable portion of this spending is based on a community's ability and willingness to pay for health products. In many low- and middle-income countries numerous individuals purchase pharmaceuticals using out-of-pocket (OOP) monies. Up to 50% of THEs are made using OOP monies of which, up to 90% go toward the purchase of medicines. The opposite trend appears to be true for high-income countries where health insurance and other financing or pricing policy may be in place (Table 3).

According to IMS Health, the largest segment of global spending growth for pharmaceuticals is expected in pharmaceutical markets in emerging economies such as China, Brazil, India, Russia, Mexico, Turkey, Poland, Venezuela, Argentina, Indonesia, South Africa, Thailand, Romania, Egypt, Ukraine, Pakistan, and Vietnam or pharmaceutical markets in emerging economies. Population growth, new healthcare reforms, and economic growth are expected to increase spending in these markets. In 2006, global spending on pharmaceuticals within pharmaceutical markets in emerging economies was 14% compared to developed markets including the European Union, Japan, the US, Canada, and South Korea. In 2011, this share increased to 20% and in 2016, it is predicted to increase to 30%. Given the forecasted increases in global spending, ensuring consistent access to medicines will remain a central focus for healthcare stakeholders. This article will outline the traits of pharmaceutical sectors within low- and lower-middle income country health systems. Further understanding of

Table 1 TPE share of THE, 2006 (%)

Income group	*Mean (%)*[a]	*Median (%)*	*Minimum*	*Maximum*
High	19.7	18.2	8.7	32.4

these system traits will enable strategic reform and improvements in this sector.

Pharmaceuticals and Health Systems

Health systems vary in form, but irrespective of the form of the health system, pharmaceuticals play a critical role within it to prevent and treat health conditions. It is important to understand the organization of each country's pharmaceutical sector in order to ensure consistent access to pharmaceuticals. Elements of financing, procurement, distribution, and service provisions must be effectively aligned to reach patients with medicines. Each of these components contributes to the overall effectiveness and efficiency of the health system.

Efficiency in a health system is a metric by which performance may be measured. Health system efficiency includes both technical efficiency – the method for producing a good or service at minimum cost – and allocative efficiency – the right collection of outputs provided in a health system to achieve overall health improvement goals. Evidence shows that in health systems with similar health expenditures per capita, technical and allocative efficiency help explain differences in population health outcomes (Figure 1).

Technical efficiency of the pharmaceutical subsystem within national health systems implies achieving best pharmaceutical related health outcomes at the lowest cost. The degree of technical efficiency varies with the structure by which financing is collected and potentially pooled to be used to procure medicines. For example, pooling arrangements may optimize technical efficiency of national health systems through the purchase of larger volumes of medicines at the most competitive prices. Allocative efficiency for pharmaceuticals in national health systems consists of product selection and resource allocation decisions that ensure medicines of greatest need and health benefit are available.

Technical efficiency and allocative efficiency couple together sustainability and equity goals of the health system. Further discussion of the elements impacting health system efficiency will be reviewed in individual detail in the sections that follow.

How Are Pharmaceuticals Financed?

In the overall health system the financing function typically: (1) collects revenue from multiple sources, (2) pools funds and spreads risks across groups, and (3) allocates funds to purchase goods and services. Within the general structure of health financing, pharmaceuticals may be financed through a variety of mechanisms.

Out-of-Pocket Spending

OOP spending typically makes up a large portion of financing for medicines in developing countries. Individuals make OOP payments most often for outpatient and chronic care. Spending of this kind typically impacts lowest income households, usually part of the informal economy, to the greatest degree. OOP can account for up to 50% of total healthcare expenditure in low- and middle-income countries, whereas in higher income countries this amount is estimated to be much less (approximately 15%). Of OOP expenditures, up to 90% are spent on medicines.

OOP spending may be individually financed from personal savings or through borrowing funds and accepting debt. In a study of 15 African countries done by Leive and Xu in 2008,

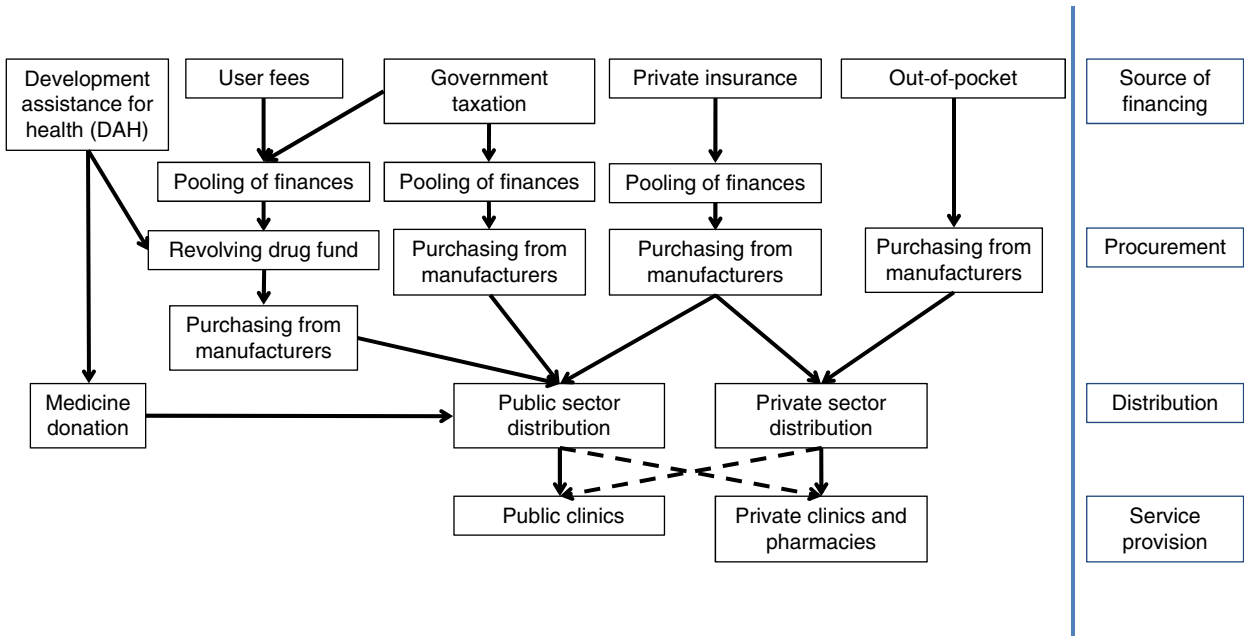

Figure 1 Pharmaceuticals in the overall health system.

approximately 30% of all households surveyed financed their OOP health expenditures by borrowing or selling assets. This form of healthcare financing is largely dependent on the populations' willingness and ability to pay for medicines.

Private Prepaid Funds

Prepayment of healthcare services and medicines is another financing mechanism available in certain contexts. Prepayment schemes are usually managed by health plans within countries. For example in South Africa, a separate healthcare company Yarona Care has developed prepayment schemes at discounted rates. Patients may purchase vouchers in advance for their expected health needs and redeem them throughout the year. Vouchers are priced to save community members money and guarantee them a network of quality service providers. This system presumes individuals have sufficient funds and are willing to pay for services in advance. Within populations with a high burden of chronic diseases, the expectation to pay for services and medicines throughout the year may be greater. Within populations with fewer long-term conditions to manage (or poor awareness and few available services for such conditions) and/or a larger emphasis on episodic care, individuals may be less inclined to purchase care in advance as their expectations for healthcare costs may be less certain.

The prepayment method of healthcare financing provides a structure to help improve healthcare resource allocation and planning at an individual level. It may also integrate technology to minimize administrative management and associated costs of voucher utilization as with the South African care model.

Revolving Drug Funds

Revolving drug funds (RDFs) involve a one-time investment of capital utilized to develop a self-sustaining medicine supply system. In low-income countries capital funds are often provided by external organizations as part of development assistance for health (DAH). Once established, RDFs are reimbursed through the sale of drugs. Funds are pooled before placing new orders of medicines directly with suppliers. RDFs create a consistent pool of monies with buffer financing to ensure timely procurement of essential medicines and consistent access for patients. RDFs act as a separate fund of money protected from fluctuations in available government resources and shifting political priorities. A fund of this nature does necessitate its own administrative management as well as cooperative coordination between invested stakeholders and funders. RDFs are a financing strategy utilized by multiple national healthcare systems in low- and lower-middle income countries to promote access to medicines.

Ensuring success of an RDF requires thoughtful consideration of the country context. Previous research has outlined a set of guidelines essential for a successfully implemented RDF. Where elements are lacking within these guidelines, further preparation or planning may be required before establishment of a revolving drug fund and/or alternative methods for improving access should be examined.

Private Insurance

Private healthcare insurance is typically paid for or provides care directly to employees by their employment firm. Employers offer insurance as a benefit to their employees, however, employees typically still pay copayments on medicines and premiums for services. The risk pooling that takes place is usually dependent on the size of the employer and/or the size of the insurance company offering a health plan to the employer. Employee-based insurance plans are less common in lower- and lower-middle income countries as many individuals work in the informal economy.

Private health insurance funds, separate from employer-supported insurance are voluntary and typically less common in most developing market contexts. Individuals contract with an insurance entity that pools the risk of all members. In general, individual private health insurance funds have low membership, low contributions, low coverage and weak regulatory environments. Private health insurance may be organized as a nonprofit entity or a for-profit entity. Typically nonprofit entities charge premiums just as for-profit entities. Nonprofit insurance plans are often arranged by religious groups, civic groups, hospitals and physician associations. Namibia and South Africa represent two countries where private-for-profit health insurance is relatively common. Private-for-profit health insurance providers represent the predominant prepaid plans in these contexts. For-profit insurance plans are funded through equity from private stakeholders as well as premium payments by enrollees. Uptake may be low as a result of the inability to afford annual fees and/or the perception that services and practitioners available for service are poor quality and so advanced payment is seemingly less appealing. Individuals may rather purchase healthcare only when necessary in these instances.

Community Health Insurance

Community-based health insurance (CBHI) is a voluntary insurance mechanism in which an organization coordinates a community of payers in order to pool risk to cover all or part of healthcare costs. At times, the organization may be a buyers' cooperative managed by representatives of the community. Studies examining the impact and effectiveness of CBHI in low-income countries have found that there is little evidence to support community-based insurance as a viable healthcare financing mechanism. Although successful in certain specific contexts, in general CBHI is not able to sufficiently mobilize financial resources. There is some evidence that suggests CBHI relieves some of the burden of OOP for patients and increases utilization of healthcare. Even with CBHI, ensuring benefits reach the lowest income community members continues to be a challenge in healthcare financing. This is a specific population group where access to care is only marginally affected by CBHI as many individuals cannot afford premiums or contributions to the insurance scheme.

In general, CBHI does not address barriers to accessing health care (i.e., affordability, perceptions of care quality, and geographic distance to healthcare facilities). Additionally, reimbursement processes tend to be burdensome for plan participants. Certain specific examples demonstrate that dropouts of CBHI membership are common. The result of this is a

smaller risk pool, which may in turn have a negative impact on the attractiveness of the health plan and future enrollment. Further research is needed to systematically summarize the characteristics of contexts where CBHI has shown a larger impact.

Social Health Insurance

Social insurance plans are a universal coverage health financing program in which membership is required for a population and members are provided a nationally determined benefit package of care. The World Health Organization has recently promoted social health insurance (SHI) plans as a means to reduce the burden of OOP on lower-income community members. Social insurance programs are typically financed through mandatory contributions from workers, self-employed, enterprises, and government. Most programs determine levels of contribution based on income along with contribution ceilings. Unemployed individuals within certain contexts are typically covered by others' contributions or by government assistance. Health risks are typically pooled across larger populations than with community-based insurance programs and private insurance (employer-based, nonprofit, and for-profit) programs and over a longer period of time in lower- and lower-middle income countries. A prerequisite to SHI is having a sufficient portion of a given population participate in the formal economy. In lower- and lower-middle income populations that have larger informal economies, payments into a national SHI may place a higher burden on the formal economic members.

The costs of running a SHI program are greater, with complex administrative, allocative and accountability mechanisms. Variations of SHIs exist across Europe, Latin America, and parts of Asia where the programs have been instituted. In these contexts, entire populations are included for coverage or coverage may be more selective with medicine coverage provided to a portion of individuals. Some SHI arrangements allow for individuals to opt out voluntarily whereas others cannot afford to include all individuals and so selectivity becomes financially necessary. Social insurance programs typically determine a formulary of covered services and essential medicines which the program will finance. These lists are often based on World Health Organization (WHO) recommended essential medicines, however, updates to lists may be slow with access to medicines potentially lagging behind healthcare need.

Taxation

This form of financing is collected in large pools of funds that are not controlled by consumer payments. For members of the formal economic sector, indirect taxation through purchases and direct taxes on income may be an effective way to collect revenue to fund public healthcare. Indirect taxes may include taxes of goods or services (e.g., alcohol or tobacco purchase taxes) or taxes on lotteries and betting. Direct taxes are typically taxes on personal income, business profits and transactions, imports and exports, and property. A portion of taxes is typically allocated to healthcare through the ministry of health.

Balance of Power in Procurement: Manufacturer, Payer, and Patient

In national procurement arrangements the balance of power between manufacturers and purchasers is more often seated with the manufacturer especially for patented medicines. For medicines that are only available from a single source (i.e., patented products or in some cases single registered manufacturer in the country), both pricing (i.e., affordability) and production (i.e., availability) are influenced to a great degree by the decisions of the monopolistic manufacturer.

In developing country markets there is often fragmentation of orders among multiple purchasing groups. This results in lack of coordination and significant wastage of resources (Figure 2).

In some instances the opposite may also be true (i.e., a single large buyer has influence over supplier(s)). In contexts where one group is responsible for the majority of purchasing for a specific product, the single buyer may be better able to negotiate prices with the manufacturer. With multisource products (i.e., products with more than one manufacturer supplying to the market) the purchasing body achieves the best possible prices (Figure 3).

In Australia and many countries in Europe, government is the principal payer for pharmaceuticals and the market resembles a monopsony. In Australia, the Pharmaceutical

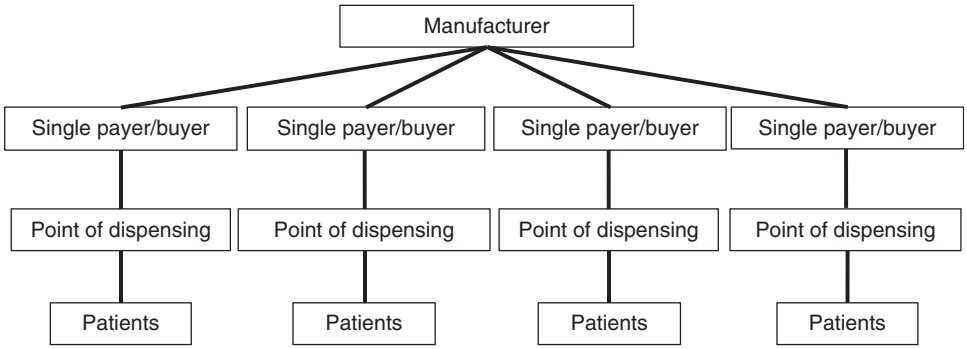

Figure 2 Manufacturer monopoly in pharmaceutical markets. *Point of dispensing refers to facilities such as hospitals, health clinics, and retail pharmacies.*

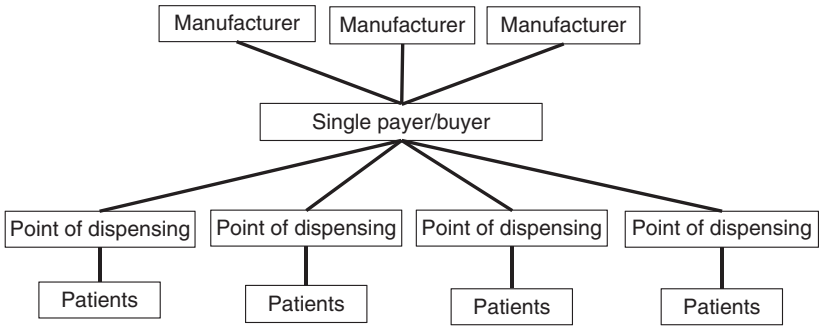

Figure 3 Buyer/payer monopsony in pharmaceutical markets. *Point of dispensing refers to facilities such as hospitals, health clinics, and retail pharmacies.*

Benefits Scheme (PBS) selects appropriate pharmaceutical reimbursement levels. In the US, Pharmacy Benefit Managers (PBMs) help align the balance of power between manufacturers and purchasers. PBMs provide services to health plans including price discount negotiation with retail pharmacists, rebate negotiation with manufacturers, and managing mail-order prescription services and claims processing systems. PBMs also help health plans develop appropriate medicine formularies, review prior authorization for specific products and substitution scenarios for generic versions of brand name drugs. In their relationships with both retail pharmacies and pharmaceutical manufacturers, PBMs manage payment for retail and mail order drugs. Acting on behalf of health plans, PBMs have been able to obtain discounted prices and improved process efficiencies. In other country contexts, more than one, but still a small number of payers may purchase from suppliers. This would most closely resemble a monopsony with the balance of power still with the payers; however, a continuum of different procurement scenarios and related balances of power exist between the two extremes, monopoly and monopsony.

In many low- and middle-income countries pooled procurement creates a balance of power between buyers and suppliers. These procurement arrangements influence affordability and the end patient price of drugs by pooling orders at a global level from multiple groups or countries and negotiating orders through bids from multiple suppliers. Pooling arrangements may take place within country or across multiple countries. Various pooling schemes are outlined in the section that follows.

Pharmaceutical Procurement and Distribution in the Public Sector

Medicine purchasing within the public sector may take place in multiple ways. Typically, procurement of medicines is based on epidemiological needs, funds availability, and sales and stock information collected from service facilities. Many countries rely on a registered list of essential medicines to determine which pharmaceuticals ought to be procured or reimbursed. Procurement varies based on the health system context and in many countries where health infrastructure continues to evolve so too does the procurement and distribution architecture. In health systems that are more centralized, often in geographically smaller countries, procurement is typically done by the ministry of health or a centralized agency acting on behalf of the ministry of health. In health systems that are decentralized, often larger countries with more extensive healthcare infrastructure, procurement of pharmaceuticals may be appropriated to the state or equivalent regional level.

National Pharmaceutical Procurement

Brazil provides an example of decentralized procurement of medicines. In Brazil, the Regulatory Council of the Pharmaceutical Market (CMED) approves medicines prices and adjusts products available on the market annually. The CMED helps to regulate purchasing prices paid by the government for medicines included in the Ministry of Health's essential medicines list. Procurement within the Brazilian Unified Health System (SUS) is entirely decentralized and performed by the Federal Union, 5564 municipalities, 26 states and the Federal District. Current evidence suggests that this fragmented administrative structure although allowing certain flexibilities may lead to allocative inefficiencies of financing. Specifically, in municipalities with smaller populations, procurement of medicines is often more expensive because of lower negotiating power on smaller quantities purchased.

Several strategies have been recommended to mitigate these procurement inefficiencies including development of pharmaceuticals in public production laboratories, creation of consortiums of municipalities to engage in small-scale pooled procurement, predetermined pricing regulation that is consistent across states and centralization of purchases for pharmaceuticals at the national level for products manufactured by single provider and/or those that have the most expensive pricing and/or products that require importation. Of these strategies, municipal consortiums for medicine procurement have been implemented and examined in southern Brazil. The Intermunicipal Health Consortium (CIS-AMMVI) improved access to medicines by reducing the purchase price and the number of stockouts. These benefits may impact smaller municipalities most as they are able to reach economies of scale and better negotiate prices in a larger tender process.

Similar to the strategy to set pricing standards across states or equivalent regions, Mexico has implemented the Coordinating Commission for Negotiating the Price of Medicines (CCPNM) and other health inputs. This national-level entity coordinates across public health institutions to collect background information including economic documentation to assist in annual negotiations for public procurement prices for patented medicines. Pricing negotiations are reported to save the country substantial financial resources; however, the political will and sustainability of this group may be less certain in the future. A coordination commission of this nature requires ongoing political support, appropriate performance indicators, and predetermined methods for assessing impact and transparency with key stakeholders.

Several centralized procurement models were setup in India at the state level to ensure consistent access to medicines. The Delhi Model Drug Policy pooled procurement for all hospitals within the state with a storage and distribution center. This policy not only organized procurement but it also pushed for implementation of standard treatment guidelines and a standard essential list of medicines, which fed into the development of a formulary for the state. In addition, a nongovernmental organization (NGO), Delhi Society for the Promotion of Rational Use of Drugs (DSPRUD) was contracted to implement technical activities related to the state policy. The Delhi model was largely seen as a success increasing access to medicines in many government hospitals.

Similarly, in Tamil Nadu, the state instituted a centralized drug purchase organization, the Tamil Nadu Medical Services Corporation Limited (TNMSC). TNMSC was developed to create a systematic method for streamlining the purchase, storage, and distribution of essential medicines in the public sector. TNMSC setup information systems including the provision of computers to warehouses for tracking stock in and out of storage and passbooks at clinics and hospitals to record inventory received. The TNMSC procurement gave structure to the previously fragmented purchasing structure. It laid out guidelines for the selection of suppliers, payment procedures, and standard essential medicines. This pooling mechanism has helped to purchase medicines at lower prices and to better ensure consistent availability of products. This model is now being used as a national benchmark for centralized procurement within each Indian state.

Centralized pooling of procurement for pharmaceutical products increases the level of influence a community of buyers may have on suppliers. Pooling higher volume orders enables suppliers to reach more efficient production at economies of scale. Buyers are better able to realize these efficiency savings because they are aligned and can negotiate in a unified fashion for lower prices. Pooling may also provide benefits to suppliers as they will be provided with a forecast of demand from a larger community of purchasers rather than relying on each individual tender. As a result, they may be better prepared with installed manufacturing and supply capacity to serve the needs of their buyers. However, in nationally centralized systems the administrative and management costs required to ensure information is collected and pooled in a timely fashion may be challenging and complex. Decentralized purchasing creates more flexibility among purchasers to order whenever necessary. The result is a procurement system that is more responsive to fluctuations in demand and may be better able to prevent stock outs. The tradeoff between the flexibility of decentralized purchasing and lower prices obtained through centralized purchasing should be considered according to each context.

Global Pharmaceutical Procurement Groups

Global pooled procurement of medicines enables countries to negotiate contracts with suppliers at the global level. As with pooling within countries, pooling orders across countries provides smaller countries or countries requiring fewer medicines for specific diseases with increased negotiating power. Joint procurement arrangements typically involve an organizing, intermediate buyer. Often, donor agencies will help facilitate this intermediate step either by setting up a new intermediary buyer as the Partnership for Supply Chain Management in the case of President's Emergency Plan for AIDS Relief or working with existing procurement groups as with vaccines for GAVI-eligible countries procured through United Nations Children's Fund (UNICEF) (Table 4).

Multiple actors in the pooling mechanism may introduce the same inefficiencies and delays in payment and shipments as with traditional individual tenders. In certain pooling arrangements, revolving funds are used to address delayed payments from buyers to ensure payment is assured to suppliers and medicines are received as needed. Revolving funds require additional management and may be relied on too heavily to fill in financing gaps. Global pooling arrangements may not be best suited to all contexts. Countries with limited domestic resources to purchase medicines (highly resource constrained) as well as contexts with large purchasing volumes and thereby individual purchasing power (i.e., Brazil, India, China) may not be well-suited to a multicountry pooling mechanism.

Setting Prices/Price Ceiling or Reimbursement Levels for Pharmaceuticals

Because pharmaceuticals constitute a large portion of the overall health expenditure, payers and governments use different levers for managing the prices of pharmaceuticals. The exact nature of the method used depends on the way the overall health system is organized.

The most direct form of controlling prices is a statutory price control used at the ex manufacturer, wholesaler, retailer, or some combination of these levels in the distribution chain. Most countries in Europe, Australia, Canada, and many Francophone African countries use such an approach. In many instances the health authorities set a price for a medicine based on the prices for that product in other countries in its region, income class, or countries with other similarities. For example, the prices in Greece are selected to be the average of the three lowest prices in the European Union (EU). In some countries medicine prices are set based on a comparison with medicines that have similar active substances. In India the price of a select group of medicines (scheduled drugs) is regulated whereas others are not regulated. Indonesia, South

Table 4 Examples of pooled procurement

Group name	*Characteristics*
UNICEF vaccine purchasing pool for GAVI-eligible countries	● GAVI-eligible low- and lower-middle income countries register with UNICEF to participate in pooled procurement primarily for vaccines ● Buyer specifies order needs with UNICEF and UNICEF responds with pricing estimate ● Buyer formally places order and pays full amount in advance ● UNICEF ensures appropriate flow of information to manufacturer(s) and monitors shipments to countries and distribution within countries ● Manufacturers deliver directly to countries
Organization of Eastern Caribbean States (OECS) (formerly Eastern Caribbean Drug Service (ECDS))	● Community of small island countries submits annual medicine, medical supplies and X-ray consumable needs to OECS ● OECS evaluates needs and selects tenders from prequalified supplier bids ● OECS awards annual contract and places orders directly with supplier ● Supplier ships directly to countries and OECS monitors delivery and quality ● Countries reimburse ECCB drug accounts upon receipt of medicines
Pan American Health Organization (PAHO) EPI Revolving Fund	● Central contracting model with Latin American and Caribbean countries specifying annual vaccine needs and submitting to PAHO ● PAHO evaluates needs and selects 1–3 supplier bids to fulfill needs ● PAHO submits prices to the buyer and the buyer confirms orders quarterly ● PAHO places confirmed orders with supplier quarterly and suppliers deliver directly to countries ● PAHO pays suppliers using a revolving fund within 30–45 days of delivery ● PAHO invoices countries and countries reimburse revolving fund within 60 days of delivery
Gulf Cooperation Council (GCC) Group Purchasing Program	● Group contracting model with countries in Persian Gulf region (7 countries) submitting pharmaceutical, vaccine, laboratory supplies and chemical needs for the next year to council group ● GCC combines information and shares tender information within prequalified suppliers ● GCC selects preliminary supplier bids and reports information to countries ● Countries are given 4 weeks to confirm or adjust orders ● GCC confirms final orders with suppliers and from then on suppliers work directly with countries utilizing purchase orders ● Supplier deliver directly to countries 1–3 times a year and countries pay directly to the supplier; suppliers pay GCC 0.5% fee
The Global Fund Voluntary Pooled Procurement Program (VPP)	● Procurement arrangement for Global Fund (GF) grantees with procurement agreement; voluntary for other GF countries ● Countries specify order details and delivery dates to GFVPP to receive quote ● GFVPP reviews and submits to prequalified procurement service agent (PSA) ● PSA invites bids from suppliers and submits price quotes to countries ● Countries review quotes and once approved, PSA prepares invoice and GFVPP disburses funds ● PSA confirms orders with suppliers and coordinates delivery to country; suppliers ship directly to countries ● Countries confirm orders in country and PSA reconciles accounts

Africa, and many other lower middle-income countries also have such schemes.

Most countries in the EU regulate their wholesalers and retailer margins in addition to control on ex manufacturer prices. The wholesaler and retailer markup regulation takes multiple forms such as fixed percentage markup, fixed absolute markup, and regressive markup (i.e., the markup decreases with increases in the product price resulting in incentives for the channel to also stock and promote lower cost products). For example, in Spain for products with a selling price lower than €22.90 the wholesale margin is 10.3% of the price; for products priced higher than €22.90 and lower than €150, a margin of 6% on the portion of the price higher than €22.90 is charged; and for products above €150 a 2% margin is allowed on the part of the price over €150. South Africa and India use a single exit price regulation where the retail price is set once the price negotiations with the manufacturer are carried out.

A less direct form of price control is through the use of formularies, which specify which drugs will be used for which condition and the price to be paid for it. In return for putting a drug on the formulary the payer (insurance company or hospital) asks the pharmaceutical company to offer discounted prices. In some cases these pricing negotiations are

carried out on behalf of the payer by specialized organizations called PBMs.

Some countries such as the United Kingdom (UK) and Australia also use pharmacoeconomic assessments and health technology assessments (HTAs) to set the prices of new medicines. This involves a cost–benefit analysis of the new medicines relative to existing treatments. Based on HTA, recommendations are made on the price and reimbursement level for the medicine evaluated. The National Institute for Health and Clinical Excellence (NICE) of the UK is a pioneer in the use of such techniques.

More recently risk-sharing between the manufacturer and the payer is gaining ground in some countries such as the UK. Under such arrangements the pharmaceutical company gets a smaller price/reimbursement level at the start and as health outcomes are realized from the use of the product the remaining reimbursement is made. These are like payment by result schemes where part of the payment is based on outcomes achieved in practice. Numerous examples exist, but a noteworthy one is where the pharmaceutical company agreed to pay NHS if the product atorvastatin failed to reduce LDL-C levels to agreed targets and a risk-sharing program for Bortezomib used to treat multiple myeloma.

Domestic Production Versus Import of Pharmaceuticals

Economic and public health views on the issue of pharmaceutical access

Domestic production as a strategy to increase access through the reduction of production and shipping lead times, decline in importation costs and the development of the local economy is an important component of the ongoing debate around improving access to medicines. Within this discussion there is often tension between economic interests and public health interests. Domestic production of pharmaceuticals is thought of as a means to create new jobs and increase the skill-level of local communities. However, this industrial economic argument for local production may sometimes be at odds with public health interest to improve access, both availability and affordability, of medicines. If quality medicines cannot be produced efficiently and cheaply in the local context, local production may not be the best investment of resources.

It is reasonable to expect that countries would want to become self-sufficient with their production, especially as they have seen domestic pharmaceutical industries developed in other developing country markets (i.e., India, China, Brazil, South Africa). However, historical examples should be considered with thorough understanding of the current realities of global trade, regulation, international economics of the pharmaceutical industry as well as the aforementioned assumed tension between economic and public health interests. Global trade, more specifically patent policy as a part of the Trade Related aspects of Intellectual Property Rights (TRIPS) agreement, has been cited by many as a complex, resource-intensive area to navigate for developing country governance structures. Context-specific information will help to establish the case for national manufacturing self-sufficiency when appropriate.

Domestic Production Business Models

Pharmaceutical companies in low- and middle-income countries are broadly organized into four main business models. The first is a pharmaceutical subsidiary of a large multinational company. The locally situated business will manufacture branded products for local and regional markets. The second business model consists of generic manufacturers producing a large portfolio of generic drugs for the global market. These drugs typically meet global quality standards and are competitively priced. The third business model consists of domestic generic manufacturers with a national focus on operations. Most manufacturers that fall into this category produce drugs for their country of residence or neighboring countries. Some, but not all manufacturers meet good manufacturing practices (GMP) standards for their products. Small-scale local manufacturers make up the fourth business model. These manufacturers typically serve local or regional markets and often do not meet GMP standards. Sometimes, small-scale manufacturers may be owned or managed by a local NGO or large hospital group. The portfolio of medicines produced is often focused on fewer drugs.

In addition to the aforementioned business models, domestic production of drugs may be setup as a combination of models. The level of production in locally situated manufacturing facilities may also vary based on the governing business model. Typically, most domestic production of medicines in low- and middle-income countries focuses on formulation and packaging of products. Chemically synthesized products (i.e., the active pharmaceutical ingredient (API)) are typically purchased and imported for local formulation into a complete product. Chemical synthesis tends to be a more complicated process; however, many generic manufacturers serving the global market are able to produce APIs for sale to others and/or as a part of their drug production. At any level of production pursued by domestic manufacturers, large capital investments are required up front to finance initial production facility development and technology transfer. Joint ventures like Cipla Ltd. Joint venture with Ugandan manufacturer Quality Chemicals and GlaxoSmithKline's joint venture with South African manufacturer Aspen may provide some examples of ways domestic production may begin in new developing country markets.

Domestic Production Decision-Framework

The decision to pursue domestic production versus importation of medicines is dependent on quality costs, regulatory costs, size of the local market, competitiveness within the local market, availability of skilled manpower, and economic status of the country. In certain contexts, domestic production does not make economic sense and investments would be better made elsewhere (i.e., investment in healthcare infrastructure or stimulation of the existing local market). Successful domestic production requires a functional ecosystem to support business sustainability. An active national regulatory authority is needed

to manage quality reviews and enforcement of standards. Further, international trade regulations may require additional investment of resources, both time and money, to compile with global policy. To cover initial capital costs related to regulatory requirements and installation of capacity, significant market share and sales volumes are needed to reach economies of scale. Without these elements, domestically produced drug prices may remain high and will struggle to be competitive both locally and globally. To address the issue of access to medicines through domestic production, countries should conduct a thorough market analysis considering the current business ecosystem. Batson, Evans and Milstein developed a framework that may be used for pharmaceuticals and vaccines to determine the production model that works best given a country's market size, GDP per capita income and current technical capacity.

Similarly, strategic policy options, similar to those Seiter outlines for different market contexts should be considered to create the appropriate mix of domestic investments (Table 5).

How Are Medicines Distributed?

Medicine distribution may take place through supply systems that are run by governments or the public sector, the private sector and NGOs or faith-based organizations (FBOs). Within each of these supply chains, characteristics such as the type of commodity, geography, flow of finances, cost of commodities, public versus private treatment seeking will be different based on the country context. Generally, procurement, distribution and provision of pharmaceutical goods are managed across groups with involvement from public, private, and NGO/FBO sectors.

Private Sector Distribution

Private sector supply chains for medicines typically include a network of importers, wholesalers, sub wholesalers, pharmacies, and drug stores. In most emerging markets, pharmaceutical manufacturers sell products to national importers and wholesalers. Beyond the national level, there are often a large

Table 5 Policy options for different market contexts

Market context	*Proposed strategies*
Countries with sizeable home market and an existing competitive industry, such as India, Brazil, South Africa	● Strengthen governance and the regulatory framework to ensure that the local industry can produce for the global market ● Gradually abandon subsidies or preferential market access to expose local industry to global competition at a pace that allows it to adapt and become stronger ● Open the market to foreign companies willing to invest in the local industry, encouraging the introduction of new technology, and development of R&D capacity to further improve competitiveness
Countries with a medium sized or small home market, or an existing industry with questionable competitiveness	● Strengthen governance and the regulatory framework to ensure safety of drugs in circulation ● If the local industry is used to a protected environment, allow two to three years for adaptation, but implement a clear path toward full enforcement of GMP standards and a market that is open for globally operating competitors ● Encourage collaboration and mergers between companies; invite foreign companies to take over local manufacturers. The goal should be to eliminate substandard manufacturing but keep as many jobs as possible ● Assist the local industry in exploring export markets
Countries with a medium sized home market, no relevant local industry, but good infrastructure	● Focus resources on developing an efficient procurement system, distribution chain, and payment systems with incentives for rational use of pharmaceuticals ● Develop strong regulatory capacity to secure safety of drugs in circulation ● Explore willingness of larger global companies to invest in local pharmaceutical manufacturing, but consider the incremental costs of upgrading the governance and regulatory framework ● If subsidies are considered for industrial policy reasons, they should neither become a burden on the health budget nor lead to higher drug prices
Countries with a small or medium sized home market, or with limited infrastructure	● Focus resources on developing an efficient procurement system, distribution chain and payment systems with incentives for rational use of pharmaceuticals ● Develop strong regulatory capacity to secure safety of drugs in circulation ● Shut down substandard manufacturing operations; assess the possibility of changing the business model from manufacturing to pharmaceutical wholesale and distribution

number of intermediaries between manufacturers and patients (wholesaler, sub wholesaler/stockist, retailer). Many private sector wholesaler networks struggle to reach more remote communities and so they rely on others to increase their distribution networks. Markups at each tier of the supply chain results in higher overall markups on medications. As a result, a complicated private sector distribution chain may negatively impact affordability to the patient. This may in turn impact a manufacturer's ability to increase sales volumes and once economies of scale have been met, lower price points (Figure 4).

Fragmentation and opacity of information as a result of fragmentation across groups may cause poor coordination in distribution of medicines. Poor coordination impacts availability of health products as stock information may be poorly communicated; however, this may be less of a concern in the private sector, than in the public sector, as business profits may provide a greater incentive for better reporting in the private sector. In addition to availability, poor coordination may also impact the ability to track suboptimal and poor quality products entering the private sector medicines market (Table 6).

Table 6 Median availability of selected generic medicines in public and private health facilities in low-income and lower-middle income countries during the period 2007–11 (percentage)

	Mean	*Maximum*	*Minimum*
Public sector	50.1	87.1	21.2
Private sector	67.0	90.7	22.2

Source: Adapted from World Health Organization/Health Action International (WHO/HAI). Medicine price and availability surveys (2007–2011). Available at: http://www.haiweb.org/medicineprices (accessed 26.07.13).

Public Sector Distribution

In most public sector distribution systems, particularly in Sub-Saharan Africa, a centrally located warehousing and distribution point, often called a central medical store (CMS) manages the top tier of distribution. CMS then distributes medicines to regional or district stores depending on the geographic characteristics (i.e., the size of the country and relative distribution network) and product- or program-specific supply systems. Often donor funding for specific products and/or health programs creates multiple vertical supply systems in the public sector.

In many public sector supply systems, the risk of stockout at the health clinics is high because of skeletal distribution and reporting systems. As is such, availability tends to be lower in the public sector when compared to the private sector (see Table 5). In some cases, where pharmaceuticals are not free, increasing the prices of certain medicines covers distribution costs. This approach may lead to disparate access to certain medicines for which there are no vertical

funding systems. In general, medicines provided in the public sector are more affordable to patients when compared with prices to mean number of day's wages in the private sector (Table 7).

Nongovernmental Organization/Faith-Based Organization Distribution

NGOs and FBOs may also play an important role in distribution of pharmaceuticals in emerging markets. Distribution managed by NGOs and FBOs is often context specific, however, typically arranged according to a customer's own prearrangement, courier services, drug supply organization delivery services, or direct delivery services. Medicines are often purchased according to customer inventory needs (pull system) or given through prepacked kits of essential medicines (push system). The level of involvement of NGOs/FBOs sector varies considerably across countries.

Summary

Pharmaceuticals play an integral role in the prevention and treatment of a variety of health conditions. Consistent access to pharmaceuticals remains a challenge in many national health systems. This is despite increasing levels of healthcare investment through domestic expenditures and large increases in DAH for low-income countries. This article reviewed the attributes of pharmaceutical sectors within low- and lower-middle-income country health systems. Such analysis is important to ensure the long-term sustainability of national health systems and also to ensure that DAH investments have the intended impact of improving access to medicines.

An optimally designed health system will operate at a high level of technical and allocative efficiency. In this form, pharmaceuticals may be purchased and distributed at the lowest cost possible and the most appropriate set of pharmaceuticals will be provided to serve the needs of each specific population. To achieve these goals, elements of financing, procurement, distribution, and provision of pharmaceuticals must be effectively aligned.

For pharmaceuticals functions of collecting funds, pooling funds and spreading risks across groups, and allocating resources to purchase products often occur through a hybrid of multiple financing strategies. The most common forms of financing include OOP payments, private prepaid funds, RDFs, private healthcare insurance, CBHI, SHI, and government taxation.

With financing secured, pharmaceuticals must be purchased at prices to ensure affordability and long-term sustainability of the manufacturers. When thinking about different procurement structures it is important to consider the influence of different stakeholders in decision making. In decentralized models, purchasing power is distributed to a larger number of individuals within the health system. Decentralized procurement may provide individuals with more autonomy and flexibility, in turn lowering the number of stock outs. Conversely, decentralized procurement may also disempower smaller groups when negotiating lower prices with national or global suppliers. In nationally centralized systems the administrative and management costs required to ensure information is collected and pooled in a timely fashion may be challenging and complex. However, if done well, centralized systems with single payers, do improve the negotiating power of the payer as compared to the supplier. The tradeoff between flexibility with decentralized purchasing and lower

prices with centralized purchasing should be assessed according to each context. Beyond national pooling, international pooled procurement arrangements are often used to facilitate pharmaceutical purchasing in low- and lower-middle income countries.

During purchasing and once pharmaceuticals have arrived in country, payers and governments use different levers to manage the prices of medicines. Price controls utilized include creating a comparison pricing standard, regulating wholesale and retail margins on pharmaceuticals, directive formularies as a part of health plans and health technology assessments. Outcomes-based pricing and risk-sharing arrangements are also gaining popularity in countries such as the UK especially for expensive chronic care medicines.

Another option often considered by countries to reduce medicine costs is to develop a domestic market for pharmaceutical production. Domestic production is thought to increase access to medicines through the reduction of production and shipping lead times, decline in importation costs and the development of local economy. Although it is reasonable to expect countries to seek self-sufficiency, not every context can support a domestic pharmaceutical industry. The decision to pursue domestic production versus importation of medicines is largely dependent on quality costs, regulatory costs, the size of the local market, competitiveness within the local market, and the economic status of the country.

Once a source is identified and medicines have been purchased, distribution is the final step required to ensure access. Pharmaceutical distribution often takes place through a combination of public sector, private sector, and NGOs/FBOs. Fragmentation within each of these sectors and across sectors often equates to poor information flows and opacity in the distribution chain. Improvements and investment in national healthcare distribution systems may facilitate more consistent availability and affordability of pharmaceuticals.

Glossary

Double marginalization Phenomenon in which pricing of any good or service turns out to be excessive because not only manufacturers that have upstream market power overcharge in equilibrium equating its marginal costs and marginal revenue from its residual demand but retailers also overcharge as they can profit from their dominant position downstream equating again marginal costs to the marginal revenue from its residual demand. It is called double marginalization when upstream and downstream firms are separated. When both are vertically integrated in one unique firm, the phenomenon disappears and price turns out to be lower as the vertically integrated firm equates marginal cost to marginal revenue just once.

Over-the-counter (OTC) medicines Medicines that can be offered in pharmacies, or in some jurisdictions in other retail outlets, and that can be readily available to the public from the store shelves. Usually, these are medicines that have been in use for some time and which may only cause minor adverse effects when not used properly. There is usually enough competition among providers of such medicines among innovator brands, other brands, and generic alternatives. In many jurisdictions, direct to consumer advertising is only permitted for OTC drugs, but in others such as in the US, direct to consumer advertising is also permitted for pharmacy-only and prescription-only medicines.

Pharmacy-only medicines Medicines that can only be obtained from a pharmacy outlet, but which do not require a doctor's prescription. Such medicines may be dispensed only with the advice and assistance of a pharmacist. Usually, these are medicines that have been available for some time and that have no serious adverse effects when properly taken.

Prescription-only medicines Medicines for which a doctor's prescription is a legal requirement.

Introduction

Dispensing medical drugs is a profession that combines the particularities of a professional service and retail industry. The focus here is on retail pharmacy, leaving aside the special character of hospital pharmacies.

First, pharmacists are responsible for a range of professional services including offering advice and assistance to those receiving their medication. Pharmacists are responsible for making sure that people receive their medication safely and professionally. Second, a network of pharmacies and other retail outlets is a major vehicle for public policies designed to make pharmaceuticals available and affordable to the public throughout a jurisdiction. However, different jurisdictions do this differently. There is no single 'template' policy model that fits all jurisdictions.

In the middle- and low- income countries, there is tension between policies aimed at safe and proper dispensing and those aimed at availability and affordability.

This article focuses on the policy challenges that arise in setting up the rules and regulations governing this professional trade, the tradeoffs that need to be evaluated when designing markets in health care and the role of health economics in promoting public policy.

The article is organized into four sections. After the introductory section, the key policy instruments that are available to policy-makers and societies are highlighted and described (Section Challenges and Policy Options). The focus is on the differences between the quality, entry, and price regulations that characterize policies based on a competitive market and on those that rely much more on a regulated command and control framework.

In Section Benefits and Risks from Regulating Pharmacies an assessment of the pros and cons of quality, entry, and price regulations is dealt with.

Challenges and Policy Options

Societies face a twofold challenge when organizing professional retail pharmacy markets.

First, the structure of the market should address the following to ensure that

1. the consumers get assistance and advice that is free from the personal interests of prescribers;
2. the consumers receive assistance and advice that is free from the personal interests of dispensers, particularly when a prescription is not filled; and
3. that the pharmacists and their assistants are professionals qualified in medicine and pharmacy.

Second, pharmacies are retail outlets that serve the cause of better access: through which professionals make affordable pharmaceuticals available to the local public. Key drivers of availability and affordability are the following:

1. Reimbursement arrangements: These should ensure that there are sufficient retail outlets or other distribution channels for pharmaceuticals across the country to dispense the medicines that are reimbursed by health care organizations.

2. Competition: Competitive pressure upstream helps retail pharmacists to get the best deal from wholesalers and manufacturers, with pharmacies ideally offering good deals to their customers and passing on to them most of the gain from the upstream competitive interaction.
3. Behavioral regulations: These ensure that providers, whether independent pharmacies or companies running pharmacy chains, do not abuse the public if they reach a dominant position in distribution and dispensing in their catchment geographical areas.

Given the objectives of safety/proper dispensing and availability/affordability, legislatures and governments regulate key elements of the industry. There are three well established traditions in high-income countries regarding the two main objectives. In most countries of continental Europe, the trade is generally reserved to licensed community pharmacies owned by independent pharmacists or by national, regional, or local governments. There are therefore rules limiting ownership of pharmacies to those who are licensed or employees of or contractors to the State. There are also rules that limit the number of pharmacies that each licensed pharmacist can own (usually a one-pharmacy-per-pharmacist rule). Moreover, in many countries, community pharmacies are subject to entry restrictions based on various tests of need.

In most European countries, chains are not permitted; vertical integration of retail pharmacies with medicine wholesalers or manufacturers is not permitted. Community pharmacies are obliged to sell the full line of authorized medicines in each country and deliver some health care services for other mandated health care providers.

By contrast, in the US and Canada there are no entry restrictions: there is free entry. Pharmacy chains owned by limited or public companies are common, although such companies contract licensed pharmacists to manage the service under stringent professional codes. There are also many independent pharmacies owned by professionals that compete with the company-owned chains. Both independent pharmacies and chains are obliged to sell the full line of authorized medicines and drugs in each country. However, they contract in a voluntary basis with mandated health care programs (Medicare and Medicaid in the US), and with health maintenance organizations, the extra services related to the reimbursement of drugs within the health plans.

The UK, Ireland, and the Netherlands adopt an intermediate regulatory stance. There is no formal regulation limiting the entry of pharmacies. Entry is effectively restricted by contracts with the mandatory health care organizations. Potential entrants do not effectively enter without securing a contract and such organizations award them only after considering carefully the incremental benefits and costs of new pharmacy openings.

In these three countries, pharmacies ('chemists' in the UK) are independent retail outlets that contract to fill prescriptions covered by the mandated health care organizations. They also dispense pharmacological products prescribed by physicians not paid by the mandated health care organizations, and they also sell other medical products not requiring a prescription, as well as a wide range of common hygiene and health-related products. Some have broadened their range to embrace photography and other chemical-based product lines, and even products and services having little or nothing to do with health or health care. These 'chemists' compete with other retail outlets that sell over-the-counter (OTC) drugs without doctor prescription, other medicinal products and any other product and service.

In the middle- and low-income countries, all types of regulation can be found depending on the historical circumstances of each. However, middle- and low-income countries often have unregulated retailers that effectively sell many types of pharmaceutical drugs usually with neither a pharmacist-manager on the premises nor qualified assistant. Such outlets typically neither satisfy the obligation to sell a full line of drugs, nor ensuring that they dispense prescription-only drugs only when a qualified prescriber prescribes them.

There are six policy instruments used by most countries in the world that distinguish these three different pharmacy models: (1) restrictions to practice: professional licensing; (2) ownership restrictions; (3) separation of prescribing and dispensing; (4) pharmacist management, supervision, and assistance; (5) zoning; and (6) price regulation.

Restrictions to Practice: Professional Licensing

Professional licensing in retail pharmacy, that is, restricting the practice of pharmacy to qualified professionals is the law in almost all countries across the globe.

Countries differ in licensing retail pharmacy according to how 'the practice of pharmacy' is defined: (1) whether, or not, the ownership of a pharmacy is part of the practice of pharmacy, and as such, it is reserved only to pharmacists; (2) whether the management of the pharmacy is part of the practice of pharmacy, and as such, it is also reserved only to pharmacists; and (3), whether dispensing of medicines is part of the practice of pharmacy and as such is also reserved only to pharmacists.

In high-income countries, pharmaceutical retailing is reserved to pharmacists. It includes professional owners of independent pharmacies and professionals, who should be hired to manage, organize, even supervise or assist part or all retailing of medicines at each one of the outlets of any company operating a chain of pharmacies. This restriction is commonly observed and generally enforced.

By contrast, in middle- and low-income countries there are gray or second-tier outlets that sell medicines. Such outlets have no pharmacist owning the outlet, or to manage, organize, supervise, or assist the dispensing of medicines.

Availability and affordability problems in middle- and low-income countries are so severe that the authorities do not enforce professional licensing regulations on the grounds that such enforcement may further reduce the reach of their weak distribution networks. Having a licensed pharmacist performing these duties is perceived as an excessive cost of servicing in the outlet, partly fixed and partly marginal, that would eventually increase the price of the dispensing service. This is particularly true when medicines are sold without any pharmacist involvement in the preparation of packages with convenient labels and patient information leaflets containing clear and comprehensible directions for use. Mexico is among the few countries in the world in which the law clearly allows

pharmaceutical products to be sold in retail outlets without any pharmacist managing, supervising, or assisting the dispensing. Pharmacist involvement is only mandated in the case of dispensing psychotropic drugs.

Ownership Restrictions

Many countries reserve the ownership of pharmacy retail outlets to professionals or the state. Some countries allow the competition of nonpharmacist-owned outlets (usually company chains) with independent pharmacies (owned by pharmacists). Others forbid professional pharmacists to own the pharmacies in which they work.

The question of pharmacy ownership is controversial. Those in favor of restricting ownership to pharmacists claim that the key to make the pharmacy trade professional is the mandatory membership of the pharmacist-owner to a professional organization. They claim that only by having the pharmacist-owner subject to the rules and supervision of the professional body will pharmacists advise and assist patients in buying their medication according to the standards of safety and proper dispensing.

Without such ownership restriction and professional supervision, the claim goes, the personal interests of pharmacist would supersede the interests of the patient. At the same time, they claim that the standards of safety and proper dispensing should be decided by these professional bodies to which pharmacist-owners are affiliated and not by other government or industry bodies, which may in turn again give priority to their interests before the patient interests.

The main argument against the restriction of ownership of pharmacies to licensed pharmacists is that pharmacists-owners can also give priority to their interests before those of their patients. Professional bodies, which are mainly controlled by pharmacy owners, do not always set up the appropriate standards of conduct, nor do they always enforce sanctions against those affiliated owners who misbehave. It may even be easier to supervise and enforce standards of conduct over company chains that are liable for the conduct of their managers and employees and over pharmacists employed to manage outlets in pharmacy chains.

There are different perceptions of legal enforcement: for example, about the effectiveness in different jurisdictions of the different mechanisms for setting standards of behavior, organizing external supervision, and enforcing sanctions when there is misbehavior. Ultimately, enforcement depends on how clear the set of rules is and how tough the judiciary is in enforcement and penalty.

Ownership restrictions are widespread in Europe. As many as 18 out of 27 EU Member States reserve ownership of any pharmacy to a licensed pharmacist. It is only the Netherlands (since 2000) and Ireland among the old EU Member States that have free pharmacy ownership, together with most of the new EU Member States: Poland, the Czech Republic, Estonia, Lithuania, Malta, Slovakia (since 2005), and Slovenia (recently deregulated). Ten of the 27 EU Member States have state-owned community pharmacies: Bulgaria, Cyprus, Czech Republic, Hungary, Italy, Luxemburg, Malta, Poland, and Slovenia. Sweden is the only case in which the entire pharmacy trade was reserved to a state-owned enterprise from 1971 to 2009. In 2009, the Swedish government started to sell part of the state-owned pharmacy chain in clusters and new private pharmacies have been established, some in joint ventures with multinational chains. The new chains compete with the remaining part of the state-owned pharmacy chain.

Among middle- and low-income countries, Tanzania, Kyrgyzstan, Uganda, and Guatemala have state-owned pharmacies and other special arrangements such as contracted independent pharmacies and franchised Non-Governmental Organization pharmacies. The Dominican Republic project 'People's Pharmacies' is a successful program sponsored by the government to make available and affordable essential generic medicines for low-income families in all state-owned and managed health care premises, including state-owned pharmacies and hospital pharmacies. Sixteen out of the 27 EU Member States allow pharmacists to own only one independent pharmacy. In the remaining 11, pharmacy chains are allowed and widespread: Austria, Ireland, Netherlands, and Sweden among the old EU Member States, and the Czech Republic, Estonia, Latvia, Lithuania, Poland, Romania, and Slovakia among the more recent ones.

Chains are widespread and compete with independent pharmacies in the US, Canada, Mexico, and the Philippines. South Africa (since 2004) and Kyrgyzstan have corporate managed care preferred pharmacy networks.

Ownership restrictions to just one independent pharmacy go together with the prohibition on vertical integration with wholesalers or manufacturers. By contrast, when ownership is free and chains allowed, it is very common for some chains to integrate vertically with wholesalers or manufacturers. In such cases, economies of scale and scope may be attained and passed on to consumers. Those economies may not be passed on to consumers when chains reach dominant positions in the distribution of the medicines of some affiliated manufacturers, or in the distribution of all medicines in some catchment areas.

In the EU, the courts have upheld ownership restrictions when they have been questioned as being contrary to the freedom of establishment in the internal market. Pharmacy is excluded from the rules of the internal market and the service directive only when member States reserve the pharmacy trade to a regulated health profession or a state-owned entity as a means of protecting health in the context of a mandated or public organized health care system.

Prescribing and Dispensing Separation

Separating prescription of medicines to doctors (or prescribing nurses) and dispensing to pharmacists is a way of reducing conflicts of interest. Most countries forbid doctors from dispensing drugs and classify medicines in one of the following categories, depending on the level of advice and assistance that pharmacist should provide:

1. Prescription-only medicines: Medicines only with the prescription of one authorized to prescribe.
2. Pharmacy-only medicines: Medicines that can be obtained only from a pharmacy outlet, but which do not require a prescription from an authorized practitioner.

3. Over-the-counter (OTC) medicines: Medicines that can be made readily available to the public in other retail outlets – as well as in pharmacies.

In the legislation, prescribing by a doctor or a nurse-prescriber and dispensing by a pharmacist is the general rule in Europe, the US, and Canada. However, Austria, Belgium, Czech Republic, Cyprus, Finland, France, Greece, Hungary, Malta, Slovenia, and the UK allow exceptionally doctors in rural areas to perform both the prescribing and dispensing of pharmaceuticals in order to make sure the availability of service in remote areas.

By contrast, many countries, particularly in Asia and Latin America, have dispensing doctors or integrated health centers and pharmacies. The problem with this integration is that dispensing doctors are influenced in their prescribing decisions by their personal financial incentives at dispensing. The Philippines have encouraged the separation of prescribing and dispensing since 1995, and fees have been designed to financially promote such separation since 2002. By contrast, South Korea has clearly mandated the separation of prescribing and dispensing. However, enforcement of prescription-only and pharmacy-only rules varies strongly across countries. In many higher-income countries, and in most middle-and low-income countries, dispensing prescription-only medicines without any doctor prescription is widespread.

In these cases, the advice of pharmacists is the key to making sure that the safety and proper dispensing of medicines to patients is paramount. In such settings, financial incentives also apply: there is a lot of evidence that pharmacists' financial interests have an impact on the kind of advice and sales services they provide.

Pharmacist Management, Supervison, and Assistance

Most countries require that a pharmacist should manage the service and be responsible for ensuring that the pharmacy (whether independent or within a chain) complies with all professional rules, regulations, and standards. They also require that at least one pharmacist is always present and in charge of supervising or assisting in the dispensing of pharmaceuticals.

This is easier said than done in independent pharmacies, particularly in 'mom-and-pop' pharmacies in middle- and low-income countries. It is not clear cut whether enforcement of the rules of the profession is easier in company-owned pharmacy chains as competitors and pharmacists unions usually track compliance, or when all pharmacies are independently owned and supervised by a professional body governed by pharmacy owners or independent experts.

As mentioned before in the section Restrictions to Practice: Professional Licensing, Mexico is among the few countries in which the law allows pharmaceuticals to be sold in retail outlets without any pharmacist managing, supervising, or assisting in their dispensing. Pharmacist involvement is required only when dispensing psychotropic drugs. Moreover, as previously observed, many low- and middle-income countries do not enforce the law requiring pharmacist management, supervision, and assistance when retailing medicines.

There is a cost–benefit tradeoff to be evaluated by policy makers: having a pharmacists manage, supervise, and assist in the dispensing of medicines is expensive, particularly in the countries that lack qualified professionals, and the pricing of medicines will reflect these extra costs.

Zoning: Restricting Entry and Location of Pharmacies by Tests of Need

In most of continental Europe, independent pharmacists are subject not only to tight licensing regulations that restrict the trade to licensed professionals but also to government regulations that limit the number of pharmacies that can be open to the public in any given catchment geographic area. In 17 of the 27 EU Member States, entry restrictions under the formal form of zoning, quotas, or distance regulations apply. Among these countries, Slovakia has deregulated entry since 2005 and Slovenia is deregulating it. Hungary experienced some deregulation of entry and reregulation between 2007 and 2010. Portugal introduced some less restrictive entry conditions in 2006.

When zoning is in place, pharmacies are authorized to enter after some needs test, usually when the population to be served reaches some specified threshold. Three EU Member States have explicit distance regulations: Greece, Hungary, and Spain. Another three Member States (the Netherlands, Ireland, and the UK) indirectly control the number and location of pharmacies by awarding contracts from national health services to a restricted number of community pharmacies. Among the Member States, only, Bulgaria, Cyprus, the Czech Republic, Estonia, Germany, and Poland do not restrict entry according to any population need test.

Outside the EU, Norway at one time restricted entry. Currently, entry is free but pharmacy market shares are restricted. Entry is also free in Iceland, the US, Canada, and the Philippines. In Latin America, there are cases like the Dominican Republic where minimum distance entry regulations are in operation, and in countries like Chile and Mexico where the number and location of pharmacies is freely determined. South Africa has a restrictive system as new pharmacies have to obtain a certificate of need. It also operates a system of competitive price bidding for franchises. Mali has placed some limits to opening a pharmacy at the capital, Bamako, with the (unsuccessful) intention of moving new entrants to rural areas. India has passed more liberal legislation between 2000 and 2004. Mexico and the Philippines have been very successful in promoting the entry of pharmacy chains only for dispensing generics brands, boosting availability, and affordability of medicines throughout their territories.

Price Regulation

Pricing regulation in the pharmacy industry takes the form of mandated dispensing fees, maximum margins (percentage over the final price), or markups (percentage on the manufacturer's or wholesale price). Margins or markups can be fixed or regressive with respect to prices, and there might be rules mandating that no discounts and promotions are offered to

the public, or that such discounts should be subject to a maximum.

Entry restrictions in Europe are typically coupled with price or retail margin regulations. Seventeen out of 25 EU Member States (all but Romania and Bulgaria, for which the authors do not have information) set the pharmacy markups by regulation. Discounts are not allowed. The other eight set maximum markups or fees for services allowing competition in discounts and promotions.

Discounts to final consumers are allowed only in Cyprus, the Czech Republic, Estonia, Lithuania, the Netherlands, Poland, Portugal, and Slovakia. Denmark, France, Germany, Ireland, and Spain allow for limited discounts in medicines not listed for mandatory health care systems reimbursement. The Netherlands, the UK, and Spain mandate some clawbacks to the national health systems that get back from pharmacies part of the discounts obtained from wholesalers and manufacturers.

In general in the EU, pharmacists are paid a fixed but regressive margin with respect to the price of each medicine sold. In Ireland, the Netherlands, and Slovakia pharmacists are paid a fixed fee for service, and in the case of the UK their purchase costs are reimbursed and there is a separate fixed fee for service.

In the US and Canada, pricing is free but it is agreed with Health Maintenance Organizations and the federal programs (Medicare and Medicaid) for reimbursed medicines.

Australia, New Zealand, and Syria have also regressive margin with respect to final prices to consumers. By contrast, in most low- and middle-income countries, pricing is regulated as a fixed margin over prices to consumers.

Benefits and Risks from Regulating Pharmacies

Having reviewed entry and price regulation in the world-wide industry, now it is time to turn to some economic analysis of the rationale for such regulations and review the practical experience with such regulations.

To start with it is required to assess how quality deterioration can result both in the presence and absence of information asymmetries. When quality deterioration is present, all four regulations outlined before (professional licensing, ownership restrictions, prescribing, and dispensing separation and management/supervision/assistance mandates) may help the industry to reduce it at a reasonable cost. Then the pros and cons of entry and pricing regulations are reviewed.

Regulating the Quality of Service

Quality deterioration

Professional services, in general, involve the application of professional human capital in order to judge individual cases. As a result of this peculiarity of the professional trades, the quality of the service provided is difficult to assess objectively. In the case of the pharmacy business, in general, a medical doctor makes the judgment as to which drug treatment is appropriate for each patient. Among the pharmacists' duties, the most important is to fill the prescription correctly, to advise the patient how best to comply with the treatment, and to prevent undesired drug interactions. In the case of OTC drugs, the pharmacist also assumes the duty of advising the patient regarding her decision on which drug is better for her specific minor ailment.

In contract theory terms, the patient is the principal and pharmacist is her agent. However, the agent has an information advantage. The pharmacist decides whether to invest effort in providing a high-quality service, or shirk and provide a low-quality service. The patient knows, but only imperfectly, about the quality of the service received after the purchase. This is a simple and typical hidden information situation usually termed a 'screening problem.' It can lead to quality deterioration phenomenon through adverse selection of service providers in the market. Patients would like to screen the high and low quality of service pharmacies out of the pool of available pharmacies. The separating equilibrium with full information is the one that allows the patients to pay for the high- or low-quality service, depending on their preferences and willingness to pay. For example, patients receiving new treatments may prefer to pay for a high-quality service, whereas patients with chronic diseases receiving repeat prescriptions may prefer to pay less for a low-quality service.

When patients cannot distinguish the pharmacy type due to the lack of information regarding the provider, and only uniform pricing is available as arbitrage is almost costless, the well-known problem of adverse selection is encountered. All pharmacies would end up by serving only at the low price and low-quality level.

Professional licensing may be used so as to regulate minimum quality standards: it screens the more able providers and deters shirking. Almost any licensing requirement imposes a fixed cost of entry that may drive out the least able providers: the entry cost is simply not affordable for the potential entrants with lower abilities.

Quality deterioration may also occur when there are no information asymmetries, when providers serve the marginal consumer having the lowest willingness to pay for quality. Minimum quality standards can help to avoid such outcomes. Such regulations are supposed to drive quality up, lifting it closer to the willingness to pay by the average consumer. In doing so, these regulations can raise welfare. Professional licensing and rules restraining management, supervision, and advising only to professional pharmacists may help out to monitor minimum standard quality regulations.

Licensing, externalities, and public goods

Professionals in general, and pharmacists in particular, provide services not only to their consumers but sometimes also to the public at large in the form of externalities or by providing public goods. When pharmacists dispense vaccines, it is not only their customers that gain some surplus but also the public at large thanks to an externality in the form of a reduced probability of other people contracting the disease in question. Likewise, when pharmacists dispense narcotics or antibiotics only with a proper prescription, it is not only that their patients benefit but also the public in general. Avoiding drug dependence or antibiotic resistance is something that improves other people's health.

The regulation of professional behavior is usually justified by rationales such as these. Codes of conduct for filling

prescriptions, checking for drug interactions, serving chronic patients, and so on, contribute to the benefit of both patients and the public at large. Pharmacists also produce positive externalities in their role of gatekeepers.

Pharmacists are paid for these services. Some argue that, while performing these duties, the pharmacist should keep the associated rents. The threat of being expelled from the licensed profession would then also entail loss of rents that further restrains them from underperformance. Entry restraints and professional body oversight is thus viewed as a mechanism for encouraging compliance with their professional obligations.

Alternatively, the pharmacist might be paid for preventive services.

Regulating Entry through A Needs Test and Pricing

Theory is ambiguous as to whether there is scope for welfare enhancing entry regulations in markets of differentiated products in the retail pharmacy industry. The literature has identified instances in which restrictions in the number of suppliers or price controls, or a combination of both, may be welfare increasing.

In each locality, entry brings the benefits of greater price competition and better local availability (access). Consumers gain from both, receiving cheaper medication and having outlets closer to where they are located. Each new entrant steals business from the pharmacies located in their catchment area but at the same time brings benefits to consumers. In industries in which there are no fixed costs of entry (an up-front cost not related to the volume of business), free entry is welfare enhancing.

Free entry may, however, be excessive. Entry is excessive whenever differentiation by location is low (consumers are not willing to pay for having more pharmacies at different locations in any catchment area). In this case, entrants add less to the consumer surplus when they enter the market than the amount they reduce the profits to incumbents by stealing their business from them. So, if the fixed costs of servicing patients are large, there is scope for a welfare enhancing regulation that restricts entry. At the same time, competition in each catchment area will take the form of an oligopoly game, so there might be also scope for pricing regulation. The equilibrium pricing game drives pricing in oligopoly well above marginal or average costs.

The more general models of pricing in oligopoly games with product differentiation show that the Nash equilibrium implies prices that differ from marginal costs. Additionally, when pharmacies have dominant positions in their catchment areas, there is also room for policy to avoid what it is known as double marginalization, when the upstream market of manufacturers or wholesalers is not competitive enough. Double marginalization appears when prices turn out to be excessive not only because manufacturers or wholesalers have upstream market power to overcharge in equilibrium but also retailers can overcharge as they can profit from their dominant position downstream. Limiting this double marginalization by allowing manufacturers or the government to set the final price can be welfare enhancing.

However, private interests might lobby for entry restrictions and pricing regulations to ensure that pharmacists obtain excess profits or pure regulatory rents. The European Commission has initiated infringement proceedings against countries that operate over tight entry and ownership regulations on the grounds that restricting freedom of establishment is neither an adequate nor a proportional public interest policy. On the contrary, the EC argues that it is a way of guaranteeing rents for incumbent pharmacies. The European Commission has initiated infringement proceedings against Austria, Bulgaria, France, Germany, Italy, Portugal, and Spain, though the results of infringement proceeding have been modest.

Attempts to reform entry and pricing regulations are problematic as the incumbents occupying the upper tail of the distribution and who gain most from the restrictions will invest heavily in lobbying to avoid policy reforms.

Concluding Remarks

Countries should choose the combination of policy options according to their efficiency and feasibility in any constrained environment.

Getting prices right (i.e., close to average costs, whether by competition, regulation, or contractual arrangement) is key to approaching an optimum. It makes entry regulation unnecessary. However, it should be borne in mind that any good price regulation or contractual arrangement has to get the number of pharmacies right when setting the price.

Adjusting the price to the costs in different localities is also important and difficult but it is essential to make sure that pharmacies are available and open to the public throughout the territory.

When countries do not have the institutions, the human capital or the technology to get the pricing right or to get the right number of pharmacies, they have to evaluate whether capture drives regulation toward undesirable outcomes and whether free pricing and entry is an attainable and reasonable second best.

Physician Labor Supply

H Fang, University of Colorado Denver, Denver, CO, USA
JA Rizzo, Stony Brook University, Stony Brook, NY, USA

Introduction

Labor supply has been a well-studied topic in the labor economics literature (Killingsworth, 1983; Pencavel, 1986; Killingsworth and Heckman, 1986; Blundell and MaCurdy, 1999). As the key clinical decision-makers, physicians provide an essential input into the production of health care for their patients. Understanding the determinants of physician labor supply has important implications for the production and cost of care and for health care access. Hence, physician labor supply is a topic of considerable interest in health economics as well.

This article examines the factors affecting physician labor supply. Labor supply measures are considered broadly, and may include annual hours worked, numbers of surgeries performed, office visits, and so on. (Strictly speaking, physician labor supply curves must include earnings as a determinant of labor supply. Many studies, however, focus on other aspects affecting labor supply, such as the competitive conditions in the market. These studies typically do not include earnings as a separate factor affecting labor supply. A likely reason is that both measures of competition and earnings would have to be treated as endogenous, prohibitively challenging data estimation issues. However, these studies are included because from a policy perspective, it is important to understand a variety of factors that may affect the physician's decision to offer services.) However, the related topic of aggregate forecasts of physician manpower is not addressed. The authors begin with a general framework discussing the competing goals of the physician in choosing labor supply and then review studies that have examined a number of key issues affecting the labor supply decision.

This article is organized into seven parts. The Section Introduction discusses the conceptual issues in the physician labor supply decision. The Section Conceptual Issues considers studies of the relationship between physician earnings and labor supply. The effects of competition and physician fee schedules on labor supply are described in the Section Earnings and Labor Supply. This section also reviews labor supply responses as possible evidence of demand inducement. The Section Competition, Fee Schedules, and Labor Supply examines the roles of the so-called 'target income hypothesis,' and more recently reference incomes as they pertain to the labor supply decision. Physician labor supply under managed care is discussed in the Section Income Targets, Reference Incomes, and Labor Supply and the effect of malpractice liability on labor supply is examined in the Section Managed Care and Labor Supply. The Section Malpractice Liability and Labor Supply concludes this article.

Conceptual Issues

The physician is assumed to maximize his utility with respect to income and leisure, both of which are 'goods'. Income includes labor income and nonlabor income. In altruistic variants of this basic framework, patients' health enters as an argument into the utility function as well. (In altruistic models, the physician plays the role of agent for his patients, with patients' health entering as an argument into the physician's utility function. As the physician has competing objectives including the desire to obtain more income and leisure, he may be an imperfect agent.) The physician chooses labor supply so as to maximize this utility function. A complex constellation of factors, including earnings potential, altruistic goals, competitive conditions, incentives provided by insurers, the regulatory environment, and the threat of malpractice litigation may affect this decision.

A long and controversial debate has centered on the notion that income targets affect the provision of physician services. The so-called target income hypothesis asserts that physicians set income targets and, when their actual incomes fall below these targets, will increase the volume of their services to offset, in whole or in part, their perceived income shortfall. In critiquing this hypothesis, McGuire and Pauly (1991) have argued that there is no conceptual basis as to how income targets are set. Moreover, they present a theoretical model which demonstrates that increasing volume of services in response to fee restrictions need not depend on income targets, but may occur in the context of a standard model of profit maximization, provided that income effects from fee reductions are sufficiently strong.

Although the standard model underlying the physician's labor supply decision is neoclassical, more recent treatments that have considered the role of target or reference incomes on labor supply have adapted models from prospect theory (Kahneman and Tversky, 1979). Borrowing from prospect theory, these models incorporate the notion that physicians set reference incomes and compare these benchmarks to their actual earnings in deciding on whether to adjust their labor supply (Rizzo and Zeckhauser, 2003, 2007). These models also incorporate the notion of loss aversion (Tversky and Kahneman, 1991; Goette *et al.*, 2004), a phenomenon in which individuals strongly prefer avoiding losses to equivalent-sized gains. Loss version posits a kink in the physician's utility curve for different marginal utilities of income below and above this reference income. When the physician's actual income is less than the reference income, the marginal utility of income is very steep in that range. The relevance of reference points and loss aversion has been well-established in the experimental psychology literature (Rabin, 1998; Heath *et al.*, 1999; Schmidt and Traub, 2002; Fellner and Maciejovsky, 2007; Rizzo and Zeckhauser, 2003, 2007). Their inclusion in models of physician labor supply provides an empirically validated framework for understanding the relevance of reference of target or reference incomes for physician labor supply.

 doi:10.1016/B978-0-12-375678-7.01113-5

Earnings and Labor Supply

Perhaps the most salient factor affecting the physician's decision to supply labor is the economic return that labor will generate. Hence, a number of studies have examined this relationship empirically. Changes in physician earnings may exert both income and substitution effects on the labor supply decision. If the substitution effect dominates, an increase in earnings will lead to an increase in labor supply. At sufficiently high earnings levels, however, the income effect may dominate, in which case one would observe a backward-bending labor supply. Early studies examined the effects of nonlabor income on physician labor supply by focusing on exogenous variations in nonpractice income, typically finding insignificant nonlabor income effects (Sloan, 1974; Hurdle and Pope, 1989).

In terms of labor income, however, most physicians are not paid by wages or salary; hence, their hourly earnings are endogenous. Sloan (1975) examined the relationship between hourly earnings and hours worked employing a two-stage estimation treating earnings as endogenous. The effects of earnings on labor supply varied somewhat according to specification, but were generally modest and in some cases statistically insignificant. Using a nationally representative database of young physicians under the age of 40 years, Rizzo and Blumenthal (1994) estimated a model of physician labor supply, treating physician earnings as endogenous and employing two-stage least-squares estimation. They obtain separate estimates of the income and substitution effects of a change in hourly physician earnings for male physicians, finding a significantly negative income effect with an elasticity of -0.26, and a significantly positive substitution effect elasticity of 0.49. The total effect of wage increase is to raise labor supply, with an elasticity in the range of 0.2–0.3. Small sample size precludes obtaining separate estimates for female physicians. A more recent study from the UK also reports a modest positive association between earnings and physician labor supply, with elasticities in the range of 0.09–0.12 (Ikenwilo and Scott, 2007).

Brown (1994) contrasts the use of aggregate versus physician-level data in estimating the earnings/labor supply relationship. Using aggregated data he finds no effect (Brown and Lapan, 1972; Brown *et al.*, 1974), but a negative relationship using physician-level data, with an elasticity of -0.2. He argues that physician-level data are preferable for estimating labor supply. Bradford and Martin (1995) also find evidence of a backward-bending labor supply curve. Thornton and Eakin (1997) estimate a model of a utility-maximizing solo practitioner. They find that an increase in nonlabor income will lead solo practitioners to allocate fewer hours to medical practice activities. In addition, they also report both income effect and substitution effects of labor income changes. Consistent with earlier research, they find that the net effect of physician service fee reductions leads physicians to reduce their labor supply, so the substitution effect dominates the income effect.

Competition, Fee Schedules, and Labor Supply

Studies relating competition and fee schedules to physician labor supply have typically sought to provide evidence of demand-inducing behavior by physicians. If physicians increase their supply of services in response to greater competitive pressures or reductions in fees, then it is taken as indirect evidence of demand-inducing behavior. In fact, even if such relationships exist, it is unclear whether these behaviors reflect demand inducement. One is on firmer ground simply interpreting them as labor supply responses to changing financial incentives.

Competition and Labor Supply

Studies of the effect of competition on labor supply have employed metrics for competition such as per capita physicians in a market area, relating this measure to various types of physician services. An early study by Fuchs (1978) examines the supply of surgeons on the number of surgeries performed, treating physician supply as endogenous, with variables measuring the appeal of a market (e.g., urban, hotel receipts) serving as instruments. The results suggest that increased competitive pressure as measured by physician supply leads to an increase in surgeries, with an elasticity of 0.3. Subsequent studies employing a similar strategy but with more complete control variables produce similar results (Rossiter and Wilensky, 1983, 1984; Cromwell and Mitchell, 1986; Birch, 1988; Grytten *et al.*, 1990; Scott and Shiell, 1997; Baltagi *et al.*, 2005).

A limitation with these studies is the choice of instruments. Employing an instrumental variable approach typical in these studies, Dranove and Wehner (1994) produce the seemingly bizarre result that greater competition among obstetrician/gynecologists (OBGYNs) increases childbirths. As it is highly unlikely that physicians induce demand for children, this result is taken as evidence that the instrumental variable approach employed in these studies is suspected. In fact, the likely explanation for their result reflects border crossing, for example, that pregnant women travel to locations where there are ample supplies of OBGYNs. Dranove and Wehner (1994) calls into question any causal interpretation between competition and labor supply or demand inducement using the instrumental variable strategy described earlier.

Gruber and Owings (1996) employ an alternative approach to address the endogeneity problem. They study the relationship between physician financial incentives and cesarean-section delivery. Between state and intertemporal variations in fertility rates are used as exogenous measures of competitive pressures facing OBGYNs. They hypothesize that, in response to declining fertility in the US, OBGYNs will substitute vaginal childbirths for the more lucrative and physician-intensive cesarean deliveries. Using nationally representative data from the period of 1970–82, they find that a 10% drop in fertility leads to a 0.6% increase in cesarean sections.

Fang and Rizzo (2009) argue that the relationship between competition and physician labor supply depends on the nature of third-party reimbursement. Using data from the Community Tracking Study Physician Survey 2000–01, they find that physician volume increases with more competition under fee-for-service reimbursement, but decreases with greater competition under managed care.

Fee Schedules and Labor Supply

A number of studies have examined physician labor supply responses to fee restrictions (Lee and Hadley, 1981; Rice, 1983; Mitchell *et al.*, 1989; Hurley *et al.*, 1990; Hurley and Labelle, 1995; Escarce, 1993, Rochaix, 1993; Nguyen, 1996; Nguyen and Derrick, 1997; Yip, 1998; Tai-Seale *et al.*, 1998; Gruber *et al.*, 1999; Mitchell *et al.*, 2000; Kantarevic *et al.*, 2008). In contrast to the competition studies, fee reductions may be considered exogenous to the individual physician. A number of these studies have found evidence of a volume offset effect; that is, physicians respond to real declines in their fees by increasing the volume of their services. However, the volume increase is not sufficient to fully recoup the income losses from the fee cuts.

Thus, Nguyen (1996) studies physician volume responses to reductions in the Medicare fee schedule reduction. The results indicate that physicians will increase their service volume by 3.7% in response to a 10% reduction in the Medicare fee schedule. Nguyen and Derrick (1997) examine the impact of Medicare fee cuts for certain 'overpriced procedures,' finding that for physicians who experience the largest fee reductions, a 10% decline in price lead to a 4% increase in volume. In a comprehensive assessment of volume offset effects for multiple specialties and payers, Tai-Seale *et al.* (1998) find that the point estimates for volume responses to fee restrictions varied across specialties, but these responses were statistically insignificant in most cases. Yip (1998) studies the effects of reductions in fee schedules on the volume of coronary artery bypass grafting (CABG) procedure using a longitudinal panel of physicians in New York and Washington States. For physicians in both Medicare and private markets, she finds that physicians whose incomes are cut by reduced fee schedules exhibit a large volume response, recouping 70% of their lost income. Gruber *et al.* (1999) investigate the effect of Medicaid fee differentials on cesarean delivery. They find that cesarean delivery for Medicaid patients is significantly less likely than for privately insured patients, reflecting that the fee differentials between cesarean and vaginal deliveries are smaller under the Medicaid program than the private insurance. Mitchell *et al.* (2000) analyze physician labor supply responses to Medicare fee reductions during the period of 1991–94 using pooled cross-sectional time series data. They focus on ophthalmologists and orthopedic surgeons performing cataract extractions and major joint repair/replacement procedures, respectively. In contrast to most previous research, they find that fee reductions are associated with fewer surgeries.

Income Targets, Reference Incomes, and Labor Supply

The target income hypothesis asserts that physicians set income targets and will attempt to reach or get closer to this target by increasing their services in response to increased competitive pressures or cutbacks in their fees. Most studies of this issue have been indirect, relating measures of competition and fee cuts to the volume of physician services. Such studies have already been addressed in Section Earnings and Labor Supply.

Few studies have related direct measures of income targets to physician labor supply. Rizzo and Zeckhauser (2003) use a unique panel data of physicians under the age of 40 years that includes a physician-specific measure of target or reference income (in particular, physicians were asked: "Considering your career stage, what do you consider to be an adequate income after expenses but before taxes from your professional activities?" The response to this question was taken as the physician's reference income (Rizzo and Zeckhauser, 2003, 2007)). They find that incomes increase substantially in response to higher reference incomes for physicians who are below their reference incomes, but not for those who are at or above. However, they also note that physicians appear to raise their incomes, not by increasing labor supply as measured by hours worked, but by performing activities that generate a higher hourly return (e.g., performing more lucrative services). A subsequent study also finds no evidence that hours worked respond to reference incomes (Rizzo and Zeckhauser, 2007).

Managed Care and Labor Supply

Managed care has grown rapidly in the US since 1980 and is the dominant form of health insurance (Robinson, 1999). Intended to control the rapid growth in health care costs in the US, managed care may exert strong effects on physician practice patterns, including labor supply, because the physician's decision-making process is likely to respond to the financial incentives and restrictions created by managed care.

Hirth and Chernew (1999) discuss two fundamentally different labor market regimes for physicians: fee-for-services and managed care, noting that physicians practicing in managed care environments are less likely to enhance their income by providing more services compared with those mainly reimbursed on the basis of fee-for-service. Libby and Thurston (2001) examine the impact of managed care contracting on physician labor supply by extending the standard labor supply model to incorporate managed care incentives. They find that managed care contracting generally reduces the number of hours that physicians practice, but the net effects become small and insignificant after accounting for the endogeneity of physician managed care contracting behavior.

Malpractice Liability and Labor Supply

Physician labor supply may also be affected by other factors such as the threat of malpractice liability. Thornton (1997) shows a significant income effect of a change in malpractice premiums on physician labor supply. In particular, higher malpractice premiums lead primary care physicians to increase their practice hours, possibly to recoup some of the income losses associated with these premiums. An alternative interpretation is that physicians regard malpractice premiums as a tort signal and attempt to work more hours to reduce the possibility of malpractice liability. Either effect leads physicians to increase labor supply. Thornton (1999) compares the magnitudes of the income effect and tort signal effect in

response to malpractice premiums. He finds that the income effect dominates, with the tort effect being much smaller.

In contrast, Helland and Showalter (2009) analyze the effect of state-level malpractice reforms during the period of 1983–88 on physician behavior. They find that an increase of 1% in the probability of incurring a malpractice suit will reduce the weekly hours worked by 0.29%. The magnitude of this elasticity increases to -1.224 for physicians aged 55 years or older. Kessler and McClellan (1996) analyze malpractice reforms designed to reduce the threat if physician liability to examine whether physicians practice defensive medicine; for example, increasing the provision of services to ward off the threat of malpractice suits. They find that malpractice reforms are associated with a significant reduction (5–9%) in physician expenditures for Medicare patients after the malpractice reforms without substantial changes in mortality or medical complications.

Conclusion

As key players in medical decision-making, understanding factors affecting the physician's decision to supply care will remain an important topic in health economics research. Much effort has been devoted to this issue already and with fruitful results. Most studies suggest that greater earnings potential and fee restrictions both lead to increased labor supply, though the response is typically fairly small and inelastic. Greater competition also appears to increase labor supply, although econometric challenges associated with much of this literature suggest that these results should be viewed with more caution. Perhaps not surprisingly, managed care has had a restrictive role on physician labor supply. Less certain are the effects of target or reference incomes and the role of medical malpractice liability.

Although the notion that reference points are used in decision-making has considerable empirical support (Rizzo and Blumenthal, 1996; Rabin, 1998; Heath *et al.*, 1999; Schmidt and Traub, 2002; Fellner and Maciejovsky, 2007; Rizzo and Zeckhauser, 2003, 2007), McGuire and Pauly (1991) rightly assert that there remains no theory as to how and why physician income targets are set and why they should affect the physician labor supply decision. Understanding these issues is an important direction for further research.

Increasingly, patients are playing a more proactive role in the care they receive from physicians (Fang *et al.*, 2008). This consumerist orientation may have implications for physician labor supply as well. Fang and Rizzo (2009) introduce the notion of 'physician demand enablement' as physician labor supply responses to patient-initiated requests for services. The effects of 'consumerist' patients on physician's willingness to supply care also warrant further study.

Physician Management of Demand at the Point of Care

M Tai-Seale, Palo Alto Medical Foundation Research Institute, Palo Alto, CA, USA

Introduction

Many perspectives can be taken to look at physician practice behaviors. Other articles in this section of the Encyclopedia and in the literature (e.g., by McGuire, Chandra, Cutler, and Song) provide extensive information on multiple approaches to studying physician practice. In general, empirical studies of physician practice behaviors build on administrative data which contain the information necessary for billing but no details on what happened in the encounter. They do not contain detailed information on how patient demand was expressed and how physician responded while they were engaged in an office visit, i.e., at the point of care. Survey data have its own problems, and can be subject to recall, social desirability, or self-perception biases. Physician management of patient demand at this microlevel needs special data to shed light on the exchanges between patient and physician. Video or audio recordings of office visits are two such data sources. This article focuses on interactions between primary care physicians and patients at the point of care, where patient demand is managed through conversations. By analyzing recordings in a detailed way, this methodological approach enables the authors to closely observe what Kenneth Arrow notes as the activities of producing medical care that are unobservable through the lens of administrative data.

Video or audio recordings of the visits allow the authors to examine the length and content of visits. They provide a comprehensive representation of the patient–physician encounter, unlike chart review which can be influenced by physicians' charting patterns and their tendency to underreport delivery of some services or overreport other services. The following two excerpts from transcripts of two visits illustrate the nuanced information about the demand for bypass surgery (Example 1) and uncertainty about incidence of disease and efficacy of treatment, and the use of heuristics in decision making under uncertainty (Example 2).

Example 1

An elderly female patient seeing her primary care physician for a dry cough, before undergoing bypass surgery that was scheduled to take place in a few weeks.

Patient: (Clasping her hands) and really, why I agreed to the surgery was because I thought that they would be able to fix the damage the heart attack had done to my heart. And they said no.
Physician: No, you can't fix that. It helps to reestablish the circulation so that you don't have any further heart attacks. … so I will see you back here after your surgery.
Patient: Yes, if I don't cancel it again.

It is seen that the patient had expressed some reservations about the operation. The physician did not address her concerns or allowing her to change her mind about undergoing the surgery.

Example 2

An elderly female patient seeing her primary care physician, after having had 3 visits during which multiple new psychotropic medications were started and stopped in the last 3 months. She complained of unsteadiness and off balance, anxiety, and forgetfulness. The following was the exchange at 17 min into the visit.

Physician: The girls are going to set up a follow-up appointment in two weeks and we will see how we're doing. You're going to stop the Lorazepam, stop Lorazepam, take Vitamin E, water pill, …
Patient: (Raising her hand as though to signal she has something to say) Now, …
Physician: (Taking her hand, shaking it, and continuing to talk) … everything else stays the same, including the Wellbutrin and we're going to see you back in two weeks.
Patient: But now, you said on that Vitamin E, 1000 twice a day, 2000?
Physician: Yes, ma'am.
Patient: Ok.
Physician: That's what the study states. It's written down here. Ok?
Patient: Yeah, sure.
Physician: (Moving to help patient down from exam table and starts walking towards the door) There you go. We'll try a little 'addition by subtraction' and hope that by stopping the Lorazepam that will stop your coordination difficulties and maybe the Wellbutrin we can continue.

Stopping Lorazepam suddenly instead of tapering it off slowly could exacerbate the patient's anxiety. The exceedingly high daily dose of vitamin E is also not indicated. From the video data it is noticed that the physician was not willing to hear any more from the patient but wanted to bring her back for another visit 2 weeks later.

Questions That Have Been Informed by Microlevel Interaction Analysis

Direct Observation Analysis

A number of studies that have shed some light on the 'blackbox' of patient–physician exchanges at the point of care using microlevel interaction analysis of video and audio recordings of office visits have been undertaken. They encompass three general areas: (1) time allocation in primary care office visits, (2) time management practice in office visits that resemble the use of a behavior rule, and (3) management of diverse demand with heterogeneous level of professional and personal uncertainties.

Time allocation in primary care office visits

Time is a scarce resource in a physician's office practice. How physicians use clinic time has important implications on

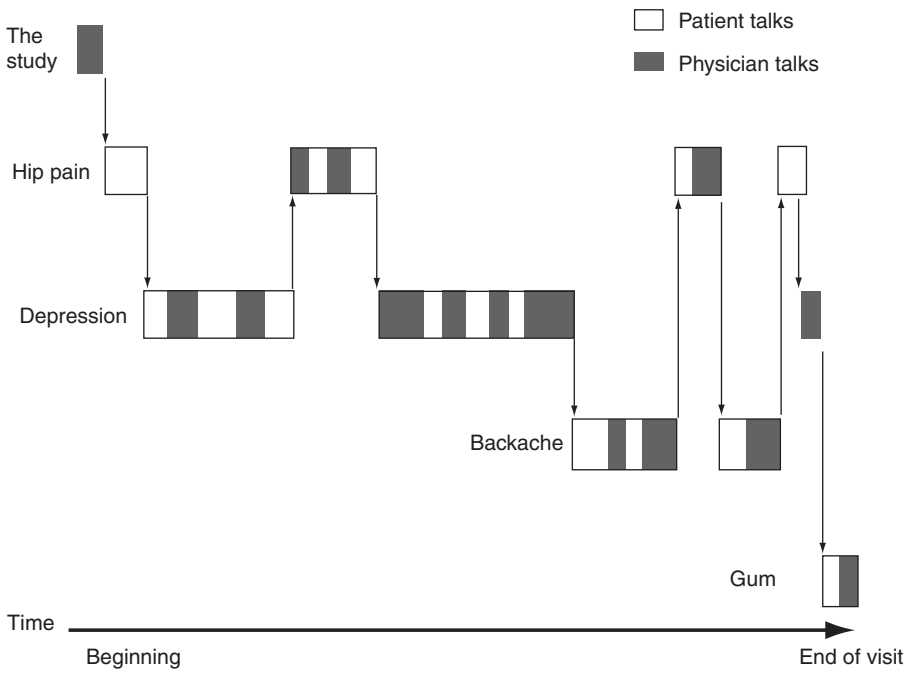

Figure 1 Flow of conversation during a visit.

quality of care, patient trust, and malpractice suits, and is one of the components of physician payments in the resource-based relative value scale. Primary care office visits are essentially communication events between patient (demand) and physician (supply) on which data and research methods from other scientific disciplines have made extensive efforts. Social psychologist Mishler views patient–physician conversations as complex, multidimensional, and multifunctional exchanges. Health services researchers recognize the unique and critical role of primary care physicians in providing patients with an 'advanced medical home' where complex comorbidities are diagnosed and treated. Despite previous research efforts on patient–physician interactions, however, the literature was silent on how physicians allocate time within a visit. The point of care exchanges that occur behind the closed door were considered hidden and noncontractible.

To examine how clinic time was actually spent during patients' visits to primary care physicians and to identify the factors that influence time allocations, a novel approach was developed to analyze video recordings of routine office visits in primary care practices. Currently, audio recordings of period health examinations (PHEs) are being analyzed in an integrated health delivery system which provides supplemental data on service utilization before and after the recorded visits. The findings have been rather thought provoking.

Specifically, not only the length of visits but also, more importantly, the content of visits in terms of units of clinical decision making referred to as 'topics,' operationalized as clinical issues raised by either participant was examined. An interaction was coded directly from an audio or video recording of the visit, along with transcripts of the interaction, based on topics sequentially introduced by patient or physician. After partitioning a visit into topics, the amount of time spent on each topic by patient and physician was further recorded. In the PHE study, the quality of communication on each topic was also measured. Figure 1 illustrates the flow of conversation in one visit, from topic to topic, over time. It is evident that the exchange took a rather free flow form, consistent with general conversation patterns in casual conversations, despite training in medical school and residencies on how to structure an office visit.

This approach of using microlevel data collected at the point of care allows the authors to examine how much time is dedicated to specific topics, the cognitive and emotional efforts invested in the exchanges across topics, and the factors that influenced how clinical time and efforts are allocated. It has been found that primary care office visits vary not only in length but also in the division of time among topics. Patients typically present multiple complaints during an office visit requiring physicians to divide time and resources during a visit to deal with competing demands. Very limited amount of time was dedicated to specific topics. In the video study, it was found that the median visit length was 15.7 min covering a median of six topics. Approximately 5 min were spent on the longest topic, whereas the remaining topics each received 1.1 min. Although time spent by patient and physician on a topic responded to many factors, length of the visit overall varied little even when contents of visits varied widely. Macrofactors associated with each site (e.g., academic medical center where physicians are paid by salary vs. physicians in fee-for-service solo practices or in a managed care group practice) had more influence on visit and topic length than the nature of the problem patients presented.

Time management practice resembling the use of a behavioral rule

The New York Times published an article about the above study entitled "The Ticking Clock in the Doctor's Office" along

with a cartoon which depicts a clock wedged between a patient and a physician. The ticking clock resembles an upward sloped shadow price of time that rises as time elapses once a visit starts. Although patient and physician both initiate discussions on topics during the visit, it is the physician who decides when the visit needs to end. The authors wanted to examine how physicians decide when to end a visit. They were most interested in the order of topics in terms of 'seriousness,' or of the physician's assessment of the benefits of spending time on the topic.

One hypothesis was that potential topics are ranked by importance and the most important topics are covered first. The efficient allocation of the physician's time can be described by a threshold value or shadow price, call it λ, such that any topic with value greater than λ is dealt with by the physician, and any topic with value less than λ is not. The value of λ is set so as to just use all of the time the physician has available. Another interpretation is that the physician has another activity with a constant value of λ. This other activity might, for example, be 'administrative work,' that can be done during the day or handled at the end of the day.

An alternative hypothesis was that physicians have a 'target' amount of time to spend with each patient, like a tennis coach who gives equal amount of time to each of his students. One way to model a 'target' is to regard the shadow price of time to be zero up to the target and infinite after the target. Under the alternative hypothesis, physician admits a new topic if and only if the value of the new topic is greater than or equal to λ given how much time has already elapsed in the visit. The target can be set by a norm that is dictated by protocols at the practice regarding the number of patients a physician needs to see each day to reach productivity goals. Under the influence of such productivity goals, the decision to end the visit is determined by a behavioral rule rather than maximization of the expected net benefit of their time with patients.

Empirically, the probability of a topic being the last topic of a visit was modeled. The key right-hand-side variables are four binary indicators of time elapsed when a topic was introduced: within 5 min of the beginning of the visit, between 5–10 min, between 10–15 min, and after 15 min. Multiple measures of the 'seriousness' of a topic were incorporated. The empirical findings support the alternative hypothesis: The likelihood of a topic being the last increased successively and significantly with each increment in the block of time for topic introduction. The results are robust to various specifications.

This example resonates with time accounting and targeting heuristics observed in behavioral economics. New York City cab drivers have been documented to quitting earlier on high-wage days and driving longer on low-wage days. Physicians are found to work under a similar behavioral rule, spending time patiently until the target is reached, then quickly closing the visit. The second example presented at the beginning of the article was from a visit in which the physician was by turns patient and inquisitive (at 5 min into the visit) and brisk and dismissive (at 17 min). He transformed the patient's raised hand for inquiry into a good-bye handshake, and escorted her from the room while telling her that he would bring her back for another visit in 2 weeks. Another approach used to close a visit was referring patients to social workers who would spend more time listening and figuring out how social services might offer support. Giving prescriptions for medications (sometimes even unindicated medications) is yet another approach to close a visit. Although fee-for-service environment clearly rewards such approach to increase demand, they are not necessarily what a perfect agent would have done. It is the opposite of what one would do to maximize the effectiveness of each visit which entails covering multiple issues at one sitting. Managing demand by limiting the number of issues addressed or not addressing some of them effectively – as evidenced in the findings – may actually contribute to backlog in access to office visits because more demand for return visits has been created to address unresolved issues.

Management of diverse demand with heterogeneous level of professional and personal uncertainties

Unlike specialty care visits in which patients usually seek service for one particular condition, for example, rotator cuff injury, carpel tunnel syndrome, that is within the expertise of the specialist, primary care office visits routinely involve multiple patient complaints that could reach beyond the expertise and comfort zone of primary care physicians. Professional and personal uncertainties pose additional layers of complexity in physician's micromanagement of heterogeneous patient demand. Nevertheless, generalists are expected to address more complex issues. Whether what they do meets this expectation is an empirical question. Direct observation study can facilitate better understanding of how well they perform to the standards and what system modifications or policy changes are needed to complement or substitute some work of the primary care physicians to reduce inefficiencies in the agency relationship.

Whether and how to respond to demand for treatment for mental illnesses

Depression is the most common mental illness that is encountered by primary care practitioners who deliver most of its treatment, especially for elderly patients. Depression treatment practice guidelines call for at least four office visits, with counseling on mental health problems lasting for at least 5 min. They also advocate educating patients about treatment options, including medications' mechanisms of action, costs, risks, and benefits. Although treatment guidelines have been developed based on clinical research and expert opinion, the 'meaning' of these standards in terms of routine medical practice is not well understood. Detailed aspects of guidelines are rarely applied in quality assessment studies. The video and audio data enabled the authors to explore in detail how primary care physicians managed patient demand for treatment for depression in routine office visits.

It was found that the median length of time spent addressing depression was only 2 min, during which the patient spoke for 1.2 min and the physician spoke for 0.8 min. Furthermore, it was found that just because a physician has seen a patient with a mood disorder for an appropriate number of visits and prescribed a psychotropic agent or even multiple agents, the appearance of adherence to current guidelines does not necessarily mean that the patient received good mental health treatment. The authors explain in details below with findings from qualitative analyses of video recordings.

Qualitative analysis of the video recordings of visits during which mental health was addressed revealed three themes which characterized how physicians managed patient's demand for depression treatment at the point of care. The first theme was taking the time to investigate the disease and the patient as a person. The visit with the longest time on mental health discussion (17 min) in the whole study sample was a visit by a 69-year-old white male who broke into tears when his physician asked him how things were. The physician explored carefully and confirmed that the patient was depressed and suicidal, with a plan to use a revolver (already loaded) in the bathtub to end his life. Although the physician was very thorough in his assessment, the treatment plan was inadequate when compared to guidelines on addressing suicidal patients. He asked the patient to give a 'no suicide contract' and asked him to call a psychiatrist.

The second theme was allocating some time to gathering information, recognizing depression, but giving inadequate treatment. A case in point of this theme was a series of three recorded visits between a female patient and a male physician (Example 2 at the beginning of the article). The time allocated to mental health in each visit was 9, 5, and 11 min, respectively. Over approximately 7 months, this patient was sequentially prescribed paroxetine hydrochloride (10 mg for 6 weeks), fluoxetine hydrochloride (10 mg for 2 weeks), venlafaxine hydrochloride (37.5 mg for 6 weeks), and bupropion hydrochloride (unknown dose for 4 weeks) and taken off of Lorazepam, which she had taken for a long time. In one of the visits, the physician turned her raised hand for inquiry into a good-bye handshake. The management of her depression and anxiety had deviated from guidelines. For instance, low dose and short course of the antidepressants could have rendered these efficacious medications ineffective. Furthermore, stopping Lorazepam abruptly could increase withdrawal symptoms, potentially compounding anxiety. Despite the deficiencies in how her conditions were managed, research or quality improvement efforts based on claims data would have characterized these visits as guideline concordant, because only visit frequency was observed.

The third theme was physician dismissing patient's cue and indications of emotional distress. Five consecutive visits between a female physician and a female patient were seen, in which perfunctory and dismissive treatment of a patient's emotional distress was apparent. This patient was hospitalized to receive a stent after percutaneous transluminal coronary angioplasty. 2 min and 40 s were spent on the patient's emotions:

Physician: What you been up to?
Patient: I have just been crying my eyes out. (Crying…)
Physician: Why?
Patient: I don't know. I can't help it. (Crying…)
Physician: Why?
Patient: And then people ask me how I am, I just cry. (Crying…)
Physician: Oh (pause). Well I am not going to ask you that anymore.

This physician's paternalistic model of medical practice did not alleviate the patient's suffering. This is a case in which the 2-min mental health care clearly failed, because the patient left the visits with her depression neither evaluated nor treated. Such omission could impede her healing from the heart disease. It was somewhat surprising to see that, in a postvisit survey, the patient was satisfied with her visit and continued to return to the same physician for her care.

Whether responding to patients' clues would lengthen visits

Patients often give clues of distress and invite their physicians to respond. Although some physicians respond immediately, others choose not to respond for fear of sinking too much time if they were to respond. Communication researcher Levinson *et al*. examined the length of visit and patients' presentation of clues and found no evidence that responding to clues lengthens visits. Actually, visits in which a physician responded to a patient's clue were shorter than when the physician missed the opportunity. For primary care, visits without clues were a mean 15.7 min. Those with one clue were 12.7 min. Visits were longer (20.1 min) when there was a missed opportunity, compared to visits where the physician demonstrated at least one positive response to a clue (17.6 min). Visits in which patients repeatedly brought up emotional issues after the physician missed an opportunity to respond to a clue were longer than those with a positive response (18.4 min).

Whether discussion on a topic ends with an explicit decision

From the perspective of clinical communication, a decision can be defined as a verbal commitment to an explicit action. A clearly stated decision can facilitate a cognitive closure in the minds of the patient and physician that the discussion on a particular topic has reached an end. Communications research repeatedly documented a deficit in informed decision making in routine office visits and the lack of clear understanding patients have about what they needed to do after they leave their visits. There was a gap in knowledge on how often explicit decisions are actually made when discussion on a topic ends. The proportion of topic discussions in the sample that ended with an explicit decision was examined. The findings suggested, while the majority of topics ended with a decision (77%), there were variations related to the content and dynamics of interactions. Topics in which patients spoke more (67 s) were more likely to end with an explicit decision. Larger number of topics in a visit was associated with lower probability of a topic ending with a clear decision.

In summary, Arrow and colleagues have commented on the challenges in monitoring agents when their actions are unobservable. When the authors studied patient–physician interactions captured in video or audio recordings, they had an invaluable opportunity to observe agent actions. Combined with data on patient behaviors, a more nuanced understanding of how physicians manage patient demand at the point of care was gained. It could be seen that physicians have been observed to be habitual in their management of time during office visits, subject to influence of other demands presented by patients, and their own familiarity with the issues. In observing longitudinal visits between the same dyads of patient and physician, it is also noticed that, in this 'repeated game' context, patients return to the same physicians even though their previous clues of their desire to receive mental health services were overlooked or dismissed. It

appears that Albert Hirschman's encouragement to individuals to exercise their abilities to exit or use their voice in order to show their dissatisfaction is challenging for patients to carry out. The assumption of full information rarely holds true in medical decision making. Physician behavior often deviates from profit maximization expected of a firm. Simple extensions of the profit or utility maximization models may not produce satisfactory explanations of principal and agent behaviors. Simon's 'Satisficing' under constraints model offers a more plausible explanation of some of their behaviors. How behavioral economics may offer promising perspectives to study these behaviors are briefly discussed below.

Perspectives from Behavioral Economics

Health care exchanges, physician practice in particular, are fertile grounds for behavioral economics research. Yet the bulk of the application of behavioral economics to issues in health economics has been on patient behaviors, particularly addictive behavior around cigarettes, drugs and alcohol, and unhealthy lifestyles. Physician behavior has just begun to be subject to investigations guided by behavior economics perspectives. Some examples of physician behaviors that can be explained by behavior economics perspectives are elucidated here.

Use of Heuristics

An important finding from behavioral economics is the use of heuristics by decision makers that works reasonably well over a broad array of circumstances, but can be far off the mark in others. Following a norm or what Frank and Zeckhauser refer to as a 'ready-to-wear' treatment would be one such heuristic. The choice of heuristics implies less attention to purposeful optimization which is consistent with Simon's satisficing behavior. Humans, as opposed to Econs, have frailties. Often, the cognitive resources to maximize is lacking: the relevant probabilities of outcomes is usually not known, all outcomes with sufficient precision can rarely be evaluated, and the memories are weak and unreliable. Wennberg told the story of physicians recommending tonsillectomy for certain percentage or number of recently seen patients. Approximately 40% of children previously deemed not needing surgery were recommended for surgery at each subsequent waves of examination by additional physicians. The findings from direct observation data are consistent with this notion.

Attribution Bias

Context under which decisions are made needs to be taken into consideration. Loewenstein argues against 'context free' thinking because visceral and emotional factors can affect decisions in unexpected ways. For example, people may overattribute other people's behavior to personal dispositions whereas overlooking situational causes or transient environmental influences on behaviors. In doing so, the decision maker falls prey to attribution bias. Case study findings suggest that some physicians overlook the effects of inaccessibility of healthy food choices and walking paths in low-income neighborhoods, or other social determinants of health and overattribute the obesity problem to obese individuals being lazy.

Groopman told a gut-wrenching story of an elderly African-American patient being labeled as noncompliant who suffered from congestive heart failure, diabetes, hypertension, coronary artery disease, and advanced rheumatoid arthritis. She had been repeatedly admitted to a major academic medical center. None of her previous physicians knew that she was unable to read the labels on the medicine bottles until an African-American internist recognized what the other physicians had overlooked. This physician paid attention to the social context of severe disadvantages of being a black woman in the rural Mississippi of the 1930s and was able to arrange for the patient's daughter to be present at discharge and be informed of plans for care at home. The patient's recovery was remarkable afterwards.

Such attribution bias appears to be fairly common. Patients' weights significantly affect how physicians view and treat them. Patients with higher body mass index are also less likely to be perceived by physicians as medication adherent. Physicians ordered more tests for obese patients, spent less time with them, and viewed them with more negativity than nonobese patients. In a study of patient–physician communication over management of chronic pain, a physician was observed to be telling an elderly female African-American patient with disabling knee pain: "all you need to do is to lose 50 pounds. So you won't be hobbling around with all the extra weight on your knees".

Anchoring and Availability Bias

Frank and Zeckhauser termed the 'My Way Hypothesis' for situations in which physicians would regularly prescribe a therapy that was quite different from the choice that would be made by their peers. Although it is possible that the physician chose that therapy because she had differential expertise, the My Way Hypothesis may also apply when a physician has had personal 'good luck' with it, a plausible heuristic, but one that falls prey to the availability heuristic, namely overweighting evidence that one can bring easily to mind. Groopman recounted an emergency department (ED) physician using a 'studied calm' approach to avoid anchoring and availability biases when a patient presented with symptoms suggestive of a kidney stone. Rather than going along with the kidney stone diagnosis made by the triage nurse, the ED physician asked what might be the worst-case scenario thereby avoiding these cognitive biases and correctly diagnosed a dissecting abdominal aortic aneurysm, a far more life-threatening emergency.

Therefore, there is systematic evidence that heuristics can frequently lead decision makers astray, particularly when probabilistic outcomes are involved, as is almost always the case with medicine. The power of the field of behavioral economics has developed from the broad insight that heuristics can lead to significantly suboptimal behavior. Application of behavior economics perspectives can help advance the understanding of micromanagement of patient demand.

What Is the Value of This Research in Improving The Functioning of Patient–Physician Interaction?

Rather than accepting the notion that agent behaviors are unobservable and noncontractible, research efforts using direct observation data available in other fields has shed some light on agent behaviors at the point of care were applied. Building on the insights from behavior economics, coupled with empirical evidence from direct observation of physician–patient interaction, a more informed understanding of how physicians manage demand at the point of care, more like Humans with frailties, rather than Econs who have full information and can do probabilistic decision analysis on the go can be attained. Better point-of-care clinical decision support systems, redesign staffing structure to provide effective support, implement incentives that are conducive for escaping the lull of the norm may be designed. Shared decision making has been shown to lead to better honoring of patient's wishes and lower procedure-based service use. This line of research might continue to contribute to improving patient–physician interaction.

Coding communications within visits at the topic level is time consuming. Establishing inter- and intrarater coding reliability takes much effort and time. Some may question if the effort is worthwhile. It has been asserted that the findings have value in improving the functioning of patient–physician interaction. For example, it is noted that many topics compete for visit time, resulting in small amount of time being spent on each topic. A highly regimented schedule might interfere with having sufficient time for patients with complex or multiple problems. Efforts to improve the quality of care need to recognize the time pressure on both patients and physicians, the effects of financial incentives, and the time costs of improving patient–physician interactions.

Where This Research Area Should Go?

To understand how physicians manage patient demand, Simon and Fuchs' admonishment about using good data must be adhered to. Direct observation using video or audio data has offered unique insights and can continue to do so. Multidisciplinary collaboration with researchers in other fields (e.g., health communication and medical education) for data and communication analysis empirical approaches can continue to be a fruitful endeavor. It would be important to have large enough sample size to enable the examination of causal relationship between communication characteristics and downstream patient-reported outcomes.

Increasingly, patients are communicating with physicians asynchronously via secure messaging through the electronic health records (EHR) and personal health record. The method for studying patient–physician communication must evolve accordingly to take advantage of the EHR as an additional source of data for data mining. Some EHR, for example, EpicCare(EPIC) EHR, offers an unobtrusive portal to study time use through analysis of EPIC access log, a feature in EPIC EHR designed for monitoring access to patient's EHR for security and privacy concerns. The EPIC access log tracks the user of the EHR, time of access, device from which the access was made, and EHR functional location of the access, for example, progress note, medication list, phone encounter, and secure messaging. EHR enables the authors to leverage existing 'behind-the-scenes' data to study how much time clinicians spend on performing tasks. Natural language processing software is making progress in harvesting useful information from this data source to inform research on physician behaviors. Continued effort can bring promises to the field.

Sensitivity to institutional changes taking place in health care is essential. The health care delivery system is undergoing fundamental changes. To be relevant, one must be mindful of the institutional context and delivery system characteristics – dynamic rather than static – in which physicians manage patient's demand at the point of care. The redesign of clinical care processes and payment incentives can be informed by this type of research. For instance, it has been observed that quite a bit of time is being spent on listening to the lung, doing the traditional litany of system review where old information was rehashed with no apparent value. For example, if a patient's grandparent died of cancer 20 years ago, repeating this information at every periodic health exam offers no new information. How much value do these clinical routines offer? Should reimbursement continue to be triggered by following these routines? Substituting tradition-based medicine with evidence-based medicine may free up some time for physicians to do more shared decision making on more important issues in patient's view at the point of care to maximize the benefit of time.

Even the definition of point of care needs to be expanded to accommodate new models of care delivery. For example, the emergence of team care makes the function of care managers and other providers on the team important forces that might affect how patient demand is managed in the world of team care. The literature is silent on how team communicates among its members and with patients, let alone the impact on demand.

Tools designed to reduce information asymmetry and uncertainty in decision making are being developed, tested, and prescribed for patients. These decision aids – for example, for prostate cancer, breast cancer, depression treatment, and end-of-life care preferences – are making significant changes in patients' understanding of options and assisting them to alter their demand for health care services. How physicians use these decision aids and how they respond to patient's modified preferences can be important areas of research. As the field pays more attention to patients with multiple chronic conditions, more refined clinical decision support systems that can be tuned to accommodate demands from multiple morbidities will be a welcome addition to practicing physicians. Direct observation data can also provide unique insight on how demand from each condition is managed at the point of care with multimorbidity patients. For those interested in accessing the video recordings that have been used in the research, they may access them if they are medical educators or researchers working to improve the doctor–older patient relationship.

Physician Market

PT Léger, HEC Montréal, Montreal, QC, Canada
E Strumpf, McGill University, Montreal, QC, Canada

Glossary

Accountable care organizations Networks of physicians, or physicians and hospitals, that contract with insurers.
Any willing provider laws Restrictions on insurers' ability to form exclusive networks by requiring them to contract with any provider who is willing to join and meets the network requirements.
Board certification A process by which physicians demonstrate their knowledge and skills in a particular specialization.
Capitation A payment mechanism where physicians receive a predetermined fixed fee for each patient they enroll in their practice in exchange for care for a fixed period of time without any marginal reimbursement.
Cournot oligopoly A market dominated by a small number of sellers where each firm makes quantity decisions taking the optimal strategies of all competitors into account.
Credence good A good whose value is difficult for the consumer to judge even after consumption (in contrast to an experience good).
***Ex post* moral hazard** The situation where patients use excessive amounts of care because they face a subsidized price due to insurance.
Fee-for-service A payment mechanism where physicians receive a predetermined fixed fee for each billable service they provide, which is generally at or above the marginal cost of production for that service.
Independent practice association A network of independent physicians that contracts with managed care organizations and employers.
Managed care organizations Organizations that integrate health insurance and healthcare service delivery and also place restrictions on which providers can been seen and the use of some services.
Monopolistic competition A market where firms or providers offer differentiated products, allowing the suppliers some market power in the short run.
Numerus clausus Refers to the limit on the number of students who may enter a program of study (e.g., medical school).
Physician-Hospital Organizations Joint ventures between hospitals and physicians.
Preferred provider organization A form of managed care where enrollees face lower prices when they see in-network providers.
Scope of practice The procedures, actions, and processes that different healthcare practitioners are licensed (or permitted) to perform.
Supplier-induced demand A situation in which physicians convince patients to demand excessive amounts of care in the presence of asymmetric information.
Switching costs Any cost, psychological, financial, or otherwise, associated with leaving one's current physician and finding an alternative source of care.

Introduction

A market is generally defined as a set of firms or individuals selling similar (or at least partially substitutable) goods or services to a given set of consumers. Under some basic conditions, competitive markets yield Pareto optimal outcomes (The First Optimality Theorem). As a result, policymakers and regulators have generally favored competition and prohibited and punished anticompetitive behavior. However, many researchers have argued that: (1) many of the basic conditions required for the existence, and Pareto efficiency, of a competitive equilibrium are unlikely to be satisfied in the healthcare market and (2) in the presence of deviations from the necessary conditions, competition may actually be welfare decreasing. Important deviations from the model of perfect competition in the physician market include imperfect and asymmetric information, differentiated products, administratively set prices, insurance, and barriers to entry (Table 1). Simply put, conditional on being in a second-best world, the effect of competition on quality and cost of healthcare may not necessarily be positive.

Although clearly being different from markets that fit the requirements for perfect competition, the market for physician services does resemble other markets involving asymmetric information, expertise, or credence goods. Markets for car repair, legal advice, and taxicab rides are classic examples with the potential for inefficient outcomes and scope for government intervention. However, the market for medical care suffers from a larger number of imperfections than most, moving quite far from the first-best being a relevant welfare benchmark. In addition to the information asymmetries seen in these other markets, insurance and administratively set prices are notable attributes of the market for healthcare and physician services which complicate the welfare implications of competition and many of the conclusions drawn from nonhealthcare analyses.

Consistent with not using the first-best as the main point of reference, physicians have been seen by many (including lawmakers and courts) to be outside the scope of competition policy (in part because of their role as 'learned professionals' in the presence of imperfect information). In 1975, the US Supreme Court ruled that learned professionals (including

 doi:10.1016/B978-0-12-375678-7.01107-X

Table 1 Deviations from first optimality theorem assumptions

Assumption	*Deviations/examples*
Full and symmetric information	1. Patients may have partial information on: a. their need for care (or illness severity) b. treatment options c. quality of care/provider d. prices 2. Information on (a) through (d) may remain partial even posttreatment in part because of an uncertain treatment-outcome relationship 3. Physicians may have partial information on: a. their patient's illness severity b. their patient's history c. their patient's preferences, income 4. Insurers may have partial information on the patient's illness severity and need for care 5. Insurers may have partial information on the care received
Differentiated products	1. Physicians provide heterogeneous services: a. diagnostic skills b. treatment style-skills c. bedside manner d. hours of operation e. location 2. Also differentiated by virtue of the patient–physician relationship: a. trust 'capital' b. knowledge of medical history
Absence of search and switching costs	1. Patients may face important search costs: a. collect information on physicians b. find out who is taking patients c. inferring or predicting alternative physicians' quality 2. Patients may face important switching costs when leaving one physician for another: a. rebuilding trust b. informing the new physician regarding medical history c. potential monetary costs or penalties
Competitive prices	1. Administratively set prices are by construction a violation of this assumption, i.e., prices cannot adjust to equate demand and supply 2. Price setting varies from one jurisdiction to another
Consumers face true prices	1. Presence of insurance an obvious violation of this assumption 2. Insured patients face either a fully or partially subsidized price depending on the deductible and copayment
No barriers to entry or capacity constraints	1. Barriers to entry in the medical market include: a. medical school admission restrictions b. licensing and other regulations (especially important for outsiders) which can include retraining, testing, internships, and language requirements c. limits on nonphysician competition through scope of practice regulation (nurses, midwives, and pharmacists)

physicians and the entire healthcare market) were indeed subject to antitrust laws, while nonetheless recognizing the particularities of the environment and the potentially perverse role of competition. In other countries, including Canada, Germany, and the Netherlands, lack of price competition among physicians is institutionalized as prices are explicitly negotiated between the government and physician associations.

Understanding several aspects of the economics of the physician market is necessary to address the aforementioned debate. First, what is the level of competition in the physicians' marketplace? Second, what factors contribute to its relative strength? Third, what form does it take (e.g., price vs. quality competition)? The idea of competition in the physician market is relevant to all contexts and healthcare systems but its form and level are dependent on the institutional context (e.g., payment mechanisms and regulations regarding balance billing) and the economic environment (e.g., the relative supply and demand of healthcare services). Although little empirical work exists investigating the market power of physicians or the welfare implications of reduced competition in the physicians' market, examining the characteristics of the physicians' market can provide a sense of the form and level of competition present in different jurisdictions.

Beyond describing competition in the physician market, its normative implications must be considered. In the context of the second best, it is unclear whether competition in the physician market will improve or harm social welfare. Theoretical work (Allard *et al.*, 2009) has shown that, in a mixed-payment system, competition may provide appropriate incentives even in the presence of noncontractible effort, information asymmetry, unobserved heterogeneity, switching costs, uncertainty, and regulated prices. More specifically, competition makes a patient's 'threat' to seek care elsewhere

more credible, and may serve as an important incentive to provide appropriate care on both contractible and noncontractible dimensions. However, it may also lead to treatment heterogeneity, overtreatment (i.e., defensive medicine) and unstable physician–patient relationships. In this article the authors examine some of the aforementioned necessary conditions for the existence and Pareto efficiency of a competitive equilibrium as a first step to understanding the broader issue of competition and welfare in healthcare markets. The authors also review conclusions from the empirical research in this area.

To address these different issues, the authors start by defining the 'players' in the physicians' market (i.e., who competes against whom), a key first step in any study of the level, form, or welfare impacts of competition in the physician market. The market is defined simultaneously by the set of suppliers and consumers in a geographic area, but geographic considerations and 'firms' will be discussed sequentially for ease of exposition. The authors first identify the set of consumers over which physicians (or other healthcare providers) compete (generally defined by a geographic area such as a zip code or Metropolitan Statistical Area (MSA)). Next, to determine the level of competition within a given market, the services over which different types of providers might compete will be considered. Not surprisingly, physicians compete with providers of their own specialty but also across specialties and even with healthcare providers who are not physicians. Once the competitors and their potential customers are identified, the authors then separately examine the different elements that may limit competition. Although most of the empirical evidence discussed here is set in the North American context, this is primarily due to greater interest in physician competition there by researchers and policymakers. The general issues and theoretical frameworks discussed here are, however, common in many jurisdictions and the underlying economic principles remain the same.

The remainder of this article is organized as follows. In Section Who Are the Patients/Consumers That Physicians Compete over?, the physicians market in terms of customers is examined, i.e., who do physicians compete over? In Section Who Competes against Whom?, the market in terms of sellers is discussed, considering the possibility that physicians may compete against nonphysician healthcare providers. In Section The Competitive Model, the authors discuss the necessary conditions for the existence of a Pareto efficient competitive equilibrium and corresponding welfare implications, and how the physicians' market may deviate from such conditions. Conclusions are drawn and remarks made in Section Conclusion.

Who Are the Patients/Consumers That Physicians Compete Over?

Physicians compete over a set of potential patients, generally defined by their geographic location. Although such geographical areas may be simple to define (e.g., all physicians within a city limit are assumed to form one market), they may not accurately reflect the actual market. That is, the set of physicians that a patient will consider likely depends on several additional factors including: (1) the type (e.g., specialty) and quality of services provided, (2) the distance to travel, (3) whether a given provider is covered by the patient's insurance, and (4) prices. For example, a patient may be willing to travel longer distances for nonemergency care than emergency care in order to get lower prices and/or greater quality and therefore considers seeking care from a wider set of physicians.

The question of prices that patients face is intricately tied to that of insurance for healthcare services. Because widespread, fairly comprehensive insurance coverage for physician services is the norm throughout developed countries, consumers of and payers for services are often not the same party. Physicians' incomes can come from a mix of public and private payers (both insurance companies and individuals), one that varies significantly across countries, regions, and medical specialties, but rarely is comprised mostly of direct, out-of-pocket payment by patients. Insurers often restrict services they pay for to those provided by providers they contract with. In Canada, this means any physician participating in the provincial health insurance plan (nearly all physicians), whereas in the US, a managed care plan may have a more restrictive network of providers. As a result, the number of insurers in a market and the ways in which they steer patients to certain providers (if at all) can have implications for whether and how physicians compete for patients directly or whether they compete for contracts with insurers. Although the presence of insurance in general may make patients less responsive to price or quality differences across physicians (Section Insurance), payers can also play important roles in reducing information asymmetries between patients and physicians and can create direct incentives for patients to seek out higher quality physicians.

Relatively few empirical studies that quantify physician markets exist, but this question can be informed by the larger literature on competition in hospital markets which faces similar issues. Studies that use geographical areas like Primary MSAs or actual consumption patterns to define markets (i.e., competitors) suffer from creating barriers that patients often traverse and from generating bias if individuals choose a particular hospital based on unobservable characteristics like quality, which may also be correlated with market share. Take, for example, a physician who is of such low quality that they only attract patients in their immediate vicinity (e.g., in the immediate zip code). By calculating the market shares (and thus corresponding level of competition via a measure like HHI) using zip codes as markets, this physician may appear to face little competition (and thus benefit from a large market share). This conclusion, however, neglects the fact that many patients in neighboring zip codes may consider this particular physician as part of the choice set but choose not to seek care because of his or her poor quality. To deal with this potential bias, recent studies have used predicted market shares based on exogenous factors rather than actual shares.

Researchers who wish to define physicians' markets and measure their degree of competition should consider similar potential biases. The authors are not, however, aware of any papers that estimate the level of competition in actual physicians' markets in such a manner or which estimate individual physician's market share. As a result, the discussion relies on

geographical markets rather than estimated potential markets, although recognizing their limitations. Although not being the sole indicator of competition, the extent to which market characteristics (i.e., provider density) vary across jurisdictions can be instructive regarding the degree of competition.

Who Competes against Whom?

Even once the geographic boundaries of a market have been defined, identifying who competes against whom in healthcare (and thus which providers constitute a particular market) is complicated by the fact that: (1) different types of providers will provide (im)perfect substitutes for each other and (2) different types of providers may have overlapping scopes of practice. Obviously, general practitioners (GPs) compete against other GPs, whereas obstetricians compete against other obstetricians (i.e., within-specialty competition). However, GPs may also compete with other specialists (from gynecology to psychiatry) as they have considerable overlap in their scope of practice.

Physicians may also compete across specialties because different types of specialists provide alternative treatments for the same health problem (e.g., 'stenting' by a cardiologist or bypass surgery by a cardiothoracic surgeon). As a result, when considering the market for a particular health problem or medical service, one may have to consider different types of physicians. Physicians may also compete with allied health professionals (AHPs) such as physician assistants (PA) and advanced practice nurses (APN) (which include nurse practitioners (NP), certified nurse–midwives, clinical nurse specialists and nurse anesthetists). Although the allowable scope of practice and level of independence of each of these groups varies from one jurisdiction to another, both have increased over the years. Dueker *et al.* (2005) found that in states where they are given a lot of professional independence, APNs have lower salaries (whereas their PA counterparts have higher salaries). They argue that this is because physicians in states where APNs are granted greater professional independence substitute away from APNs toward PAs in their hiring decisions for fear that they will take on greater roles in hospital settings. This is not surprising as the authors also find that greater independence of APNs negatively impacts physicians' salaries. Finally, physicians are likely to compete with other 'nonmedical' healthcare providers such as chiropractors, osteopaths, and acupuncturists. As a consequence, a more complete vision of the market should consider these alternatives.

The legal context that frames the physician market includes licensing and scope of practice regulations. These largely determine the market, both geographically and with respect to specific services, and establish the 'rules of the game' in which competition flourishes (or doesn't). These frameworks vary across jurisdictions, which can include an entire country (physician licensing and registration by the General Medical Council in the UK) or encompass states or provinces (provincial-level licensing in Canada). Although potentially helping to disseminate information and maintain or improve quality, these regulatory mechanisms are also likely to reduce competition, issues that will be discussed further in Section Limits to Supply and Barriers to Entry.

The Competitive Model

As noted previously, competitive environments yield Pareto efficient outcomes under specific conditions. If they are met, deviations from the competitive equilibrium lead to losses in social welfare. Because physicians provide differentiated services, entry into the market is strictly controlled, prices are often set administratively and patients generally do not face true prices because of insurance, physicians may have considerable market power. However, because the conditions underlying the First Welfare Theorem are unlikely to be met in the healthcare setting (Arrow, 1963), it is not obvious that such market power decreases welfare relative to greater competition.

In the context of concerns about physicians' market power, accusations of collusion and anticompetitive behavior in the physicians' market have become more prevalent and the US Department of Justice concluded that physician collusion when negotiating with third-party payers was in violation of the Sherman antitrust rules. Recent empirical work suggests that in spite of these prohibitions, physicians benefit from considerable market power. More specifically, Wong (1996) found that the GP and family physicians' market is consistent with monopolistic competition (and not with monopoly or perfect competition), whereas Gunning and Sickles (2010) found that the medical and surgical specialists' market is consistent with Cournot oligopoly.

In the following subsections the authors discuss each of the conditions required for a competitive market to reach efficient outcomes in greater detail. Beforehand, however, the authors present some summary statistics on the density of different types of physicians across different jurisdictions in order to get a sense of the level of competition (or at least, how it may vary across different specialties and jurisdictions). Given that physicians are unlikely to vary greatly in terms of individual market shares, market-level HHIs are unlikely to provide much more information than simple concentration ratios.

Across Organization for Economic Co-operation and Development (OECD) countries, the number of physicians averaged 3 per 1000 population in 2007 and the average number of GPs was 0.9 per 1000 and 1.8 specialists per 1000. Considerable variation also exists across countries in each of these measures (**Table 2**). The number of physicians ranged from 1.5 per 1000 in Turkey to 5.5 per 1000 in Greece. Specialists greatly outnumbered generalists in central and eastern European countries and in Greece. Other countries, notably Belgium, France, and Portugal, have maintained a more equal balance between specialists and generalists. This variation in provider densities suggests differences in the degree of competition in physician markets across these jurisdictions.

The number of nurses averaged approximately 9 per 1000 population across OECD countries, ranging from 1.3 per 1000 in Turkey to 16 per 1000 in Denmark. The number of midwives averaged 72 per 100 000 women, ranging from 1 per 100 000 women in the US to 178 per 100 000 women in Australia. Such variation in the densities of providers that are

Table 2 Physician supply across selected OECD countries, 2007

	Practicing physicians per 1000 population	*General practitioners (GPs) per 1000 population*	*Specialists per 1000 population*	*Ratio of GPs to specialists*
Greece	5.4	0.3	3.4	0.1
Belgium	4.0	2.0	2.0	1.0
Switzerland	3.9	0.5	2.8	0.2
Sweden	3.6	0.6	2.6	0.2
Germany	3.5	1.5	2.0	0.8
France	3.4	1.6	1.7	0.9
OECD	3.1	0.9	1.8	0.5
Australia	2.8	1.4	1.4	1.0
UK	2.5	0.7	1.8	0.4
US	2.4	1.0	1.5	0.7
Canada	2.2	1.0	1.1	0.9
Japan	2.1	na	na	na
Mexico	2.0	0.7	1.3	0.5
Korea	1.7	0.6	1.1	0.5
Turkey	1.5	0.5	1.0	0.5

Notes: Data is from 2007, or the latest year available.

Practicing physicians are defined as the number of doctors who are providing care directly to patients. In many countries, the numbers include interns and residents (doctors in training). The numbers are based on head counts, except in Norway which reported full-time equivalents before 2002. Ireland, the Netherlands, New Zealand, and Portugal report the number of physicians entitled to practice (resulting in an overestimation). Data for Spain include dentists and stomatologists (also resulting in a slight overestimation).

Not all countries are able to report all their practicing physicians in the two broad categories of specialists and generalists. This may be due to the fact that specialty-specific data are not available for doctors in training or for those working in private practice.

complements and substitutes to physicians can also have implications for competition in the physician market.

Studies show that demographic factors such as age and gender can also have important implications for the supply of providers and level of competition, because those with different characteristics often practice in different locations (i.e., hospitals vs. private practice), work fewer or more hours, and select different specialties. In 2007, on average 40% of physicians across OECD countries were women, ranging from more than half of physicians in central and eastern European countries and Finland to less than 20% in Japan. The share of women physicians has increased from 29% in 1990 across the OECD and from 20% to 30% in the US between 1990 and 2007, and now account for nearly half of all medical students there (NCHS, 2009). Characteristics such as gender, age, and race are important predictors of specialty choice for some specialties but variation in expected income across specialties is also important.

A third factor that is linked to the competitiveness of the physician market is the issue of adequate physician supply, which remains an important policy topic especially with respect to urban/rural differences. For example, in the US the number of practicing physicians per 10 000 civilian population was 25.7 in 2008, but largely rural states like Wyoming and Idaho had only 18.7 and 17.0, respectively, whereas Massachusetts had 39.7 and Maryland had 35.3 (NCHS, 2011). Low physician-to-population ratios in rural jurisdictions mean that those providers face less competition from other physicians. Furthermore, the range of explicit policies and incentives that encourage physicians to locate in 'underserved areas' (e.g., the US National Health Service Corps, Quebec's Differential Remuneration Program) clearly demonstrate that the market is not competitive in the sense that wages do not freely adjust to equilibrate supply and demand. Some of the factors that prevent such a wage adjustment are discussed in the following section.

Information and Physician Payment Methods

One of the defining characteristics of healthcare markets and the patient–physician relationship is the presence of incomplete and asymmetric information. Patients may have greater knowledge about their symptoms, habits, medical history etc., whereas physicians are likely to have privileged information about the patient's illness and alternative treatment options. It is precisely because of their medical expertise that physicians act as their patients' agent (i.e., they act on their patients' behalf regarding medical decisions).

Under the traditional fee-for-service (FFS) system, physicians receive a fixed payment for each service they provide that is above the marginal cost of production. If physicians are paid via a blended payment (partial capitation plus FFS), or if there are multiple insurers across which physicians can cross-subsidize, FFS payments need not be above marginal cost (e.g., the US Medicaid program).

As a result, the FFS payment system rewards the volume of services. This incentive may lead physicians to manipulate information that they provide to their patients in order to encourage them to consume more care than they would chose themselves if they were fully informed. This implies patients would consume units of care whose marginal benefit is less

than its marginal cost. The physician may manipulate the patients' information, and thus their choice, by either exaggerating the illness severity or the need for care. This phenomenon is known as supplier-induced demand (SID). If patients' demand is responsive to the quality of services, then FFS may also reward quality via volume. Of course, the distinction between quality that improves the value of healthcare services versus amenities that are perceived by patients as higher quality but do little to improve value beyond patient satisfaction is an important one.

Several theoretical models and empirical analyses tackle this issue. In a classic article, McGuire and Pauly (1991) presented a model of healthcare provision and costly inducement of care. In a setting with only one type of care (or patient), they show that physicians will wish to induce care in the presence of a decreased fee (in order to recoup lost earnings) only if the income effect dominates the substitution effect. In the thoracic surgery setting, one study found that surgeons whose fees were reduced under Medicare recouped some of the lost earnings by increasing the number of surgeries they performed.

McGuire and Pauly's model has two types of patients, with private or Medicare health insurance coverage, each with their respective reimbursement rate. They show that a decrease in one reimbursement rate (i.e., the Medicare fee) can lead to an increase in the amount of care provided to the now more generously reimbursed patient (i.e., those with private insurance), again if the income effect dominates. Another study found that obstetricians who faced more competition (through falling birth rates) responded to the potential reduction in their income by inducing demand for cesarean deliveries (which are more lucrative than vaginal births).

To reduce this incentive for volume, alternative forms of physician payments such as capitation and salary have been introduced. In a capitation system, physicians receive a fixed payment for each patient they enroll in their practice in exchange for care for a given period of time without any marginal reimbursement. By not tying a physician's income to volume, the capitation payment system completely eliminates the incentive to provide inefficiently high levels of care. Although this may reduce or eliminate SID, it has been associated with reduced quality and quantity of care (i.e., physicians may wish to manipulate information not to encourage care but rather discourage it). One study found that the increase in managed care has limited some of physicians' ability to induce care via supply-side constraints. Similarly, salaried physicians have no incentive to induce care but may have little incentive to provide the appropriate quantity and quality of care (as their income is invariant, at least in the short run, to such decisions). Although less competitive markets may allow physicians to exploit their market power (say, through SID) their willingness to do so will depend, in part, on the way that they are paid.

Differentiated Medical Services and Switching Costs

Although physicians may provide similar sets of services, they are likely to be different along several dimensions like quality (including time spent with the patient, diagnostic skills, treatment recommendations, bedside manner). Even in the presence of a common specialty and types and levels of quality, patients are unlikely to see their physicians as perfect substitutes by simple virtue of the patient–physician relationship. More specifically, patients may have developed a sense of trust with their regular physician. Furthermore, the physician is likely to have privileged information regarding the patient's health history and need for care. Because of these aspects, patients may face important switching costs when seeking care from an alternate provider and physicians are likely to exert some degree of market power. One way physicians may exploit such market power would be to price discriminate across patients. It is precisely the potential for this behavior that is at the root of uniform administrative pricing for physician services. Although administratively set prices eliminate physicians' ability to price discriminate, they may nonetheless exploit their market power through other means (which in turn will depend on the level of competition). The authors discuss this issue in the next section.

Fee Setting and Organizational Response
