Encyclopedia of

Health Economics

Anthony J. Culyer

ENCYCLOPEDIA OF
HEALTH ECONOMICS

How to go to your page

This eBook set contains 3 volumes.

The chapter numbers are contiguous between the first two volumes, but Volume 3 begins anew. To search for pages in Volume 3 use the example below:

To go to page 18 of Volume 3, type "Vol 3:18" in the "page #" box at the top of the screen and click "Go."

To go to page "306" of Volume 3, type "Vol 3: 306"… and so forth.

Please refer to the eTOC for further clarification.

GUIDE TO USING THE ENCYCLOPEDIA

Structure of the Encyclopedia

The material in the encyclopedia is arranged as a series of articles in alphabetical order.

There are four features to help you easily find the topic you're interested in: an alphabetical contents list, cross-references to other relevant articles within each article, and a full subject index.

1 Alphabetical Contents List

The alphabetical contents list, which appears at the front of each volume, lists the entries in the order that they appear in the encyclopedia. It includes both the volume number and the page number of each entry.

2 Cross-References

Most of the entries in the encyclopedia have been cross-referenced. The cross-references, which appear at the end of an entry as a See also list, serve four different functions:

i. To draw the reader's attention to related material in other entries.
ii. To indicate material that broadens and extends the scope of the article.
iii. To indicate material that covers a topic in more depth.
iv. To direct readers to other articles by the same author(s).

Example

The following list of cross-references appears at the end of the entry Abortion.

> *See also*: Education and Health in Developing Economies. Fertility and Population in Developing Countries. Global Public Goods and Health. Infectious Disease Externalities. Nutrition, Health, and Economic Performance. Water Supply and Sanitation

3 Index

The index includes page numbers for quick reference to the information you're looking for. The index entries differentiate between references to a whole entry, a part of an entry, and a table or figure.

4 Contributors

At the start of each volume there is list of the authors who contributed to that volume.

SUBJECT CLASSIFICATION

Demand for Health and Health Care

Collective Purchasing of Health Care
Demand Cross Elasticities and 'Offset Effects'
Demand for Insurance That Nudges Demand
Education and Health: Disentangling Causal Relationships from Associations
Health Care Demand, Empirical Determinants of
Medical Decision Making and Demand
Peer Effects, Social Networks, and Healthcare Demand
Physician-Induced Demand
Physician Management of Demand at the Point of Care
Price Elasticity of Demand for Medical Care: The Evidence since the RAND Health Insurance Experiment
Quality Reporting and Demand
Rationing of Demand

Determinants of Health and Ill-Health

Abortion
Addiction
Advertising as a Determinant of Health in the USA
Aging: Health at Advanced Ages
Alcohol
Education and Health
Illegal Drug Use, Health Effects of
Intergenerational Effects on Health – *In Utero* and Early Life

Long-Term Care
Production Functions for Medical Services
Understanding Medical Tourism

PREFACE

What Do Health Economists Do?

This encyclopedia gives the reader ample opportunity to read about what it is that health economists do and the ways in which they set about doing it. One may suppose that health economics consist of no more than the application of the discipline of economics (that is, economic theory and economic ways of doing empirical work) to the two topics of health and healthcare. However, although that would usefully uncouple 'economics' from an exclusive association with 'the (monetized) economy,' markets, and prices, it would miss out a great deal of what it is that health economists actually do, irrespective of whether they are being descriptive, theoretical, or applied. One distinctive characteristic of health economics is the way in which there has been a process of absorption into it (and, undoubtedly, from it too); in particular, the absorption of ideas and ways of working from biostatistics, clinical subjects, cognitive psychology, decision theory, demography, epidemiology, ethics, political science, public administration, and other disciplines already associated with 'health services research' (HSR) and, although more narrowly, 'health technology assessment' (HTA). But to identify health economics with HSR or HTA would also miss much else that health economists do.

… And How Do They Do It?

As for the ways in which they do it, in practice, the overwhelming majority of health economists use the familiar theoretical tools of neoclassical economics, although by no means all (possibly not even a majority) are committed to the welfarist (specifically the Paretian) approach usually adopted by mainstream economists when addressing normative issues, which actually turns out to have been a territory in which some of the most innovative ideas of health economics have been generated. Health economists are also more guarded than most other economists in their use of the postulates of soi-disant 'rationality' and in their beliefs about what unregulated markets can achieve. To study healthcare markets is emphatically not, of course, necessarily to advocate their use.

A Schematic of Health Economics

To think of health economics merely in these various restricted ways would be indeed to miss a great deal. The broader span of subject matter may be seen from the plumbing diagram, in which I have attempted to illustrate the entire range of topics in health economics. A version of the current schematic first appeared in Williams (1997, p. 46). The content of the encyclopedia follows, broadly, this same structure. The arrows in the diagram indicate a natural logical and empirical order, beginning with **Box A** (Health and its value) (**Figure 1**).

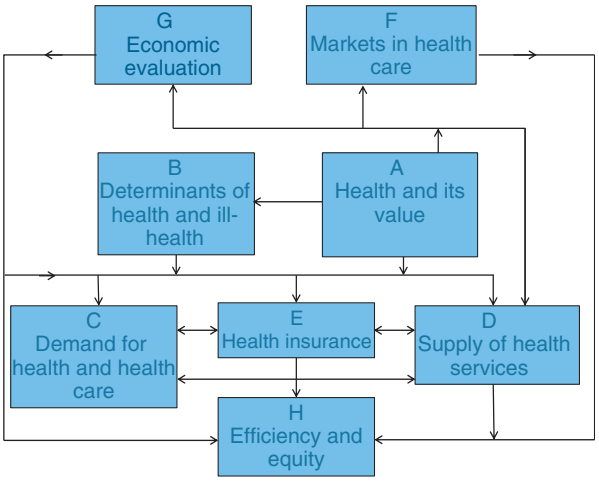

Figure 1 A schematic of health economics.

Box A, in the center-right of the schematic, contains fundamental concepts and measures of population health and health outcomes, along with the normative methods of welfarism and extra-welfarism; measures of utility and health outcomes, including their uses and limitations; and methods of health outcome valuation, such as willingness to pay and experimental methods for revealing such values, and their uses and limitations. It includes macro health economic topics like the global burden of disease, international trade, public and private healthcare expenditures, Gross Domestic Product (GDP) and healthcare expenditure, technological change, and economic growth. Some of the material here is common to epidemiology and bioethics.

Box A Health and its value

Concepts and measures of population health and health outcomes.
Ethical approaches (e.g., welfarism and extrawelfarism).
Measures of utility and the principal health outcome measures, their uses, and limitations.
Health outcome valuation methods, willingness to pay, their uses, and limitations.
Macro health economics: global burdens of disease, international trade, healthcare expenditures, GDP, technological change, and economic growth.

Box B (Determinants of health and ill health) builds on these basics in various 'big-picture' topics, such as the population health perspective for analysis and the determinants of lifetime health, such as genetics, early parenting, and schooling; it embraces occupational health and safety, addiction (especially tobacco, alcohol, and drugs), inequality as a determinant of ill health, poverty and the global burden of disease in low- and middle-income countries, epidemics, prevention, and public health technologies. Here too, much is

Box B Determinants of health and ill health

The population health perspective.
Early determinants of lifetime health (e.g., genetics, parenting, and schooling).
Occupational health and safety.
Addiction: tobacco, alcohol, and drugs.
Inequality as a determinant of ill health.
Poverty and global health (in LMICs).
Epidemics.
Prevention.
Public health technologies.

shared, both empirically and conceptually, with other disciplines.

From this it is a relatively short step into **Box C** (Demand for health and healthcare): here we are concerned with the difference between demand and need; the demand for health as 'human capital'; the demand for healthcare (as compared with health) and its mediation by 'agents' like doctors on behalf of 'principals'; income and price elasticities; information asymmetries (as in the different types of knowledge and understandings by patients and healthcare professionals, respectively) and agency relationships (when one, such as a health professional, acts on behalf of another, such as a patient); externalities or spillovers (when one person's health or behavior directly affects that of another) and publicness (the quality which means that goods or services provided for one are also necessarily provided for others, like proximity to a hospital); and supplier-induced demand (as when a professional recommends and supplies care driven by other interests than the patient's).

Box C Demand for health and healthcare

Demand and need.
The demand for health as human capital.
The demand for healthcare.
Agency relationships in healthcare.
Income and price elasticities.
Information asymmetries and agency relationships.
Externalities and publicness.
Supplier-induced demand.

Then comes **Box D** (Supply of healthcare) covering human resources; the remuneration and behavior of professionals; investment and training of professionals in healthcare; monopoly and competition in healthcare supply; for-profit and nonprofit models of healthcare institutions like hospitals and clinics; health production functions; healthcare cost and production functions that explore the links between 'what goes in' and 'what comes out;' economies of scale and scope; quality of care and service; and the safety of interventions and modes of delivery. It includes the estimation of cost functions and the economics of the pharmaceutical and medical equipment industries. A distinctive difference in this territory from many other areas of application is the need to drop the assumption

Box D Supply of health services

Human resources, remuneration, and the behavior of professionals.
Investment and training of professionals in healthcare.
Monopoly and competition in healthcare supply.
Models of healthcare institutions (for-profit and nonprofit).
Health production functions.
Healthcare cost and production functions.
Economies of scale and scope.
Quality and safety.
The pharmaceutical and medical equipment industries.

of profit-maximizing as a common approach to institutional behavior and to incorporate the idea of 'professionalism' when explaining or predicting the responses of healthcare professionals to changes in their environment.

Supply and demand are mediated (at least in the high-income world) by insurance: the major topic of **Box E** and a large part of health economics as practiced in the US. This covers the demand for insurance; the supply of insurance services and the motivations and regulations of insurance as an industry; moral hazard (the effect of insurance on utilization); adverse selection (the effect of insurance on who is insured); equity and health insurance; private and public systems of insurance; the welfare effects of soi-disant 'excess' insurance; effects of insurance on healthcare providers; and various specific issues in coverage, such as services to be covered in an insured bundle and individual eligibility to receive care. Although the health insurance industry occupies a smaller place in most countries outside the US, the issues invariably crop up in a different guise and require different regulatory and other responses.

Box E Health insurance

The demand for insurance.
The supply of insurance services.
Moral hazard.
Adverse selection.
Equity and health insurance.
Private and public systems.
Welfare effects of 'excess' insurance.
Effects of insurance on healthcare providers.
Issues in coverage: services covered and individual eligibility.
Coverage in LMICs.

Then, in **Box F**, comes a major area of applied health economics: markets in healthcare and the balance between private and public provision, the roles of regulation and subsidy, and the mostly highly politicized topics in health policy. This box includes information and how its absence or distortion corrupts markets; other forms of market failure due to externalities; monopolies and a catalog of practical difficulties both for the market and for more centrally planned systems; labor markets in healthcare (physicians, nurses, managers, and allied professions), internal markets (as when the public sector of healthcare is divided into agencies that commission care on behalf of populations and those that

Box F Markets in healthcare

Information and markets and market failure.
Labor markets in healthcare: physicians, nurses, managers, and allied professions.
Internal markets in the healthcare sector.
Rationing and prioritization.
Welfare economics and system evaluation.
Comparative systems.
Waiting times and lists.
Discrimination.
Public goods and externalities.
Regulation and subsidy.

provide it); rationing and the various forms it can take; welfare economics and system evaluation; waiting times and lists; and discrimination. It is here that many of the features that make healthcare 'different' from other goods and services become prominent.

Box G is about evaluation and healthcare investment, a field in which the applied literature is huge. It includes cost-benefit analysis, cost-utility analysis, cost-effectiveness analysis, and cost-consequences analysis; their application in rich and poor countries; the use of economics in medical decision making (such as the creation of clinical guidelines); discounting and interest rates; sensitivity analysis as a means of testing how dependent one's results are on assumptions; the use of evidence, efficacy, and effectiveness; HTA, study design, and decision process design in agencies with formulary-type decisions to make; the treatment of risk and uncertainty; modeling made necessary by the absence of data generated in trials; and systematic reviews and meta-analyses of existing literature. This territory has burgeoned especially, thanks to the rise of 'evidence-based' decision making and the demand from regulators for decision rules in determining the composition of insured bundles and the setting of pharmaceutical prices.

Box G Economic evaluation

Decision rules in healthcare investment.
Techniques of cost-benefit analysis in health and healthcare.
Techniques of cost-utility analysis and cost-effectiveness analysis in health and healthcare in rich and poor countries.
Techniques of cost-consequences analysis.
Decision theoretical approaches.
Outcome measures and their interpretation.
Discounting.
Sensitivity analysis.
Evidence, efficacy, and effectiveness.
Economics and health technology assessment.
Study design.
Risk and uncertainty.
Modeling.
Systematic reviews and meta-analyses.

The final Box, H, draws on all the preceding theoretical and empirical work: concepts of efficiency, equity, and possible conflicts between them; inequality and the socioeconomic 'gradient;' techniques for measuring equity and inequity; evaluating efficiency at the system level; evaluating equity at system level: financing arrangements; evaluating equity at system level: service access and delivery; institutional arrangements for efficiency and equity; policies against global poverty and for health; universality and comprehensiveness as global objectives of healthcare; and healthcare financing and delivery systems in low- and middle-income countries (LMICs). This is the most overtly 'political' and policy-oriented territory.

Box H Efficiency and equity

Concepts of efficiency, equity, and possible conflicts.
Inequality and the socioeconomic 'gradient.'
Evaluating efficiency: international comparisons.
Techniques for measuring equity and inequity.
Evaluating equity at system level: financing arrangements.
Evaluating equity at system level: service access and delivery.
Institutional arrangements for efficiency and equity.
Global poverty and health.
Universality and comprehensiveness.
Healthcare financing and delivery systems in LMICs.

A Word on Textbooks

The scope of a subject is often revealed by the contents of its textbooks. There are now many textbooks in health economics, having various degrees of sophistication, breadth of coverage, balance of description, theory and application, and political sympathies. They are not reviewed here but I have tried to make the (English language) list in the Further Reading as complete as possible. Because the assumptions that textbook writers make about the preexisting experience of readers and about their professional backgrounds vary, not every text listed here will suit every potential reader. Moreover, a few have the breadth of coverage indicated in the schematic here. Those interested in learning more about the subject to supplement what is to be gleaned from the pages of this encyclopedia are, therefore, urged to sample what is on offer before purchase.

Acknowledgments

My debts of gratitude are owed to many people. I must particularly thank Richard Berryman (Senior Project Manager), at Elsevier, who oversaw the inception of the project, and Gemma Taft (Project Manager) and Joanne Williams (Associate Project Manager), who gave me the most marvelous advice and support throughout. The editorial heavy lifting was done by Billy Jack and Karen Grépin (Global Health); Aki Tsuchiya and John Wildman (Efficiency and Equity); John Cawley and Kosali Simon (Determinants of Health and Ill health); Richard Cookson and Mark Suhrcke (Public Health); Erik Nord (Health and its Value); Richard Smith (Health and the

Macroeconomy); John Mullahy and Anirban Basu (Health Econometrics); Tom McGuire (Demand for Health and Healthcare); John Nyman (Health Insurance); Jim Burgess (Supply of Health Services); Martin Gaynor and Sean Nicholson (Human Resources); Patricia Danzon (Pharmaceutical and Medical Equipment Industries); Pau Olivella and Pedro Pita Barros (Markets in Healthcare); and John Brazier, Mark Sculpher, and Anirban Basu (Economic Evaluation). Finally, my thanks to the Advisory Board: Ron Akehurst, Andy Briggs, Martin Buxton, May Cheng, Mike Drummond, Tom Getzen, Jane Hall, Andrew Jones, Bengt Jonsson, Di McIntyre, David Madden, Jo Mauskopf, Alan Maynard, Anne Mills, the late Gavin Mooney, Jo Newhouse, Carol Propper, Ravindra Rannan-Eliya, Jeff Richardson, Lise Rochaix, Louise Russell, Peter Smith, Adrian Towse, Wynand Van de Ven, Bobbi Wolfe, and Peter Zweifel. Although the Board was not called on for frequent help, their strategic advice and willingness to be available when I needed them was a great comfort.

CONTENTS OF ALL VOLUMES

VOLUME 1

VOLUME 2

VOLUME 3

Abortion

T Joyce, City University of New York, New York, NY, USA

Glossary

Difference-in-differences It is subtracting the change in an outcome for a 'control' group from the change in the same outcome among the 'treated' group.

Household production It is the use of time and goods to create commodities such as health.

Identification strategies These are research designs that uncover parameters or associations of interest.

Induced abortion An intentional stoppage of a pregnancy by medication or by surgery.

Infant mortality These are the deaths within the first year of life.

Instrumental variables A statistical method in which a variable is used to isolate variation in a regressor variable that is orthogonal to unobserved components of the outcome of interest.

Pregnancy intention It is the status of a pregnancy as planned, mistimed, or unwanted.

Spontaneous abortion It is the natural termination of a pregnancy.

Introduction

Induced abortion is not an obvious topic in a volume on health economics. Although being a common procedure, abortion does not contribute to rising medical expenditures or inflation. There were 1.1 million surgical abortions in the US in 2008, but the number of abortions has fallen overtime, although the inflation-adjusted cost of a first trimester abortion has remained remarkably stable at approximately $450. Nor have there been dramatic technological breakthroughs in the delivery of abortion. The most significant innovation is RU-486, more commonly referred to as the 'abortion pill.' However, its impact on the demand for and availability of abortion services has been modest at best. Finally, abortions are extremely safe with only 0.7 deaths per year per 100 000 procedures between 1988 and 1997. In contrast, the maternal mortality rate in the US is 15 times greater.

So why include an article on abortion? Two reasons. First, induced abortion, a medical procedure performed only by physicians, is one of the most contentious and divisive issues in the politics of many countries today. In the US, clinicians who perform abortions and staff workers who assist them have been murdered and their clinics vandalized. Politicians are defined by their stance on abortion and Supreme Court nominees must tread carefully when discussing the precedent set by the Court's decision in Roe versus Wade. Academic research on abortion has not been protected from this scrutiny. Donohue and Levitt's (2001) study linking the legalization of abortion to the decrease in homicide rates 20 years later was extremely controversial, received widespread exposure in the popular press, and became a central chapter in the hugely successful book Freakonomics.

The second reason to include a review of abortion is because the indirect effect of abortion on health is potentially large but empirically challenging to document. Induced abortion, the focus of this article, also represents a conscious decision to end a pregnancy, unlike spontaneous abortion which is an involuntary and largely random termination of pregnancy. Arguably the most notable link between abortion and health or well-being is the hypothesized relationship between abortion and crime (Donohue and Levitt, 2001). If Donohue and Levitt are correct, then the legalization of abortion averted 15 000 homicides over a 10-year period (Joyce, 2009). But homicide is but one measure of well-being. If abortion has a profound effect on crime, then it likely affected other measures of well-being such as marriage, schooling, drug use, and sexually transmitted diseases to name but a few. And yet the empirical challenge of isolating a cohort effect from constantly evolving period effects may be insurmountable given the data and methods available to researchers.

In this article the focus is on the link between induced abortion and health. Health is broadly viewed to include measures of well-being such as crime and drug use in addition to the more commonly associated measures of health such as infant mortality. Given space limitations, the author concentrates primarily on the US experience with legalized abortion from roughly 1970 to present. The history of abortion in the US is available from a number of sources (Garrow, 1998). The author concentrates instead on two empirical challenges for researchers that have tried to uncover a link between abortion and health. The first is identification. How does one measure the impact of a pregnancy that is never carried to term? The second is data. Unlike births, induced abortions are not part of a national vital registration system. Moreover, abortions are poorly reported in surveys as women are reluctant to admit to them. Finally, the review is selective. The author discusses in detail papers believed to be the most important because of the quality of the research design and their impact on subsequent research. There is more to be learned by careful study of the best papers than a quick pass through the entire literature.

The article is organized as follows. The author first discusses the conceptual mechanisms by which abortion is linked to health. This is followed by a description of data on abortion and the demographics of abortion. The next few sections discuss empirical work supporting possible links. The literature is broadly divided between studies on the determinants of abortion and its impact on fertility and those that estimate either the structural or reduced-form association between abortion and health. There has been relatively little work on the supply side of abortion markets.

Conceptual Link between Abortion and Health

How does one study the health of a fetus that has never been born? The simple answer is that you cannot, which necessitates indirect approaches. Demographers, for example, consider abortion as an expression of an unwanted pregnancy. They assume that the wantedness of a pregnancy varies along a continuum from those that are aborted to pregnancies that are mistimed but carried to term. Thus, even pregnancies that result in live births may be characterized as unwanted and contrasted with the outcomes of births described as wanted. Data on wantedness in the US come from surveys of new mothers in which they are asked about their pregnancy intention when they first discovered that they were pregnant. Births are classified as wanted, mistimed, or unwanted on the basis of a series of responses by the mother. Mothers whose pregnancies are unwanted at conception are hypothesized to smoke more or receive less prenatal care than mothers whose pregnancies were planned. As a result, births from pregnancies that are unwanted are expected to be less healthy than births from pregnancies that are wanted. Neglect is hypothesized to continue after birth. Children who were unwanted at conception may receive less nurturing than those who are wanted. The result would be lower academic achievement, behavioral problems, and possible delinquency as adolescents (Brown and Eisenberg, 1995).

It is unclear whether unwanted pregnancies based on post hoc surveys of women who gave birth provide insights as to the outcomes of pregnancies that are aborted had they instead been carried to term. Early studies of wantedness in Europe tried to estimate the impact of the latter by analyzing outcomes of women who were denied abortion. The most famous sample is the Prague Cohort of 1961–63. A total of 220 children whose mothers were twice denied an abortion for the same pregnancy were matched to children whose pregnancies had been wanted and followed for 30 years. There were few differences between the unwanted cohort and their wanted controls at birth, but by the age of 20 years, there was evidence of less personal satisfaction and psychological instability.

Economic models that linked abortion and health were first discussed by Grossman and Jacobowitz (1981). The authors argued that abortion as a method of fertility control helps parents to achieve a desired family size. Using models of the family and household production pioneered by Becker and Lewis (1973); Grossman and Jacobowitz (1981) incorporated abortion reform into a model of infant mortality. Parents maximized a utility function that depended on consumption goods, the number of births, and the survival probability of each. Both the number of children and their survival probability were choice variables. The survival probability depended on a set of endogenous inputs. Thus, parents affected the health of an infant by their choice of goods (e.g., cigarettes) and medical care during pregnancy. The model generated a structural and reduced-form production function of child survival. Grossman and Jacobowitz (1981) argued that subsidized family planning services and legalized abortion decreased the cost of fertility control which lowered the optimal number of births but raised the survival probability of each.

This quantity–quality framework became the explicit model in many of the empirical analyses that followed. Lowering the price of an abortion allowed women and parents greater control over the timing and number of children. This gave parents more control over the quality of each child as parents used time and market goods to enhance a child's health and human capital. Thus, pregnant teens could delay birth until they were more financially and emotionally prepared for parenthood. Older women could terminate unwanted fetuses that could divert resources from their current children or abort fetuses that were at a greater risk of poor health. With the advent of genetic testing and advanced sonography, abortion as a fetal selection mechanism became even more explicit.

Refinements of the selection mechanism followed. Abortion was characterized as one decision along a sequence that included the decision to get pregnant, the decision to abort or give birth, and the decision to marry or remain single (Grossman and Joyce, 1990; Lundberg and Plotnick, 1990). Increases in the cost of abortion impacted these other decisions. For instance, some women use pregnancy as a way to assess the suitability of a potential father. Increasing the cost of an abortion raises the price of this 'option,' resulting in fewer abortions but fewer pregnancies as well.

Abortion as a sorting mechanism is not the only pathway through which women and their potential offspring were affected. Akerlof *et al.* (1996) developed a model in which women's bargaining position with men was weakened by the availability of safe, legal abortion. Before abortion, sex was more closely linked to commitment. If an unmarried woman became pregnant, there was pressure on the man to 'to do the right thing' by marrying her. Abortion altered that expectation. Women willing to abort could have sex without an implied commitment of marriage in the case of pregnancy. Men could insist that a pregnancy be terminated instead of marriage. This put women opposed to abortion at a disadvantage in attracting men. To compete for men they had to be more willing to have sex without a commitment of marriage. The model predicts that the legalization of abortion will result in a decrease in 'shotgun' marriages and an increase in out-of-wedlock childbearing. Both predictions are consistent with the stylized facts in the 1970s. The link to health comes through the immiseration of women and children as the number of female-headed households rise. Economists used the model by Akerlof *et al.* (1996) to argue that the legalization of abortion could be associated with the rise in crime, in direct contradiction to Donohue and Levitt (2001).

The Akerlof *et al.* (1996) framework has not been used in the empirical literature on abortion and health. The quantity–quality framework has been the mainstay in the literature. By enabling parents to achieve an optimal number of births, abortion enhances the resources devoted to the children who are born. Thus, any empirical association between abortion and health rests importantly on the association between abortion and fertility. This may seem obvious because an aborted pregnancy is an averted birth. However, other methods of fertility control are substitutes for abortion which implies that a rise in the abortion rates need not be associated with a fall in birth rates. Couples that may have used condoms before the legalization of abortion may be less vigilant about contraception after legalization. A pregnancy that occurs under a regime on legalized abortion may not have occurred

under a regime in which abortion is prohibited. Without demonstrating that a change in the birth rate is associated with a decrease in the price of an abortion, it is difficult to establish that parents are trading off quantity for quality.

Abortion: Data and Demographics

Data

One of the biggest challenges in studying abortion is measuring its incidence. There was no national surveillance system for abortion until 1973, the year of the US Supreme Court decision in Roe versus Wade. In that year the Alan Guttmacher Institute (now the Guttmacher Institute) published its first national estimate of abortions by state. The Guttmacher survey of abortion providers was conducted annually from 1973 to 1988 with exception of 1983. After 1988, however, the periodicity of the survey was increased to every 4 years: 1992, 1996, 2000, 2004, and 2008.

The second major population-based source comes from the Centers for Disease Control and Prevention (CDC). The CDC collects data from state health departments and reports abortions by state, year, and several demographic factors: age, race, marital status, gestational age, type of procedure, parity, and previous induced abortions. There are two advantages to the CDC data. First, the availability of abortion by characteristics of the patient enable studies of policies based on age or gestational age. Second, data are available annually, whereas the Guttmacher Institute reports data periodically. As with data from the Guttmacher Institute, the CDC reports abortions by state of occurrence. In addition, the total number of abortions as reported by the CDC is approximately 15% lower than that reported by the Guttmacher Institute, and the degree of undercounting varies substantially by state. Further, not all states report abortions to the CDC or abortions cross-classified by characteristics of the patient; California and Florida are two populous and notable examples. Finally, the limited cross-tabulation of the data prevents analyses by race or by gestational age.

Although the Guttmacher Institute's periodic survey of abortion providers yields the most widely accepted estimate of the number of abortions, they have two important limitations for policy evaluations. First, abortions are tallied according to the state in which they occur and not according to the state in which a woman resides; and second, data are not available by age or any other characteristic at the state level. To overcome these limitations, Guttmacher researchers have applied the distribution of abortions by state and age as reported by the CDC to estimate the number of abortions by age. They also use information from the CDC on the proportion of abortions provided to nonresidents in a state along with other sources to estimate abortions by state of residence. Thus, it is important to remember that Guttmacher's report of abortions by state of residence are an estimate and that they are unlikely to accurately measure cross-state travel by subpopulations in response to a change in policy. This is an important drawback, which is often ignored.

The third major source of data is state health departments. The CDC uses these same data in its surveillance reports. The major advantage of obtaining them directly from the state is that some states make available to researchers individual-level data on induced abortions, which allows for a more refined aggregation of data than what is available from the CDC. This can substantially improve the internal and external validity of an analysis (the ability to measure what one sets out to measure). The two major drawbacks to these data are similar to those stated above: completeness of reporting varies by state and residents who leave their state for an abortion are rarely counted by the state in which they reside. However, the latter drawback can be overcome if researchers are able to secure data from neighboring states.

The lack of data by state of residence is a major limitation. Studies of parental involvement (PI) laws and mandatory delay statutes based on data by state of occurrence will overestimate the decline in abortions associated with the laws, not only because residents leave the state for an abortion but also because nonresidents stop entering the state for an abortion. Studies of PI laws in the 1980s and the early 1990s were particularly vulnerable to this source of bias, as only 13 states had such laws in 1988. This made travel outside one's state of residence feasible. More recent evaluations are less vulnerable to this source of bias because 35 states, including almost all states in the South and Midwest, now have PI laws. This makes traveling to a state without a law very challenging.

Other information on abortion is available from population-based surveys. The National Longitudinal Survey of Youth 1979 and 1997 ask respondents about previous abortions. The National Survey of Family Growth also queries respondents about past abortions. However, surveys grossly underestimate the number of abortions as many women do not report them. Moreover, the underreporting is not random: young, poor, and minority women appear to underreport more than other demographic groups. This has greatly limited the use of these data to evaluate policy.

Another source of data on the characteristics of women who have abortions comes from the Guttmacher Institute and its periodic survey of abortion patients. Using a sample of nationally representative abortion clinics, researchers survey patients waiting to have an abortion. The data are weighted to be nationally representative. In addition to data on age and race, they have information on income and insurance status.

Demographics

The abortion rate is defined as number of induced abortions per 1000 women of 15–44 years of age. In the US in 1973, there were 744 600 abortions and the rate was 16.3. As shown in **Figure 1**, the abortion rate rose after the decision in Roe versus Wade and peaked in 1981 at 29.3. It has fallen almost continuously since then. In 2008, there were 1 212 400 abortions and the rate stood at 19.6.

Table 1 shows the abortion rates by characteristics of the patients in 1998 and 2007 based on the CDCs annual surveillance of reporting states. The abortion rate was greatest for women of 20 to 24 years of age at 35.6 per 1000 in 1998 and 30.0 per 1000 in 2007. The teen abortion rates fell 25.3% over the same period from 19.8 to 14.8. The abortion rate of Blacks (37.8 in 1998) was more than 3 times that of Whites, and the

rate for Hispanics more than 2 times that of Whites in both 1998 and 2007. Abortion rates have fallen for all three groups since 1998. More than 90% of abortions are performed at 13 weeks or less gestation. The percent of abortions less than or equal to 8 weeks gestation has risen from 55.8% in 1998 to 63.6% in 2007. This coincides with the growth in medical abortions which accounted for almost 14% of abortions among reporting states. The percent of abortions at or after 21 weeks gestation fell from 1.5% to 1.3% between 1998 and 2007.

Abortions by education, poverty status, and insurance coverage are shown in Table 2. These estimates are from the Guttmacher Institute's periodic survey of abortion patients and are weighted to be nationally representative. Several figures stand out. First, differences by poverty status are striking. In the year 2000, women from families with less than 100% of

the federal poverty level in that year have more than four times the abortion rate of women from families at 300% or more of the federal poverty level. The abortion rate of women with Medicaid coverage, at 57 per 1000 Medicaid recipients, are even higher than those of women in poverty. However, differences in abortion rates by education, a permanent measure of human capital, are much more muted.

In sum, age, race, and income are the three most important correlates of abortion rates in the US. They suggest that young, Black women in poverty are at much higher risk of an unintended pregnancy than their older, White counterparts. The figures also underscore the importance of abortion as a method of fertility control among young, poor, and minority women. If the elasticity of demand for abortion services is greater among less advantaged groups, then policies that raise the cost or lessen the availability of abortion services are likely to impact these groups more than women whose rate of unintended pregnancy is less.

Overview of Studies on Health

Studies of the relationship between abortion and health have progressed with advances in the field of applied microeconometrics. Borrowing from the medical sciences, random control trials (RCTs) have become the gold standard. RCTs remain rare in economics, but their acknowledged quality has pushed researchers to design studies with strong internal validity and transparent sources of identification. In this section, the author reviews the evolution of studies linking abortion and health through the improvement in research design. Early studies of abortion and health relied on cross-sectional variation to identify an association. The second phase of studies on abortion and health leveraged panel data and changes in policy to understand the determinants of abortion and its impact on fertility. A related group of studies used panel methods to estimate the cohort effect of abortion legalization on broad measures of well-being. The most recent set of studies has employed abortion legalization as an instrument for births in an effort to estimate changes not only in the health of birth cohorts exposed to legalized abortion *in utero* but also to estimate the potential health of children that were not born.

Early Studies of Abortion and Health

As noted above, Grossman and Jacobowitz (1981) were the first to use the household production function framework to associate access to abortion with infant health. The empirical work involved regressions of county-level neonatal mortality rates averaged over 3 years from 1970 to 1972 on measures of the cost of fertility control and other inputs into the production of health. They used two measures of abortion availability: Dichotomous indicators of whether the county was in a state that had reformed or legalized abortion by 1970 and the 3 year average of the state abortion rate (abortions per 1000 live births) from 1970 to 1972. And they applied coefficients from the cross-sectional regression to estimate the reduction in neonatal mortality attributable to each input. Overall the model could explain between 35% and 53% of the decline in neonatal mortality between 1971 and 1977. However the most striking result was that the abortion rate accounted for more than 50 of the explained decline for both White and non-Whites.

A series of papers followed the Grossman and Jacobowitz (1981) framework but with more recent data and greater attention to the endogeneity of abortion in the production of infant health. In one study economists estimated the reduced form production function of infant health. The outcome was again the county-level neonatal mortality rate averaged over 3 years (1976–78). They included proxies for the price of inputs such as the number of abortion providers in the county or the number of maternal and child health clinics. The results suggested that an increase in the number of abortion providers was strongly associated with decreases in neonatal mortality. Other economists used the county-level neonatal mortality rate in an effort to estimate the structural production function of infant health. They were interested in the pathways through which abortion affected survival. Thus, they also estimated structural models of low birth weight and preterm births. They included the abortion rate as well as the number of teenage users of family planning clinics as determinants of each outcome. They used two-stage least squares (TSLS) to account for the endogeneity of the abortion rate with number of abortion providers per county as an instrument (more on the instruments below). They found that state-level abortion rates were inversely correlated with neonatal mortality, low birth weight, and preterm birth. Moreover, they argued that abortion improved newborn survival by lowering the incidence of low birth weight births. Others followed this approach by estimating structural models of infant survival. However, their objective was to understand the relative contribution of government programs. These include participation in the Supplemental Nutrition Program for Women, Infants, and Children (WIC), inpatient days in neonatal intensive care units, use of family planning clinics, as well as maternal and child health clinics. As did other economists, these authors used TSLS with the availability of clinics, abortion providers, and neonatal beds as instruments. They reported that the abortion rate explained approximately half of the decline in neonatal mortality between 1964 and 1977 accounted for by the model.

The aforementioned studies used aggregate data to correlate the abortion rate with county-level measures of health. All reasoned that areas with higher abortion rates had a more optimal distribution of birth outcomes as less healthy or desired fetuses were aborted. An ecological approach appeared the only way to associate abortion to health. At the individual level, a pregnancy that is terminated is eliminated from the sample of births. There seemed to be no individual-level analog to the aggregate analysis. However, in two papers, economists applied the emerging econometrics on censored samples to analyze the effect of pregnancy resolution on birth outcomes (Grossman and Joyce, 1990). In both papers, the authors used individual-level data on births and abortions in New York City. The birth and abortion files contained information on age, race, marital status, parity, schooling, as well as measures of the availability of family planning and abortion services by neighborhood. The authors concatenated the files

to create a sample of pregnancies that resulted in either an induced abortion or a live birth. They argued that the sample of births represented a nonrandom draw from the population of pregnancies. In one paper, the authors used the decision to give birth conditional on pregnancy as an expression of wantedness. Women who were selected in the birth sample were more likely to obtain timely prenatal care than those who aborted had they instead carried to term. They estimated the observed counterfactual by using the inverse Mill's ratio to obtain the expected number of months a woman would have delayed prenatal care had she not aborted. The difference between the expected and actual months of delay for women with the same observables became an estimate of the impact of 'wantedness' on the demand for health-producing inputs. They found that women who had a greater probability of giving birth had less than expected delay in prenatal care.

Grossman and Joyce (1990) extended the model to include birth outcomes while treating prenatal care as an endogenous input into the production of health. They also provide a framework that signed the effect of changes in the cost of abortion, the cost of contraception, and underlying health endowment of the fetus. They treated contraception and abortion as substitutes. An increase in the cost of contraception or a decrease in the cost of abortion raises the probability of becoming pregnant. However, an increase in the cost of abortion holding the cost of contraception constant raises the probability of giving birth, conditional on becoming pregnant. For instance, assume that Black women face a higher cost of contraception due to less access and information. A decrease in the cost of abortion will lower the probability of giving birth conditional on pregnancy, increase the demand for healthy inputs, and increase birth weight. This is what the authors found for Black women but not for Whites.

These early papers were important because they tried to develop an empirical test of the association between abortion and health. They used the household production framework to incorporate the cost of fertility control in models of the quantity and quality of children. The statistical analyses became progressively more sophisticated as researchers applied recent advances in econometrics to account for the endogeneity of inputs. However, the identification strategies used then would never meet the standards of today. First, all data were cross-sectional. The lack of a panel precluded fixed effects, which would have limited the identifying variation to within-area changes in policy. Instead, authors compared the impact of abortion rates on birth outcomes in, for example, Utah relative to New York. Given the limited number of covariates, the likelihood of omitted variable bias was large. Even reduced-form analyses suffered from problems of endogeneity. The number of abortion providers in a state or county, for instance, represents the interplay of the supply and demand of abortion services instead of some exogenous measure of price. The sample selection models used by Joyce and Grossman (1990) were novel applications at the time but again lacked a credible identification strategy. More importantly, the robustness of these models depends on the availability of instruments that predict the probability of giving birth but which have no direct effect on the birth outcome. None of the instruments in the two papers could be credibly excluded from the birth outcome equation. Despite these serious drawbacks, this early work motivated subsequent studies that paid much greater attention to identification and for much of the 1990s focused on reduced-form policy questions.

A paper by economists in the mid-1990s provided a segue to the reduced-form policy-orientated papers that soon followed. The authors took the model of Grossman and Joyce (1990) as their starting point. They used individual data from the National Longitudinal Survey of Youth 1979 (NLSY79) to estimate the impact of the price of abortion on birth outcomes. State policies regarding the public financing of abortion through Medicaid served as proxies for the price of abortion in the reduced-form production function of infant health. They found no association between Medicaid financing restrictions and birth weight. In the second part of the paper, they estimated the birth probability equation and found a robust association between Medicaid financing of abortion and the decreased probability of giving birth. For Black women, the availability of Medicaid financing lowered the probability of birth by 0.10 over a mean of 0.88, which is a large effect.

Several features of the analysis are noteworthy. First, the authors used 10 years of data from the NLSY79 and were able to exploit changes in policy over time. Second, they focused on the reduced form instead of the structural production function of health. However, they used random effects instead of state-fixed effects to control for unobserved cross-state heterogeneity. A random effects specification assumes that unobserved state factors (the random effects) are uncorrelated with the policy under study; in this case Medicaid financing of abortions. This was unlikely because mostly liberal states continued to use public funds for abortion after the Hyde Amendment in 1976. In addition, there is very little within-state variation in Medicaid financing of abortion. The big changes in Medicaid came in the late 1970s with the Hyde Amendment. In other words, despite the use of longitudinal data, their policy estimates are essentially obtained from cross-sectional variation in Medicaid financing of abortion. Nevertheless, the paper represented a bridge to subsequent papers in the 1990s that took advantage of panel data with state-fixed effects to eliminate confounding from hard-to-measure differences between states and counties.

Abortion Policy and Fertility in the 1990s

Work on abortion and health in 1990s was shaped by the advances in applied microeconometrics. A series of seminal papers in the econometric literature described the conditions that must hold before instrumental variable methods would yield even limited estimates of treatment effects. The 1990s also saw more emphasis on transparent sources of variation and the quality of the comparison group. The difference-in-difference (DD) methodology became popular because it focused on the reduced form and plausible counterfactuals. There was also much more use of panel data given the attention to pre–post contrasts. Another development was interest in the effect of abortion policy on fertility. This relationship is key to the household production model. If researchers can not demonstrate a relationship between the price of fertility control and the number or timing of births,

then abortion may not play an important role in the quality–quantity trade-off envisioned by its early proponents.

The most important policy change in the US was the legalization of abortion. This occurred largely in two steps. From September of 1969 through December of 1970, abortion became de facto or *de jure* legal in 5 states (Alaska, California, Hawaii, New York, and Washington) and the District of Columbia (Lader, 1974). Abortion became legal nationally with the US Supreme Court decision in Roe versus Wade in January of 1973. The two-step process toward national legalization provided plausibly exogenous sources of variation with which to identify the effect of the availability of abortion services on fertility. An early paper looked at the impact of the legalization of abortion in New York on teen birth rates in New York City in the years before Roe. Lacking data from a control state, the authors used an interrupted time series analysis to estimate the monthly change in White and non-White teen births after abortion became legal in July of 1973. They found that White and non-White births fell 14% and 18%, respectively, in the 24 months after the law went into effect.

Levine *et al.* (1999), however, were the first to exploit the staggered process of legalization within a DD strategy to obtain the most credible estimates of the effect of a decrease in the price of fertility control on birth rates. Using natality data from all 50 states and the District of Columbia, they contrasted changes in fertility from 1961 to 1980 among the early versus the later legalizing states. Overall birth rates fell almost 5% more among women in the early compared with later legalizing states. However, when the authors took account of distance to the nearest legalizing states, the results showed that birth rates fell 10% among those that lived more than 750 miles away from the nearest state in which abortion was legal. Surprisingly, there was no distance gradient for those who lived within 750 miles. Specifically, birth rates fell 4.5% regardless of whether women resided 250 miles away or between 250 and 750 miles from a state with legalized abortion. The study was a classic example of a DD and provided convincing evidence that the early legalization of abortion had an immediate effect on fertility. Some of these same authors would further exploit this natural experiment to analyze changes in well-being associated with changes in fertility.

Post-Roe Policies

Although induced abortion was declared a fundamental right, it remained highly controversial. State governments moved quickly to find the legal limits of regulation. Three state policies have dominated both the political discourse and academic research. The first is the Hyde Amendment, which prohibited the use of federal funds to cover the cost of an abortion unless the mother's life is in danger. The second is PI laws which require that a physician notify or obtain consent from a parent or parents before performing an abortion on a minor, usually defined as girls less than 18 years of age. The third policy is a mandatory delay and counseling statute. This requires that women receive state-mandated information regarding the abortion procedure, the status of the fetus, and alternatives to abortion usually 24 h before the termination. Each policy has been used by economists to analyze changes primarily in abortion and birth rates, although some have looked at the reduced-form association with health. In this summary the focus is on a selected group of studies based on the quality of the design and their impact on subsequent work.

Medicaid

In 1976, Congress passed the Hyde Amendment, which bans federal funding of abortion in all but the most extreme circumstances. The statute prohibits expenditure of federal funds for abortion services except in cases where the continuation of the pregnancy threatened the woman's life. Currently, 17 states use their own funds to pay for all or most medically necessary abortions sought by Medicaid recipients.

The impact of Medicaid financing restrictions has been analyzed extensively. A review by researchers at the Guttmacher Institute in 2009 listed 37 studies related to the Hyde Amendment. In this article, the focus is on studies by economists that use panel data designs or that exploit a particularly unique experiment. The Journal of Health Economics published two studies of the Hyde Amendment in the same issue in the Winter of 1996. In both the studies, researchers used a panel of states. In one study, authors analyzed abortion rates from 1974 to 1988, whereas in the other researchers used data from 1977 to 1988. Both studies found that the restrictions were associated with a decline in abortion rates of between 3% and 5%. One group of researchers used TSLS to account for the endogeneity of abortion providers; however, the instruments were not convincing. The authors used the natural logarithm of the number of hospitals to predict the natural logarithm of abortion providers and yet many hospitals provided abortions, which undermined the exclusion restriction. The other group of researchers analyzed birth and pregnancy rates in addition to abortion rates. They found that increases in the cost of an abortion lowered birth rates in models that used a 1-year lag in the Medicaid restrictions. Moreover, the decline in births was greater than the fall in abortion rates. The latter finding is hard to reconcile for as it suggests that the decline in births not only offsets the likely rise among some women who carry to term but also induces an even larger group to avoid pregnancy altogether.

Arguably the best 'natural experiment' of the Medicaid financing of abortions occurred in North Carolina (Cook *et al.*, 1999). The State allocated a fixed sum of funds to be used by poor women for abortions as a substitute for resources restricted by the Hyde Amendment. However, between 1978 and 1994, the fund expired five times before the end of the fiscal year in June. The cutoff occurred once in months of December, January, and March and twice in the month of February. The authors found that the cutoff was associated with a fall in abortions and a commensurate rise in births. The effects were greater for Blacks than for Whites and for women with less than 12 years of schooling compared with those with more. Specifically, abortion among Blacks fell 9.5% overall, whereas births rose by 4.7%. In absolute terms, there was a one-to-one correspondence between the fall in abortions and rise in births among Blacks.

The study from North Carolina is particularly convincing. The timing of the funding cutoff varied by year and month and thus would have been difficult for a woman to anticipate.

The authors found no jump in abortions in July as the fund was replenished. The fall in abortions coincided with a rise in births, and effects were greater among groups with higher rates of poverty. The study in North Carolina provides a useful contrast to the previous studies of publicly funded abortions in the US. There is an important trade-off between internal and external validity in these studies, which will be relevant in the discussions that follow. The study in North Carolina has the stronger internal validity, but it pertains to a single state. Nevertheless, the funding cutoff occurred five times, which strengthened the design considerably. However, the panel data studies have the advantage of analyzing changes in 50 states with more than 34 'natural experiments.' However, the number of experiments is misleading. There is limited state variation in the timing of Medicaid funding restraints as the vast majority of restrictions went into effect in 1977 or 1981. Finally, the natural experiment in North Carolina was only able to address short-term changes in abortion and births, whereas the panel studies were able to test for longer term impacts, which may dissipate over time as women adjust to the restrictive funding environment. Despite these caveats, a clear conclusion is that the cutoff of public funding for abortions reduced abortion rates among poor women. The first-order effect should be a rise in births, for which the study in North Carolina provides convincing evidence.

Parental involvement laws

The Supreme Court's decisions in Planned Parenthood of Central Missouri versus Danforth in 1976 and Bellotti versus Baird in 1979 made it constitutional for states to require minors seeking abortions to obtain parental consent or to notify their parents provided that there is an alternative approval mechanism such as a court bypass procedure. Thirty-eight states currently require parental consent or notification of at least one parent or in some instances other adults such as a grandparent or guardians.

Evaluation of PI laws on abortion and births has been hampered by limited data. Ideally, researchers would like age-specific abortion rates by state of residence from 1974 to 2008. These data do not exist. The CDC collects abortions by age for approximately 40 states, but they refer to abortions by state of occurrence. The Guttmacher Institute has used the CDC data to estimate abortions by state of residence, but the Guttmacher researchers acknowledge that their estimates do not take into account travel by subgroups. This becomes a major source of bias in studies of PI laws because resident minors leave the state in response to a PI requirement and nonresident minors stop coming into the state. Abortions by state occurrence will show a substantial drop in abortions to minors when in fact many abortions to minors that would have occurred in the state before the law are performed in other states after the law. This has been demonstrated repeatedly (Cartoff and Klerman, 1986). A second important issue is that researchers have used abortions and birth rates of 18- and 19-year olds as either a counterfactual for changes in birth and abortion rates for minors or as a falsification test. However, the most affected group of minors is 17-year olds. They have the most pregnancies and they are the least willing to involve their parents. Yet, three-quarters of minors who are 17 years of age when they become pregnant will give birth as 18-year olds. As a result, a comparison group of 18-year olds in a DD analysis is contaminated because it includes a large proportion of girls who were exposed to the PI law during pregnancy when they were 17 years of age. Similarly, a falsification test in which the birth rates of 18- or 19-year olds is regressed on a PI law may show little change or even a rise in births. Here too the test is compromised because the 17-year olds who were exposed to the law as minors gave birth when they were 18 years of age.

As with Medicaid financing restrictions, economists have tended to use panel data of state abortion rates to evaluate PI laws. One author reported that PI laws were associated with a 20% fall in the abortion rate of teens of 15–19 years of age. The major limitations were that the author used CDC occurrence data from 1978 to 1990, which fails to account for travel by resident and nonresident minors and the author included 18- and 19-year olds who were unaffected by the law. Another economist used Guttmacher data on teen abortion rates by state of residence for 1985, 1988, 1992, and 1996. He reported a 15% decline in the abortion rate of minors. However, his data do not take into account movement across borders and he only had 4 years of nonconsecutive data. Two economists analyzed data from three states: South Carolina, Tennessee, and Virginia. They found little association with the conditional probability of abortion given pregnancy. They attributed the null finding to travel by minors out-of-state. However, pregnancy resolution as an outcome was uninformative about possible decreases in pregnancy in response to the law. Two other economists analyzed county birth rates from 1973 to 1988. They found that PI laws were associated with a 3% decrease in the birth rate of minors but a 2% decrease in the birth rate of teens of age 18 and 19 years. In absolute terms, however, the fall in the older teen birth rate exceeded that of minors, a result that could be interpreted as a relative rise in the birth rate of minors.

Finally, a study in Texas was able to overcome a number of the empirical challenges that have hampered previous studies (Joyce *et al.*, 2006). First, the authors had data on abortions to residents of Texas. Second, they were able to collect data from the neighboring states as to the number of Texas minors that went out of state after the law. Few minors left Texas because all of the border states except New Mexico enforced a PI law. Third, the authors measured abortions and births by age at conception, which minimized the misclassification bias in previous work. They found that the Texas notification law was associated with a 16% fall in abortion rates among minors who were 17 years and 6–9 months of age at conception and a 4% rise in births. Subsequent work demonstrated that some minors who were almost 18 yeas of age when they conceived waited until they were 18 years of age to abort, even if the delay caused them to terminate substantially later in pregnancy. Finally, they showed that using age at the time of the abortion or birth and ignoring the misclassification resulted in a much larger fall in abortions with no rise in births. This provides some explanation for the findings by other economists who reported no change in births associated with PI laws. In all the other studies authors used age-specific birth rates based on the teen's age at the time of birth and not at conception.

The studies of Texas by Joyce and colleagues are to the PI literature what the study by Cook *et al.* (1999) is to the

literature on Medicaid financed abortions. Both studies have strong internal validity, given the design and quality of data, but both pertain to a single state, which limits their external validity. Studies that use state panels with many law changes would seem superior, but less accurate data on residents and the difficulty of accounting for trends in the outcomes have undermined their internal validity. This trade-off between internal and external validity continues in the studies of mandatory delay and counseling laws as will be shown next.

Mandatory delay and counseling

Many states require a waiting period between the time a woman has been counseled about her abortion and the actual procedure. About 23 states require a mandatory waiting period of 24 h. Utah requires a waiting period of 72, another state 18 h, and one state requires that counseling take place on a day before the abortion but did not specify the length of the waiting period. Four other states had mandatory counseling and waiting period laws whose enforcement had been enjoined. These laws specify that certain information must be given or offered to the women at the initial visit. The required counseling usually includes, among other things, the gestational age of the fetus, information about fetal development, the risks of abortion and childbirth, and resources available for pregnant low-income women. Some mandatory counseling and waiting period laws stipulate or have been interpreted to mean that a woman can be counseled via mail or phone about her procedure; others require that the woman be counseled in person, which usually means she must visit the facility twice – once for counseling and again for the procedure.

The constitutionality of mandatory delay statutes was not confirmed until the 1992 US Supreme Court decision Planned Parenthood of Pennsylvania versus Casey. Thus, there have been relatively few studies and few have found any significant impact of these policies on abortion and birth rates. One problem has been the use of state panels through 1997 or 1998. These studies were statistically underpowered as only a small percentage of women in these panels were exposed to the law. Another reason why these laws have had relatively little impact is because most states allow information to be given over the phone or the internet. This imposes relatively little burden on either the patient or the clinic and would only affect abortions if the required information was persuasive. A recent case-study analysis in Texas found no change in the abortion rate of Texas residents after the state required a 24 h delay and mandated information in January of 2004. The law did not have an inperson requirement as women could obtain the information over the internet (Colman and Joyce, 2011). In contrast, states that require that patients receive the mandated information in person, at least 24 h before the procedure, have demonstrated a greater impact on abortion rates. The burden of an inperson statute is potentially substantial if it necessitates that a woman who lives far from the clinic stay overnight. Mississippi provides such a case. The state imposed a mandatory delay and counseling law with an inperson requirement in August of 1992. Three studies of the law's impact, all using different counterfactuals, found that the law was associated with approximately a 10% decrease in abortion rates, an increase in second trimester abortion rates, and a substantial rise in women leaving the state for an abortion. The key to each study was the quality of the data. Researchers were able to measure abortions to residents of Mississippi obtained in other states. They also had data on the gestational age of the fetus at the time of the termination. However, as with Medicaid financing of abortions and PI laws, the external validity of studies based on a single state is a key limitation.

What conclusion can bedrawn from analyses of state policies in the post-Roe era? The first is that raising the cost of abortion affects behavior. Abortion rates fall, women travel to less restrictive states, and abortions occur later in pregnancy. What is less clear is the magnitude of these changes. The impact of a policy depends on the availability of alternatives. Very poor women may be unable to raise the necessary funds for an abortion. If minors have to travel hundreds of miles to find an abortion provider in a state without a parental notification statute, then they may carry the pregnancy to term. If women must see a physician twice and wait at least 24 h between visits before a procedure can go forward, then her termination is likely to be delayed. Measuring the impact of these policies on births is more challenging. Statistical power is limited. If the birth rate is approximately 3- to 4- times the abortion rates, then even a 10% decrease in abortion would at most result in a 2.5% increase in births. If some women respond to the new law by avoiding pregnancy, the increase will be even less.

The small change in births induced by these policies makes it very difficult to detect changes in health associated with each. The finding from studies report changes in suicide, maltreatment of children, and homicide associated with these laws are implausible. The reduced-form strategy used in many of these studies is vulnerable to omitted variable bias. One researcher, for example, reports that Medicaid restrictions increase suicides among women but mandatory delay laws protect against suicide. Two other economists report an increase of 30–60% in child abuse victims associated with mandatory delay laws. The rationale is that mandatory delay laws result in more unwanted children, but they never show that mandatory delay laws increase birth rates. Another study found that PI laws increase rates of gonorrhea among women less than 20 years of age compared with women 20 years of age and older from 1981 to 1998. However, it has been difficult to show that PI laws had any impact on abortion rates in the 1980s and the early 1990s and so any effect of sexually transmitted diseases is suspect. Moreover, data on sexually transmitted diseases by race are poorly reported in the US. In large racially diverse states, race was unknown in 30–40% of reported cases of gonorrhea.

In the next section the issue of abortion and health will be taken up but with the next generation of studies. The research designs improve. There is more attention to the credibility of the 'first-stage' and the quality of the instruments. The underlying theory can still be traced to the quantity–quality model of household production, but there is less interest in theory and more emphasis on the empirics.

Back to the Future: Roe versus Wade as an Instrument

Advances in research design and insistence on greater rigor in the application of instrumental variables greatly has improved

applied economics since the late 1990s. The literature on abortion and health was similarly affected. Researchers realized that changes in policies regarding Medicaid financing of abortion, PI laws, and mandatory delay statutes did not alter the timing or number of children sufficiently to power analyses of maternal health and child well-being. Thus, researchers returned to abortion legalization in the US and abroad in which there was greater evidence of changes in fertility associated with the more dramatic fall in the price of fertility control. Two papers led the way. In the first, researchers used the legalization of abortion in the US as an instrument for teen childbearing in models of schooling and labor market outcomes. With data from the 1980 Public Use Microdata Samples (PUMS) from the US Census , the authors showed that the longer a teen was exposed to legalized abortion, the lower the likelihood of becoming a teen mother or married before the age of 20 years. The impact of legalization on childbearing was substantially greater among Blacks than among Whites. The racial pattern persisted in the reduced-form models of high school graduation, college attendance, and labor force participation. The authors then used exposure to legalized abortion as an instrument for Black teen out-of-wedlock childbearing in models of school, work, and poverty. They did not pursue a similar analysis for Whites because there was no reduced-form evidence to support it. The results were large. Teen motherhood reduced college entrance by 20 percentage points when estimated by ordinary least squares (OLS) but by 56 percentage points when estimated by TSLS. Differences between OLS and TSLS for labor force participation were even greater. The authors concluded that on balance the data suggested that abortion legalization increased schooling and employment among Black women. Nevertheless, the authors noted that despite the change teen fertility, it was difficult to detect the consequences of teen childbearing even with large samples from the US Census. They go on to encourage researchers to find other sources of exogenous variation in fertility in order to identify the effects of teen childbearing on downstream outcomes.

In the same year, Gruber *et al.* (1999) published an important paper entitled, 'Abortion Legalization and Child Living Circumstances: Who is the Marginal Child?' They too used the 1980 PUMS to analyze changes in the health and well-being of cohorts born before and after the legalization of abortion. Legalized abortion, they argued, changed the distribution of women who gave birth which, in turn, altered the average circumstances under which subsequent cohorts of children were raised. Improved circumstances after Roe would be evidence of positive selection. They also noted that increases in the average circumstance of a cohort implied that the conditions of the marginal child, the one who would have been born had the women not ended the pregnancy, would have to have been worse for average well-being to rise.

The authors estimated both reduced-form and structural models of child well-being using the two phases of abortion legalization in the early 1970s. The reduced form showed that the average change in each outcome was associated with increased access to legalized abortion. In these regressions, the authors found that the rate of low birth weight birth associated with pre-Roe legalization fell from 7.7% to 7.6%, whereas infant mortality dropped from 1.9 per 1000 live births to 1.86 per 1000. The reduced-form results also suggested that children after legalization were less likely to live with a single parent, to live in poverty, or to receive welfare. Effect sizes were approximately 3% of the mean for each outcome. Changes in well-being associated with the marginal child were much larger. The TSLS estimates suggest that the probability of dying in the first year was 40% greater for the marginal child, although the rate of low birth weight was 14% greater. The results by race were less consistent. Although the impact of abortion legalization on the birth rates of non-Whites was twice as large as on Whites, none of the reduced-form estimates of changes in non-White living circumstances or infant health were associated with abortion legalization. The same was true for the marginal child as estimated by TSLS.

In a sequel to the marginal child, the researchers analyzed the impact of abortion legalization on adult outcomes with data from the 2000 census. As before, cohorts pertained to individuals born between 1965 and 1979 and who were 21 to 35 years of age as of the 2000 census. As in Gruber *et al.* (1999), they regressed measures of well-being on the two-phases of legalized abortion in 1970s. The outcomes include the percent in poverty, in single-parent household, on welfare, incarcerated, employed, a high school dropout and a non-college graduate. In only 2 of the 7 outcomes was there an association with early legalization and in only 3 of the outcomes was there any association with all phases of legalization. In the TSLS models in which each outcome was regressed on the birth rate instrumented by the cost of abortion, less than half the outcomes were associated with worse conditions for the marginal child.

The 'marginal child' papers provided a novel and more general empirical framework for estimating the impact of abortion legalization on the child that was not born. Instead, of only associating abortion legalization with average changes in affected cohorts, these authors provided a clever method of estimating the counterfactual outcome. There are, however, important limitations to the empirical work and results. First, in both papers, the authors could not separate age from period effects because they only had data on each outcome at a single point in time. The inclusion of state-specific quadratics in age may have accounted for some of the variation in period effects, but period effects can be very powerful determinants of crime, employment, single parenthood, etc. Second, a lack of selection effects among non-Whites is difficult to explain, especially in light of other work that demonstrated robust effects of abortion legalization on education and employment among Black women. Not only did the legalization of abortion affect non-White fertility more than Whites, but also the non-Whites are more likely to be incarcerated, on welfare, single parents, and high school dropouts. If abortion is improving the circumstances of White children, indicative of positive selection, why would an even greater relative and absolute decrease in fertility among non-Whites not affect their circumstances even more? Either there is negative selection among non-Whites or unmeasured period effects are confounding estimates. Third, it is difficult to interpret the first-stage estimates in this study. There are many interactions in which the omitted category is obscure and the exclusion restrictions are hard to justify. Despite these issues, the marginal child papers were an important advance in the literature.

Abortion and crime

Clearly, the most sensational association with abortion came from Donohue and Levitt's (2001) paper linking the legalization of abortion to the precipitous drop in crime. The mechanism was not novel. Citing Grossman and Jacobowitz (1981) and Gruber *et al.* (1999), Donohue and Levitt (2001) argued that the child who was not born would have grown up in worse living circumstances, received less parental support, and as a result would have been more prone to criminal behavior as a teen and adult. The paper received remarkable attention in the popular press and its basic finding reached an even broader audience with the publication of Levitt and Dubner (2005) book, Freakonomics. The empirics were simple. The authors regressed total crime rates on lags of the abortion rate adjusted for state and year-fixed effects. They also regressed age-specific arrest rates for those of 15–24 years of age on the lagged abortion rate. In both specifications they found that abortion rates could explain upward of 50% of the decrease in crime in 1990s.

The results were quickly challenged. It was straightforward to show that their story did not line up with simple plots of age-specific homicide rates (Joyce, 2009). For instance, homicide rates soared between 1985 and 1992 among young, African-American males in large urban areas and then dropped almost as precipitously thereafter. There were relatively modest changes in murder rates among other groups who were also exposed to legalized abortion *in utero*. Most criminologists attributed the increases in homicides to the crack cocaine epidemic which spurred a rise in gang violence. However, no credible data on crack-cocaine use by state, year, and age existed which created a potentially significant omitted variable problem. This was aptly demonstrated by two economists who first replicated Donohue and Levitt's regressions but then added state–year interactions. The association with the abortion rate fell by 50–60%. Another economist used a triple difference strategy to eliminate the confounding effect of crack cocaine by comparing the crime rates of 19-year olds born before abortion was legalized to that of 17-year olds born just after. Both groups experienced the same period effects (i.e., the crack-cocaine epidemic) but only the younger cohort was exposed to legalized abortion *in utero* (Joyce, 2009). Joyce found no association between legalized abortion and crime. A full airing of the debate is beyond the scope of this article. Regardless of the ultimate judgment of the Donohue and Levitt thesis, their work stimulated further research. Economists examined the association between legalized abortion and drug use, whereas others correlated legalized abortion with teen pregnancy, a female proxy for delinquent behavior. Economists also convincingly linked legalized abortion to sexually transmitted diseases. The strength of these papers rested on use of abortion legalization as the identifying source of variation. Legalization, much more than subsequent policies regulating abortion, had a clear, measurable impact on fertility. And yet the challenge in all these papers is identification of a cohort effect amidst often powerful period effects. In the case of abortion and crime, it was the crack epidemic of the late 1980s and the early 1990s that confounded estimates. With teen pregnancy, it was welfare reform and the expanding economy in the 1990s. Thus, studies that analyzed changes in outcomes around the time of legalization are more convincing because the confounding from period effects is arguably more easily controlled. Even with more proximate outcomes, the health effects of abortion are exceedingly difficult to identify. Recall that Gruber *et al.* (1999) found exceedingly modest declines in low birth weight and infant mortality among cohorts exposed versus unexposed to legalized abortion. In fact, more recent research suggests that the 1–2% declines in their paper are probably too small to be detected with the proper adjustment of the standard errors.

One paper illustrates just how difficult it can be to associate even dramatic changes in the cost of fertility control with well-being (Pop-Eleches, 2006). In December of 1966, Romania outlawed abortion and all methods of fertility control in response to the declining birth rate in the country. The result was an immediate doubling of the birth rate from 14.3 births per 1000 population to 27.4 a year later. The author used this unprecedented fertility shock to estimate its impact on the educational and labor market outcomes of the birth cohorts born just before and after the ban. The overall result was an increase in well-being, a result directly at odds with the US experience. The seemingly contradictory finding resulted from the positive increase in childbearing among families of higher socioeconomic status. Once the author adjusted for the composition change, exposure to the ban was associated with decreased schooling. The author interpreted the latter effect as the negative impact of unwantedness. The author found no association with labor market outcomes. The author also reported a 27% increase in infant mortality and a 30% increase in low birth weight. The changes in infant health were relatively short lived and thus may have been caused in part by lack of prenatal and obstetric services.

The increase in fertility in Romania was 20 times the decrease observed with abortion legalization in US and yet, even with such a huge jump in the birth rate, changes in well-being were somewhat modest or relatively short lived. This underscores the point made previously: detecting cohort effects on downstream outcomes is extremely challenging. Without large, exogenous shocks, distinguishing cohort from age and period effects may exceed researchers' ability to detect them with extant data.

Summary

The Romanian study provides an appropriate bookend to the work of Grossman and Jacobowitz (1981). The 25-year interval saw a large body of research devoted to identifying an empirical link between abortion and well-being. A tentative conclusion would argue for a positive association between the availability of legalized abortion services and increases in the health and well-being of the exposed cohorts. But even this modest assessment comes with many caveats. The early cross-sectional estimates must be discounted because the potential for confounding is overwhelming. Reduced-form estimates based on panel data that exploit change in policies such as parental involvement laws or Medicaid financing restrictions lack a sufficiently robust first stage to identify effects on health. The return to the early years of abortion legalization improved the first stage, but even then, statistically significant findings

were not consistent and the most sensational estimates with respect to homicide have been largely discredited. Thus, the author ends with the Romania study for it provided the outsized experiment so valued in applied microeconometrics. But even in this case, the association between large changes in fertility and more schooling among the affected cohorts was modest. This suggests that long-term effects of changes in the cost of fertility control on the well-being of affected cohorts may well exist, but effects are probably too small and data too imprecise to identify them econometrically.

Ambulatory care Care provided outside hospitals to patients who are not bedridden and live in the community.
Attrition Reduction in number of a sample of respondents to a repeated survey (from initial survey year to subsequent ones).
Catastrophic care Care that is needed to prevent death or extreme disability.
Cost sharing, copayments, and coinsurance These three terms are used interchangeably in this article, to mean a payment made at the point of use by the patient that is not reimbursed by any health insurance.
Exogenous A variable is exogenous if it is not a function of other parameters or variables in the model.
Income effect Change in consumption of a good as a result of a change real income.
Instruments or instrumental variables Variables used as proxy of factors which are suspected of being not entirely exogenous. The instrument correlates with the factor but its influence on the dependent variable is exogenous.
Longitudinal studies Studies in which the same individual subject is observed repeatedly over time.
Marginal value The maximum value attached to a little more or less of a good, service or desired characteristic.
Moral hazard Moral hazard refers to the possibility that insured individuals will behave in such a way after an insured event has occurred that will increase the claim cost to insurers, partly because the user-price of care is lower through insurance and demand may therefore rise.
Out-of-pocket Amount of money spent directly by a patient at the point of use and is not reimbursed by insurance (see cost sharing: what is not covered by any insurance plan).
Social epidemiologists Social epidemiologists are interested in the social determinants of the distribution of health in a population.
Social experiment A field experiment (not in the laboratory) to answer an economic or social policy questions.
Subsidy Part of the price of a service that is covered by an insurance plan or a public agency.

Introduction

It is evident that lack of (or poor) insurance coverage is a barrier to access healthcare. Evidence that insurance status is linked to access to healthcare seems overwhelming: those with insurance always use substantially more than those without.

Economists tend to be more skeptical, for the following two reasons: they question the causality behind the observed link between coverage and utilization; they question the inference from differences in utilization to differences in access to care. The causality issue is currently not important and it is summarized briefly in Section Health Insurance Increases Utilization. The distinction between utilization and access is currently a matter of scientific investigation among economists and social epidemiologists, and this review of the literature will mostly focus on this issue. Section Interpreting the Causal Effect of Insurance: Moral Hazard or Access? summarizes the theoretical debate on the inference question, which can be described as follows: Is the difference in utilization resulting from insurance coverage a matter of moral hazard – the insured use more than they need – or access – the uninsured do not use what they need? It is shown that the empirical answer depends on how healthcare need is defined and measured. Sections Effect of Insurance on the Subjective Assessment of Unmet Need by Survey Respondents, Insurance and Utilization of Medically Necessary Care, and Effect of Insurance on Health Outcomes: Adverse Events and General Health and Mortality then review the empirical evidence on the impact of insurance on the utilization of care that is needed, using three different definitions of need. In Section Effect of Insurance on the Subjective Assessment of Unmet Need by Survey Respondents, a subjective definition (what is perceived as unmet need) is used; in Section Insurance and Utilization of Medically Necessary Care, a more objective definition of need as what is clinically recommended to survive or maintain good health is used; last, in Section Effect of Insurance on Health Outcomes: Adverse Events and General

Health and Mortality, an outcome-oriented definition of need and evidence on the effect of lack of coverage on mortality and health status is used. Section Policy Implications concludes and draws policy recommendations.

Health Insurance Increases Utilization

The causality issue is as follows: When we observe differences across insurance it is noticed that individuals are not assigned to a given health insurance status but they make their own decisions on whether to be insured or not. Of course, these decisions are constrained, by how much individuals can spend overall compared to the price of health insurance, but, nevertheless, individuals at the same level of income and faced with the same premiums make different decisions regarding coverage (Bundorf and Pauly, 2006). If that decision is somehow linked to their utilization of healthcare services in a way that is not observed (in the survey used by the analyst), the correlation between insurance status and utilization may be spurious and it would be wrong to infer causality from it. For example, if individuals were to buy health insurance only because they wanted to commit to visit a doctor once a year, and get their tension and cholesterol checked, the correlation between insurance status and utilization of these services would be perfect. However, that would not mean that covering the uninsured would change their behavior: if the reason why they do not buy insurance is as they do not value the services it covers, they then might not be interested even if the services were free of charge at the point of use.

One way to address the issue is to run a social experiment: the health insurance experiment (HIE), conducted by the RAND Corporation randomly assigned approximately 2000 households to a variety of plans with varying cost-sharing arrangements (Newhouse and the Insurance Experiment Group, 1993). Because individuals were assigned to the plans rather than choosing them, any difference in utilization can be safely interpreted as causal. The results from that social experiment indicate a clear causality from coverage to utilization: individuals assigned to plans with lower copayments used more outpatient services, prescription drugs, and even inpatient services. The latter finding has been recently disputed by Nyman (2007), who argued that it is an artifact because of attrition (those who are poorly covered through the experiment and need hospital care quit the experiment and revert to their former plan); Newhouse et al. (2008) responded that subjects have no incentive doing that because they are more than compensated for the loss if (and only if) they stay in the experiment. It is true that the attrition rate was much higher in the higher coinsurance plan than in the free plan but it remains undecided whether subjects left the experiment (although they had no interest doing it) when in need of hospital care and not well covered (Nyman's suggestion) or whether they left for other reasons (the HIE Group's response to Nyman).

Beside social experiments, which are costly and constrained by ethical issues (it is not feasible to assign subjects to no coverage at all and some stop loss must be put in place, which does not allow the researchers to test the effect of not being insured), economists use a variety of econometric strategies to test causal inference in observational studies and all find a causal link from insurance status to utilization pattern.

Interpreting the Causal Effect of Insurance: Moral Hazard or Access?

It is evident that coverage influences utilization and it can be said that not being insured causes lower levels of utilization of healthcare services. The remaining issue is one of interpretation: Do the uninsured use less because they cannot afford the services when they are ill? Or do the uninsured buy exactly the amount of healthcare they need, whereas the insured overconsume healthcare because they do not have to pay for it at the point of use? Or is it that both interpretations are partially true: Some among the insured 'overconsume' and some among the uninsured cannot access the care they need. To understand the issues underlying the difference in interpretations we need to go back to the economic theory of health insurance and introduce concepts such as moral hazard. As will be clear at the end of this section, a key concept for the understanding of the access versus moral hazard controversy is the concept of need: if we could tell what is needed and what is a matter of preference in healthcare services utilization, we could tell which part of the variation in utilization across insurance status is a problem of access for the uninsured and which is moral hazard of the insured.

Andersen (1995), and most social epidemiologists, equated access to utilization: if one uses fewer services it is because they cannot use as much. He distinguishes between 'potential access' (enabling factors such as availability of services, coverage, regular source of care, travel costs, and waiting time) and 'realized access' (actual utilization). But the economists disagree on the proposed theory. As noted by Hurley (2000), access is a process-oriented concept and is unrelated to actual use: the difference between such a conception and Andersen's is that, for a given level of accessibility, individuals with different preferences make different choices. For most economists, access is similar to 'opportunity,' and individuals are always free to use opportunities as they see fit. Some of the difference between the insured and the uninsured is a matter of access (the medical need of the uninsured is not met), and some is a matter of want (the insured use nonneeded care).

The objective is of course to evaluate the respective roles of access and want in the difference in utilization across insurance status. To do so, one needs to understand the way health insurance works and interferes with decisions made by individuals regarding their utilization of healthcare services. The following is drawn from Nyman (2003).

Although standard (nonhealth) insurance pays a lump sum in case a detrimental event occurs (life insurance pays a given sum in case the insured dies), health insurance typically pays back through reduced prices of healthcare. Being covered by health insurance, therefore, means gaining access to discounted healthcare services. Some plans have a limit on reimbursement, but most public plans do not set such limits on reimbursements for acute care (hospitalizations, visits to a family doctor, and drugs prescribed by a doctor).

As a result, insured individuals live 'in a different world' than the uninsured, a world with lower prices of healthcare services. Proponents of the moral hazard hypothesis posit that because the uninsured are faced with the true price of healthcare, they buy units of healthcare services until they reach a level at which the marginal value of an extra unit is less than the price they have to pay. The insured do the same, but because they face a lower price of healthcare they buy more than what would satisfy them (to be exact, what would maximize their satisfaction) if they were not insured. The analysis of health insurance is similar to the analysis of subsidies for specific goods (e.g., food): when a price is artificially lowered, individuals do not get the right information about the relative values of goods and favor the subsidized one to the detriment of nonsubsidized goods.

The economic theory of health insurance is not only about this substitution effect but also involves what economists call income effects: If we compare two individuals with the same level of income, one benefiting from a discount on the price of one specific good but not the other one, it is clear that the former has more purchasing power than the latter. In that sense, they are richer and can make the decision to allocate that extra purchasing power as they see fit. If they decide to buy more healthcare services, because they are sick and made richer by their health insurance coverage, they are not substituting away from other potential uses of their money. They make a rational decision to allocate their extra purchasing power where it is needed.

The moral hazard story goes as follows: "Being insured means I will take advantage of lower prices of healthcare to use more of them, whether I am sick or not, need it or not. It is the fact that they are cheaper than if I was uninsured that motivates me the most."

The income transfer story is as follows: "Being insured means that when sick and in need of care, I will be richer than if I was uninsured. I will then spend more on healthcare because this is what I need to do (I am sick) and I can afford it. It shows clearly that the 'income effect' is the translation in economic theory of the access problem of social epidemiology."

It is of course impossible to separate these two mechanisms empirically on the basis of the difference in utilization across insurance status: they both predict the exact same difference in utilization.

The only notion being observed that would allow to separate the two mechanisms is 'need': Recall that the income effect occurs because the insured benefits from an income transfer when sick, whereas the substitution effect is independent of health states. One useful way to look at access versus moral hazard would, therefore, be to look at the differential effect of coverage on care that is 'needed' versus care that one could go without.

So far, we have only moved the question one step further and still need to define what 'needed' means in healthcare. As shown by Culyer (1998) and the literature on equity in healthcare utilization, need is an elusive concept, and it is impossible to provide a theoretical definition of need that would satisfy most. Rather, need is defined as how it is measured in empirical studies.

How do we measure need? Here, three ways of defining needed care are suggested:

- Subjective: Do they feel they could not access care they needed?
- Objective, process-oriented: Needed care is the type of care that is clinically necessary to maintain health.
- Objective, outcome-oriented: Access barrier can be inferred from lower utilization if and only if lack of coverage causes poorer health outcomes.

These questions were investigated in the RAND HIE: the objective was not only to measure the causal link between coverage and utilization but also to describe which services were underused by the less well covered (or overused by the better covered) and to measure the impact of being less well covered on health (a 2–4 years follow-up was included in the experiment). It is very often stated that the RAND shows a strong difference in utilization as a result of differences in coverage but no difference at all in health outcomes. Some use that often stated conclusion to infer that 100% of the difference in utilization is because of moral hazard and nothing to access problems. Interestingly, this is not the interpretation of the HIE group members themselves: first, they show that the insured utilize more of both clinically recommended and futile care than the uninsured, implying that the difference is due in part to both access problems and moral hazard. Second, they observe that in some groups (the poor and the sick) being less well covered has consequences on health. However, the effect is offset on average because the better covered also seem to suffer (surprisingly) from 'too much healthcare.' The combination of these two effects is the often cited 'no effect on health' but the RAND experiment itself does not conclude to the absence of a link between being less well covered and deteriorating health. In a sense, there must be an effect because one of the result of the RAND is that those in the plans with higher copayments used less inpatient care, and it is hard to imagine that the better covered would be admitted to a hospital to receive treatments with absolutely no effect on their health, simply for the sake of staying in a hospital.

Effect of Insurance on the Subjective Assessment of Unmet Need by Survey Respondents

A simple way to assess needed care is to directly ask respondents of a survey to state whether they had to forgo care they needed in the recent past (typically 12 months). The price to pay for such simplicity is the subjective component of the perception of need: if subjective perceptions of need correlate in a systematic way with decisions not to buy insurance, the value of such subjective assessment is low. Also, it must be noted that unmet needed care can be the result of many factors beyond lack of insurance (lack of time, procrastination, and fear).

An idea to test a causal link between coverage and perception of unmet need that should not be affected by systematic variations in how subjective need is defined is to take advantage of exogenous changes in health insurance coverage.

One such shock is the 1996 Reform of Welfare in the US that led to reductions in the caseload of the temporary assistance for needy families (TANF). Women who lost TANF also lost public health insurance after 12 months and follow ups show substantial increases in self-reported unmet need for a variety of healthcare services.

Insurance and Utilization of Medically Necessary Care

To overcome the subjectivity of self-reported unmet need, we can define needed care as what is necessary to maintain health. A stringent definition is that care is needed if and only if not receiving it would lead to death or severe disability, and the evidence on the causal effect of coverage on utilization of such care is reviewed (see Section Care That is Needed in Life-Threatening Situations or When Quality of Life Would Be Greatly Affected without Treatment). A more lenient definition is that care is needed as long as clinical consensus is that not receiving that type of care would affect intermediary health outcomes and the evidence based on that clinical definition of need is reviewed in Section Differences in Utilization of Clinically Recommended Care.

Care That is Needed in Life-Threatening Situations or When Quality of Life Would Be Greatly Affected without Treatment

A first approach is to describe what individuals facing a health shock (an illness or injury necessitating treatment if the patient wants to recover) do when they are not covered. Most of the literature on insurance and the economic consequences of health shocks is recent and from low- and middle-income countries; the literature on health shocks in rich countries is mostly about health and labor supply, and the case of the uninsured is less often considered because in most rich countries, to the possible exception of the US, public insurance covers potentially catastrophic health shocks.

In low- and middle-income countries (Ethiopia, Vietnam, and Laos), the uninsured pay for medical care in case of health shocks necessitating catastrophic spending through informal insurance mechanisms (microfinance schemes, informal lending, or transfers), drawing from their assets and savings, or cutting back on other consumption items. The only exceptions seem to be China, where the uninsured spend less out-of-pocket than the insured in case of health shocks, and Thailand, where the poor who need treatment for end-stage renal disease use therapeutic strategies or less frequent dialysis, which have side effects but keep them alive.

In the US, bankruptcy can be used to protect assets in case of large medical bills. Approximately 1 million households filed for bankruptcy caused by medical bills in excess of US$1000 in the US in 2001. Bankruptcy is not enough, though, and 61% of them also had to cut back healthcare.

In the US, as in China, the uninsured spend less out of pocket than the insured in case of a severe health shock, suggesting that lack of insurance makes medical services less affordable and, therefore, reduces access. Of course, another way to spend less out of pocket is to receive care free of charge, through charity. It is documented that public and not-for-profit hospitals in the US deliver care free of charge to patients unable to pay for care in cases of severe illnesses and accidents.

A less stringent definition of health shocks is 'nonavoidable hospitalizations.' These are hospitalizations that cannot be avoided by effective, timely, and continuous outpatient (ambulatory) medical care for certain chronic conditions – they are also called admissions for non-ambulatory care sensitive conditions (non-ACSCs). Among adults, their necessary character can be disputed: for instance, a cataract excision is a non-ACSC (no primary care can really prevent cataract), can be 'necessary' in some cases (to cure near blindness) but can also be discretionary in other cases (when vision quality is diminished); similarly, a hip replacement can be needed (the patient cannot walk without it) or discretionary (the patient can walk but feels some pain or discomfort). However, in the case of children (younger than 15 years of age), it can be argued that what is not preventable is more likely to be needed to prevent future health problems.

A study of non-ACSC pediatric admissions from 1983 to 1996 based on the US National Hospital Discharge Survey uses exogenous expansions of the Medicaid program between 1983 and 1996 (increase in children population covered by 16% points overall but at different times in different states) to estimate a causal link, rather than a simple correlation, between Medicaid coverage and use of hospital care for non-ACSC. If utilization of non-ACSC hospitalizations increases with enrollment in Medicaid, this is an indication of a causal link between lack of coverage and difficulties to access needed care. They find that Medicaid expansions led to an increase in non-ACSC admissions: any increase in enrollment by 1% increases the probability of admission for a non-ACSC by 0.81%. Therefore, there was an access problem to inpatient care for children without insurance before the expansion. When admitted, these newly covered children also receive more procedures than when they were not covered.

Similarly, the implementation of a universal National Health Insurance for the elderly in Taiwan had a stronger effect on low- and middle-income elderly than on high-income elderly individuals, suggesting that there was an access problem linked to ability to pay for treatment without insurance.

Differences in Utilization of Clinically Recommended Care

Although ambulatory care services are less expensive, some authors consider that they are 'needed' when proven to be effective, in the sense that not using them negatively affects health. As a result, if the uninsured can be shown to use less preventive services than the insured that could be interpreted as a problem of access to care. What is known on the causal effect of insurance on the utilization of clinically recommended services (such as mammography) or intermediary clinical outcomes (such as blood pressure) is now reviewed.

Changes in insurance status in longitudinal studies identify both a causal effect of copayments on mammography and a causal effect of loss of coverage on postemergency room visit to an ambulatory care doctor in the US.

Levy and Meltzer (2001, 2004, 2008) reviewed studies on insurance and intermediary health outcomes. Studies testing for a causal link are selected. Some of the studies reviewed in Levy and Meltzer will be reviewed in Section Effect of Insurance on Health Outcomes: Adverse Events and General Health and Mortality (those on final outcomes such as mortality, self-assessed health, or functional ability). They show a clear effect of loss of coverage on blood pressure, but some of these studies cannot conclude at any substantial effect of coverage on intermediary health outcomes.

Effect of Insurance on Health Outcomes: Adverse Events and General Health and Mortality

Introduction of copayments in public schemes (medication insurance for the elderly and welfare recipients in Quebec in 1996 or the California Public Employees Retirement System (CalPERS) in 2001) reduces utilization and substantially increases the probability of adverse events (more than double in Quebec).

Moving to studies testing the effect of insurance on mortality and general health; most studies do not measure the effect of insurance on utilization and infer access problems directly from detrimental effect of lack of insurance on health outcomes. Historical data (European countries in 1870–1914) show that an increase of 10% points in the proportion of population covered by health insurance led to a reduction in mortality by 0.9–1.6 per 1000. The 1.6 effect is certainly implausibly high but it should be kept in mind that expansions of coverage were usually targeted at individuals toward the lower end of the income distribution, where mortality was very high and at a time when their income did not allow them any contact with a doctor. As a result, these estimates are of effects at the maximum rate of return of coverage on access and of access on health. On the contrary, the introduction of Medicare in 1965 had no discernible effect on the change in mortality around 1970: Regions in the US with lower rates of insurance after the age of 65 years did not see any more substantial decrease in their mortality than regions with higher rates (which were less affected by Medicare as a result). The fact that Canadian provinces did not implement universal coverage at the same time (between 1962 and 1972) can be used to identify a significant effect of universal coverage: a reduction of 4% in infant mortality and of 1.3% in low birth weight.

Another approach uses the exogenous discontinuity in insurance status for most Americans when they turn 65 years: There is indeed a decrease in the mortality rate (compared to the trend before the age of 65 years) of approximately 13%, but it is hard to attribute it entirely to Medicare (Americans tend to retire at the age of 65 years as well, which can be good for health). Moreover, the effect does not vary at all across race and location or self-employed status although insurance status pre-Medicare varies substantially across these variables. A randomized trial in Oregon studies the effect of getting coverage on health outcomes (30 000 low-income individuals were randomly selected to benefit from Medicaid coverage and 10 000 applied – these are compared to similar individuals on the waiting list who were not selected) and finds an effect on self-assessed health at 1 year follow-up. The data are still under analysis and more should be known soon about objective measures such as blood pressure.

Studies using instruments (variables that affect health through insurance but are not subject to the endogeneity issue of insurance status, such as spouse's union status, immigration status, and number of years in the US, work loss in the previous 5 years, or state-level unionization rates or Medicaid eligibility and generosity of benefits) find large and significant effects of insurance on health (self-assessed health, general mortality, and human immunodeficiency virus-acquired immunodeficiency syndrome-related mortality), but the quality of the instruments can be discussed.

One particular relationship has been studied in more detail and remains disputed in the empirical literature: the effect of insurance on infant and children health. The effect of expansions of health insurance for pregnant women, infants, and children in the 1980s (1979–92) in the US on birth outcomes and children health is estimated as strong and negative on mortality (expansions yielded a decrease in mortality by almost 40%) by Currie and Gruber (1996). However, Dave et al. (2008) rightly pointed out that this is implausibly high. Their objection is that the quasiexperiment is not methodologically sound: if some unobserved variable explains that states where efforts on public maternal and natal health were made also were those states where Medicaid expansions took off first, using eligibility by year and state will overestimate the effect of insurance on mortality).

The study of expansions in insurance for infant and pregnant women finds a weak effect on birth weight (likely because of crowding out: overall, the expansions led to only a 10% points increase in the proportion insured) but a substantial effect on infant mortality (expansions decreased it by 8.5%). Last, the study of expansions in insurance for pregnant women on infant mortality found that the effect was strong for infants whose mother lived closest to a hitech hospital. It is also found that better educated women (not dropouts or teen mothers) actually used less hitech care (notably caesarian section) after the expansions, likely because of the fact that they switched from a private insurance to Medicaid, but without any notable effect on their infant's health (a case of futile care because of private insurance and generous coverage).

Overall, the lack of insurance increases the probability of adverse events and is the cause of poorer self-assessed health and higher infant mortality. Its effect on adult mortality and low birth weight is less clearly documented.

Policy Implications

It can be safely concluded that access problems are part of the difference in utilization across insurance status: It is not only about moral hazard and the difference also stems from the fact that the uninsured do not benefit from an income transfer when sick and, as a result, cannot access needed medical care. They access charity care if the intervention is a matter of survival or to prevent disability, delay recommended care such as follow-up after emergency admission or ambulatory care after new symptoms of a chronic condition,

and are much less likely to be screened for cancer, or have their blood pressure or cholesterol measured. As a result, not being insured has consequences on health, documented by downstream adverse events, self-assessed health, and, possibly, longevity.

From a normative perspective, this means that some of the difference in utilization between the insured and the uninsured is welcome: it does not mean that the insured spend 'too much' on care because they are overcovered but that the sick who are insured can use the income transfer they receive from the healthy to access needed care. This review shows that inpatient services that are nonavoidable and expensive should enter a universal plan; it also shows that preventive services and ambulatory care services that meet clinical recommendations should also be covered for the less well-off, who cannot afford it if not covered. There is no literature that would allow us to determine what is not affordable if not covered. It has been suggested in some countries with public insurance that affordability should be the main criterion for coverage: for instance, the 'bouclier sanitaire' (health shield) discussed in France in 2007–08 was a project to replace the current universal public plan with various copayments for various services (and exemptions for the chronically ill) with a full coverage plan with a deductible set at 10% of income. In Ontario, Canada, the same idea forms the basis of a tax deduction for those who have to spend more than a share of their taxable income on prescription drugs out of the pocket. The issues with such attempts at solving moral hazard (through deductible) and access (universal coverage and no copayment beyond the deductible) are threefold: first, there is no clear definition of affordability and the 10% threshold is rather arbitrary (Glied 2008); letting physicians determine what is needed without imposing any cost sharing on patients seems to be a more promising avenue to solve moral hazard and access simultaneously (the difficulty being to provide doctors with the right incentives to deliver services that are needed only). Second, the chronically ill with low or middle income will reach the deductible every year and will be penalized for being chronically ill though they are not at fault. In the US, this would prove a progress compared to the situation before the latest reform (where preexisting condition were a cause for exclusion of coverage), but in most European countries and Canada that would be a regression. Third, the deductible set at 10% of income would not address the issue of access to preventive care: in the case of preventive care, the issue does not seem to be that individuals cannot pay for it (except the very poor), but rather that the benefits (positive effect on health) accrue in the future, whereas the cost is borne immediately.

Glossary

Dynamic rationality A decision process such that a plan made in the present for a future period is consistent in the sense that the plan remains optimal when the future period arrives.

Exponential discounting Discounting future costs or benefits through a process in which the rate of time preference does not depend on the time interval between the moment of choice and the actual events.

External cost An involuntary cost that is imposed on a third party. For example, second-hand smoke from cigarettes, or traffic accidents resulting from alcohol-impaired driving.

Hyperbolic discounting Discounting future costs or benefits through a process in which the rate of time preference depends on the time interval between the moment of choice and the actual events, specifically, the instantaneous rate of time preference for a choice τ time units away can be expressed as $\gamma(1+\alpha\tau)^{-1}$, where γ and α are positive parameters.

Mental accounting The process by which an individual weighs the costs and benefits of an action or a consumption choice.

Normative implications Logical conclusions from a theory, which refer to the actions that should be taken by a welfare-maximizing policy maker.

Present bias The tendency to overweigh benefits or costs that are incurred in the present relative to those which are incurred in the future. Present bias suggests individuals do not discount exponentially.

Rational choice Behavioral patterns that are minimally consistent in the sense that if A is selected over B and B is selected over C, then A must be selected over C. May loosely be considered as behaviors intended to achieve some goal through weighing off broadly defined costs and benefits.

Reinforcement Consuming more of an addictive good today will increase the value given to consumption of the addictive good tomorrow.

Tolerance The consumption of a given amount of an addictive good in the future will yield less satisfaction, the higher is consumption of the addictive good today.

Utility A numerical representation of preferences in which more preferred consumption choices are given a higher number than less preferred consumption choices.

Utility projection bias The tendency of an individual to incorrectly predict that future preferences will closely resemble current preferences.

Introduction

What do economists add to the multidisciplinary discussion of addiction? In this article, economic theories of addiction, statistical evidence produced by economists on addictive behaviors, and resulting policy implications are described.

The manner in which economists approach addictive behaviors differs in some ways from the approaches of other disciplines. Medical and public health research often views addiction as, by definition, maladaptive. Addicts passively submit to urges rather than actively make rational consumption decisions. Consumption of an addictive good is itself beyond the control of the individual. The National Institute on Drug Abuse uses the following definition:

> Addiction is defined as a chronic, relapsing brain disease that is characterized by compulsive drug seeking and use, despite harmful consequences. It is considered a brain disease because drugs change the brain – they change its structure and how it works. These brain changes can be long lasting, and can lead to the harmful behaviors seen in people who abuse drugs.

By this definition, addiction is characterized by physiological changes and research often focuses on the neurological and psychological mechanisms underlying those changes (see Redish *et al.*, 2008 for a cross-disciplinary review of addiction research). Alcohol and other drug addictions are found to cause physical changes in body functioning, such as reductions in functioning of neurotransmitter activity like dopamine, and these neurotransmitters are part of the brain's reward system (Koob and Le Moal, 2008). These physiological changes are often observed in conjunction with, and indeed difficult to disentangle from, psychological changes such as increased depression and anxiety (Newlin, 2008).

Economists differ in generally focusing on models intended to reveal how social phenomena involving addictive behaviors emerge, which requires models suitable for investigating the manner in which addicts alter their behaviors as incentives change. By how much do smokers change their cigarette consumption if tobacco taxes increase, and over what time period? Do illicit drug addicts change their behavior as criminal penalties imposed on drug possession vary, and if so, how is the market for illicit drugs affected? What are the

private and social costs of addictive behaviors? How are addictive behaviors related to income? Which policies tend to reduce harms to addicts and to nonaddicts? These sorts of questions are better addressed using a combination of abstract behavioral models combined with statistical evidence on addictive behaviors, prices, and other incentives than by detailed exploration of physiological mechanisms.

Following Becker and Murphy (1988), economists often use the following definition:

Addiction: A good or activity is addictive for a given person at a given time if an increase in the person's consumption today causes an increase in consumption tomorrow, other things equal.

Loosely speaking, you are addicted to cigarettes in the economic sense if smoking more today causes you to smoke (or want to smoke) more tomorrow. Increased consumption of a nonaddictive good, however, does not cause you to want to consume more today if you happened to consume more of it yesterday; your desire to drink milk today is independent of your past milk consumption. Note that this notion of addiction does not require the addiction to operate through an action of the drug on the brain, although it is consistent with such an action. Nor does this definition require that the activity is maladaptive; a person may be addicted in the economic sense to, for example, health-enhancing exercise. Finally, whether a given good or activity is addictive may vary across people and over time within a given person's life.

The economic definition of addiction is a purely behavioral definition, as opposed to alternate conceptions involving physiological processes. Nonetheless, in Becker and Murphy's canonical model, people exhibit reinforcement and tolerance, elements of alternate conceptions of addiction. Reinforcement here means that increasing consumption of an addictive good today increases the marginal value that is given to consumption of the addictive good tomorrow. Tolerance suggests that consuming a given amount of the addictive good today yields less utility when consumption of the addictive good yesterday was higher.

The implications of this apparently straightforward notion of addiction are surprisingly complex. In the next Section Perfectly Rational Addiction, the canonical addiction model in economics, the rational addiction model of Becker and Murphy (1988), is discussed. This model is highly stylized, imposing strong assumptions about preferences and information, but the model is able to mimic many aspects of addictive behavior, make predictions that are possibly surprising but verified by evidence, and provide a framework for empirical analysis of taxation and other policies intended to limit consumption of addictive goods. Research building on this framework to incorporate more realistic behavioral and information assumptions is considered in Sections Imperfectly Rational Models of Addiction and Irrational Models of Addiction. Following Cawley (2008) economic models are distinguished as falling into one of the three categories: models of perfect rationality, models of imperfect rationality, and models of irrationality. Finally, in Sections Empirical Evidence and Policy Implications of Addiction Perspectives the statistical evidence and policy implications stemming from this line of research are discussed.

Perfectly Rational Addiction

Economic models typically assume that people have well-defined goals and tend to make decisions that further those goals. For example, one's goal as a commuter driving home from work may be to choose a route to minimize your driving time, and model worlds with many drivers each attempting to achieve that goal are used to predict how changes in a road system would affect traffic patterns. People in a model are 'rational' if they make decisions that are consistent with their goals. It is important to emphasize that 'rational' in this context is a technical jargon: It loosely means people weigh the benefits and the costs of a given action when making their decision, but it does not make any judgment about what defines a cost or a benefit per se (Mas-Colell *et al.*, 1995).

Consider a simple example of a model of consumer choice invoking this rationality assumption. A person can buy cigarettes or various other goods and services with a given amount of money. Given income and the prices, all affordable combinations of cigarettes and other goods define a 'menu' from which the person must choose. If the price of cigarettes is US$10 per pack and people have US$100 to spend, then 11 packs of cigarettes is not on their menu. If they can consistently rank these options from most to least preferred, which implies that if they rank A higher than B and B higher than C, they must rank A higher than C, then they are rational in the economic sense of the word. Given their rankings, how their choices will vary as the economic environment varies can be predicted. Whether a given change in economic environment makes the person better off in a well-defined sense – that is, makes an option available which is preferred to the current choice – can also be deduced from the model.

The rational addiction model extends this sort of analysis to capture special properties of addictive goods and activities. Canonical models of consumer choice take preferences as given: At some time, for example, a consumer has preferences over cigarettes and other goods and services, and chooses accordingly. The rational addiction model is dynamic; it is a model of decisions and outcomes over time, a complication which is necessary to capture the idea that addictive behaviors today affect behavior and outcomes in the future. Preferences over the addictive good and other goods and services at a given time are endogenous in the rational addiction model, as they depend on previous behavior.

The standard rational addiction model makes strong assumptions over this dynamic process, although these assumptions are weaker and more realistic than had been previously invoked in the literature. Before Becker and Murphy (1988) some economists had attempted to model consumption of addictive goods as 'habits' that have some but not all features of addictive behaviors. In these models, how much you smoke today depends on how much you have smoked in the past, but you do not take into account that your consumption in the future will change if you choose to smoke more today. People in these models are myopic and naive: They are constantly surprised when they discover that how much they smoked yesterday has changed their desire for cigarettes today.

Becker and Murphy (1988) consider the other extreme case: Instead of completely failing to understand that

tomorrow's outcomes depend on today's behaviors, Becker and Murphy consider a world in which people understand this relationship perfectly. They model addiction as stock, not unlike a capital stock, that increases or decreases over time according to the flow of consumption. Abstinence leads to depreciation in the addictive stock over time – if you quit smoking today, your level of addiction to cigarettes will decay over time. This decay is offset by consuming the addictive good – smoking more today increases your stock of addiction. Whether you become more or less addicted over time depends on whether you consume enough of the addictive good to offset the decay in your addiction. This model is intended to capture stylized facts about the dynamics of addiction: Addiction does not start or stop instantaneously, rather, an addiction is built up over time through use of the addictive substance and addiction decays over time with abstinence or decreased consumption. The rational addicts choose current consumption being fully aware of how their behavior today affects their stock of addiction, and thus their behavior, tomorrow.

Becker and Murphy prove that people in such a world will display behaviors that are typically associated with addiction. The model predicts that a rational addict builds tolerance and goes through withdrawal. Sufficiently strong addictions generate 'cold turkey' quitting behavior as opposed to quitting slowly by gradually decreasing consumption over time. Further, the model allows economists to predict how addicts will respond to a change in the price of the addictive good, and hence provides a lens through which tax policy toward tobacco, alcohol, and other addictive goods can be viewed. Finally, the model generates a falsifiable prediction about behavioral responses to price changes: An anticipated future increase in the price of the addictive good will cause rationally addicted people to immediately reduce consumption of the addictive good. This effect follows from the rational addict understanding that a future price increase will make consuming at current levels in the future more costly, and the pain of withdrawal is diminished if consumption is reduced by small amounts over time rather than a large amount in the future. Likewise, a price decrease in the past will result in more past consumption, leading to a higher addictive stock, and greater consumption levels today. A consequence of this model is that all prices, past, current, and future, influence the person's current consumption decision.

An extension of the rational addiction framework to multiple addictive behaviors can also explain cyclical binging and abstinence. Palacios-Huerta (in press) shows binging behavior is a prediction of the rational addiction model in which there are multiple, substitutable, addictive goods. For example, consider someone who is addicted to both cannabis and to alcohol but considers them substitutes. If the two behaviors deplete one's health stock in different ways (one through liver damage and the other through lung damage), binging behavior will result as individuals alternate between the two activities, binging on alcohol while lung health recovers and binging on cannabis while liver health recovers.

These models help us understand addictive behaviors in realistic settings in which there is a complicated relationship between consumption of various drugs and policies, which may fail if they ignore these relationships.

The rational addiction model has a number of important consequences with respect to how the policy is evaluated and implemented. First, people who discount the future heavier are more likely to engage in addictive behaviors. This is particularly relevant in explaining why smoking uptake is so much higher among youth rather than adults. Second, the full effect of a permanent change in prices on individual behavior cannot be judged in the short run. Facing a price increase, the addict will reduce consumption gradually over time. Becker and Murphy predict that in the long run addiction leads to a more price-responsive demand, a hypothesis that is confirmed in the empirical literature discussed in Section Imperfectly Rational Models of Addiction. Finally, announcing future change in tax policies will impact current consumption.

The Becker and Murphy (1988) model is subject to two major criticisms. The first is that the model predicts that addicts will never regret their choices. A large body of evidence falsifies this prediction. The second criticism is that strong assumptions are made about information. In particular, people can accurately predict the future effects of their current consumption. A much-criticized welfare implication follows: The rational consumer always makes optimal consumption choices, and policy interventions designed to deter consumption of addictive goods are generally welfare reducing.

Imperfectly Rational Models of Addiction

Several extensions followed the Becker and Murphy (1988) model to address the restrictive assumptions of perfect rationality. Two assumptions that have received attention are the assumption of perfect information and foresight and the assumption of exponential discounting. Models that address these concerns otherwise follow a common strategy to Becker and Murphy (1988); people continue to make decisions that they believe – at the time the decision is made – are in their best interest.

The perfectly rational consumer correctly predicts the effect that consumption of an addictive good will have on their behavior in the future. However, this assumption is contrary to evidence that suggests people are very poor judges of their future preferences and tastes: People tend to bias estimates of their future tastes toward being like their current tastes (Loewenstein *et al.*, 2003). This utility projection bias is particularly troublesome when nonaddicted people need to make judgments about the impact that consumption of an addictive good will have on their future preferences. Badger *et al.* (2007) show that even seasoned heroin addicts underestimate the influence of their addiction on behavior. To address this issue, Orphanides and Zervos (1995) extend the rational addiction model to allow people to be uncertain about how addictive they will find a good or activity. People update their beliefs about the addictiveness of the good by observing the actions of those around them and through their own experimentation. People try their first cigarette, for example, without knowing how addictive they will find smoking. In this model, addicts may regret their past choices even though they make the best choices they can with the information available at the time. Some people will underestimate their potential for addiction and regret having become an addict.

For most addictive goods, such as cigarettes or narcotics, consumption leads to an immediate benefit while the cost, such as poor health, is realized in the future. For this reason the manner in which people discount the future has important consequences for the rational addiction model. Dynamic rationality implies that people discount exponentially and consistently. That is, a predetermined and constant rate of discount is applied to every period in the future. Models of hyperbolic discounting instead assume that people have a present bias, applying a larger discount rate to events far in the future than events that are to occur sooner. A number of controlled experiments find that hyperbolic discounting is a more accurate depiction of behavior than exponential discounting (for a review of the evidence on hyperbolic discounting see Frederick *et al.* (2002)). If this type of discounting accurately reflects the decision process, then people will underweigh the future costs of their actions at the time decisions are made. Gruber and Koszegi (2001) extend the perfectly rational model to include hyperbolic discounting. This model yields dramatically different normative implications than the Becker and Murphy (1988) framework, as there is an 'internality' – one's smoking today harms one's future self, and one's present self and one's future self are, in effect, in conflict.

In the canonical rational addiction model, and some extensions thereof, people make lifetime consumption plans and adjust them as new information is revealed. A different approach to modeling the behavior of a rational addict is taken by Gul and Pesendorfer (2007) who consider people who make a consumption plan, but need to exert costly self-control to see it through. Consider a rational alcoholic who determines an optimal consumption plan of four drinks per day. According to the Becker and Murphy framework, absent any changes in information, the rational alcoholic will see this plan through, consuming four and only four drinks daily. However, such a plan requires self-control. The temptation of having extra alcohol in the house may cause the alcoholic to deviate from the four drink per day plan, and instead have five or six drinks. This deviation from the plan in the current period makes self-control in future periods even more difficult. In this framework, an addictive good is harmful if people experience an ever-widening gap between their planned optimal consumption and their actual consumption. Like the Becker and Murphy model, addicts in this model respond to anticipated future price increases by decreasing current consumption patterns, and may exhibit binging and abstinence cycles. However, unlike the Becker and Murphy model, this model can explain the use of short-term commitment devices, such as rehabilitation centers, by addicts.

Irrational Models of Addiction

Most researchers outside the field of economics do not think about addiction in a rational decision framework. This largely follows from an empirical anomaly: Addicts commonly express a strong desire to reduce or stop their consumption of addictive goods but fail to follow through. The ability of addiction to override rationality is captured in a statement made by David Kessler, former commissioner of the Food and Drug Administration: "Once they have started smoking regularly, most smokers are in effect deprived of the choice to stop smoking" (statement to the House Subcommittee on Health and the Environment 25 March 1994).

The economist views a consumer as irrational if decision making ignores relevant information and incentives. For example, models of myopic decision making can be thought of as irrational; people do not consider how current decisions will impact future outcomes. It has been argued that addiction leads to a failure in the processing of information, and therefore causes the addict to deviate from rational decision making. Clinical evidence suggests that addicts exhibit a bias in their mental accounting, placing too little weight on the negative consequences of their behavior (see Tomer (2001) for a discussion). Further, the observed procrastination of addicts, wishing to quit but continually putting off action, suggests that rational behavior does not fully capture addictive behavior.

Even if the consumption of addictive substances is irrational, surely addicts are rational in some facets of their lives. Bernheim and Rangel (2004) model a 'cue-triggered' decision process built on three premises. First, the consumption of addictive goods by an addict is often a mistake. Second, increased consumption of addictive goods makes addicts more sensitive to random environmental cues that trigger mistaken consumption. Third, addicts understand the cue-triggered process and take steps to manage their susceptibility. The cue-trigger model draws on neurological evidence that addictive substances interfere with the operation of pleasure and reward processes in the brain. In this model, people face a dynamic decision process in which environmental cues trigger a 'hot' decision-making mode during which the substance is consumed regardless of relevant incentives and information. When operating in a 'cold' mode people fully consider the current and future consequences of their actions, including how decisions influence the likelihood of being cued into a hot mode. For example, if stressful circumstances exacerbate the cravings associated with cigarette addiction, then a person trying to quit smoking will likely take steps to avoid stressful circumstances. Addicts in this model are aware of their propensity to make consumption mistakes and will take steps to precommit to future consumption and mitigate cues.

Empirical Evidence

How well do any of the models previously discussed capture the behavior of addicts? In this section, the econometric literature on addictive behaviors are discussed.

An advantage of the rational addiction model is that it provides a framework in which to develop statistical models of the consumption of addictive goods (Becker *et al.*, 1994). A key insight from this framework, and a testable implication, is that past, current, and future prices will all affect consumption behavior. From models that estimate the size of these effects researchers can predict how policy changes such as tax increases or decreases will impact across people and across time. These models are estimated using either aggregate or individual-level data on consumption of

addictive goods, prices, incomes, and other determinants of consumption. The addictive good under scrutiny varies across studies: There are many studies of tobacco and smoking behavior; other possibly addictive goods that have been empirically examined in this framework include alcohol, marijuana, cocaine, gambling, and even coffee.

The key and oft-replicated finding from the empirical literature on addictive goods is that people, even addicts, respond to an increase in the current price of addictive good by decreasing current consumption (Chaloupka and Warner, 2000; Gallet and List, 2002; DeCicca *et al.*, 2008; Sen *et al.*, 2010). If the consumption of addictive goods were an entirely irrational behavior, then consumption would not vary systematically and predictably with prices. Contrary to irrationality, it is well established that consumption of addictive goods responds to price incentives. This implies that the consumption of addictive goods is, at least to some degree, rational.

Much of the empirical literature considers one addictive good or activity in isolation, but some work attempts to model joint consumption of multiple addictive goods. Generally, a change in the price of one addictive good will affect consumption of all addictive goods. Examples include Dinardo and Lemieux (2001), who present statistical evidence suggesting that youths substitute alcohol and cannabis, and Cameron and Williams (2001), who estimate own- and cross-price effects in demand for alcohol, tobacco, and cannabis and find that alcohol and cannabis may be substitutes, whereas alcohol and cigarettes are complements. Jofre-Bonet and Petry (2008) document a complex pattern of substitutes and compliments between various addictive substances for heroin and cocaine addicts. They find that heroin and cocaine addicts use marijuana, valium, and cigarettes as substitutes.

The intertemporal influence of prices on behavior constitutes the main estimable difference between nonaddictive goods and addictive goods: The consumption of nonaddictive goods is not influenced by past or future prices. Using this testable hypothesis, many papers claim to find strong evidence of rational addiction, even for goods such as coffee (Olekalns and Bardsley, 1996). However, Auld and Grootendorst (2004) demonstrate that using aggregate data (e.g., total cigarette sales by the US state over time) to estimate addiction models tends to yield spurious evidence in favor of addiction; these methods are biased in favor of finding evidence of addiction even when the good under scrutiny is actually nonaddictive. This problem can be avoided by using individual-level data or using quasi-experimental empirical strategies. For example, Gruber and Koszegi (2001) use the preannouncement of state excise taxes on tobacco and show that smokers are forward looking in their behavior.

Similarly, statistical models show that past consumption affects future consumption in the manner predicted by rational addiction models, with an effect that diminishes over time (Gilleskie and Strumpf, 2005). The effect of past consumption on current behavior has also been found to vary markedly across people in the manner predicted by economic theory (Auld, 2005). Keeler *et al.* (1999) find that smokers respond to price incentives and that smokers with higher socioeconomic status are more likely to quit, all of which is predicted by the rational addiction model.

The empirical literature has had less success in cleanly distinguishing between different models of addiction. Goldfarb *et al.* (2001) note that commonly used empirical methods in this literature cannot be used to support or refute rational models over nonrational models. In particular, all economic models of addiction predict the observed responsiveness to prices. Levy (in press) extends the empirical literature by deriving the conditions under which the perfectly rational model of addiction can be tested against models that exhibit present bias and utility projection bias. Further, he derives estimating conditions that allow him to distinguish between the two forms of bias. Using data from the US National Health Interview Survey he finds that observed behavior strongly rejects perfect rationality, and estimates of projection bias and utility bias are strong and consistent with previous studies of nonaddictive behaviors. Consistent with the existence of these biases, Gruber and Mullainathan (2005) find that tobacco taxes increase self-reported happiness for people with a high propensity to smoke. This is suggestive that taxes are correcting for an internality.

Policy Implications of Addiction Perspectives

The extent to which people operate in the perfectly rational framework of Becker and Murphy has important normative implications that impact policy. Under the assumptions of the perfectly rational framework, people consume addictive goods according to their individual preferences and policy interventions are welfare improving only to the extent that they account for externalities associated with addictive consumption. For example, policy to reduce alcohol consumption is only welfare improving to the extent that it reduces externalities (involuntary benefits or, here, costs imposed on third parties), such as traffic accidents and violent crime.

However, even small departures from perfect rationality may imply a greater role for policy (Laux, 2000; Suranovic *et al.*, 1999). Policy intervention can be welfare enhancing when people have incorrect or insufficient information, or if the decision-making process is in part driven by irrational behavior such that 'internalities' (costs a person imposes on their future self as a result of irrational behavior) result. However, the specific type of policy intervention that should be implemented depends to a large extent on the model of consumer behavior. Further, it should be cautioned that policies designed to correct internalities are by definition paternalistic and hence controversial (Viscusi, 2002).

Taxation

One oft-suggested tool for intervention policy is taxation. There are sound reasons to tax addictive goods that do not hinge on their addictive property. The external costs of some addictive goods, such as second-hand smoke from cigarettes, can and should be internalized with taxes. Generating government revenue by taxing inelastically demanded goods creates fewer market distortions than taxing goods with elastic demand. Therefore, addictive goods with inelastic demand should be heavily taxed for revenue creation. These arguments

do not rest on improving the welfare of potential addicts per se.

Addiction itself has no clear-cut implication for tax policy because different models generate different optimal tax policies. For example, if people have time-inconsistent preferences, such as in hyperbolic discounting models, or incorrectly forecast utility with a present bias, then the optimal tax will be higher than those predicted by perfectly rational models of addiction with only externalities (Gruber and Koszegi, 2001; Levy, in press). Present bias and utility-projection bias mean that people place too little importance on, or systematically misjudge, how current behavior will impact their future selves. Therefore, taxes on addictive goods can enhance welfare by forcing people to internalize the impact of their current behavior on their future selves. In a simulation of their hyperbolic discounting model, Gruber and Koszegi (2001) estimate that a tax of at least US$1.00 per pack of cigarettes should be applied to correct the present bias in discounting. With both a utility projection bias and a present bias in discounting, Levy (in press) estimates that an optimal corrective tax should be set considerably higher.

Not all economic models of addiction imply corrective tax policy to improve the well-being of addicts and potential addicts. In the temptation model of Gul and Pesendorfer (2007), individuals optimally consume the addictive good given the temptation they face and their ability to commit to future consumption. In this framework, tax policy, when used alone, is always welfare reducing: A tax increases the cost of consuming the addictive good but does not remove or reduce temptation. Likewise, in the cue-triggered decision-making model, Bernheim and Rangel (2004) find that taxation of addictive goods may be harmful, as it may do little to change the consumption behavior of addicts and instead crowds out consumption of nonaddictive goods. Even if taxation is beneficial, Bernheim and Rangel find that banning consumption of the addictive good may be a superior policy to taxation.

Bans

Bans and restrictions are perhaps the most commonly used policy intervention with respect to addictive substances. Many models of imperfect rationality and irrational behavior predict that bans can be welfare improving. Gul and Pesendorfer (2007) show that prohibitive policies are always welfare improving because they limit the opportunity to make addictive consumption choices, thereby reducing temptation. A partial ban, say in the workplace but not at home, is considered by de Bartolome and Irvine (in press) who model the short-run behavior of an addict. The addict likes higher overall consumption of the addictive good but dislikes variance in consumption throughout the day. The workplace ban reduces daily consumption through the addict's dislike of variance; reductions in workplace consumption of the addictive good are not fully reallocated to consumption at home. These models, however, are not designed to evaluate the overall implications of prohibitions and, in particular, do not attempt to assess unintended consequences of prohibitions (Miron and Zweibel, 1995) nor the operation of black markets (Lee, 1993), so these policy implications must be considered as only part of a much larger story.

Partial bans in the form of controlled distribution offer another policy instrument. In a cue-triggered model of behavior these can be used to improve welfare. Specifically, when distribution is controlled in such a way that addicts are forced to 'stock-up' in cold states, rather than make purchases as hot states arise, they will choose the optimal level of consumption for their future selves. Partial bans allow the cold state decision maker to commit to hot state consumption. Such policy could potentially be achieved through the use of prescriptions or time-specific restrictions on sales.

Information and Insurance

When people lack information about their susceptibility to addiction, public provision of accurate information about addictive goods can enhance welfare (Orphanides and Zervos, 1995). Further, continued research and dissemination of information on the assessment of individual risk with respect to addiction can be welfare enhancing, even when people know the true distribution of risk across the population. Such efforts will assist people in better assessing their uncertain susceptibility to addiction. The need for accurate information also means that there is a welfare case to be made for restricting misleading advertising campaigns (Orphanides and Zervos, 1995). Similarly, limiting cue use in advertising for addictive goods is potentially beneficial (Bernheim and Rangel, 2004).

When uncertainty exists about susceptibility to addiction or the environmental cues which an individual will face in the future, there is an opportunity for a welfare-enhancing policy intervention through insurance provision. This insurance may come in the form of subsidization for rehabilitation and withdrawal treatment. It should be noted that the moral hazard and asymmetric information problems that accompany this market are nontrivial (Orphanides and Zervos, 1995).

Finally, Tomer (2001) argues that even with full information addicts may incorrectly weigh the costs and benefits associated with their behavior, placing too little weight on the negative consequences of their actions. In this way, continued addiction may be the result of systematic mental accounting of errors in which the addict places too little weight on the potential loss of family, friends, and other forms of social capital, and too much weight on the immediate cravings associated with addition. In this case, interventions by family and friends, to make the benefits of abstinence salient, will be welfare improving. Such interventions are commonly used in cases of severe addiction.

Summary

Economists approach addiction from a behavioral point of view and with a focus on assessing and measuring the effects of policy interventions, such as taxation and prohibitions. The canonical model, Becker and Murphy's (1988) rational addiction model, considers a world in which people are aware that their consumption of addictive goods today will affect their behavior in the future and make choices accordingly. This model provides a framework to analyze addictive behaviors and

has led to a large and detailed body of empirical evidence. The model has also been extended in many ways to incorporate more realistic psychological, physiological, and social aspects.

The standard model makes several predictions that are falsified, notably including the prediction that addicts do not regret their past decisions. A number of theoretical investigations relax or otherwise modify the assumptions of the standard model to address this failing. In these models, people may not know themselves well enough to predict whether they will find some good or activity addictive, or they may have self-control problems that prevent them from quitting a harmful addiction even though they realize that addiction is harmful. Policy implications vary across theoretical models as the assumptions driving the model vary, so the theoretical literature has not come to a consensus on optimal policy toward addictive goods. Current research continues to incorporate results from other disciplines, such as neuroscience, into economic models.

Economists have also produced a large body of statistical evidence detailing what kind of people consume various addictive goods, the extent to which people respond to changes in the price of addictive goods, and how consumption varies with prices, income, and other incentives over short and long time periods. This literature shows that addicts do respond to prices and other incentives, that past consumption of addictive goods causes current consumption of addictive goods, and that consumption of a given addictive good is best understood as a part of a profile of consumption of various addictive goods rather than in isolation, for example, policy makers should consider the effects of a change in heroin policy on alcohol consumption in addition to heroin consumption.

Adoption of New Technologies, Using Economic Evaluation

S Bryan, University of British Columbia, Vancouver, BC, Canada; Vancouver Coastal Health Research Institute, Vancouver, BC, Canada, and University of Aberdeen, Aberdeen, UK
I Williams, University of Birmingham, Birmingham, UK

Glossary

Acceptability The requirement that economic analyses provide information that is seen by end-users to be relevant and appropriate to the decisions they face, takes into account relevant contextual factors, and is delivered in a timely fashion.
Accessibility The requirement that economic analyses can readily be understood and interpreted by end-users.
Cost-effectiveness acceptability curve (CEAC) The CEAC plots the probability that the intervention in question is cost-effective against a range of possible threshold values.
Coverage A decision to 'cover' a technology indicates that its cost will be reimbursed as part of an insurance package.
Interactive model of research utilization A model in which policy formulation is understood as a nonlinear process involving multiple agents and influences.
Net-benefit statistic The net-benefit statistic expresses the additional health effects in monetary units by using an estimate of the 'maximum willingness to pay' per unit of health gain.
Problem-solving model of research utilization A model in which empirical and analytical evidence is applied directly to a policy problem, enabling the optimal solution to be identified and implemented.

Introduction

The overarching central issue addressed by the discipline of economics is resource scarcity. In one sense or another, all economists are working on questions that have some connection to scarcity and limits. Thus, the primary purpose of economic analysis, and cost-benefit and cost-effectiveness analysis (CEA) in particular, is to support decision-making necessitated by the scarcity problem. Therefore, economic evaluation information is generated with the direct intention of influencing policy – but is that objective achieved? This is the central question addressed in this article.

The policy frame here relates to decisions on coverage of medical interventions. A decision to 'cover' a technology indicates that its cost will be reimbursed as part of an insurance package, and so it involves setting limits on the health care services that can be accessed or provided. Coverage decisions are taken in health systems where private insurance is widely seen and in systems dominated by publicly funded insurance programs.

This article initially provides a definition of economic evaluation typically undertaken to inform coverage decisions and then introduces a case study, the UK's National Institute for Health and Clinical Excellence (NICE). The problem, reflected in the lack of use of such information, is then outlined, with supporting evidence from the published literature presented. The article then provides a discussion of how some of the barriers and obstacles to use might be overcome.

Normative Economic Evaluation

Much economic evaluation work in health care, seeking to support coverage decision making, has a 'normative' bent. That is, the role of the economist has been to indicate the nature of the resource allocation decision that ought to be followed if certain objectives are to be achieved. An important prerequisite for such a normative stance is that the analyst has a good understanding of the objective function (i.e., what should the health service be seeking to achieve?) and the decision rules to be applied. As Culyer (1973) points out, the process of agreeing objectives is not necessarily straightforward:

> In the real world … policy makers and most other people who seek economic advice do not have well-articulated ideas of their objectives. One of the first tasks of a cost-benefit analyst, for example, is usually to seek to clarify the objectives – even to suggest some.
> Culyer (1973, p. 254)

Many health economists have taken Culyer at his word, proposing an objective of maximising population health benefits and, although there are those who argue for a broader set of objectives, the proposition does receive some support from policy makers and the public more generally. The difficulties and disputes arise primarily around attempts to measure health. Over the course of the past 20 years or so the subdiscipline of health economics has had a methodological focus on health measurement and valuation. The result is a measure of health that can be operationalized for use in policy making, that is, the quality-adjusted life-year (QALY). The decision rule, therefore, is to invest in those technologies that produce the largest QALY gains for a given level of cost. To inform such decisions, normative analyses tend to provide results in the form of an incremental cost-effectiveness ratio (ICER), a net-benefit statistic and a cost-effectiveness acceptability curve (CEAC).

- The ICER reports the ratio of additional costs to additional health effects associated with a new intervention (e.g., cost per QALY gained).
- The net-benefit statistic expresses the additional health effects in monetary units by using an estimate of the

 doi:10.1016/B978-0-12-375678-7.01414-0

'maximum willingness to pay' per unit of health gain, where available.

- The CEAC plots the probability that the intervention in question is cost-effective against a range of possible threshold values to define cost-effectiveness.

A National Institute for Health and Clinical Excellence Case Study

Perhaps the most researched example of use of economic evaluation in coverage decision making is the UK's NICE. In many respects, NICE has set the standard for evidence-informed coverage decision making and openness to the application of economic analyses.

The Institute, established in 1999, has as one of its functions the appraisal of new and existing health technologies. Coverage decisions made by NICE are based on explicit criteria and are informed by evidence, including an economic evaluation. The evidence is interpreted and considered by the Technology Appraisal Committee, and that Committee formulates recommendations and guidance on the use of the technology in the National Health Service (NHS) in England and Wales.

There can be no doubt that the technology appraisal decisions at NICE are driven in large part by the results of economic analyses. This was stated explicitly by the Institute's Chairman, Sir Michael Rawlins, who stated that in determining its guidance, NICE would take six matters into account, including both clinical and cost-effectiveness (Rawlins and Culyer, 2004). Further, in the Secretary of State's Direction to NICE when it was established in 1999, the intent was clearly stated: NICE should consider the broad balance of clinical benefits and costs.

As a crude example to demonstrate that cost-effectiveness drives decisions, in the appraisal of statin therapy for secondary prevention of coronary heart disease, the ICER ranged from £10 000 to £16 000 per QALY gained and the guidance from NICE states: 'Statin therapy is recommended for adults with clinical evidence of coronary vascular disease' (NICE, 2006). However, when the ICER is much less favorable, in the case of Anakinra for rheumatoid arthritis the ICER was in the region of £105 000 per QALY gained, the guidance tends to be negative: "Anakinra should not normally be used as a treatment for rheumatoid arthritis. It should only be given to people who are taking part in a study on how well it works in the long term" (NICE, 2003).

This general picture is supported by the analyses of decisions taken by NICE and other agencies presented by Clement *et al.* (2009, p. 1437): agencies such as NICE make "recommendations that are consistent with evidence on effectiveness and cost-effectiveness but that other factors are often important." Qualitative work by Bryan *et al.* (2007, p. 41) tells a very similar story – examples of quotes from NICE committee members:

> "I think economic evaluation was regarded as being important from day one."

> "It [the CEA] seems to me to be the clincher really. If it's too high then it's not going to get funded."

The Problem

The NICE story is positive but it is important to understand that it is an outlier in terms of policy use of economic evaluation in health care. The broader literature on this topic has a consistent refrain, with concern expressed regarding the usefulness, or more precisely the lack thereof, of CEAs when applied in decision making processes. Responses to this concern have tended to centre on questions of how evaluation research by health economists can be made more useful and accessible to policy makers.

As a framework for considering these issues, the authors have previously grouped barriers to the use of economic analyses in health care decision-making under two headings: accessibility and acceptability. The accessibility concern includes issues such as interpretation difficulties, the aggregation of results, difficulties in accessing information, shortage of relevant skills, etc. Under an acceptability or relevance banner, a whole range of barriers might be considered relating to the timeliness of information provision, and the quality and nature of the information.

Thus, if one accepts this framework, the necessary requirements for economic evaluation evidence to be used in decision-making, relate both to accessibility and to acceptability. For the information to be accessible, it is required that the results of the economic analyses can readily be understood and interpreted by end-users. This is mainly concerned with issues of the presentation of information. For the information to be acceptable, it is necessary that economic analyses provide information that is seen by end-users to be relevant (i.e., providing data on parameters that are likely to influence the decision of the policy maker), information that is appropriate to the decisions they face, taking into account relevant contextual factors (e.g., budgetary arrangements commonly seen in the NHS), and that such analyses are seen as providing information in a timely fashion.

This article will now summarize the main themes that emerge from the published literature on this topic. The authors will then return to NICE and reflect further on its use of economic evaluation in light of these accessibility and acceptability criteria. The article will conclude with reflections of going forward, drawing on contributions from a more 'positive' approach to economics.

Empirical Work

This part of the article discusses the work of others who have researched the use of economic evaluation in health care decision making. A formal review of literature in this area has been published by Williams *et al.* (2008) and this article draws, in part, from that work.

The vast majority of empirical work in this field was conducted from the mid-1990s onwards. In terms of method,

there are three strands to the empirical literature:

- Surveys and questionnaires.
- Studies specifically of the NICE appraisals process, drawing solely on secondary sources.
- A prospective, case study approach, represented by a single study.

One of the most innovative pieces of research, going beyond surveys and interviews, was conducted by McDonald (2002). Based within an English Health Authority, she offered health economics support as a participant observer of a Coronary Heart Disease Strategy. She found that CEA was not geared toward assisting in the decision making processes prevalent at local levels of the NHS in England. This work highlighted barriers beyond those identified in previous UK studies. These are discussed below.

In a US context, use of formal CEA in technology coverage decisions is, if anything, even less commonly seen.

Successful application of CEA to policy has thus proved to be a challenge to decision makers across a range of health care systems. This low level of use occurs despite evidence suggesting that decision makers appreciate the potential value of cost-effectiveness information to the policy.

Studies of NICE have largely relied on data collected from secondary sources. Although these vary in approach to data analysis, each identifies CEA as a prominent feature in the Institute's work, in contrast to decision makers from all other studies.

Barriers to the Use of Economic Evaluation

Research indicates a plethora of active barriers to use of CEA. In relation to accessibility, there are three dimensions reported as significant within the literature. The first relates to the shortage of relevant analyses. Early studies in particular emphasize the difficulties decision makers face in obtaining economic evaluations. The second barrier derives from uncertainty or ignorance over how and from where existing studies can be accessed. This is compounded by the funding and access difficulties inherent in commissioning a new CEA that can be delivered in a timely manner. Finally, and – within this category of barriers – most consistently, studies demonstrated a lack of expertise in comprehension and interpretation. It is clear from studies at local levels that decision makers struggle to understand health economic analyses including the concepts and language used, and the presentational styles adopted.

These problems of accessibility are compounded by barriers relating to the perceived acceptability and ease of implementation of CEA. A small number of studies indicated that perceived methodological flaws were a major impediment to utilization. More commonly, studies found that decision makers did not always consider the source of CEAs to be independent. The pharmaceutical industry has been active in using CEAs to promote their products and studies repeatedly emphasize the distrust this engenders in decision makers.

Studies employing qualitative methods have uncovered factors relating to the complexity and interactive nature of the decision making environment, and therefore the competing drivers of decisions. Far from reflecting a problem-solving research-led model, health care decision making is subject to multiple influencing factors including: political considerations, administrative arrangements, equity concerns, societal opinion and the values and attitudes of decision makers. Interestingly, this multiplicity of competing considerations was also indicated in more recent quantitative analysis of NICE decisions.

The study by McDonald (2002) uncovered fundamental value conflict between decision makers' guiding principles and those underpinning normative health economics. She reinforces the assertion that single objectives are not routinely present in decision making and details instances of decision making which could not be said to be following any single maximization principle. As a participant observer, her attempts to introduce a rational, problem-solving approach to resource allocation resulted in a 'paralysis' caused, in part, by complex funding constraints. Rational approaches to policy formulation were considered by decision makers to be less satisfactory than standard nonrational practices of 'muddling through' in a context of resource scarcity.

Finally, studies from across the range of methodological types suggest that decision makers perceive recommendations from CEAs to be difficult to implement. For example, budget holders operating within short-term budgeting cycles may be under pressure to contain cost over and above promoting efficiency and others experience difficulties redirecting resources across inflexible financial structures. Such barriers have been expressed in terms of the savings identified in economic evaluations being unrealisable in practice. Health economists are then accused of being ill informed on structural aspects of health systems.

Overall, the literature reveals a growing realization that interventions by health economists in the area of research utilization have neither addressed the totality of factors which influence policy makers nor accounted for the complexity of health care decision making processes.

Prescriptions for Improvement

Typically, the published research draws on a similar range of potential solutions to the problem of low levels of usage. These include the need to standardize and improve methods of CEA and to increase the available evidence base for decision makers both in terms of volume and timeliness. A strong strand within prescriptions for greater usage focused on education and training for decision makers so that CEA can be better accessed, understood and applied.

Overall, responses to reported barriers tended to centre on questions of how research by health economists can be made more useful and accessible to policy makers. Prescriptions for overcoming accessibility barriers usually involve a combination of increasing resources, improving the means of communication with decision makers, and providing decision makers with training in interpreting health economics.

However, it is less clear from the literature how barriers relating to organizational and political context are to be addressed. There is little, for example, by way of prescriptions for shaping the health care system in order to incentivize and facilitate the use of CEA. Indeed, one study author, McDonald (2002), is pessimistic as to the appropriateness of seeking to

increase the use of CEA. Her argument is that, as a result of the complex and sometimes perverse structures of the English NHS, it is unhelpful to prescribe rational frameworks for NHS decision makers because this serves only to highlight to decision makers the gap between the rationalist ideal and the structural and political reality of the system.

Further National Institute for Health and Clinical Excellence Reflections

This part of the article draws on the authors' qualitative empirical work looking at the challenges for NICE in making full use of economic evaluations. Although issues of accessibility, broadly speaking, are not acute at the national level in the UK, organizations like NICE still have some important issues to address in this field. The NICE Appraisals Committee is in the highly unusual situation of having, for every topic they consider, an economic analysis undertaken specifically for their purposes. Thus, they avoid the frequently cited problems encountered by those working at a local level in the NHS of not being able to access cost-effectiveness (CE) information in a timely manner.

In terms of the challenge of interpreting CEAs, the qualitative study uncovered poor levels of understanding of CE information. The extent to which this is a serious barrier depends, to some extent, on the role NICE Committee members are expected to play and the overall approach to decision making being adopted. If all Committee members have a vote on the policy decision then they all need to understand all relevant information presented, including the CEA. A failing on the part of analysts that was revealed from the authors' research concerned the presentational style of CE studies. The highly technical nature of the CE studies being undertaken for NICE, and their presentational style, make for difficulties in understanding for the noneconomist. The need for improvements in the presentation of CE studies was a strong message from the authors' work.

A commonly cited acceptability concern with the CEAs is that they fail explicitly to consider the opportunity costs of the decisions being made. In the authors' research this was raised by a number of committee members including both health economists and health care managers. The CEA at NICE typically presents the problem in terms of a one-off decision concerning the coverage of a given health technology, commonly a new drug. No explicit consideration is therefore given to the sacrifice that would be required in order for the additional resources to be made available (assuming that the incremental cost is positive). An attempt to negate this problem involves use of a CE threshold, and defining technologies that have ICERs that fall below the threshold as cost-effective uses of NHS resources (regardless of their true opportunity cost). This issue has been highlighted by other commentators. However, although the necessity of using a CE threshold was acknowledged by most of the authors' research subjects, it was also viewed as problematic because the basis for the threshold value or range is very unclear.

In summary, the data from the authors' qualitative work with NICE suggest that for analyses to be viewed as acceptable, it is necessary that they provide information: (1) that end-users see as relevant (i.e., providing data on parameters that are likely to influence the decision of the policy maker), (2) that is appropriate to the decisions being faced, taking into account relevant contextual factors (e.g., budgetary arrangements commonly seen in the NHS), and (3) that can inform implementation of decisions in a complex decision making environment.

The Research-Practice Divide

This article has explored some of the reasons for the moderate impact of economic evaluation on health policy. There is little dispute that such findings are a source of concern to the discipline of health economics and that for such analyses to be a valuable decision making tools then change of some form is required. Commentators have identified weaknesses in methodologies adopted in economic analyses and there have been concerted attempts to improve their quality through, for example, the development of methodological standards. Difficulties in implementation may also derive from limits to the generalizeability of studies, resulting from factors such as: variations in disease epidemiology, relative prices, levels of health care resources, organizational arrangements, and clinical practice patterns.

However, one of the most challenging issues is contextual and relates to the difficulty in implementing hypothetical savings predicted by CEAs. It has been noted that the erroneous assumption of incremental divisibility of interventions and their benefits underpins many CEAs. Adang *et al.* (2005) have developed checklists to address the issue of reallocating resources within a real world context in order to get better information as to whether savings can indeed be made.

Important as these developments undoubtedly are, they also need to be accompanied by a concerted attempt to understand the differences in respective domains of 'research' and 'practice'. Much valuable work has been done on techniques for reducing or bridging the gap between the 'two communities' of researchers and decision makers. A review of studies by Innvaer *et al.* (2002) suggests that 'personal contact' between researchers and decision makers is one of the most commonly reported facilitators of evidence-based decision making. Lavis *et al.* (2003) argue that such interaction enables researchers to improve the production of analyses although simultaneously enhancing their adaptation by policy makers. However, these prescriptions for closer contact between researchers and decision makers also need to avoid naivety: it has been seen that other barriers exist. Also, incentives and rewards for researchers are less likely to recognize the value of incremental influence than they are outcomes that have a more direct influence on policy formation. In other words, the academic institutional environment in which economic evaluations are produced is not always conducive to such an interactive approach.

Much of the health economics literature to date has concentrated on barriers of accessibility of CEA results. This suggests a view that improvement in the process by which evaluations are communicated to decision makers, and the latter's capacity to understand their recommendations, ought to be the focus of attention and activity if impact is to be maximized. In other words, the emphasis is on tweaking the process

at both ends in order to support rational implementation of research findings. A focus on barriers to the acceptability of economic evaluation directs us away from such an approach. Instead, it is seen that there is substantive disjuncture between researchers and decision makers in terms of objective functions, institutional contexts and professional value systems. The literature in this area charts a growing realization of the conditions and contingencies of the health decision making environment. There has been a move away from an assumption of policy involving simple, rational choices to a realization of an interactive process with competing aims and considerations. Issues such as system rigidities, value conflict and competing objectives are difficult to overcome as this requires broader changes to the macropolitical and institutional environment of health care policy making.

A More 'Positive' Approach?

In contrast to the default normative approach taken in economic evaluation in health care, a positive analysis would simply generate information on the likely costs and benefits associated with alternative courses of action. Dowie (1996) describes such research as knowledge-generating, as opposed to decision-making. A distinguishing feature of positive analyses is that there is no *a priori* objective specified. Such analyses might involve the use of profile or cost consequence approaches to reporting results. This is where the predicted impacts of the intervention in question are detailed, possibly in a tabular form, without any attempt to summarize or aggregate across different dimensions. Kernick (2000) is a strong advocate of such an approach:

> Cost consequence analysis emphasises the importance of presenting data on costs and benefits in disaggregated form, implying a recognition of the value judgement from decision makers and an acceptance that benefits and disadvantages cannot always be condensed into a single output measure.
>
> Kernick (2000, p.314)

Traditional economic evaluation work evokes a conception of research utilization defined by Weiss (1979) as the 'problem-solving model'. In this model empirical and analytical evidence is applied directly to a policy problem and supplies the information required to enable the optimal solution to be identified and implemented. For the problem-solving model to apply, the recommendations of a normative economic analysis, for example, would need to be implemented directly by the relevant policy maker and would be seen as the driving force behind the decision reached. As Weiss (1979) indicates:

> … when this imagery of research utilisation prevails, the usual prescription for improving the use of research is to improve the means of communication to policy makers.
>
> Weiss (1979, p.428)

However, there are a number of weaknesses with the problem-solving model. For example, some have called into question the likelihood of establishing a single, agreed objective. Although many economists may adopt a normative view that the problem-solving model has much to recommend it, it has to be recognized that, the real world rarely lives up that aspiration. For example, in a review of UK studies into factors effecting evidence-based policy-making, Elliott and Popay (2000) conclude that many policy problems are often intractable or not clearly enough delineated to be tackled directly and comprehensively. They also find that research evidence is frequently unlikely to be sufficiently clear-cut and unambiguous to translate directly into policy. They also call into question the assumption of a straightforward policy process in the problem-solving model and conclude that dissemination of health services research results has been hampered by a preoccupation with the rational, problem-solving model. In these circumstances, Weiss's 'interactive' model of research utilization, in which policy formulation is understood as a nonlinear process involving multiple agents and influences, has far greater descriptive validity.

The distinction between problem-solving and interactive models of research utilization correlates, to some extent, with the binary of normative and positive approaches to health economic analyses. The requirement for agreement of purpose and objectives between researcher and decision maker is a defining premise of both normative economic evaluation and problem-solving conceptions of policy research utilization. Positive approaches to evaluation, however, may be seen as more helpful to decision makers involved in policy processes that are marked by interaction and competing or multiple objectives. An understanding by the analyst of the nature of the policy environment into which the analyses are being placed is required. This will allow more informed choice to be made concerning the appropriate approaches to analysis and presentation of results.

In highlighting the failure of health economists to consider issues of the acceptability of the data they generate, Kernick (2000) argues that:

> The history of any movement determines its structure and the way in which meaning is generated within it. Health economists tend to adopt a straightforward view … Just as the NHS was configured in part to reflect the needs of doctors and not patients, the development of health economics was set to reflect the requirements of the academic discipline and not the realities of the emerging healthcare environment.
>
> Kernick (2000, p.312)

Conclusions

And so to conclude, the driving force behind the push to make more use of economic analyses in health care resource allocation decisions is the desire to make decision processes, and the decisions themselves, more rational. In turn, greater rationality in the system contributes to openness and transparency, and so necessitates that the information on which decisions are based is accessible to a wide audience – the more accessible the information used in decision-making, the easier it is to be inclusive in the decision-making process and the more transparent is the basis on which the decision is made.

This accessibility concern represents one of the challenges to the health economics community in terms of producing

evidence that is more reflective of real world practices but also highlights a potential training agenda: clinical and managerial decision makers in health care require some level of expertise and understanding of economic evaluation in order to provide input into the decision making process. Additional areas of focus for health economists include the need to overcome perceived weaknesses in the methods of their analyses, and the need to work with those at the front-line in health care to ensure alignment between the health maximization objectives often assumed in economic analyses and the broad range of other objectives facing decision-makers in reality. That is not to suggest that the decision-maker always 'knows best' but analyses based on false assumptions regarding objectives serve no purpose.

Advertising as a Determinant of Health in the USA

DM Dave, Bentley University, Waltham, MA, USA
IR Kelly, Queens College of the City University of New York, Flushing, NY, USA

Overview

Advertising is ubiquitous, found on television and radio, newspapers and magazines, mail and flyers on the windshield, billboards and sports arenas, and now on the computer, and virtually no one is immune to being exposed to it. The American Marketing Association defines marketing, of which advertising is a subset, as "the activity, set of institutions, and processes for creating, communicating, delivering, and exchanging offerings that have value for customers, clients, partners, and society at large" (Grewal and Levy, 2009). To advertise itself is simply "the action of calling something to the attention of the public especially by paid announcements" (Merriam-Webster, 2011). What distinguishes an advertisement from other forms of marketing is that: (1) someone has paid to get the message shown; (2) the message must be carried by a medium; (3) legally, the source must be known; and (4) it represents a persuasive form of communication (Grewal and Levy, 2009). This article will provide a survey of economic views of advertising in general, which will provide the context for a better understanding of the relevance of advertising for health behaviors and health care markets.

Modern advertising began early in the twentieth century with the advent of Kellogg cereals and Camel cigarettes (Bittlingmayer, 2008). It is a huge industry, currently with over 14 000 establishments (Bureau of the Census US Department of Commerce, 2007) and over $200 billion in expenditures (Bittlingmayer, 2008).

Why consumers respond to advertising will be analyzed in more detail in the next section. It is this question that economists ultimately seek to answer in the context of the separate views – that advertising is persuasive, informative, or simply complementary to the advertised product. A brief survey of these different views of advertising is provided in this article, which can help frame the relevance and public health consequences of advertising for health behaviors and healthcare markets. The reader is referred to Bagwell (2007) for an excellent, comprehensive review of the economics of advertising, and also Schmalensee (1972) for an earlier take. Elements of each of these views exist in most industries, with variations across industry. A firm may generally view advertising as capital (albeit intangible) that depreciates over time (Bagwell, 2007). Most empirical studies find that most of the effects of advertising are short-lived and that most effects of advertising depreciate within a year. There has therefore been limited empirical evidence for the 'goodwill effect' in advertising, causing a firm's current advertising to be influenced by past advertising (Bagwell, 2007).

The nature of advertising has changed dramatically over time with the advent of new technology and media. Although the means of advertising in healthcare markets can vary across firms and industries (in part because of advertising restrictions), conventional media include magazines, newspapers, billboards, radio, television, and direct mail. With 77% of households using the Internet (Statistical Abstract of the United States, 2009), the computer has also emerged as an important medium for advertising. In addition, firms are also increasingly relying on product placement in movies and video games, and other forms of digital media. Although the volume may presumably diminish the individual effect of an advertisement because it is difficult for a potential consumer to focus on more than one ad at once, online advertising can more effectively tailor ads to individuals.

The number of establishments classified as 'advertising agencies' in 2007 was 14 355, up from 13 879 in 1992. Advertising expenditures rose from $2.1 billion in 1940 to $237.4 billion in 2002 (Bittlingmayer, 2008). Note that the North American Industrial Classification System (NAICS) code used by the Economic Census for advertising agencies (which do not include 'related services' such as public relations) is 541 810, corresponding to the standard industrial classification code used before 1997 of 7311. According to the Census, "[t]his industry comprises establishments primarily engaged in creating advertising campaigns and placing such advertising in periodicals, newspapers, radio and television, or other media. These establishments are organized to provide a full range of services (i.e., through in-house capabilities or subcontracting), including advice, creative services, account management, production of advertising material, media planning, and buying (i.e., placing advertising)." The intensity of advertising is often measured by the advertising-to-sales ratio. Advertising-to-sales ratios for industries relevant to our discussion are shown in **Table 1**. The advertising-to-sales ratio for the pharmaceutical industry, especially, understates the level of promotional efforts because it does not include other forms of promotion such as sampling to physicians and other

Table 1 Advertising expenditures as a percent of sales for selected industries, 2010

Industry	*Ad-to-sales ratio, 2010*
Distilled and blended liquor	14.4
Food and kindred products	11.5
Eating and drinking places	10.2
Beverages	6.1
Pharmaceutical preparations	4.2
Malt beverages	3.7
Wine, brandy and brandy spirits	3.3

providers and direct marketing to providers. In 2005, the pharmaceutical industry spent 20% of its sales on promotional activities. The Dorfman-Steiner (1954) condition for optimal advertising gives some insight as to why certain industries (or firms) may engage in higher levels of advertising:

$$\text{Advertising/Sales} = \varepsilon_{QA}/\varepsilon_{QP}$$

The condition positively relates advertising intensity, as measured by the advertising-to-sales ratio, to the elasticity of sales with respect to advertising (ε_{QA}) and negatively to the elasticity of sales with respect to price (ε_{QP}), expressed in absolute magnitudes. Thus, the more price-inelastic is the good, the higher is its advertising intensity, *ceteris paribus*. Alcohol, tobacco, and prescription drugs, for instance, are found to be relatively price-inelastic, and these industries also devote a relatively greater fraction of their sales to advertising and promotion.

Advertising in healthcare markets is controversial, especially when it has been found to raise the overall market for unhealthy behaviors (for instance, smoking or junk food) or found to contain deceptive or misleading information. Thus, inevitably, advertising must have a certain degree of oversight. Federal agencies that regulate advertising include the Federal Trade Commission (FTC), the Federal Communications Commission (FCC), and the Food and Drug Administration (FDA). Other agencies such as the Bureau of Alcohol, Tobacco, and Firearms also play a role in regulating advertising (Grewal and Levy, 2009). The FTC, established in 1914, enforces the truth in advertising laws and identifies deceptive practices. The FCC, established in 1934, "enforces restrictions on broadcasting material that promotes lotteries; cigarettes, little cigars, or smokeless tobacco products; or that perpetuates a fraud." It also enforces laws to prohibit or limit obscene, indecent, or profane language (Grewal and Levy, 2009). The FDA, established in 1930, regulates labeling, health claims, and required disclosure statements. Many are unaware that advertising for weight loss products (discussed in Section 'Conceptual Framework') is not 'drug advertising' according to the FDA; as a dietary supplement, it is classified as a food and faces fewer standards than other drugs (Grewal and Levy, 2009; Cawley *et al.*, 2010).

The article is organized as follows. Section 'Conceptual Framework' provides a conceptual framework outlining the economic views of advertising. Advertising in several health markets – particularly those pertaining to tobacco, alcohol, food, soft drinks, cereal, weight loss products, and prescription drugs – is analyzed in Section 'Advertising in Health Markets'. Section 'New Directions' provides a glimpse into directions for future research in the area, particularly surrounding the advent of online advertising and drawing insights from neuroeconomics to the study of advertising. Section 'Summary' concludes.

Conceptual Framework

It is often presumed that the average consumer is responsive to advertising and promotion. However, one of the key questions with respect to advertising by firms in markets for healthcare inputs is whether advertising raises 'selective' or brand-specific demand versus 'primary' or industry-wide demand (Borden, 1942). The answer to this question has normative implications and relevance for public health. For instance, is advertising by the cigarette industry combative and solely reflective of a market share transfer or does it also lead to an overall expansion of the market? This was one of the disputes that was central to the litigation initiated in 1999 by the US Department of Justice (DOJ) against cigarette manufacturers. As a starting point, it is helpful to draw upon three principal views that have emerged with respect to why consumers may respond to advertising: (1) persuasive, (2) informative, and (3) complementary.

Chamberlin (1933) integrates advertising into his theory of monopolistic competition, observing that advertising can help firms to differentiate their products and generate an outward shift in firm-level demand. According to Chamberlin, advertising impacts demand by altering consumers' tastes and preferences. Under this 'persuasion' hypothesis, brand-level demand would not only shift outward in response to advertising but also become relatively less elastic, possibly leading to higher prices. Advertising-induced product differentiation and creation of brand capital may deter entry and enhance the monopolistic power of incumbent firms, especially if these established firms also enjoy scale economies in advertising and production (Kaldor, 1950). Thus, under the persuasion view, advertising can have significant anticompetitive effects, a point that was also emphasized by Robinson (1933).

Chamberlin (1933) also pointed to the transfer of information to consumers as another explanation for why consumers respond to advertising. This informative view of advertising took on a formal expression in Ozga (1960) and Stigler (1961). In markets characterized by imperfect information, advertising can effectively reduce search costs by conveying direct or indirect information to consumers regarding the existence, quality, price, and other attributes of products. As Bagwell (2007) noted, in such markets, advertising emerges as an endogenous response and solution to the information asymmetry. In contrast to the persuasive view, advertising plays a more constructive role under the informative view, and may also have pro competitive effects. As consumers receive low-cost (relative to incurring search costs) information on products and brands, the firm's demand becomes relatively more elastic and price dispersion in the market is reduced. Advertising can thus promote competition among incumbent firms and facilitate the entry of new firms as well as the introduction of new products.

Nelson (1974) contended that even when advertising does not hold direct information content, it may still signal indirect information regarding product quality and firm attributes. For instance, advertising can signal that a firm is an efficient producer because these firms would benefit the most from expanding demand. Advertising can also enhance the match between products and buyers in markets where consumers have heterogeneous valuations. And, advertising may help consumers recollect their previous experience with the product and lead to repeat-business. Because this effect is more valuable for firms producing high-quality products, advertising may thus indirectly signal quality even for new consumers.

Nelson (1970) distinguished between search goods, wherein the consumer can determine quality before purchase though perhaps after incurring some search costs, and experience goods, wherein the consumer can assess quality only after consumption. Advertising addresses an informational imbalance for experience goods by providing indirect information content regarding quality, and advertising intensity is thus predicted to be higher for experience goods. In contrast, advertising for search goods (for instance, eyeglasses, consumer electronics, or credit cards) would be focused on providing direct information regarding price, location, availability, and product attributes.

Darby and Karni (1973) also found it useful to distinguish a third category of goods that have 'credence' attributes, for which the consumer is unable to accurately evaluate quality even post consumption. This market failure of imperfect information for experience and credence goods also potentially gives firms an incentive to engage in misleading advertising claims (Darby and Karni, 1973; Nelson, 1974). Where market-based mechanisms are unable to deter deceptive advertising, there is a role for government regulation and publicly funded dissipative counter-advertising.

Although the persuasive and informative views provide conflicting assessments of the role of advertising, the third view of advertising provides a framework under which advertising is complementary to the advertised product. That is, advertising does not need to exert any direct influence on consumer preferences, and it may or may not possess information content. Within a household production framework, Stigler and Becker (1977) modeled the advertised product with its associated advertising expenditures as inputs into the production function for each final commodity, implying a complementarity between the advertised product and its advertising. Under this framework, a higher level of advertising can raise demand because the consumer now believes that he can obtain a greater output of the final commodity from a given input of the advertised good. In a related but separate framework, Becker and Murphy (1993) directly modeled advertising as an input into the individual's utility function. Advertising raises demand in this framework by increasing the marginal utility of the advertised good. Note that this complementarity follows from the fact that there does not exist a separate market for advertising messages – considerable transactions and monitoring costs make it infeasible to separately sell advertising to consumers.

Both of these paradigms, which impart a complementary role to advertising, also bridge back to the informative view. For instance, if advertising enables consumers to produce information at lower cost (Verma, 1980), then consumers can indeed more efficiently convert market goods into valued final commodities, as assumed by Stigler and Becker (1977). And, even if advertising in uninformative, it may still play a constructive role because consumers may value it directly, as assumed by Becker and Murphy (1993).

The upshot of this discussion is that no single view of advertising is applicable in every setting. Furthermore, from a public health standpoint, the debate centers around whether advertising reflects a brand-switching process or a market expansion process, especially in relation to the market for unhealthy inputs such as cigarettes, underage drinking, and junk food – or in different terms, whether advertising is combative (predatory) or cooperative. Because advertising can affect both selective (brand-centric) as well as primary (market) demand under all three views, the question cannot be resolved based on theory alone and empirical evidence needs to bear upon the specific demand effects of advertising in various markets. With that said, markets for most healthcare inputs have some predominant experience attributes – such as tobacco and alcohol products, over-the-counter (OTC) and prescription medications, and snacks and beverages. Thus, advertising intensity for many of these goods tends to be higher relative to the average industry (2.1%; see **Table 1**). These views of advertising also highlight potential effects on price, which depend on the extent to which advertising expenditures raise operating costs, affect price elasticity of demand, and allow firms to take advantage of scale economies. Finally, the concentration effects of advertising – that is, whether it facilitates entry or whether it augments the monopoly power of established firms – depends on whether advertising is purely persuasive in nature and leads to spurious brand differentiation or whether it redresses imperfect information and makes demand more elastic.

Advertising in Health Markets

Tables 1 and **2** suggest that, with the exception of restaurants that tend to be more monopolistically competitive, industries that more heavily advertise generally tend to be more concentrated, with Herfindahl–Hirschman indices of at least 1000 (characteristic of mild concentration) or four-firm concentration ratios of at least 80% (characteristic of very concentrated industries). Scale economies in advertising exist, and larger firms are better able to spend on advertising. Studies by Kaldor and Silverman (1948) and Doyle (1968) supported the notion that advertising intensity and concentration are highly linked, leading to an oligopolistic structure (Bagwell, 2007). Nelson (1975) found a significant relationship between advertising intensity and concentration for search goods but not for durable goods or nondurable experience goods. The markets for tobacco, alcohol, food, soft drink, weight loss products, and prescription drugs are analyzed below in more detail.

Advertising of Tobacco

Rather than compete directly on price, firms in highly concentrated industries such as the cigarette industry often use advertising to differentiate their brands and increase sales. In 2005, cigarette manufacturers spent $13.1 billion (or approximately 10% of their sales) on advertising and promotion, making cigarettes among the most heavily advertised and promoted products in the US. As reported in **Table 3**, this level also represents a 111% increase in total marketing expenditures over the past decade. Cigarette manufacturers had relied heavily on television advertising in the 1960s, though the application of the Fairness Doctrine to cigarette advertising in 1967 and the mandated antismoking messages subsequently reduced the commercial value of televised ads. Following a

voluntary industry ban in 1970, cigarette broadcast advertising was officially banned by the Public Health Cigarette Smoking Act starting in 1971. Advertising practices were further restricted by the 1998 Tobacco Master Settlement Agreement (MSA), which also banned most forms of outdoor advertising. Cigarette advertising in magazines with youth readership increased dramatically post-MSA, but then later fell after public pressure (Hamilton *et al.*, 2002) (also see **Table 3**). Since 1970, and particularly accelerating after the MSA, firms' total marketing budget has shifted away from media-based advertising in favor of other promotional activities (such as coupons, added bonuses, promotional allowances, and event sponsorships). There was also a proliferation of cigarette brands over this period in an effort by firms to segment the market and thereby enhance their monopolistic power. The Family Smoking Prevention and Tobacco Control Act, signed into law in 2009, currently gives the Food and Drug Administration (FDA) authority to regulate the content, marketing, and sale of tobacco products.

Saffer (2000) noted that advertising by the cigarette industry is "designed to create a fantasy of sophistication, pleasure, and social success" and generate a product personality that will appeal to specific market segments. In other words, such advertising contains persuasive attributes and could raise demand by generating potentially spurious brand differentiation. Consistent with this persuasive view of advertising, Brown (1978) found decreasing average costs and increasing returns to advertising capital with sales, implying

that advertising potentially creates substantial barriers to entry in the cigarette industry.

Given the external costs of smoking and related public health concerns, the key debate has understandably centered on whether and the extent to which cigarette advertising and promotion raise total cigarette consumption and expand the overall market. There is a large literature that has evaluated the effects of tobacco advertising and promotion on consumption outcomes. Rather than survey this literature (Chaloupka and Warner, 2000), the main findings and issues that have emerged from these studies are reviewed below. Empirical studies have been challenged in trying to isolate a marginal change in consumption when advertising and promotional activities of tobacco companies are at or close to the point of saturation (Ross and Chaloupka, 2002) and have produced mixed findings. Consider the advertising response function shown in **Figure 1**, which can apply to the national or local market level, and to the industry as a whole or at the brand level. Because of diminishing marginal product, the function flattens out at some point and consumption becomes increasingly less responsive to advertising. Diminishing returns may be unavoidable because the effectiveness of additional advertising will decrease once the most responsive buyers have already been reached. In the context of the informative view of advertising, as an increasing number of potential buyers receive information regarding the advertised product, additional advertising is less effective because an increasingly greater proportion of individuals who are exposed to the ads are already familiar with the product.

Earlier studies generally relied on annual or quarterly aggregated data at the national level and find either no effects or very small positive effects of advertising on cigarette consumption. This is perhaps to be expected because loss of variance at such a high level of aggregation makes it difficult to reliably identify effects. As cigarettes are heavily advertised and promoted, the marginal product of aggregate national advertising (measured at a range around A_1 in **Figure 1**) may be very small or zero. Estimates based on a single time-series of aggregate national data are also likely confounded with unobserved trends and the simultaneity between advertising and sales.

Subsequent studies based on local or individual-level cross-sectional or panel data are more indicative of advertising-induced primary market-expansion effects. These studies typically use local-level (for instance, gathered at the level of the state or metropolitan statistical area) advertising data, which have greater (and plausibly more exogenous) variation owing to differences in advertising costs across markets and because of pulsing (which is a burst of advertising, in a specific market, that lasts for a short time and then stops). Goel and Morey (1995), for instance, used annual state-level data spanning 1959–82 and found significant effects of lagged cigarette advertising on consumption. Roberts and Samuelson (1988) developed a model of non price competition for an oligopolistic industry and applied it to their study of the cigarette market, utilizing data for six firms spanning 1971–82. They concluded that "advertising primarily affects the size of market demand and does not alter firm market shares" (p. 215). In a study using individual-level data on 6700 youth, combined with measures of televised cigarette advertising, counter-advertising, and self-reported time spent watching television, Lewit *et al.* (1981) found that smoking ads on television are significantly associated with higher youth smoking.

Studies that examine the impact of advertising bans provide further evidence on whether cigarette advertising expands the overall market. These studies also bypass some of the limitations stemming from the simultaneity between advertising intensity and sales. However, the passage of advertising restrictions may not be strictly exogenous and depends on past trends in smoking prevalence. If advertising only leads to brand-switching with no primary effects on market demand, then advertising restrictions should not have any effects on consumption. Banning advertising on certain media would potentially shift the advertising response function downward, as shown in **Figure 1**. Even if an advertising ban does not reduce the total level of advertising, it will reduce the average and marginal effectiveness of advertising as firms substitute from the banned media to the non banned media. Increased use of non banned media reduces average and marginal effectiveness because of diminishing marginal product. If firms try to compensate for the advertising ban by increasing total advertising expenditures, this would correspond with a

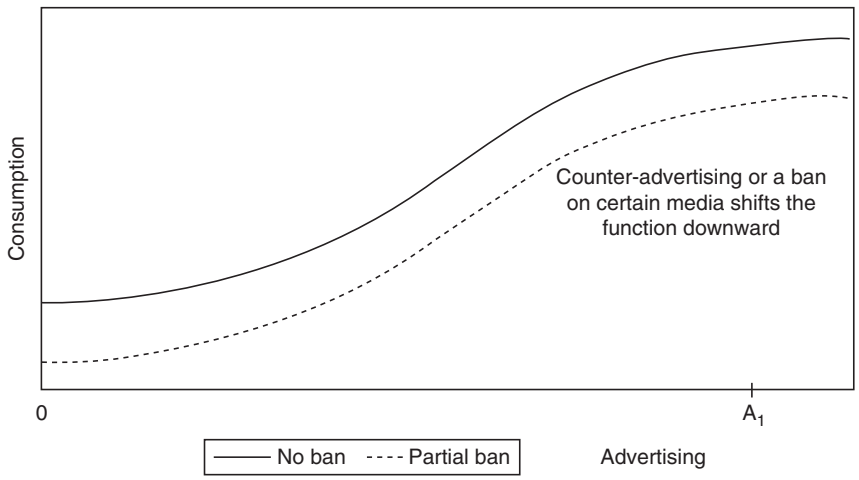

Figure 1 Advertising response function.

movement to a higher level of advertising on the lower advertising response function in **Figure 1**. **Table 3** provides some evidence that this may be the case for the cigarette industry. Consistent with an advertising-induced market expansion effect, Goel and Morey (1995) found that the broadcast ban on cigarette advertising lowered consumption. Saffer and Chaloupka (2000) studied the effects of tobacco advertising bans on tobacco consumption in 22 high-income countries over the period from 1970 to 1992. They found that although a limited set of advertising bans has little or no effect (because firms have many remaining media options), a comprehensive set of media bans can reduce tobacco consumption by 6–7%.

Cigarette brands may also have some credence attributes – wherein the consumer is not able to fully assess the product quality even after consumption. This can provide an incentive for firms to engage in potentially misleading advertising. For instance, the US Department of Justice maintained in a lawsuit filed in 1999 that the cigarette manufacturers falsely marketed and promoted their low-tar and light cigarette brands as being less harmful than conventional cigarettes. The consumer may be persuaded by these claims and would not be able to judge their veracity even post consumption at least over the short-term.

Given the possible market expansion effects of cigarette advertising and the presence of such misleading or imperfect product information, antismoking advertisements (or counter-advertising) have been undertaken by the public sector. Between 1967 and 1970, the Fairness Doctrine required broadcasters to donate air time to antismoking ads. At their peak, the ratio of antismoking ads to smoking ads was one-third (Saffer, 2000). Funds from the 1998 Master Settlement Agreement further provided for many state-initiated anti-tobacco campaigns. Studies have generally found such counter-advertising to be effective in reducing cigarette consumption. Emery *et al.* (2005), for instance, studied individual exposure to antitobacco advertising across the largest 75 media markets in 48 states between 1999 and 2000. They concluded that state-sponsored counter-advertising is associated with greater antitobacco sentiment and reduced smoking among youth. Interesting content analyses by Goldman and Glantz (1998) have suggested that the most effective antismoking messages focus on the tobacco industry's manipulation of its customers and the least effective are ads that portray smoking as unhealthy. This suggests that health-related messages currently may not be conveying any new information to consumers, and that the effectiveness of antismoking messages may derive from their directly counteracting the persuasive qualities of smoking ads and moderating the complementarity between smoking and smoking ads (for instance, through smoking ads portraying social prestige).

Advertising is also highly prevalent for products aimed at helping consumers quit smoking, such as nicotine-replacement therapy. Smoking-cessation products can be classified as experience goods because the consumer needs to use them before being able to assess their efficacy, and theory predicts a relatively high advertising intensity for experience goods. Avery *et al.* (2007) studied the market for such smoking cessation products and noted that the industry spent between 10% and 20% of its sales on advertising. They specifically studied the effects of magazine advertising of such products using individual-level data matched with salient individual-level measures of advertising exposure, paying careful attention to endogeneity concerns, and found that smokers who are exposed to more advertising are more likely to attempt to quit and are more likely to have successfully quit. Adopting the same identification strategy, Dave and Saffer (2013) also found that magazine advertising for smokeless tobacco (ST) products, which is one of the few conventional media available for manufacturers following bans in other media, leads to a higher probability of using ST. ST, which is safer than smoking though not completely safe, is also sometimes used as a cessation aid by smokers. Hence, the debate centers on the potential role of ST use and ST marketing as tools in an overall tobacco harm-reduction approach.

There is some indirect evidence on the competitive effects of advertising in the cigarette market. Brown (1978) found decreasing average costs and increasing returns to advertising, and concluded that advertising may create barriers to entry, based on data that preceded the 1970 television ban. Eckard (1991) utilized the television advertising ban as a natural experiment to study the effects of advertising, and found that concentration within the industry actually increased after the ban. This is in line with Thomas (1989), who found decreasing returns to scale with respect to advertising in the cigarette market, thus yielding a potential advantage to smaller firms with multiple brands. Indeed, the extent of brand proliferation and brand-level competition in the cigarette market is consistent with this finding.

In summary, the role of advertising in tobacco markets is controversial. The public health community contends that such advertising encourages smoking and particularly influences experimentation and smoking initiation among youth. The tobacco industry maintains that their advertising only affects selective demand through brand-switching and does not influence the overall size of the market. Manufacturers also suggest that their advertising provides important information content, for instance, regarding tar and nicotine (Chaloupka and Warner, 2000). Although earlier studies did not find significant market-level effects of cigarette advertising, more sophisticated analyses seem to indicate that advertising does impact primary demand. Further evidence gleaned from studies of advertising restrictions, antismoking ads, and advertising of smoking cessation products is also consistent with this market expansion effect. These studies also point to potential avenues through which advertising impacts the overall market demand, and these pathways are consistent with all three views of advertising discussed in Section 'Conceptual Framework.'

Advertising of Alcohol

Similar to the tobacco industry, the alcohol industry in the US is highly concentrated (see **Table 2**). The US brewing industry, for instance, is dominated by three firms, which account for almost 80% of beer sales. Beer brewers spent approximately $975 million in 2007 on advertising, with the top three firms accounting for 72% of these expenditures. Total advertising and promotional spending for all alcohol companies are on

the order of $4 billion (Jernigan and O'Hara, 2004). Advertising by the alcohol industry aims at raising sales through brand differentiation and customer loyalty, and advertising practices are self-regulated, primarily following a set of industry standards. For instance, industry guidelines allow alcohol-related ads to be placed in media where at least 70% of the audience is above the legal drinking age. Advertising messages also cannot directly appeal to under age youth. Some major broadcast networks adhere to a self-imposed ban on liquor advertising, though there are no such restrictions on cable networks.

The issues relating to the promotion and advertising of alcoholic beverages are similar to those discussed above with respect to tobacco, but with one exception. Unlike smoking, the majority of drinkers consume alcohol safely with little external harm. Thus, from a public health standpoint, the key debate with respect to market expansion has centered on problem drinking, which imposes considerable external costs (for instance, motor vehicle fatalities), and centered on the effects of advertising on youth drinking. On both of these fronts, although some studies have indicated that alcohol advertising is associated with more problem drinking and more underage drinking, the evidence is far from conclusive.

Anderson *et al.* (2009) reviewed 16 longitudinal studies that assessed adolescents' exposure to media-based advertising and their drinking behavior. They concluded in favor of evidence suggesting that exposure to advertising messages is associated with a higher likelihood that the adolescent will initiate drinking, and associated with higher drinking among baseline drinkers. Many of these reviewed studies, however, are based on small, often nonrepresentative, samples and utilize measures of recalled exposure to ads, which may be potentially confounded with unobserved predisposition toward drinking or pro drinking sentiment.

Saffer and Dave (2006) utilized cross-sectional data from the Monitoring the Future Surveys and longitudinal data from the National Longitudinal Survey of Youth (1997 cohort), both nationally representative, to study the effects of probable advertising exposure on adolescent drinking behavior. They bypassed the problems associated with self-recalled advertising exposure and instead exploited variation across and within markets with respect to the level of alcohol advertising in broadcast and print media. Estimates indicate significantly positive but relatively small effects of media advertising on alcohol participation and binge drinking (elasticity estimates of approximately 0.09 and 0.17, respectively), though there is some heterogeneity in this response across gender and racial groups. The authors simulated the effects of a 28% reduction in total alcohol advertising (based on the range observed in their data) and concluded that the reduction in advertising could decrease adolescent binge drinking from 12% to approximately 10% and decrease monthly alcohol participation from 25% to approximately 23%.

Experimental studies have investigated how individuals' drinking beliefs and behaviors respond to short-term advertising exposure in a controlled setting. Findings from this literature have been mixed. For instance, Lipsitz *et al.* (1993) alternately showed televised beer commercials, anti drinking public service announcements, and soft-drink commercials to three groups of fifth- and eighth-grade students. They did not find any significant differences in expectancies regarding drinking outcomes across any of the groups. Slater *et al.* (1997) examined the responses of high-school students to television beer advertisements embedded in sports or entertainment programs. They found that the responses were split along gender lines, with female students reacting more negatively to the beer advertisements than male students, especially when viewing sports content. The authors also found that white adolescents who responded favorably to the ads were more likely to report current drinking and future intentions to drink, though the effects were relatively small. It is difficult to disentangle causality in this study because favorable reaction to advertising may simply reflect the student's underlying predisposition to drinking.

Saffer and Dave (2006) also reviewed prior econometric studies on the effects of alcohol advertising on alcohol consumption for the general adult population, according to the source of variation in the advertising measure (time-series, cross-sectional, panel, advertising bans). The vast majority of these studies did not show any substantial positive effects of advertising on overall alcohol consumption. The bulk of these studies though have utilized national time-series data, which often lack variation and confound effects with other unobserved trends. However, given that most individuals consume alcohol without imposing external costs, the more relevant question concerns whether alcohol advertising impacts problem drinking per se. Saffer (1991, 1997) provided indirect evidence on this issue. The study found that countries that ban broadcast alcohol advertisements have lower rates of traffic fatalities as well as alcohol consumption (Saffer, 1991). Saffer (1997) studied the effects of broadcast and outdoor advertising in 75 media markets on motor vehicle fatalities. It was found that a total ban on alcohol advertising could save as many as 5000–10 000 lives, implying an advertising elasticity of between 0.12 and 0.25.

Econometric studies find more consistent and stronger evidence of brand-switching effects in the alcohol industry. Fisher and Cook (1995), for instance, analyzed US data spanning 1970–90 and did not find any evidence that advertising impacts overall alcohol consumption. However, they did find that increased liquor advertising is associated with a reduced consumption of wine, suggesting cross-beverage market share effects. Nelson and Moran (1995) further found that advertising reallocates inter brand market shares, and to a smaller extent also inter beverage market shares, consistent with Fisher and Cook (1995).

Broadcast advertising in the alcohol industry generally aims at brand differentiation, whereas price-based advertising is more common in the print media, especially newspapers. There is some evidence that such price-based advertising leads to pro competitive effects consistent with the informative view of advertising. Sass and Saurman (1995) indicated that large national brewers gain market share at the expense of smaller firms when states restrict advertising of retail prices. They found that the presence of restrictions on price advertising increased market concentration at the state level, both absolutely and relative to measures of national concentration. Additional restrictions on non price advertising did not affect market concentration. Milyo and Waldfogel (1999) exploited the US Supreme Court ruling that overturned Rhode Island's ban on price advertising of alcoholic beverages. Using

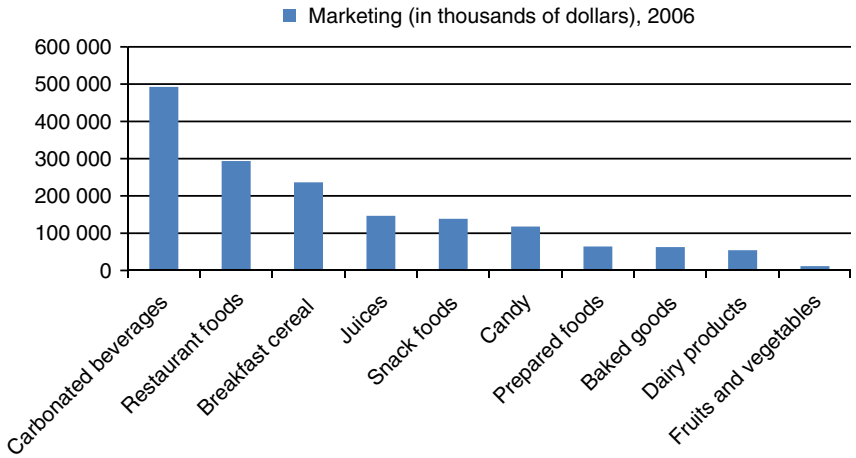

Figure 2 Total youth marketing for reported brands, 44 companies. Adapted from Federal Trade Commission (2008). *Marketing Food to Children and Adolscents: A Report to Congress.*

Massachusetts as a control, they found that price-based advertising substantially reduced the price of the advertised good, though there was little effect on the price of the non advertised good and no significant effect on price dispersion.

In summary, most evidence points to very weak or nonexistent advertising-induced market expansion effects in the alcohol industry. Several studies do not find strong positive effects of advertising on total alcohol consumption. There is some evidence that this overall nil effect may be masking salient effects for certain subpopulations. For instance, some studies have indicated that alcohol advertising increases indicators of problem drinking (for instance, motor vehicle fatalities) and drinking among adolescents, though in both of these cases the elasticity magnitudes are relatively small (and certainly smaller than estimated price responses). It should be noted that many of these econometric studies have estimated advertising effects conditional on price, which precludes one of the mechanisms through which advertising may impact primary or selective demand – that is, through changes in the retail price. This is especially relevant for price-based advertising. Tremblay and Okuyama (2001), for instance, made the point that if the elimination of advertising restrictions promotes price competition, then elimination of the self-imposed broadcast advertising ban in the liquor industry could cause alcohol consumption to rise even if advertising had no direct effect on market demand. There is more consistent evidence of advertising-induced brand-switching effects both at the brand level and the beverage level. This is in accord with the persuasive view of advertising, wherein the main role of advertising and promotion is to generate potentially spurious brand differentiation and enhance the brand's monopolistic power. At the same time, there is also some indication from studies based on cross-state restrictions of price-based advertising that such advertising can lower retail prices and have pro competitive effects.

Advertising of Food and Soft Drinks

Total marketing expenditures in 2006 for the food and beverage industry were highest in the carbonated beverages and restaurant foods categories, with $3.19 and $2.18 billion spent, respectively (Figure 2). Breakfast cereal ranked third in terms of marketing targeted at *youth* (ages 2–17), with $792 million spent. Overall, however, juice and non carbonated beverages and snack foods ranked higher than breakfast cereal, with $1.25 billion and $852 million spent, respectively. The levels of concentration across food and soft drink industries vary, with carbonated soft drink, cereal, and snack foods relatively concentrated compared to other food categories (see Table 2).

Similar to the tobacco and alcohol industries, the soft drink industry is relatively concentrated, with a Herfindahl–Hirschman index of 1094.5 in 2007 (Table 2). There is evidence that the soft drink industry might be more cooperative than predatory in nature, which would render them more likely to capture demand that does not exist rather than capturing a competing company's demand (Gasmi *et al.*, 1992). The Coca-Cola and Pepsi companies are the leading advertisers in the carbonated drink industry, and when the sugar rationing that was implemented in 1942 ended, soft drinks advertising on television experienced a significant increase (Wilcox *et al.*, 2009).

The breakfast cereal industry is characteristic of a very tight oligopoly, with a Herfindahl–Hirschman index of 2425.5 in 2007 (Table 2). There has been evidence that, within the cereal industry, incumbent firms often respond to the entry of new firms with advertising, in order to limit the sales of new entrants (Bagwell, 2007, p. 1729). This anticompetitive behavior may provide support for the persuasive view of advertising in this context, as opposed to the informative view. Yet Ippolito and Mathios (1990) suggested that, in response to growing evidence of fiber's potential cancer preventing benefit, a ban on advertising health claims for food products was lifted in 1985. As a result, consumption of cereal increased. (Kellogg had already begun its advertising campaign highlighting the link between fiber and cancer in October 1984, in violation of FDA policy.) The authors suggested that this lowered the search costs of obtaining health information.

In the food industry, it is not always clear whether advertising is *persuasive*, *informative*, or whether it has elements of

both. Glazer (1981), for example, examined the effect of an exogenous event on food prices: a newspaper strike in Queens and Long Island, NY, for 2 months in 1978. According to his study, the lack of information on prices during that time led to an increase in prices, perhaps indicating that in this context, advertising is informative (Bagwell, 2007). This may be because of the more competitive nature of the market analyzed. The marketing literature contends that *informative* advertising generally occurs in the early stages of a product's life cycle (to build brand awareness and generate demand); *persuasive* advertising occurs in the growth and early maturity stages of the product life cycle (when a product has gained a certain level of brand awareness); and *reminder* advertising – used to remind or prompt purchases – are for products that have gained market acceptance and are in the maturity stage of their life cycle (Grewal and Levy, 2009).

Some trends in food and beverage consumption are noteworthy (see Statistical Abstract of the US at http://www.census.gov/compendia/statab/cats/health_nutrition/food_consumption_and_nutrition.html). For example, per capita consumption of total fat increased from 56.9 lb in 1980 to 85.2 lb in 2008. Per capita consumption of carbonated soft drinks increased from 35.1 gallons in 1980 to 46.4 gallons in 2003. Whether the link between consumption and advertising is causal is discussed in more detail below, in the context of advertising exposure by children.

Researchers have estimated that children's exposure to advertising has increased from approximately 20 000 commercials in the late 1970s to over 40 000 commercials in the early 2000s (Kaiser Family Foundation, 2004). There is particular concern that food and beverage advertising targeted at children is harmful, as the nutritional content of these products is questionable, with most being high in fat, sugar, or sodium (Kaiser Family Foundation, 2004; Powell *et al.*, 2011). Children may not be rational decision-makers or may not be able to appropriately differentiate between advertising and regular programming on television. The exposure to advertising may lead to increased consumption of these products – suggesting that advertising may be cooperative, leading to an overall increase in consumption, rather than predatory or combative – and ultimately contributing to increased rates of childhood obesity.

There is strong suggestive evidence of the link between advertising and consumption or obesity (see the comprehensive reports by the Institute of Medicine, 2006, and the Kaiser Family Foundation, 2004, for excellent reviews of these studies), yet the potential endogeneity of advertising is an issue. Endogeneity may arise because of a firm wanting to locate in areas where demand is already high, which may support the informative view, as advertising is simply an endogenous response to imperfect consumer information (Bagwell, 2007). Moreover, the advertising/sales ratio may be influenced by profit margins and other variables (Bagwell, 2007). Higher levels of advertising may also be more feasible for firms that are concentrated and profitable.

Companies may also target areas where demand is low to capture additional demand, maybe revealing their cooperative nature. At the same time, companies may be cooperative in areas where demand is high, as mentioned above, to further increase demand on the intensive margin. If industry behavior is combative in this context, ordinary least squares estimates are likely biased upward.

Research suggests that food marketing can have a significant impact on consumption among children in the short-term (Epstein *et al.*, 2008; Halford *et al.*, 2004, 2007; Harris *et al.*, 2009) and the longer-term (Barr-Anderson *et al.*, 2009). One study found that adiposity in children increased with exposure to fast food advertising and that banning those advertising practices could reduce the incidence of childhood overweight by 18% (Chou *et al.*, 2008).

The Institute of Medicine (2006) report concluded that there was substantial evidence that "food and beverage marketing influences the preferences and purchase requests of children, influences consumption at least in the short term, is a likely contributor to less healthful diets, and may contribute to negative diet-related health outcomes and risks" (p. 307). The report goes on to say that "[n]ew research is needed on food and beverage marketing and its impact on diet and diet-related health and on improving measurement strategies for factors involved centrally in this research" (p. 309). In contrast to research in the tobacco and alcohol industries on the effects of advertising on consumption, research in this area is still in its infancy.

Chou *et al.* (2008) used an instrumental variables approach to carefully address the potential endogeneity of advertising, and found significant effects of televised fast-food restaurant advertising on body mass index (BMI) and obesity in children and adolescents, using the National Longitudinal Survey of Youth (children of the 1979 cohort and the 1997 cohort). The price of an advertisement and the number of households with a television in the market area served as instruments for fast food advertising. These instruments were found to be valid in that they strongly predicted advertising yet were legitimately excludable from the BMI equation. The authors then analyzed potential effects of two types of regulation: (1) treating food advertising as an ordinary business expense (and thus eliminating the tax deductibility of advertising) and (2) a complete advertising ban on television. Because the corporate income tax rate was 35%, elimination of the tax deductibility of food advertising costs would be equivalent to increasing the price of advertising by approximately 54%, which in turn would reduce fast-food restaurant messages seen on television by 40% and 33% for children and adolescents, respectively, and would reduce the number of overweight children and adolescents by 7% and 5%, respectively. A ban would reduce the number of overweight children aged 3–11 by 18% and the number of adolescents aged 12–18 by 14%. Yet this may be an overestimate; as Saffer (2000) had correctly pointed out, bans on advertising were only effective if they were comprehensive – covering all media, not simply television. Otherwise, the industry would simply shift its advertising expenditures to other media outlets.

Andreyeva *et al.* (2011) used the Early Childhood Longitudinal Survey (Kindergarten cohort) to show that soft drink and fast food television advertising is associated with increased consumption of soft drinks and fast food among elementary school children. They perform several robustness checks to address the potential endogeneity of advertising. Little effect was found for cereal advertising, which may be because of the strong correlation between cereal consumption

and having breakfast, which promotes reduced overall caloric intake.

In summary, most evidence points to advertising-induced expansion effects in the carbonated soft drink and fast-food restaurant industries, and to weak or nonexistent expansion effects in the cereal industry.

Compared to the cigarette and alcohol industries, the food and non alcoholic beverage industries face relatively little regulation. In light of potential adverse effects of advertising on obesity, however, some self-regulatory efforts have been put forth. One such effort is the 2006 Children's Food and Beverage Advertising Initiative (Council of Better Business Bureaus, 2009), whereby participating companies made efforts to improve the nutritional quality of foods marketed to children. Some question these self-regulatory efforts, though, arguing that a few nutritious products are introduced whereas the unhealthy products continued to be heavily marketed (Kunkel *et al.*, 2009).

Several industrialized countries such as Sweden, Norway, and Finland have banned commercial sponsorship of children's programs. Sweden also does not permit any television advertising targeting children under the age of 12 (Kaiser Family Foundation, 2004). There is no similar ban in the US. The FDA regulates and sets standards for the food industry in the US, and these standards vary by state. There has, however, been an increased focus on the potential effect of advertising on obesity in children. In the White House Task Force on Childhood Obesity Report to the President, the following recommendations related to marketing were made, suggesting that advertising in these industries affect childhood obesity:

- The food and beverage industry should extend its self-regulatory program to cover all forms of marketing to children, and food retailers should avoid in-store marketing that promotes unhealthy products to children (Recommendation 2.5).
- All media and entertainment companies should limit the licensing of their popular characters to food and beverage products that are healthy and consistent with science-based nutrition standards (Recommendation 2.6).
- The food and beverage industry and the media and entertainment industry should jointly adopt meaningful, uniform nutrition standards for marketing food and beverages to children, as well as a uniform standard for what constitutes marketing to children (Recommendation 2.7).
- Industry should provide technology to help consumers distinguish between advertisements for healthy and unhealthy foods and to limit their children's exposure to unhealthy food advertisements (Recommendation 2.8). (Solving the Problem of Childhood Obesity within a Generation, 2010).

The FCC has acknowledged the problem and has partnered with the FTC and the Task Force on Childhood Obesity. (See http://reboot.fcc.gov/parents/media-and-childhood-obesity.) Yet it generally remains the case that an advertisement must clearly misinform the consumer in order to be regulated. Increased government involvement in this context is an ongoing debate, with recent studies suggesting that Congress should become more involved by enforcing corporate accountability, changing how advertising is treated for tax purposes, encouraging alternative solutions to regulation, and utilizing the Interagency Working Group Proposal on Food Marketing to Children (Termini *et al.*, 2011).

Another issue that has been raised is the Federal government's role as advertiser: Beef. It's What's for Dinner; Pork. The Other White Meat; Got Milk?. Most of us have heard these slogans in advertisements for beef, pork, and milk. Yet many of us are unaware that they are sponsored by the Federal government, through its 'checkoff' programs (Wilde, 2007), overseen by the United States Department of Agriculture (USDA) starting 1996. (See the Commodity, Promotion, Research and Information Act of 1996: http://www.ams.usda.gov/AMSv1.0/getfiledDocName=STELPRD3479032.) Researchers such as Wilde question the government's well-funded federally sponsored checkoff programs, which "promote increased total consumption of beef, pork, and dairy products, including energy-dense foods such as bacon cheeseburgers, barbecue pork ribs, pizza, and butter" (Wilde, 2006). At the same time, the USDA's Dietary Guidelines recommend a balanced diet with higher levels of whole grains, fruits, vegetables, fish, and low-fat dairy products consumption, which are not advertised by the government to the same degree.

Although weight loss products (discussed in the next section) go relatively unregulated, nutritional claims for food and beverages have been addressed with regulations on food labels, which can be viewed as an indirect form of advertising. Using the National Health Interview Survey, Variyam and Cawley (2006) showed that the implementation of new nutritional labels as a result of the Nutrition Labeling and Education Act of 1990 (effective in 1994) was associated with a decrease in body weight and the probability of obesity.

More recently, calorie posting for chain restaurants (with 20 or more stores in a state) was mandated, starting with New York City in 2008 and eventually becoming a requirement for all states as part of the new health care law (Adamy, 2010; Bollinger *et al.*, 2011). Approximately 20 cities or states mandated calorie postings on menus after New York City (Adamy, 2010). Preliminary studies for New York have shown mixed effects on consumption: Bollinger *et al.* (2011) used data from Starbucks to find that the average number of calories per transaction falls, while Elbel *et al.* (2009) compared New York to New Jersey to find no significant difference.

Advertising of Weight Loss Products

Perhaps one of the most striking examples of deceptive (and yet acceptable) advertising is in the OTC weight loss drug industry. Using magazine and television ads to determine effects on consumption, Cawley *et al.* (2010) showed that people are not as responsive to clearly deceptive advertising compared with nondeceptive advertising. They concluded that although nondeceptive advertising may be more cooperative in nature, deceptive advertising may be more combative in nature, or have no apparent effect.

Research in this area is new, and yet a striking 20.6% of women and 9.7% of men have used OTC weight loss products (Cawley *et al.*, 2010) at some point in their lives. As mentioned in Section 'Overview,' consumers are also ill-informed about government regulation, with half of all consumers under the

impression that these weight loss products are approved for safety and efficacy by the FDA before being sold to the public (Cawley *et al.*, 2010). These OTC weight loss products may accurately be placed in the aforementioned third category of goods that have 'credence' attributes (Darby and Karni, 1973), for which the consumer is unable to accurately evaluate quality even after consuming the good. For instance, since medications have person-specific effects, a consumer may not be able to judge their true effectiveness even after consuming them. These attributes, combined with high turnover of firms in this industry, makes deceptive advertising possible.

Although the FTC Act prohibits 'unfair or deceptive acts or practices,' including both misstatement of facts and failure to disclose important information that consumers should know, it does not prohibit 'puffery' – claims that are so exaggerated that they are clearly incorrect, and no reasonable person would truly believe them. Puffery is defined as "the legal exaggeration of praise, stopping just short of deception, lavished on a product" (Grewal and Levy, 2009).

Advertising of Prescription Drugs

Between 1980 and 2009, expenditures on prescription (Rx) drugs in the US increased from $12 billion to $250 billion, representing an increase of 1974% (see Figure 3).

Most of the increase until the mid-1990s followed the growth in national health expenditures (NHE). However, since around 1995 spending on Rx drugs has outpaced the growth in NHE, making it one of the fastest growing components of health care costs. Consequently, the share of drug spending in NHE roughly doubled between 1994 and 2004, from 5% to 10% (Centers for Medicare and Medicaid Services - CMS; see Figure 4).

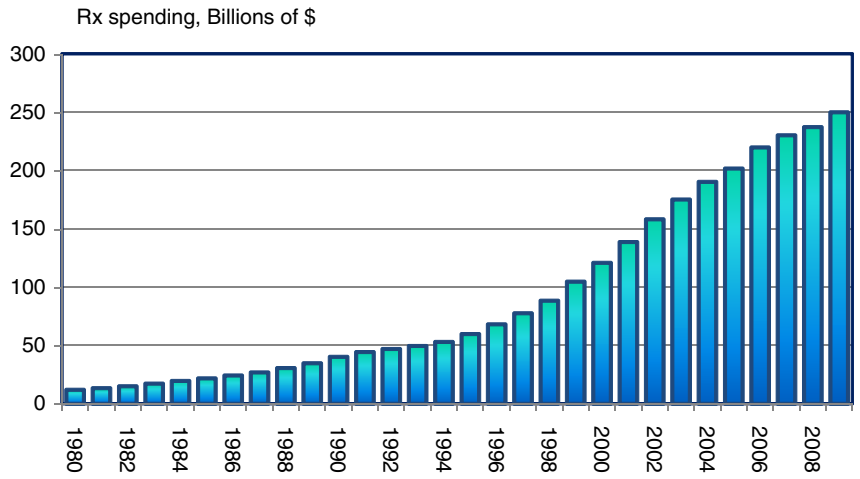

Figure 3 US prescription drug spending. Adapted from Centers for Medicare and Medicaid Services (CMS).

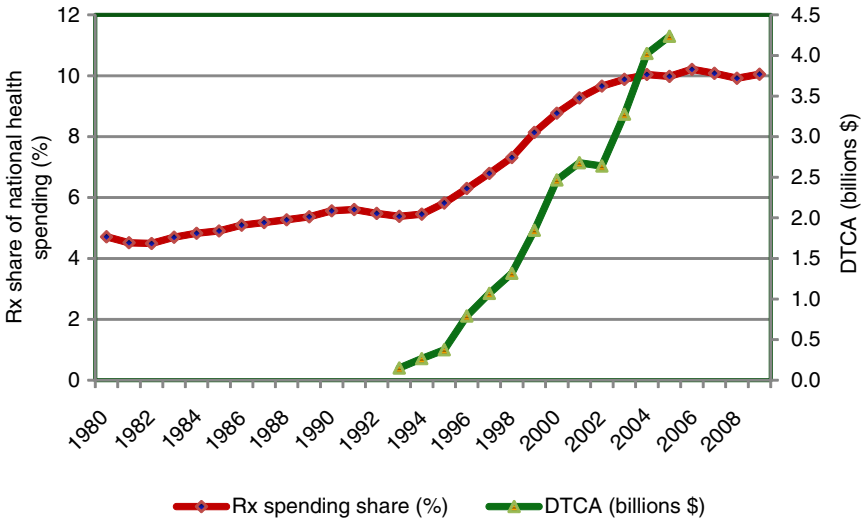

Figure 4 Rx spending share of national health expenditures and direct-to-consumer advertising. Based on data from CMS, Dave and Saffer (2012); Frank, R. G., Berndt, E. R., Donohue, J. M., Epstein, A. and Rosenthal, M. (2002). Trends in direct-to-consumer advertising of prescription drugs. Kaiser Family Foundation February. Available at: http://www.kff.org/rxdrugs/loader.cfmurl=/commonspot/security/getfile.cfm&PageID=14881; Donohue, J. M., Cevasco, M. and Rosenthal, M. B. (2007). A decade of direct-to-consumer advertising of prescription drugs. *New England Journal of Medicine* **357**(7), 673–681.

The growth in the share of prescription drug expenditures has coincided with the growth in pharmaceutical promotion, which increased from $11.4 billion in 1996 to $29.9 billion in 2005 (Donohue *et al.*, 2007). The promotion-to-sales ratio for the pharmaceutical industry is approximately 20%; this compares to an all-industry average of 4–5%. Pharmaceutical products tend to have experience attributes, a low price elasticity of demand (because of the presence of insurance and third-party payers), and a relatively high sales-advertising elasticity – all of which contribute to a high advertising and promotion intensity.

Promotion of prescription drugs is generally limited to patented drugs. It includes direct-to-consumer advertising (DTCA) on broadcast and print media as well as direct-to-physician promotion (DTPP) through visits by company representatives to physician offices (known as detailing), free samples provided to physicians and advertising in professional journals. Although DTPP still comprises most of the promotional budget, the largest relative increase in promotion between 1995 and 2005 resulted from the expansion of DTCA into broadcast media. The share of total promotional spending allocated to DTCA increased from less than 1% in the early 1990s to 8.6% in 1996 to 14.5% in 2003 (see **Figure 5**).

This expansion of DTCA was precipitated by the FDA's clarification of the rules governing broadcast advertising in 1997 and 1999, making it feasible for companies to promote via television and radio advertisements. For a number of years, the FDA had guidelines requiring the advertiser to provide detailed information on usage and risks that is contained in the drug's FDA-approved product label insert, thereby confining ads to print form. The new regulations now require broadcast advertisements to include only 'major statements' of the risks and benefits of the drug along with directions to alternate information sources for full disclosure. This clarification of what constitutes adequate disclosure removed a major barrier that had initially made TV and radio advertisements infeasible. Specifically there was no broadcast advertising in 1993, but it now comprises the primary form of DTCA – amounting to $2.55 billion in 2005.

These new regulations remain a controversial policy and are facing increased scrutiny from Congress and consumer groups. Currently only the US and New Zealand permit broadcast DTCA. At the heart of this debate is whether pharmaceutical promotion and advertising are welfare-promoting. The pharmaceutical industry claims that such advertising educates patients on potential treatment options, opens up lines of communication between the patient and the physician, and can even increase patient–physician contact or expand appropriate treatment for under treated conditions, consistent with the informative view of advertising. Congressional leaders have contended that DTCA raises prescription drug costs, consistent with brand differentiation and the persuasive view of advertising, and requested that the policy be revisited. Some consumer groups maintain that consumers may be harmed by misleading advertising and that the recent expansions in DTCA are responsible for the increases in expenditures on prescription drugs.

Growth in prescription drug spending is broadly driven by increases in utilization and price, and shifts in the composition of drugs being used, all of which may be impacted by DTCA. A comprehensive assessment regarding the welfare effects of pharmaceutical advertising and promotion requires information on three broad but related issues: (1) effects on primary versus selective demand; (2) effects on price; and (3) effects on competition. To inform on the first question, many prior studies gave focus on how DTCA and DTPP have affected pharmaceutical sales and patient adherence. Rosenthal *et al.* (2003) studied brands in five therapeutic classes using aggregated US monthly time-series data from August 1996 to December 1999. They employed an instrumental variables methodology to account for the endogeneity of DTCA and concluded that consumer advertising was primarily

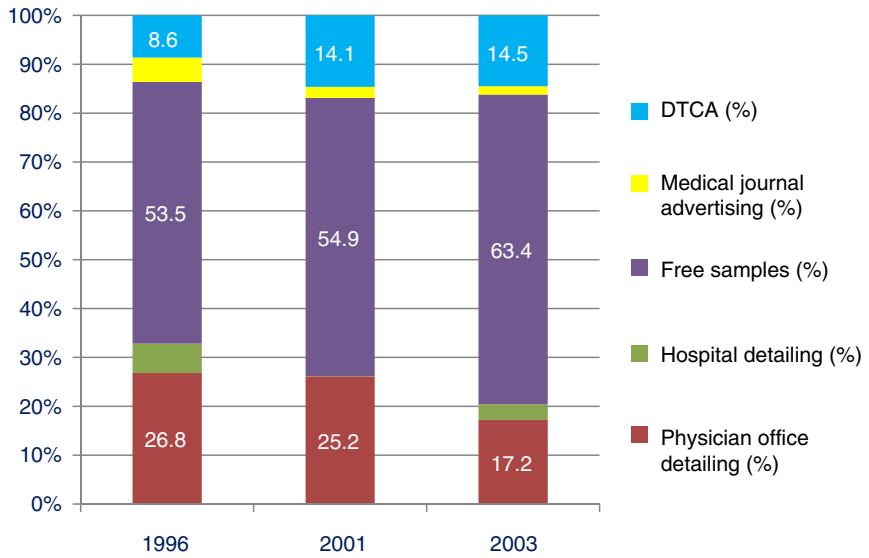

Figure 5 Components of pharmaceutical promotion. Based on data from Donohue, J. M., Cevasco, M. and Rosenthal, M. B. (2007). A decade of direct-to-consumer advertising of prescription drugs. *New England Journal of Medicine* **357**(7), 673–681, and authors' calculations from data used in Dave and Saffer (2012).

effective in raising sales for the entire therapeutic class. Other studies have also noted this market-expansion effect of DTCA, and suggested that DTCA may be more effective in increasing aggregate class demand than in increasing the demand for a particular drug (Iizuka and Jin, 2005, 2007).

These studies combine broadcast and nonbroadcast DTCA into a single aggregate measure, and utilize older data from a time-period when DTCA was just starting to take off and much of it still comprised nonbroadcast forms. This may obscure certain effects since the shift in FDA guidelines specifically applied only to broadcast DTCA; the composition of DTCA has increasingly shifted away from print and toward television and radio advertising as broadcast DTCA became more feasible as a form of promotion for the pharmaceutical industry. Second, both of these forms of DTCA may be expected to have differential effects on pharmaceutical prices and sales.

Dave and Saffer (2012) utilized monthly data on all prescription drugs in four major therapeutic classes from 1994 to 2005, thereby exploiting the period enveloping the FDA's shift in regulations as a natural experiment and exogenous shock to consumer advertising. They separately analyzed the effects of broadcast and nonbroadcast DTCA. Based on drug fixed effects models, they found that broadcast DTCA did impact own-sales with an elasticity of 0.10, and this response is higher relative to nonbroadcast DTCA. This study also found some evidence that class-level DTCA may raise sales for the non advertised drugs. Assuming that physicians are prescribing an equally effective drug, this may be a spillover benefit of DTCA in some cases because non-advertised drugs tend to be older and also cost less.

Directly bypassing the potential endogeneity of advertising, Kravitz *et al.* (2005) examined how DTCA impacts the prescribing behavior of antidepressants in a randomized control trial setting. Standardized patients, mostly professional actors, were assigned to visit physicians and make a specific brand request (referring to a DTC ad), a general drug request, or no request. Results pointed to the role of brand-specific DTCA in raising own-demand by leading to a prescription for that brand, as well as in raising overall class demand.

Additional evidence on the demand effects of DTCA is also provided by studies that examine patient adherence. For instance, Bradford *et al.* (2006), using patient-level data from 1998 to 2004 merged with DTCA information at the national and market levels, found that higher levels of DTC television advertising of statin treatment was significantly associated with improvements in the likelihood of attaining cholesterol management goals for at least some patients. Donohue *et al.* (2004) studied claims data for depressed patients between 1997 and 2000 matched with information on DTCA. They found that consumer advertising of antidepressants was associated with an increase in the number of people diagnosed with depression who initiated medication therapy and a small increase in the number of individuals treated with antidepressants who received the appropriate duration of therapy.

Studies have also examined the impact of advertising aimed at health-care providers, which historically has been the primary form of promotion used by the pharmaceutical industry. Berndt *et al.* (1995), for instance, considered the role of detailing, medical journal advertisements and DTCA in the market for antiulcer drugs before the shift in FDA guidelines. The DTCA examined in this study is very limited and confined only to print media because the study predated the FDA's shift in regulations that made broadcast DTCA feasible. They found the strongest demand effect for detailing and the smallest effect for DTCA. Many other studies also confirmed larger effects of physician-directed promotion relative to those for consumer-directed promotion.

Overall, most of these studies point to positive demand effects of DTCA and DTPP, and generally find that DTCA has stronger class-level effects whereas DTPP has stronger brand-specific effects. There is some suggestive evidence from studies utilizing newer data that DTCA may also have some brand-specific effects, particularly broadcast DTCA, though all studies point to DTPP being more effective relative to DTCA in raising sales. Some of the research also highlights a potential benefit of DTCA – that is, encouraging consumers to seek treatment and take their medications as prescribed.

With respect to the effects of advertising and promotion on price, the evidence is more limited. This paucity of research partly derives from the difficulty in obtaining salient measures of Rx drug prices because of the presence of third-party payers and unobserved rebates from drug manufacturers to third-party payers.

As underscored by the discussion on the three views of advertising, the potential effects on price primarily depend on the strength of scale economies in production and on the impact of advertising on the price elasticity of demand. Under the persuasive view of advertising where the shift in demand becomes relatively more inelastic, advertising raises price as long as there are no strong economies of scale in production to counteract the inelastic demand. Under the informative view of advertising, prices are predicted to decrease because demand would become relatively more elastic.

The few studies that have focused on advertising-induced price effects appear to be in accord with the persuasive view. Rizzo (1999), for instance, found that increased detailing efforts among antihypertensive drugs reduced the price elasticity. This reduction may consequently result in higher prices, though Rizzo did not examine the direct link between detailing and price. The study was based on pooled annual data from 1988 to 1993, which predates the DTCA policy shift, and only considers promotion to physicians. Law *et al.* (2009) examined pharmacy data for Plavix (an antiplatelet drug used to prevent stroke and heart attack in at-risk patients) from 27 Medicaid programs over the period 1999–2005. Plavix initiated DTCA in 2001. This study found that, although there was no change in the preexisting trend in demand, there was a sustained increase in cost per unit of $0.40 (11.8%) after the expansion in DTCA.

Dave and Saffer (2012), utilizing a larger sample of all Rx drugs in four therapeutic classes, also found that DTCA raised the average wholesale price, though the estimated elasticity was of a relatively small magnitude (0.04). Consistent with the positive impact on price, this study also found that the consumer price response became relatively more inelastic during the period when DTCA was expanding. Saffer and Dave presented simulations suggesting that expansions in broadcast DTCA over 1994–2005 accounted for 19% of the overall growth in prescription drug spending, with two-thirds of this

impact driven by an increase in demand and the remainder because of higher advertising-induced prices.

One challenge faced by these empirical studies concerns the simultaneity between advertising and pricing decisions. For instance, Bhattacharya and Vogt (2003) presented a model of joint price and promotion determination over the drug's life cycle. The dynamic profit maximizing strategy for the firm was to initially employ a relatively high level of promotion and to set a relatively low price. These levels would not only increase current quantity demanded, but also raise future demand because high promotion and low prices increased the physicians' and the consumers' stock of knowledge about the drug. In subsequent periods, promotion could be decreased to lower costs and price could be raised to increase revenue.

This trajectory of higher prices and lower advertising over the drug's life cycle is also consistent with the Dorfman-Steiner (1954) condition for optimal advertising discussed in Section 'Overview'; the optimal advertising-to-sales ratio is a positive function of the elasticity of sales with respect to advertising and is inversely related to the elasticity of sales with respect to price. Thus, the decline in advertising over the drug's life cycle is consistent with an age-related decline in the sales-advertising elasticity (Berndt, 2006). It is also consistent with an increase in the price elasticity as the drug ages and newer drugs enter the therapeutic class. A positive association between advertising and price inelasticity may thus reflect causality in both directions – for persuasive goods, advertising may make demand more inelastic, but *ceteris paribus* more inelastic demand also leads to a higher optimal level of advertising.

While both Rizzo (1999) and Dave and Saffer (2012) attempted to address this simultaneity through additional controls, the results should be interpreted in the context of the limitations noted. Nevertheless, these studies point to certain anticompetitive effects of Rx drug promotion. Further evidence is gleaned from studies that have investigated the effects of advertising on entry in the pharmaceutical markets. Scott Morton (2000) found that advertising by branded drugs before patent expiration and generic entry may have a very small deterrence effect on subsequent generic entry depending on the type of advertising, though this effect becomes insignificant in models which instrument for advertising. In a classic study, Benham (1972) found that eyeglass prices were substantially higher in states that prohibited all advertising relative to states with no restrictions. Prices were slightly higher in states that allowed only non price advertising than in states with no restrictions. This strand of the literature suggests that non price advertising by the Rx industry may exert some small upward pressure on prices and possibly have anticompetitive effects, though the evidence is far from conclusive and requires further study.

In summary, DTCA has emerged as a marketing force in the US healthcare system and is only expected to grow along with expenditures on prescription drugs. Although the debate surrounding DTCA is unlikely to be resolved anytime soon, DTCA should be evaluated both in terms of its costs as well as its benefits. The benefits derive from improved health because of increases in the number of individuals using prescription drugs and increased adherence with drug therapy. Detecting and treating health conditions at an earlier stage, through primary care, may also be more cost-effective relative to treatment at a later stage through acute care. Pointing to another potential benefit of promotion, Kwong and Norton (2007) found that detailing (but not other types of advertising) may have a significant positive effect on the number of new products entering into clinical development, with markets for chronic disease with high levels of detailing being more attractive to pharmaceutical firms.

Studies that show advertising-induced market expansion effects generally interpret these findings as welfare-improving. Although there was certainly an element of improved adherence and expanded treatment underlying the market expansion, David *et al.* (2010) showed that increased levels of promotion and advertising lead to increased reporting of adverse medical events for certain conditions. This suggests that promotion-driven market expansion could raise the risk that the drug is prescribed inappropriately. In addition to potential misuse, the costs of DTCA also result from increased drug prices and increased use of more expensive drugs in place of equally effective lower-priced drugs. Higher drug and health care expenditures in turn can raise insurance premiums and may lead to a larger prevalence of uninsured.

New Directions

Online Advertising

The Pew Research Center showed that Internet usage among Americans has increased by approximately 72% since 2000, with an estimated 46% of respondents using the Internet in 2000 and 79% in 2010 (Pew Research Center, 2011). Residential broadband subscribers increased from 5.2 million in 2000 to 70.1 million in 2008, a 1248% increase over 8 years. With more households having access to the Internet, online advertising, a form of 'interactive media' (which also includes mobile phones) has become more prevalent, as is evident in **Figure 6**. Online advertising was in existence in the early 1990s (Li and Leckenby, 2006), yet as **Figure 6** reveals, as recently as 2000 online media suppliers represented less than 5% of total suppliers, compared with 14% in 2009.

As Li and Leckenby (2006) pointed out, "the internet has capacities to extend the function of advertising far beyond what traditional media are able to accomplish... The expanded function of internet advertising comes from its horizontal integration of three key marketing channel capacities (communication, transaction and distribution) and vertical integration of marketing communications, including advertising, public relations, sales promotion and direct marketing" (p. 203).

Figure 7 shows the importance of control ownership by the advertiser or consumer in determining the effectiveness of Internet advertising (Li and Leckenby, 2006). This Interactive Advertising Model (IAM), developed by Rodgers and Thorson (2000), revealed the increased complexity of Internet advertising as compared with advertising in other media. Some ad formats are controversial; for example, interstitial ads, which include pop-ups and pop-unders, could be intrusive and irritating, particularly for individuals who were in 'search mode' rather than in 'surf mode' (Li and Leckenby, 2006). (Banner ads, by contrast, are usually viewed voluntarily.) New formats adopted by Internet advertisers included three-dimensional

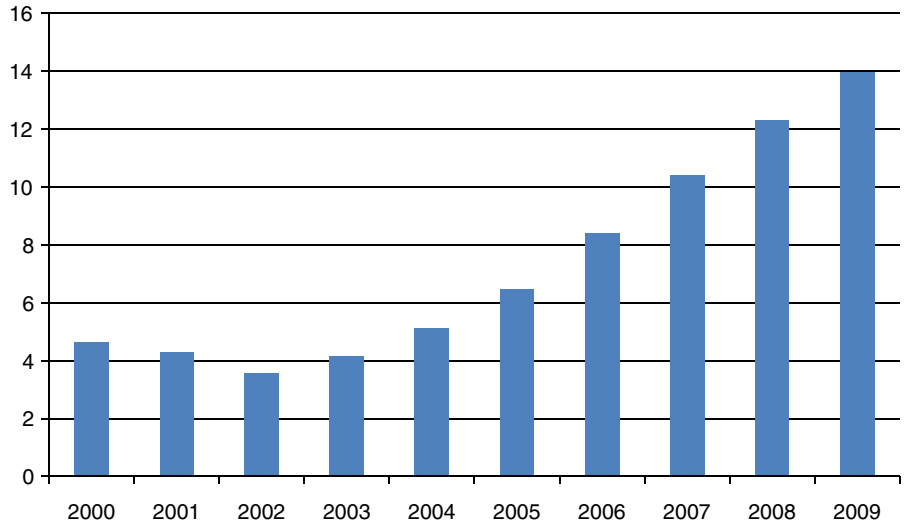

Figure 6 Percentage of online media supplier advertising revenues (out of total). *Note*: Authors' calculations based on data from the Statistical Abstract of the U.S. Online media suppliers include all online digital suppliers in direct, national, and local markets.

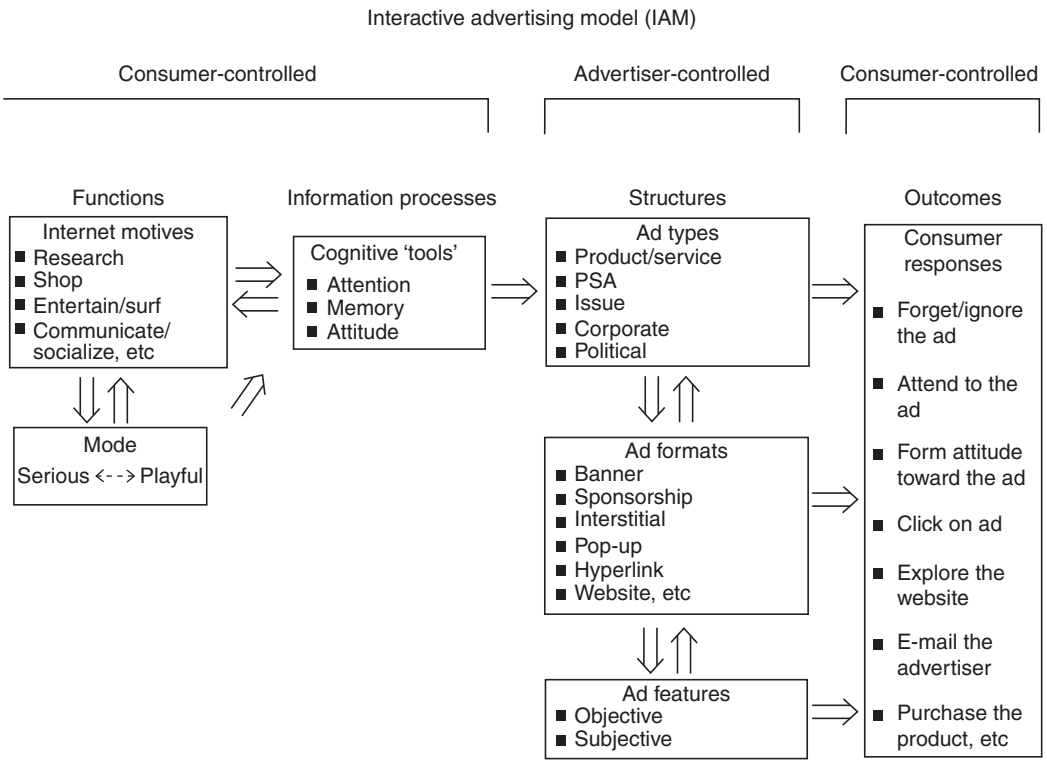

Figure 7 The interactive advertising model (IAM). Adapted from Rodgers, S. and Thorson, E. (2000). The interactive advertising model: How users perceive and process online ads. *Journal of Interactive Advertising* **1**(1), 42–61.

visualization and product placement in online games (Li and Leckenby, 2006). There were also virtual worlds in which companies could pinpoint when avatars look at specific ads (Grewal and Levy, 2009).

The FTC warns advertisers that if they wish to advertise on the Internet, the same rules apply for electronic advertising as for other forms of advertising (Federal Trade Commission, 2000). Advertising must not mislead consumers or make claims that are unsubstantiated. The FTC summary also sets forth guidelines to protect consumer privacy, particularly relevant for online advertisers.

Neuroeconomic Framework

Economists have integrated insights from behavioral economics and neuroscience in a budding area of research known

as neuroeconomics. Bernheim and Rangel (2004, 2005), for instance, presented a theory of addiction based on a neuroeconomic framework of decision-making. This area of research provided a promising new direction for advertising studies on two fronts. First, the persuasive view of advertising posits that advertising impacts demand through potentially spurious brand differentiation, which in turn affects consumer preferences. However, as Bagwell (2007) noted, studies remain "agnostic as to the underlying mechanism through which advertising shifts tastes" (p. 1825). Assimilating insights from neurological research with regard to how decisions are made can help advance our understanding of the mechanisms underlying the response to advertising. Second, relevance for public health and policy requires not just knowing the average population response but also an understanding of how advertising particularly affects behaviors of at-risk individuals – that is, those who impose external costs on others and who are the targets of public policy. For instance, is advertising predicted to affect drinking behaviors of heavy alcohol users or affect junk food consumption habits among overweight/obese individuals? Neuroeconomic models of decision-making, particularly in the context of goods with addictive properties, have distinct predictions in this regard.

Consider the following neuroeconomic model based on Bernheim and Rangel (2004, 2005). Saffer (2011) provided a related discussion on alcohol advertising, and Ruhm (2012) provided a discussion of neuroeconomic models as they applied to overeating and obesity. Individuals have been found to rely on two neural systems to make decisions relating to addictive consumption. One system reflects a rational mechanism (RM), where choices and decisions are based on reasoning and rational cost–benefit calculus. When decisions are made according to the RM, the individual is in a 'cold state' and here the standard neoclassical demand model is applicable. The other neural system reflects a hedonic forecasting mechanism (HFM), where choices are based on 'cravings' and short-term rewards. The HFM does not involve higher reasoning, and is in control when decisions must be made very quickly. In this case, the individual is defined to be in a 'hot state.' The switching mechanism between cold and hot states depends on environmental cues such as advertising, the individual's addictive stock accumulated through past consumption experience, and other factors.

Under this neuroeconomic framework, advertising would increase primary demand and lead to overall market expansion effects, not just brand-switching effects. The model also indicates that the response to advertising is a learned behavior, and individuals with a higher addictive stock may be particularly susceptible to advertising-related cues. Individuals can also override evaluations of the HFM by exercising cognitive control and asserting dominance of the RM; this points to individual heterogeneity in the response to advertising based on factors that affect the costs of exercising cognitive control.

In summary, it is known from various studies conducted for healthcare markets that advertising can affect both selective and primary demand, can be persuasive and in turn affect tastes and preferences, and can have an average population response that may mask heterogeneous responses across individual characteristics, population subgroups, and along the consumption distribution. It is less clear *why* these responses are observed. Integrating insights from cognitive psychology, neuroscience, behavioral economics, and other disciplines provides a promising avenue for further understanding these responses.

Summary

This article has provided a conceptual and empirical framework through which to study the economics of advertising in the context of markets for health inputs. The Dorfman–Steiner model positively relates advertising intensity to the advertising-sales elasticity and negatively relates it to the price elasticity of demand. The competing informative and persuasive views of advertising are explored, in addition to the view of advertising simply as a complement to the advertised good. Search and experience goods are distinguished and briefly discussed. These attributes, combined with the product's price and advertising elasticities, generally determine the advertising intensity of the product.

An analysis of advertising in select health markets is covered, with a focus on selective versus primary demand effects and relevance for public health. Econometric studies typically find effects on consumption for tobacco, soft drinks, fast-food restaurants, and prescription drugs, which reflect an advertising-induced industry expansion effect. For the alcohol industry, there is some evidence of small positive overall demand effects for certain segments of the population such as problem drinkers and youth. More empirical research, however, needs to be conducted, particularly addressing the potential endogeneity of advertising. A key obstacle for researchers is the high price of acquiring detailed advertising data. Currently, advertising data are only provided by a few companies, including Nielsen and TNS (now part of Kantar Media).

Future research in this area will increasingly stress the roles of online advertising, which allows greater targeting of the product to the potential user, and neuroeconomics, which may yield insights on the pathways underlying the consumer response. The emerging research combining behavioral economics and neuroscience is timely, for instance, as online purchases made after exposure to advertising may have higher probabilities of being 'hot state,' impulsive purchases. Some thoughts are provided on new directions for research in these increasingly important topic areas.

Advertising Health Care: Causes and Consequences

OR Straume, University of Minho, Braga, Portugal

Introduction

This overview starts by giving a brief introduction to the economic theory of advertising, including a short presentation of the two main models of advertising and discussion of how advertising affects market outcomes in light of these two models. These theoretical underpinnings are then used to discuss the causes and potential effects of advertising in health care markets, with tentative implications for the social desirability of such advertising. A distinction is made between advertising of health care providers (hospitals or physicians) and advertising of prescription drugs, which are treated separately in this overview. Not only does drug advertising constitute the main bulk of total advertising expenditures in health care markets but it also involves some particular issues (and controversies) that demand separate attention.

The Economics of Advertising

Advertising is a widespread feature of economic life and has been a major topic for economic research since the early twentieth century. This research has led to the emergence of two distinct and competing views about what advertising is, with very different implications about the effects – positive as well as normative – of advertising. We can think of these as two different models of advertising.

Informative versus Persuasive Advertising

The informative advertising model takes as a starting point that most markets are characterized by asymmetric information, where consumers are ex ante imperfectly informed and need to search for information about products offered in the market. Because this search is costly, too few consumers will learn about the existence, price, and quality of products, causing market inefficiencies. According to the informative advertising model, advertising is a means to convey product information to consumers, which reduces consumers' search costs and thus reduces the inefficiencies caused by asymmetric information.

The persuasive advertising model, however, has a very different starting point. According to this view, the main purpose and effect of advertising is to change consumers' tastes and perceptions about the advertised product. Advertising is therefore a means to create 'artificial' product differentiation and brand loyalty, thereby increasing consumers' willingness to pay for the product. Whereas informative advertising has a positive effect in terms of reducing information imperfections, the persuasive view arguably implies that advertising is socially wasteful because its main effect is to distort the 'true' preferences of consumers.

Effects of Advertising

The informative and persuasive models of advertising predict very different effects of advertising, particularly with respect to competition and prices. Because real-life advertising rarely conforms to either of the two stylized models, but usually includes both persuasive and informative elements, an assessment of how advertising affects market outcomes, with corresponding implications for the social desirability of advertising, is a challenging exercise.

The main purpose of advertising is to increase demand for the advertised product. However, there are two sources of demand increases. Advertising could induce consumers to switch from a similar product offered by a competing firm toward the advertised one, or it could induce demand from new consumers who did not previously purchase any product from the market in question. The former is commonly referred to as business-stealing, whereas the latter is referred to as market expansion.

Advertising generally affects market prices. Theoretically, the price effects depend crucially on whether advertising is predominantly informative or persuasive. Informative advertising results in more consumers becoming aware of the existence and objective characteristics (including price) of available products. This makes demand more elastic (more price sensitive) and intensifies competition between competing brands, leading to lower prices in the market. However, persuasive advertising creates artificial product differentiation and brand loyalty, making consumers less willing to substitute between competing brands. This makes demand less elastic and allows firms to charge a higher price.

In many markets, with health care being a prime example, quality (rather than price) is a key characteristic of the products and services offered. Compared with the price effects, the effects of advertising on quality is theoretically less well established. If quality is observable and firms compete mainly on quality, informational advertising should lead to higher quality through increased competition.

However, quality is often not easily observable and it is therefore harder to assess to which extent advertising contains truthful information about quality. An important distinction can be made between search goods and experience goods. The quality of search goods can be ascertained before the purchase of the good, whereas the quality of experience goods can only be confirmed after the good is consumed. This suggests that producers of experience goods may have stronger incentives to advertise untruthfully about quality. However, in markets where consumers generally make repeated purchases, advertising in itself could function as a signal of high quality. Under the assumption that high-quality goods will be subject to more repeat purchases, producers of such goods will have incentives to advertise more to attract more first-time customers. This argument does not depend on the truthfulness of the advertising. Thus, seemingly persuasive advertising could

have an informational value as a signal of high quality. However, the empirical evidence of a positive relationship between advertising and quality is mixed.

Advertising might also affect entry of new firms/products into the market. The potential entry-deterring effect of advertising is a much-researched topic. From a theoretical viewpoint, it is possible that persuasive advertising might deter entry by creating brand loyalty to incumbent firms' products, implying that potential entrants would have to advertise more to capture these brand-loyal consumers, thereby increasing entry costs. However, there are also theoretical arguments suggesting that the optimal entry-deterring strategy is to underinvest in advertising. The key argument for this seemingly paradoxical result is that reducing the number of loyal consumers through lower advertising levels is a way for incumbent firms to commit themselves to higher output levels (or lower prices) in case of entry. Thus, incumbent firms might be able to deter entry by credibly committing themselves, through low pre-entry advertising levels, to become tough competitors post-entry. In either case, the empirical evidence of entry deterrence through advertising remains ambiguous.

Advertising of Health Care Providers

Below, the basic economics concepts and theories of advertising outlined above are used to discuss advertising in health care markets specifically. The present section deals with advertising of health care providers (hospitals or physicians) while the subsequent section deals with drug advertising.

Why Do Health Care Providers Advertise?

Because advertising is a means to increase demand, health care providers have incentives to advertise only as long as they can increase demand. Thus, incentives for advertising essentially require that providers' revenues are positively correlated with demand and that patients are able to choose their preferred provider. It is therefore no coincidence that health care advertising is mainly done by private health care providers. Traditionally, health care advertising has been more prevalent in the US, which has experienced health care advertising since the 1970s, particularly from for-profit providers. However, the introduction of market-based reforms in several European countries has made advertising relevant also for public (government-funded) health care providers, resulting, for example, in the lifting of the advertising ban on UK hospitals in 2008. In general, more competition in health care markets have been accompanied by a huge increase in advertising by health care providers (both hospitals and physicians) over the past couple of decades, although the advertising intensity in the health care sector remains as a relatively low fraction of total spending.

Is Heath Care Advertising Informative or Persuasive?

An important characteristic of health care markets is the high degree of asymmetric information, in which providers have generally much more information than patients about the quality of the services offered. This makes informative advertising potentially more valuable as a means to reduce informational market imperfections. However, because health services are often complex and highly nonstandard products that make information harder to assess and compare, this arguably also increases the scope for persuasive advertising (for example, by using celebrities to endorse products or services). The slower consumers revise their beliefs about quality, the stronger the incentive to mislead consumers through persuasive advertising. However, as previously argued, even purely persuasive advertising might have informational value if it functions as a signal of quality. This argument is clearly applicable to health care services, which are better characterized as experience goods rather than search goods.

Although the empirical evidence is scant, there exists research indicating that physician advertising leads to higher prices, which suggests that such advertising is predominantly persuasive. However, this is clearly an under-researched topic in the health economics literature.

Direct-to-Consumer Advertising and the Role of Physicians

A distinguishing feature of health care markets is that demand for health care is often a result of the interaction between patients and physicians, where, in most health care systems, general practitioners (GPs) act as gatekeepers to secondary health care (hospitals) through their referral decisions. Consequently, the effects of direct-to-consumer advertising (DTCA) must be analyzed and understood in the context of the physician–patient relationship.

DTCA can in principle have two different effects on demand; it can increase the number of patients seeking treatment for a particular condition and affect the choice of health care provider for patients seeking treatment. In health care systems that practice GP gatekeeping, the latter effect is determined by the patient–physician relationship. In a gatekeeping system, GPs provide information and affect patient choices. However, a more educated population arguably implies that patients play a more active role (vis-à-vis the GP) in the process of choosing health care providers, and DTCA is an alternative source of information for patients.

If the GPs are well-informed perfect agents for patients, there is little or no role for positive effects of DTCA. In this case, the patient will only disagree with the GP's recommendation if he is being misled by false advertising. However, GPs may not be perfect agents for their patients, either because GPs are not perfectly informed about available treatments or the two parties have different preferences with respect to the type of information they value. For example, GPs may care less about price information than patients do. Thus, to the extent that DTCA conveys accurate and relevant information to the patient, it may have positive effects in terms of reducing provider–patient mismatches if GPs are not perfectly informed or they do not always act in the best interest of the patient.

The above discussion ignores the potential effect of DTCA on the number of physician visits. A more thorough discussion of DTCA will be given in the context of drug advertising in the Section Advertising of Prescription Drugs, in which this is a more contentious issue.

Is Health Care Advertising Socially Wasteful?

If total demand for health care is relatively advertising-inelastic, the effect of advertising is mainly business-stealing. This could improve the matching between patients and providers, but it could also imply a waste of resources, as a form of 'medical arms race.' This depends on the extent to which advertising works as an instrument to reduce information imperfections in the health care market. Informational advertising can also have a positive welfare effect if it lowers prices (or raises quality) through increased competition.

If advertising leads to a demand expansion, this could still be socially wasteful if this expansion is 'artificially' created by persuasive advertising, leading to overconsumption of health care. However, even persuasive advertising can have positive welfare effects if such advertising works as a reliable signal of quality, as discussed in the Section The Economics of Advertising.

Advertising of Prescription Drugs

In contrast to health care providers (physician or hospitals), pharmaceutical companies spend a considerable share of revenues on advertising, often exceeding the share spent on research and development of new drugs.

With respect to advertising, there is a key distinction between prescription drugs and so-called over-the-counter (OTC) drugs. Because OTCs may be sold directly to consumers without a physician's prescription, the natural advertising target is therefore consumers. For prescription drugs, by contrast, there are potentially two different advertising targets: consumers and physicians. Therefore, prescription drugs are advertised through two different channels: DTCA (if allowed) and physician detailing. In the following, the two different channels of prescription drug marketing will be discussed and compared.

Direct-to-Consumer Drug Advertising

In contrast to advertising of OTC drugs, DTCA of prescription drugs is currently banned in all developed countries, except in the USA and New Zealand, although steps towards liberalization have been taken in several countries. In the US, DTCA has been allowed since the 1980s, though subject to regulation. New and more liberal guidelines were adopted in 1997.

What are the main effects of direct-to-consumer drug advertising? There is little doubt that DTCA results in an increased total number of drug prescriptions, the most important contributing factor being that DTCA increases demand for physician consultations. Thus, in addition to direct advertising costs, there are considerable indirect costs of DTCA because of a higher number of physician consultations and more drug prescriptions. The extent to which these costs are outweighed by higher patient benefits depend on whether advertising-induced consultations are necessary or unnecessary, and whether advertising-induced prescriptions are cost-effective or not.

Like advertising of health care providers, direct-to-consumer drug advertising could also affect competition between pharmaceutical companies and thus drug prices. Drug advertising does not normally contain price information, but increased information about the existence of competing drug therapies may increase competition and lead to lower prices. Although DTCA is mainly undertaken by patent-holding firms, these are seldom pure monopolies due to the existence of therapeutic substitutes in many submarkets.

The contentious nature of DTCA of prescription drugs, reflected in the widespread ban on such activities, requires a more thorough discussion of the relevant arguments.

A main argument in favor of DTCA is that it contributes to consumer education by increasing awareness of alternative drug treatments. This is the standard informative advertising viewpoint, and the validity of this argument clearly relies on the informational content of DTCA. However, another important side-effect of DTCA is that information about alternative drug treatments may also increase consumer awareness about the underlying medical conditions, thus increasing the likelihood that potentially serious diseases are detected at an earlier stage.

Besides the potential for reducing informational inefficiencies, DTCA arguably also promotes greater patient autonomy by motivating patients to play a more active role in their treatment. One could also argue that DTCA works to counterbalance the effect of physician detailing. If persuasive drug detailing towards physicians leads to a distortion of prescription choices, this could partly be corrected by making patients better informed about alternative drug treatments through DTCA.

However, several arguments have been put forward against allowing DTCA of prescription drugs. Although DTCA has the potential to reduce inefficiencies caused by imperfect information on the demand side of the market, this requires that consumers are equipped with sufficient background knowledge to understand and properly evaluate the information given by DTCA. If this is not the case, DTCA might lead consumers to demand drug treatment against medical conditions that are either nonexistent or better left untreated. Thus, DTCA might induce overconsumption of drugs and encourage the use of unnecessary medication. Similarly, DTCA might also contribute to overmedication by creating a bias in favor of drug treatment instead of nonpharmacological interventions, such as lifestyle changes.

Although DTCA can have positive effects in terms of promoting greater patient autonomy, there is also a potential flip side. If DTCA has mainly a persuasive, rather than an informative effect, this might introduce more costs and strains in the physician–patient relationship, in which physicians have to spend more time correcting misinformed views because of DTCA. Physicians might also face increased pressure from patients to prescribe new and less-well tested drugs.

DTCA versus Physician Detailing

Although DTCA is banned in most countries, advertising targeted towards physicians – so called detailing – is generally allowed (though regulated). Indeed, physician detailing constitutes the main share of total drug marketing expenditures.

This form of drug marketing includes visits by sales representatives to physicians, as well as advertising in medical journals. Because face-to-face advertising is more costly, the likely impact on prescription choices is also higher.

Like DTCA, physician detailing can, in principle, have both market-expanding and business-stealing effects. It has a market-expanding effect if it increases physicians' propensity to choose drug treatment over nonpharmacological treatments, and it has a business-stealing effect if it affects physicians' propensity to prescribe drug treatment A over drug treatment B. Like other types of advertising, detailing can reduce informational inefficiencies and improve the matches between medical conditions and drug treatments, if the informational content of this type of marketing is sufficiently high. However, it would be naive to disregard the possibility that there is also a substantial persuasive element to physician detailing. In fact, empirical studies showing that detailing reduces the price elasticity of demand suggest the existence of a significant persuasive effect.

An interesting question is whether DTCA and physician detailing are complement or substitute marketing strategies for pharmaceutical companies. Although detailing clearly affects prescription choices, empirical evidence suggests that DTCA has a larger effect on physician visits than on prescription choices, implying that DTCA mainly has a market-expanding effect. If the effect of detailing is mainly business stealing, while the effect of DTCA is mainly market expansion, this suggests that detailing and DTCA are complement strategies: More DTCA leads to a higher number of physician visits, which increases the profitability of spending resources on physician detailing to influence prescription choices.

Thus, if DTCA and physician detailing are complement strategies, an unintended side-effect of allowing DTCA is that it would lead to increased levels of physician detailing as well.

Drug Advertising and Generic Competition

A major concern for policy makers and regulators of pharmaceutical markets is to ensure that competition in the off-patent market is sufficiently stimulated. An important question in this respect is how advertising affects competition in the off-patent market. More specifically, how does advertising affect the probability of generic entry and how does it affect price competition between brand name and generic drugs?

A robust empirical regularity in the off-patent market for prescription drugs is that brand name drugs are consistently priced higher than their generic versions. Some early empirical studies even found that brand name prices tended to increase after generic entry. From an economics perspective, the persistent positive price difference between brand name and generic drugs is somewhat puzzling, as competition between homogeneous products (brand names and their generic versions) should be expected to lead to fierce price competition with uniformly low drug prices as a result. This strongly suggests that brand name and generic drugs are vertically differentiated in the eyes of consumers (or prescribing physicians), where brand name drugs are somehow perceived to be of higher quality. The most prominent theoretical explanation for the price difference between brand names and generics is that it is a result of persuasive advertising of the brand name drug during the patent period, creating a brand-loyalty that allows for brand-name drugs to be charged a higher price than its generic alternatives after patent expiry. Given that brand-name and generic drug versions have, by definition, identical active chemical ingredients and absorption rates, the observed price difference is a strong indicator of a significant persuasive element in drug advertising, which is usually considered to be detrimental for welfare.

The vertical differentiation created by brand-name drug advertising relaxes price competition in the off-patent market and allows for higher prices, not only of the brand-name drugs but also of the generic competitors. This suggests that brand-name drug advertising has potentially two counteracting effects on generic entry. On the one hand, persuasive advertising creates brand-loyalty that, all else being equal, reduces demand for generics and makes generic entry less profitable. However, such advertising creates 'artificial' vertical differentiation and relaxes price competition, which, all else being equal, makes generic entry more profitable. The second effect is more likely to dominate if advertising also has a market-expanding effect, which allows for generally higher drug prices in the market.

Whether advertising stimulates or deters generic entry (i.e., which of the two mentioned effects dominates) depends crucially on the strictness of price regulation in the off-patent market. If price regulation is very strict, advertising leads to brand-loyalty without a corresponding increase in prices. In this case, advertising is likely to have an entry-deterring effect. However, the price competition effect might dominate if price regulation in the off-patent market is absent or sufficiently lax.

The above reasoning implies that even purely persuasive advertising might have positive welfare effects if it induces generic entry after patent expiration. Persuasive advertising relaxes price competition by creating artificial vertical differentiation, but this might also induce generic entry that would otherwise have been deterred because of strong price competition (in the absence of advertising).

Notice that the above discussion implies that, to the extent that brand-name drug producers can deter entry through advertising, the nature of the optimal entry-deterring strategy is a priori ambiguous. Patent-holding firms might overinvest in advertising in order to build up brand-loyalty and thereby make generic entry less profitable. However, because advertising may partly benefit generic entrants, through market expansion and relaxed price competition, the optimal entry-deterring strategy might instead be to underinvest in advertising.

Finally, although the results are somewhat mixed and inconclusive, the empirical literature on strategic entry deterrence in pharmaceutical markets does not seem to produce very strong evidence that brand name advertising deters entry.

Aging: Health at Advanced Ages

GJ van den Berg, University of Mannheim, Mannheim, Germany; IFAU Uppsala; VU University Amsterdam, and IZA
M Lindeboom, VU University Amsterdam, HV Amsterdam, The Netherlands

Introduction

This article examines how health and mortality at advanced ages evolves from conditions early in life. Here, the authors summarize the findings, examine econometric strategies to identify causal effects, and discuss the implications of the findings for public policies aimed at improving population health.

The larger part of health care that individuals consume during their life course is concentrated in the final few years of their life. Proximity to death may be the driving factor of these costs, but age may also have an additional effect on healthcare spending. The latter view is in line with a simple health capital model and implies that in the context of the trend toward aging, increases in healthcare costs are to be expected. More in general, healthcare costs across cohorts vary if mortality and morbidity rates differ across age cohorts. A second empirical observation is that health is known to be very unevenly distributed at advanced ages.

Socioeconomic differences are important determinants of late-life health variation across individuals. There is a strong connection all over the industrialized world between an individual's current socioeconomic status (SES) and his/her current health (the association between income and health is commonly denoted as 'the gradient'). The magnitude of this gradient differs across countries, and SES-related inequality in health has increased over the past decades. Clearly, the statistical relation between SES and health can also be explained by a reverse causality from health to SES, or by a mutual dependence of SES and health on common determinants such as genetic characteristics, education, or conditions early in life. This naturally leads to a dynamic view in which causal pathways between various factors may create associations between SES and health at different stages of life.

Recent evidence suggests that much of the association between SES and health during middle age and old age is driven by a causal effect of health on SES, rather than the other way. Furthermore, already at relatively young ages, substantial health differences exist between different SES groups. Recent papers in this area (see Van den Berg and Lindeboom, 2007, for a survey) suggest that the determinants of health and SES-related differences in health may originate earlier in life. Heckman *et al*. (2006) show that "early intervention programs targeted to disadvantaged children have had their biggest effect on noncognitive skills: motivation, self-control, and time preference," and that these noncognitive skills are powerful predictors of educational attainment, lifestyle, and health behaviors. Their work also shows that for severely disadvantaged children early-childhood interventions are important and can have a long-lasting effect on cognitive and noncognitive functioning.

Motivated by the above, the authors therefore start with a discussion of the relationships between conditions early in childhood and later-life health. Section Causal Effects of Early-Life Conditions reviews the epidemiological and economic literature in this field, presents evidence of the importance of early-childhood conditions for later-life outcomes, discusses the methodological problems in this area when researchers have to rely on observational data, and proposes appropriate research designs that allow one to assess the causal effect of early-childhood conditions on health and mortality later in life. Section Indirect Effects: Causal Pathways from Early Childhood by Way of Education to Later-Life Morbidity and Mortality discusses mechanisms that may underlie the causal effect of early-childhood conditions, focusing on the role of education. Section Summary and Implications for Health Policy concludes and addresses policy implications.

Causal Effects of Early-Life Conditions

Empirical Approaches and Empirical Findings

For expositional reasons, this section begins with a subsection on the methodological approaches used in the empirical literature to detect long-run effects of early-life conditions. This includes a discussion of empirical findings that capture the overall causal effect. The overall effect can be a direct causal effect or it can be the result of a causal pathway that involves intermediate events during life. Section Direct and Indirect Long-Run Effects discusses the difference between direct and indirect effects in more detail. Section Indirect Effects: Causal Pathways from Early Childhood by Way of Education to Later-Life Morbidity and Mortality discusses empirical studies of indirect effects that include data information on events occurring along the pathway of interest.

A natural starting point to analyze whether early-life conditions are important is to compare health and mortality outcomes among elderly individuals who faced different living conditions early in life. Empirical studies have shown that adverse socioeconomic conditions early in life are associated with susceptibility to a wide range of health problems later in life. Similarly, medical studies have shown that individuals with a low birth weight (sometimes adjusted for gestation time) are more likely to suffer from health problems later in life.

Observed associations do not necessarily imply the presence of causal effects of early-life conditions. Individual socioeconomic and medical conditions during early childhood and health outcomes later in life may be jointly affected by unobserved heterogeneity. For example, certain genes may simultaneously influence the average level of the parents' income, the birth weight, and the health outcomes later in life. To be able to detect causal effects, one needs to observe exogenous variation in the early-life conditions, and relate this to outcomes later in life. In all fairness, it should be noted that

 doi:10.1016/B978-0-12-375678-7.00302-3

even if descriptive studies do not capture causal effects, they are still useful from an intervention point of view. Markers for unfavorable future health outcomes can be used as a flag for monitoring or initiating interventions to mitigate such outcomes.

A recent approach has recently become popular to detect causal effects, by using data on indicators Z of individual conditions X early in life with the following property: the only way in which the indicator Z can plausibly affect high-age morbidity or mortality Y is by way of the individual early-life conditions X. (An extreme example is where Z is the outcome of a lottery in which individuals with a baby may win some money. More common examples are given below.) By analogy to the econometrics literature, such indicators Z may be called instrumental variables. Typically, these are not unique characteristics of the newborn individual, his/her family, or household, but rather temporary characteristics of the macro-environment into which the child is born. In that case they are also called contextual variables. Indicators Z with the above 'exclusion restriction' property do not give rise to endogeneity and simultaneity biases, because they are exogenous from the individual's point of view. Moreover, they do not have direct causal effects on health later in life except through early-life conditions. If one observes an association between such an indicator Z and the health outcome Y later in life, then one can conclude that there is a causal effect of early-life conditions X on that health outcome Y.

In the current context, three types of such 'instrumental variables' Z may be distinguished. First is the season of birth. The idea is that the month of birth has no other effect on health outcomes later in life than by way of the early-life conditions of the child. Note that this requires that the composition of newborns is not systematically different across seasons, in terms of unobserved characteristics of the newborns. The literature has typically found significant effects of the season of birth on the mortality rate later in life, with an order of magnitude of a few months of extra lifetime if one is born in the fall, as compared with the late spring. In the southern hemisphere, these effects are mirror-imaged, in the sense that the effect of a month of birth is similar to the effect of the month half a year earlier or later in the other hemisphere. In equatorial areas, seasonal effects are in accordance to what constitutes the rainy (monsoon) and the dry season.

A second type of exogenous variation is provided by epidemics, wars, famines, and other disastrous events. Lumey *et al.* (2011) provide an excellent overview. For a recent example, see Lindeboom *et al.* (2010), who examine whether exposure to nutritional shocks early in life affects later-life mortality. They use historical data that include the period of 1845–48, which includes the Dutch potato famine. During this period, potato crops failed due to the Potato Blight disease and bad weather conditions. They found strong evidence for long-run effects of exposure to the Potato famine. The results were stronger for boys than girls and lower social classes appeared to be more affected than higher social classes. Studies based on the Dutch 'hunger winter' under German occupation at the end of World War II and on China's great famine indicated significant long-run effects on adult morbidity, but not on adult mortality. These studies confirmed that malnutrition has a separate effect on adult morbidity (and sometimes) mortality. Experimental animal research has also provided support for the theory that there are long-run effects of malnutrition during pregnancy.

Almond (2002) examines individuals born around the time of the 1918 influenza epidemic. He finds significant effects on the mortality rate later in life, and this finding has been confirmed by subsequent studies using epidemics. Similar to many of these studies, Almond investigates primarily the sign and significance of the mortality-rate differences between birth cohorts, and not the exact size of the effect. This is because the interest ultimately is not in the size of the effect of the indicator Z on the mortality rate, but in the issue of whether there is a causal effect from early-life conditions X on the mortality rate. Long-run effects may, of course, be nonlinear in terms of early-life conditions. In that case, the relevance of long-run effects of disastrous conditions may be limited, and may not lead to a full understanding of the effects of less spectacular variation in early-life conditions.

A third approach was pioneered by Bengtsson and Lindström (2000). They use the transitory component (or deviation) in the price of rye around the time of birth as an indicator of food accessibility early in life – any observed relation between this indicator and the mortality rate later in life signifies the existence of a long-run causal effect of food accessibility on mortality later in life. Similarly, the transitory component in the local infant mortality rate was used as an indicator of exposure to diseases early in life. This study uses data from a relatively small area in Sweden from the eighteenth and nineteenth centuries. The results indicate that individuals born in years with epidemics lived on average a few years less than otherwise, conditional on surviving the epidemic itself. Van den Berg *et al.* (2006) use the state of the business cycle at early ages as a determinant of individual mortality. Cyclical macroeconomic conditions during the pregnancy of the mother and childhood might affect mortality later in life because they are unanticipated and affect household income. In a recession, the provision of sufficient nutrients and good living conditions for children and pregnant women may be hampered. Van den Berg *et al.* (2006) find that the average lifetime duration in the Netherlands in the nineteenth century was reduced by approximately 1–3 years if the individual is born in a recession, as compared with having been born in a boom (under otherwise identical conditions during life, and conditional on surviving early childhood). Van den Berg *et al.* (2011) find analogous effects on cardiovascular mortality, using Danish data.

One important requirement for the analysis of causal long-run effects of early-life conditions is that the individual data cover a sufficiently long time span. After all, the dates of birth and death (or high-age health) must be observed for a substantial number of individuals. An implication of this requirement is that the existing studies have necessarily considered cohorts of individuals who were born a long time ago. In this sense, the most recent evidence comes from studies of individuals born in the Dutch hunger winter (1944–45) and from studies of more recent birth cohorts from developing countries. One way to circumvent this restriction would be to focus on adult health proxies such as adult height (see the upcoming sections).

Direct and Indirect Long-Run Effects

Empirical Approaches and Empirical Findings listed studies that use exogenous variation in the environment to show that there are causal effects from early childhood on later-life morbidity and mortality. The present subsection briefly sets out the main mechanisms underlying these long-term causal effects. Although there are many ways in which early-life conditions may affect outcomes later in life, it can be distinguished roughly between two main views.

First, adverse prenatal and postneonatal (from birth to 12 months) conditions can have a direct effect on later-life morbidity and mortality. The main idea is that the development of vital organs and the immune system is programmed when the body is exposed prenatally or just after birth to adverse conditions. According to the 'developmental programming' or 'fetal origins' hypothesis), this may lead to increased vulnerability to chronic diseases in later life. The most commonly mentioned factors mentioned in the literature are malnutrition and exposure to infectious diseases. Other factors are increased stress in the household and lower income to cover housing accommodation costs. Most of the empirical studies mentioned in this section are consistent with a direct effect. As it can be seen, in order to detect long-run effects, it is natural to focus on temporary shocks around the birth date. Any long-run effect found in this way could be a direct effect. Moreover, the estimated size of the mortality effects is usually moderate and in line with the medical evidence. The type of shock is informative regarding whether the effect concerns malnutrition, disease exposure, other adverse conditions, or just bad conditions in general.

Exposure to infectious diseases and malnutrition is likely to be less relevant for the developed world today than it was in the past. However, Bozzoli *et al*. (2009) recently examined the effect of income and disease exposure on adult height in populations, where height is used as a proxy for lifetime health. They use postneonatal mortality as a measure for nutrition and disease load in early childhood and examine their effect on height for cohorts born from 1950 to 1980 in the US and 11 European countries. They find a strong negative relationship between adult height and the burden of disease and malnutrition.

According to the second main view, adverse conditions early in life have indirect effects in that they may be the start of a causal chain of events or pathways during life that leads to worse health later in life. For instance, poor early-life conditions may lead to poor health early in life and later in childhood, which may affect educational outcomes and subsequently social status and health in adulthood. Or, more generally, a poor start may affect an individual's life career, which may ultimately lead to higher mortality rates. The authors discuss this view in more detail below, but before that it is good to note that some studies have stressed that it is the interaction with social factors later in life that determines whether people who are exposed to adverse early-childhood conditions will be more vulnerable to ill health in later life. For example, among individuals born in recessions, the decline in mental fitness after experiencing a negative life event at high ages (such as a stroke, surgery, illness, or death of a family member) is worse. Among women, marriage leads to increased mortality in child-bearing ages, but this increase is smaller if the woman was born under favorable economic conditions around birth, as captured by the business cycle early in life. In a similar vein, the body accommodates to stress, and that it is repeated stress that leads to higher risks of chronic diseases.

Indirect Effects: Causal Pathways from Early Childhood by Way of Education to Later-Life Morbidity and Mortality

Figure 1 shows the main causal pathways that are considered. Note that compared to all the previous sections, the setting has been expanded: it is not restricted to the pathways that can be tracked down to the causes early in life, but also other possible determinants of later health are considered. The direct effect that links infant health to later-life morbidity and mortality is not discussed explicitly here (see Section Causal Effects of Early-Life Conditions).

Note that the methodological complications in the case of indirect effects are even larger than in the case of direct effects. In the former case, most studies typically restrict attention to just one of the arrows in the diagram, conditioning on the individual position at the starting point of the arrow. In general, this starting position can be endogenously affected by earlier events in the life of the individual or by unobserved determinants that also have a causal effect on the outcome.

The Effect of Child Health on Educational Attainment

Quite a few studies in the development literature study the effect of child health or child nutrition on schooling outcomes. Ordinary least squares (OLS) estimates generally suggest a strong association between child health or nutrition and educational attainment. Several studies have tried to assess the causal effect of child health via Instrumental Variable approaches and sibling fixed-effect approaches. These studies seem to confirm the naïve OLS estimates, but the size of the effect is generally larger. Miguel and Kremer (2004) used a

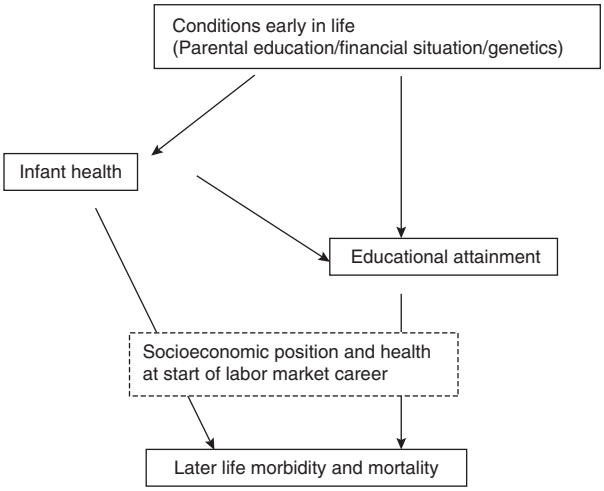

Figure 1 A graphic representation of the indirect effects of early-childhood conditions.

randomized experiment to evaluate a program of a school-based treatment with a deworming drug in Kenya and found that absenteeism in treatment schools was substantially lower than in comparison schools, and that deworming increased schooling by approximately 1 month per pupil treated.

The literature for developed countries is small. Case *et al.* (2005) used British data from the Child Development Study to look at (among other things) the effect of childhood health on educational attainment. They found a strong association between childhood health and later educational attainment. It appears that the presence of chronic conditions in childhood has a stronger impact on educational attainment than does health at puberty. Their conclusion: the negative effect of bad health is cumulative in its effect on education. These results are based on observational data that follow a single cohort, which makes it difficult to make causal statements. Case and Paxson (2006) use adult height as a measure for childhood conditions and childhood health, and find that the height premium in adulthood (i.e., better labor market outcomes for taller people) can be explained by childhood scores on cognitive tests and by the fact that taller children selected into occupations that have higher cognitive skill requirements. Currie and Stabile (2003) examine the relationship between several common health disorders, such as attention deficit hyperactivity disorder (ADHD), depression, anxiety, and aggression, on future educational outcomes. They conclude that early-childhood mental health problems affect educational outcomes and that there is little evidence that income protects against the negative effects of mental health. A recent and innovative approach of Ding *et al.* (2006) focuses on a specific set of conditions (ADHD, depression, and obesity), and uses genetic markers that strongly predict these conditions as instruments. They find strong effects of these health conditions on student grade point averages. The larger part of this effect seems to be driven by the effect for females; for males they find no effect.

The Effect of Education on Later Health and Mortality

Since Cutler and Lleras–Muney (2007) recently provided an excellent review of the literature on education and health, there is no need to fully review the papers discussed in their study, and can be drawn from their findings. Cutler and Lleras Muney performed some analyses of their own that confirm the strong association between education and (later-life) health. There is evidence for a causal effect of education on health. The most convincing evidence comes from studies that use changes in minimum schooling laws. This implies that one can make statements about the effect of additional schooling only regarding those who are at the bottom of the schooling distribution. Identifying which mechanisms generate these causal impacts remains speculative. The better educated have the better jobs and higher incomes, which may lead to better health and lower mortality rates at later ages. Case and Deaton (2003) find that people in manual occupations have worse self-reported health, and that there is a greater rate of health declines in these occupations. Their argument: much of the differences in health are driven by health-related absence from the labor force. Smith (2005) found that current and lagged financial measures of SES have no effect on future health, but that education does. This holds for older and for younger workers, thereby suggesting a potentially important role for factors such as the rank in the social distribution, the ability to process information and health behaviors.

The Whitehall studies of British civil servants show that morbidity and mortality fall with increases in social class. A low position in the social distribution leads to low control and high (job) demands, which in turn lead to stress, which puts workers at risk for cardiovascular disease. There is a strong relation between a measure for control and cardiovascular disease risk and this relationship also holds for non-civil servants. Cutler and Lleras–Muney (2007) argue that social position cannot be the main determinant of SES-related health differences. Life expectancy has increased in the developed world over the past three decades, although income inequality and crime have increased and social networks generally have become smaller. Also, some studies have shown that there are gradients in diseases that are not related to stress.

Schooling provides individuals with skills that help them acquire and process information, which helps them make better decisions. For example, consumer health information has been shown to increase the demand for medical services. More information increases the probability of care use, but conditional on care use, the quantity of care use is not related to information. Apparently, poorly informed consumers tend to underestimate the productivity of medical care in treating disease. However, differences in knowledge by SES create only modest differences in health behaviors by SES. Indeed, as noted by Cutler and Lleras–Muney (2007), although both educated and uneducated people today are well aware of the dangers involved with smoking, smoking is still more prevalent among the uneducated. Of interest is whether this association between smoking and schooling is causal, and if so, what mechanisms drive this effect. This can be addressed using Vietnam draft-avoidance behavior as an instrument for college attendance. The cohort of males born between 1945 and 1950 could avoid the Vietnam draft by enrolling into college, and this can be used as an instrument for college enrolment. The female cohort born between 1945 and 1950 can be used as a control group. It turns out that the level of education does causally affect smoking, and that those who initiated smoking are more likely to stop once they enter college. Peer effects or endogenous time preferences are likely to be important determinants. Improved information-processing capabilities due to increased schooling do not seem to be important. Subjective time discount rates are not related to smoking, but more general measures of time preference and self-control, such as impulsivity and financial planning, are related to smoking.

Summary and Implications for Health Policy

The literature suggests that long-run effects of early-childhood conditions are important for morbidity and mortality later in life. There are roughly two channels: direct long-run effects due to 'programming,' and indirect effects via education, health, and SES at different points in the life course.

Direct effects are likely to be quantitatively relevant for developing countries, where exposure to extreme conditions is more common, and where behavior later in life may be less successful in mitigating early-life effects. There are, however, some other studies that point toward the relevance of environmental insults, disease exposure and malnutrition for cohorts born in the twentieth century in developed countries. Of importance for *healthcare* policy is that this suggests that one can expect mortality differentials across different cohorts and that the younger cohorts do not necessarily live longer in better health. Also, policies focused on vulnerable families (those living in poor circumstances, exposed to stress, and employing bad health behaviors) can be effective in improving the health of the next generation.

Childhood conditions may affect child health, and this may persist into adulthood. The evidence on the effect of family income is mixed, at least for developed countries – although any effect that might be found is expected to be modest. Most studies point at a potentially strong role for the family-specific environment. This includes parenting skills, health behaviors, and maternal and paternal health. Maternal health is probably the most important determinant for child health. This does not mean that there is no role for health policies. Policies aimed at improving the health of young adolescents can be effective in improving the health of the next generation. These interventions may reverse the impact of a poor start early in life and improve health in adolescence and beyond.

Education is undoubtedly one of the strongest determinants of health in later life. Education increases income and labor market opportunities and positively affects health-enhancing behavior. The effect of education on health behavior is causal and likely to be of core importance for health later in life. Policies focusing on educational outcomes should intervene at early ages. Recent work Heckman *et al.* (2006) shows that early intervention programs targeted to disadvantaged children have their biggest impact on noncognitive skills such as motivation, self-control, and time preference. Studies cited in The Effect of Education on Later Health and Mortality show the importance of these factors for health behaviors. Heckman *et al.* (2006) show that these noncognitive skills strongly influence schooling decisions and later wages.

In sum, with new cohorts one should focus on early health and education interventions. It would be useful to screen babies and young children at their household circumstances, to determine whether nutrition, heating, stress levels, and other indicators are at acceptable levels. Programs targeted to children of disadvantaged households should be implemented at an early age. Among existing cohorts, it is useful to screen individuals born in particularly adverse conditions, to verify whether they are susceptible to cardiovascular disease and other diseases thought to be programmed early in life.

It is important to emphasize that even if early-life conditions have a small overall effect on the per-period morbidity or mortality rate later in life, it may nevertheless be very important from a policy point of view to intervene in the lives of individuals with an adverse starting position. After all, the benefits of such interventions will be reaped over a very long time period, and intervention is facilitated by the fact that there is a time interval in between a particular cause and the moment its effect materializes. This is quite different from the instantaneous effects of current events on the health of elderly individuals, like a summer with unusually high temperatures. Such instantaneous effects may be large, but they may be relevant only over a short period, and policy makers would have to react very quickly to prevent the negative health implications.

Alcohol

C Carpenter, Vanderbilt University, Nashville, TN, USA

Introduction

Alcohol is extremely prevalent in contemporary society. According to the World Health Organization, in 2005 the per capita alcohol consumption totaled 6.13 l of pure alcohol for every person age 15 and older worldwide. More than a quarter of this consumption is estimated to be from illegal or homemade production and thus not likely to be reflected in standard statistics on alcohol sales. People in the developed world drink much more heavily than people in less developed places such as sub-Saharan Africa. Populations with strong religious prohibitions on drinking (e.g., the Islamic faith) also exhibit much lower drinking rates. Beverage type varies substantially throughout the world: In many European and South American countries, wine is the primary alcoholic drink consumed. In the Western Hemisphere, Northern Europe, and Australia, beer is the most widely consumed alcoholic beverage. For example, in the US a little more than half of total alcohol sales is attributable to beer, approximately a third is spirits, and the remainder is wine. Worldwide, however, nearly half of the total consumption is attributable to neither beer nor wine but rather spirits (which is more common in southeast Asia).

Alcohol consumption has remained relatively stable throughout the world since 1990. With respect to demographic patterns worldwide, men are much more likely to drink and to drink more heavily than women, although it is notable that almost half of all men and two-thirds of all women in the world did not consume alcohol in the past 12 months. Heavy episodic drinking varies substantially across the world in complex ways. For example, it is not always the case that high per capita consumption is associated with higher rates of heavy episodic drinking: Many Western European countries, for example, have very high per capita consumption rates despite having low heavy episodic drinking rates, suggesting that patterns of drinking in those countries are more moderate. Moreover, it is not always the case that higher income countries have higher rates of heavy episodic drinking within a broad geographic area: In Europe and the Americas, for example, heavy episodic drinking is more prevalent in the lower income countries, whereas in Africa and southeast Asia, the relationship is reversed.

Alcohol consumption has both positive and negative aspects. The positives derive from the fact that people enjoy consuming alcohol, moderate alcohol has been suggested to have some health benefits, and there is ample evidence that drinkers earn more than abstainers in developed countries. The most commonly cited negatives include the problem that some of the social aspects of drinking and the direct pharmacological effects of alcohol can lead to a variety of adverse outcomes such as premature death and illness, crime, risky sexual activity, and alcohol dependence. Economists and economics have played an important role in informing the policy and academic debate about alcohol use and alcohol control by providing a conceptual framework for evaluating not only the costs but also the benefits of alcohol use when thinking about optimal alcohol control and by measuring and testing the relationships among alcohol use, alcohol control policies, and outcomes. This article discusses the economics of alcohol use and alcohol control policies and provides a very broad summary of what is known about the causes and consequences of alcohol consumption.

Alcohol's Pharmacological Profile

A substantial portion of the economics research on alcohol addresses whether and to what extent alcohol causes adverse outcomes such as premature death and morbidity. The most prominent channel through which these adverse events are thought to occur is biological. People's 'blood alcohol concentration' (BAC) from drinking affects their level of impairment. The most important determinant of impairment is the size of the dose. The number of drinks consumed, the speed with which they are consumed, and the alcohol content of the drinks are the major determinants of the dose. Dose size is moderated by numerous individual characteristics. Heavier and more muscular individuals have more water mass and as a consequence will reach a lower BAC than a smaller, less muscular individual who has consumed the same amount of alcohol. Individuals also differ substantially in the rate at which the liver metabolizes alcohol. For example, there is evidence that older individuals metabolize alcohol more slowly than younger individuals and that chronic drinkers metabolize alcohol more rapidly than less frequent drinkers.

Generally speaking, a 160 lb man will reach a BAC of 0.02% (or 2 g per 100 mm of blood) after one standard-sized drink (roughly one shot (1–1.5 oz) of liquor, one 12 oz beer, or one 5 oz glass of wine). That same man will reach a BAC of 0.05%, 0.07%, 0.09%, and 0.12% after two, three, four, and five drinks, respectively, and will accordingly reach increasingly higher BACs with successive drinks (assuming no time between drinks). A similarly sized woman will, on average, reach a higher BAC after the same number of drinks due to sex-specific differences in body composition.

Though the exact level of impairment at a given BAC varies from person to person, intoxication due to alcohol usually follows several stages associated with different BAC levels. At low BACs (below 0.05%), alcohol can induce enjoyment, happiness, and euphoria characterized by increased sociability and talkativeness. Loss of inhibitions and reduced attention are also characteristic of this level of intoxication. At higher BACs (0.06–0.10%), disinhibition is more apparent, as are impairments in judgment, coordination, concentration, reflexes, depth perception, distance acuity, and peripheral vision. Because these impairments can be dangerous in certain environments, many countries set the BAC at which a driver is considered legally impaired at approximately 0.05% or 0.08%

(and often lower for younger or less experienced drivers). In the range 0.11–0.30% BAC, individuals experience exaggerated emotional states, including anger and sadness; they may also have a higher pain threshold, reduced reaction time, loss of balance, slurred speech, and moderate-to-severe motor impairment. At extremely high BACs (above 0.35%), individuals are likely to suffer from incontinence or impaired respiration, or they may lose consciousness and even die from respiratory arrest. For lower levels of BAC, many of the effects have been documented in controlled laboratory settings, particularly impairments of driving-related skills and tasks, as well as aggression.

Alcohol's pharmacological profile is distinct from that of other commonly consumed drugs. Probably the closest to alcohol in its pharmacological effects is cocaine, which has similarly been shown to increase aggression, reduce self-control, and increase irritability. Amphetamines can also produce an increase in aggression; however, unlike the aggression induced by alcohol, it is sometimes accompanied by a paranoid psychotic state that may independently contribute to violent acts. In contrast, marijuana has generally been found to inhibit (rather than promote) aggressive behavior in humans, mice, and primates. Similarly, opiates have been shown to decrease aggressive behavior and hostility in animals and humans, though the period of opiate withdrawal is usually characterized as increasing risk for aggressive behaviors. Thus, alcohol has a pharmacological profile that is significantly different from that of the most commonly consumed illicit drugs.

The differential pharmacological effects of alcohol and other drugs on human behavior raise a potentially important issue regarding the economics of alcohol regulation. Specifically, it is possible that alcohol use is fundamentally linked to the use of other drugs. If alcohol and other drugs are complements in consumption, then an increase in the price of alcohol (through, e.g., stricter regulations) will reduce not only drinking (through the own-price effect) but also the use of other drugs (through a cross-price effect). In contrast, if alcohol and other drugs are substitutes in consumption, then an increase in the price of alcohol will reduce drinking but will lead to an increase in the use of other drugs. Existing research is mixed on this question, but these relationships are important to consider when designing optimal alcohol control policies because the effects of those policies on the use of other drugs – and the independent effects of other drug use on outcomes – need to be acknowledged.

Economics Perspectives on Alcohol Use and Alcohol Regulation: Distinguishing Factors

Economics may not be the first discipline that comes to mind as relevant for studying alcohol. As such, it is useful to clarify the distinguishing characteristics of the economics way of thinking that are relevant for understanding this important topic. Arguably one of the most important distinctions is that economists put value not only on the costs of alcohol consumption in terms of productivity losses, health impairments, and criminality but also on the benefits of alcohol consumption. That is, a great deal of alcohol consumption is utility increasing, and these benefits of drinking must be taken into account when considering tighter restrictions on alcohol availability. The public health tradition, in contrast, generally calls for stricter alcohol control to reduce alcohol-related harms without consideration for the benefits of drinking that accrue to most moderate drinkers. Economics recognizes that adoption of stricter alcohol control policies for the purposes of harm reduction imposes deadweight loss on moderate, responsible consumers. Higher taxes, for example, may reduce alcohol consumption by people whose drinking causes them to be at risk for adverse health events or to commit crime but may also reduce the consumption by law-abiding drinkers. Because a large share of the population consumes alcohol and does so in a responsible way, the foregone value of alcohol consumption by this group cannot be easily dismissed.

This does not mean that economists oppose any move to tighten alcohol restrictions. But the discipline does provide a unified framework for thinking about the conditions under which government intervention in the form of alcohol control may be justified. Specifically, if drinkers impose costs on other members of society (e.g., an alcohol-involved driver may kill or injure someone, or a drinker may commit a crime against someone), it is said that the marginal social costs of alcohol are greater than the private costs (i.e., there is a negative externality), leading unregulated private markets to result in too much alcohol consumption and resulting in alcohol-related harms. In this case, economics theory justifies correcting this behavior in a variety of ways. Next, a host of alcohol control regulations are described that have been proposed and adopted across many places and that deal with the negative externality problem in very different ways. It is important to remember, however, that because economists value both the benefits of drinking and the harms, the socially optimal level of alcohol consumption and alcohol-related harms will be lower than in a completely unregulated environment but will be strictly positive.

A final distinguishing feature of the economics tradition with respect to research on alcohol use and alcohol control is that the discipline of economics has been a leader in the social and public health sciences in advancing methodologies regarding causal inference. In many cases, including alcohol consumption, researchers are faced with the problem that observed associations between a treatment (here, drinking) and an outcome (e.g., death, illness, productivity, crime, etc.) may be simultaneously determined. That is, factors that affect the treatment may independently affect the outcome. In the case of drinking and adverse health outcomes, for example, one might worry about population heterogeneity in risk attitudes and discount rates (i.e., how much people trade off utility today against utility at a later date). It could be that heavily discounting the future causes people to both consume alcohol and engage in other risky behavior that puts them at risk of an adverse health event. If so, one might observe that people who drink are at an increased risk for adverse health events even if there is no direct causal effect of alcohol. Put differently, those same people might have experienced the adverse health event even in the absence of their drinking; alcohol consumption and adverse health events may both simply reflect their high discount rate. To see the importance of disentangling correlation from causation, note that alcohol

availability can be (and is) regulated by local, state, and federal governments. If the correlations between alcohol use and adverse events are not causal, then tighter alcohol control will not be an effective means to improve population health; if, in contrast, alcohol use does cause adverse events, then stricter alcohol policies can be expected to reduce not only drinking but also subsequent adverse outcomes. The relative importance of distinguishing correlation from causation varies dramatically across disciplines, with economics very much at the end of the spectrum that cares deeply about this distinction. Public health, health services research, and sociology do not place as much of a premium on this component of research; in these traditions, detailed descriptive analyses of associations between alcohol use and individual-level factors are more common.

How do economists deal with the evaluation problem (sometimes referred to as 'omitted variables bias,' 'unobserved heterogeneity bias,' 'endogeneity bias,' 'simultaneity bias,' and others) when treatment assignment is nonrandom? First, note that the ideal solution to nonrandom treatment assignment commonly used in the natural sciences is to randomize treatment and compare outcomes between the treated and untreated; because the treatment assignment was manipulated to be random, the difference in outcomes can be causally attributable to the treatment. In the real world, however, researchers cannot randomize alcohol consumption, and so social scientists have had to take different approaches. One is to try to control for as many of these omitted factors as possible in regression models either directly or through the use of single indices such as propensity scores; these approaches are common in health services and some economics research. In the past few decades, however, economists have pushed for stronger research designs that mimic the experimental variation in the natural sciences. This class of methods, commonly referred to as 'quasi-experimental' approaches, includes difference-in-differences (DID), instrumental variables (IV), and regression discontinuity (RD) approaches, among others. When applied appropriately, each of these designs isolates variation in the treatment that is thought to be 'exogenous to outcomes' or to create variation in treatment that is 'as good as random' for some subpopulation of interest, thus overcoming the omitted variables bias problem. An example with respect to alcohol availability, alcohol consumption, and outcomes is research that has capitalized on labor strikes for workers at government-run liquor stores in Scandinavia (where the government owns a liquor monopoly), which exogenously reduced alcohol availability, alcohol consumption, and subsequent alcohol-related problems. These rigorous standards for identification of treatment effects also distinguish the economics approach to studying alcohol consumption and alcohol control from other disciplinary traditions.

Alcohol Control Policies and Alcohol Consumption

A great deal of economics research on alcohol use has focused on estimating the effects of alcohol control policies on alcohol consumption, both because this type of policy evaluation is independently interesting and because many policy-induced changes in alcohol consumption can be used to identify causal effects of alcohol use on outcomes (e.g., mortality and morbidity). Research on alcohol control policies is particularly appealing to economists because of the fundamental tenet in economics that demand curves slope downward. That is, the price of a commodity and the quantity demanded of that commodity are inversely related. In the context of alcohol consumption, this means that policies and practices that raise the full price of drinking either directly (e.g., through alcohol taxes, which are passed through to consumers in the form of higher alcohol prices) or indirectly (e.g., through other types of availability restrictions) should reduce the quantity of alcohol consumed. Although alcohol taxes are probably the most widely studied alcohol control policies in the economics literature (and have been summarized in multiple recent meta-analyses), many others have also received scholarly attention, including the presence of government liquor monopolies; age-based alcohol availability restrictions (e.g., minimum legal drinking ages (MLDAs)); drunk driving laws (e.g., BAC limits, driver license suspensions, random breath tests, and sanctions/penalties for driving under the influence); spatial restrictions on alcohol availability (e.g., liquor license restrictions); temporal restrictions on alcohol availability (e.g., Sunday alcohol sales bans or bar/pub closing hours); advertising and sponsorship restrictions (including health warnings); other 'circumstance' regulations such as prohibitions on alcohol sales at sporting events; and legal liability for bartenders and bar owners for serving intoxicated persons, among others.

The most common approach taken in this literature to test whether the demand curve for alcohol slopes downward has been to relate drinking rates (using either individual-level survey data on alcohol consumption or aggregate data on alcohol sales) to variation across places in the alcohol control environment at a point in time. This approach is made possible by the fact that places (e.g., localities, states, provinces, countries, etc.) vary substantially in their chosen menu of alcohol control policies. For example, some places have higher alcohol taxes and/or severe penalties for alcohol-involved driving compared to other places. A finding that drinking rates are lower in places where alcohol is more difficult to obtain (i.e., where individuals face higher full prices to drink) is usually taken as evidence that demand curves slope downward, or that drinking is negatively related to price.

One weakness of the type of approach described in the previous paragraph is that the types of designs that rely on variation across places at any one point in time may suffer from the omitted variables biases. For example, if places that are very religious are the ones that are more likely to have high alcohol taxes and strict availability restrictions, then the inverse relationship might be observed between the full price of obtaining alcohol and drinking rates that is due to the religious attitudes of people in that area, not due to the policies and prices themselves. This criticism has in the past decade led economists to incorporate other types of research designs commonly found in other applied microeconomics disciplines (most notably labor, public, and development economics). As such, the more commonly accepted standard for evaluation research on alcohol control policies and alcohol consumption is to compare changes in drinking rates coincident with changes in alcohol control policies (e.g., alcohol

excise tax increases or tightening of availability rules). The advantage of this 'changes on changes' or 'DID' type of specification is that, because areas usually adopt different alcohol control policies at different times, researchers can use the staggered timing of adoption to rule out the possibility that permanent unobserved differences about individual places are driving the observed relationships between alcohol prices (broadly defined) and alcohol consumption. In practice, this amounts to including dummy variables, or fixed effects, for each area in multivariate regression models of drinking that include controls for area-specific alcohol policies.

Results from this and other types of quasi-experimental approaches have been somewhat less conclusive about the role of alcohol taxes in determining alcohol consumption behaviors, in that they have not uniformly returned evidence of significant relationships between alcohol excise tax increases and alcohol consumption decreases, particularly for research on youths and for research focusing on the US. Part of the lack of clarity around the effects of alcohol taxes on consumption is that in the US there have been relatively few large alcohol tax increases in the past three decades; by construction, this makes estimating difference or change-based models more difficult. (The lack of alcohol tax change variation is notably different from the case of tobacco.) Similarly, studies of spatial, temporal, and other 'circumstance'-type regulations of alcohol availability have not produced overwhelming evidence that these policies seriously affect overall alcohol consumption, which is perhaps not surprising because it is not particularly costly to undo the effects of these types of restrictions (e.g., purchasing alcohol on Saturday can undo the effects of a Sunday alcohol sales prohibition). There is, however, ample evidence from these types of stronger designs that age-based alcohol restrictions (such as MLDAs) causally reduce alcohol use. For example, research in the US has shown that state experimentation with lower drinking ages in the 1970s and early 1980s led to higher drinking rates among youths who were newly legal to drink, and similarly state increases in drinking ages back to age 21 (the current MLDA in the US) led to lower drinking rates among youths who were no longer legally allowed to drink. Moreover, research has also shown that alcohol use increases sharply and discretely exactly at a country's MLDA, even when other policies do not change discontinuously at the same threshold. This further bolsters the idea that minimum drinking age policies causally reduce alcohol consumption. Because drinking ages affect the total price of obtaining alcohol through time and convenience costs for youths who are too young to legally consume alcohol, studies of minimum drinking ages have played an important role in confirming that demand curves do, indeed, slope downward for alcohol.

Finally, it can be noted that research exploiting changes in place-specific alcohol control regulations to identify the effects of higher effective prices for obtaining alcohol on drinking rates – with improvements over comparisons of drinking rates across areas at a point in time – are not a panacea. Specifically, these studies must also contend with the fact that alcohol policy changes may themselves likely be the result of unobserved population preferences, because in democratic societies voters elect officials who make or change policy. If sharp changes in attitudes toward alcohol underlie the changes in alcohol control policies, then studies using DID can still be biased. In this situation, other strategies that are less prone to these criticisms, such as RD or IV, can be useful alternatives.

Causal Effects of Alcohol Consumption on Outcomes

The other area where economists have contributed substantially to the literature on alcohol is in estimating causal effects of alcohol consumption on outcomes. Adverse health events such as mortality, crime, and risky sexual behavior are the most widely studied outcomes, and the pharmacological profile of alcohol consumption makes a causal role for alcohol in determining each of these outcomes eminently plausible. Of course, extreme alcohol consumption can directly lead to respiratory failure and death. But there are many other pharmacological mechanisms as well. By reducing reaction time and peripheral vision, alcohol-involved driving can directly increase motor vehicle fatality risk. By altering perceptions of right and wrong and compromising a person's ability to reason through the consequences of one's choices, alcohol consumption can increase risk-taking that could lead to many other types of nonvehicle-related accidents and to the commission of several types of crime. By increasing aggression and exaggerating emotional state, alcohol consumption can increase the likelihood individuals will commit a violent crime. By incapacitating a person, alcohol consumption can increase criminal victimization risk. And the social aspects of drinking can put people in situations that independently increase their risk of an unwanted physical or sexual encounter. All of these channels make it plausible that alcohol use can cause adverse events.

The plurality of research studies in economics examining the effects of alcohol have examined mortality as the outcome of interest. Although mortality is rare, it is very well measured and is an unambiguously negative outcome. Mortality also has the advantage that certain types of deaths are more likely to be alcohol related than others, for example, motor vehicle fatalities are far more likely to be attributable to alcohol than cancer deaths, and studies of the blood alcohol levels of decedents show that very high proportions of deaths from suicide, falls, drowns, burnings, and other 'external' causes are alcohol involved. This means that a relationship between alcohol prices and policies and deaths that are more commonly thought to be alcohol related can provide stronger evidence of a causal role for alcohol use in mortality events. Motor vehicle fatalities are by far the most commonly studied mortality outcome; in the US these data provide the additional advantage that accident characteristics such as time (e.g., nighttime vs. daytime) and day (weekend vs. weekday) can strongly correlate with the likely involvement of alcohol as a contributing factor. Morbidity and nonfatal injury share many of these same benefits (to researchers) as mortality, but availability of comparable large-scale morbidity data spanning multiple places and time periods has been much sparser in the past three decades (with a few exceptions such as occupational and workplace injuries, which are tracked administratively).

Many economics studies report that areas with higher alcohol taxes or stricter alcohol availability regimes have lower motor vehicle fatality rates, though as with the alcohol

consumption evidence, studies in this literature have not uniformly shown that alcohol excise tax increases lead to significant motor vehicle mortality decreases. Other quasi-experimental approaches, however, have strongly demonstrated that higher full alcohol prices reduce mortality. For example, economics research has used DID approaches to demonstrate that higher (lower) drinking ages reduce (increase) motor vehicle fatalities in the age groups newly illegal (legal) to drink that are likely to have involved alcohol. More recently, RD approaches have also shown that mortality rates for motor vehicle deaths and suicides increase discretely at the MLDA, suggesting a causal role for alcohol in these mortality events. Perhaps not surprisingly, drunk driving laws such as state movements to lower legal blood alcohol-content thresholds have also been shown to directly and significantly reduce motor vehicle deaths likely to have involved alcohol.

Of the other adverse outcomes associated with (and possibly caused by) alcohol consumption, crime and risky sexual behavior have received the most attention from economists. Both of these outcomes have the advantage over mortality that they are very common events routinely associated with alcohol. Indeed, vast public health literatures show that individuals who consume alcohol are more likely to commit crime, more likely to have been arrested for a crime, more likely to be victims of crime, more likely to have engaged in sexual activity, more likely to have engaged in sexual activity at an earlier age, more likely to have had unprotected sex, more likely to have had an unplanned pregnancy, and more likely to have had a complicated birth. To what extent are these relationships causal effects of alcohol use?

Several studies have used the money price of alcohol in an IV framework to try to disentangle alcohol's causal role in crime and violence. These studies generally find that individuals in places with low alcohol taxes are more likely to drink, more likely to commit intrahousehold violence, more likely to get into physical fights, and more likely to carry weapons, though concern about omitted variables biases from using cross-sectional variation in alcohol taxes and prices to identify these effects is a serious issue. However, multiple economics studies have used DID methods to examine whether alcohol price increases lead to crime decreases, and these studies have found evidence supporting a causal effect of alcohol availability on certain types of crime – especially violent crime. Studies of drinking ages using the similar approach of relying on state policy changes have also provided evidence that alcohol availability is causally related to crime, and more recent research also using the minimum drinking age in an RD framework has shown that arrests increase discretely at the MLDA – further evidence for a causal effect of alcohol use on the commission of crime.

Economists have also studied alcohol's causal role in sexual activity using quasi-experimental approaches and have found some evidence that alcohol taxes are negatively related to the probability of sexual intercourse and are positively related to the likelihood of using condoms during intercourse. Other economics research has documented a negative relationship between the full price of alcohol and both teen birthrates and rates of sexually transmitted infections such as gonorrhea and syphilis, including in models that rely on changes in alcohol prices and policies for identification of alcohol's effects. Arguably stronger evidence for such a relationship comes from research designs based on drinking ages, as these studies have shown that youths exposed to relatively more lenient drinking ages were more likely to have births than otherwise similar youths who came of age in the same state but just a few years before or after and who were exposed to relatively less lenient drinking ages. Because these youths are likely to be very similar on observed and unobserved dimensions, omitted variables bias concerns are mitigated.

In summary, much of the economics literature addressing the causal effects of alcohol use on adverse outcomes has used a variety of quasi-experimental approaches to try to overcome the potentially severe omitted variables bias concerns. These studies have had mixed success in relying on tax-induced variation in alcohol consumption, in part because large alcohol tax changes have historically been rare (at least in the US); often this has translated into precision challenges for research designs that rely on alcohol tax variation. Studies employing alternative alcohol control policies such as drinking ages have produced stronger evidence in this respect, both because there are many policy changes to work with and because multiple age-based designs can be used (e.g., DID and RD approaches). Of course, drinking-age-based designs do not necessarily tell much about the effects of alcohol at higher points in the age distribution, so more research is needed on these important questions.

Finally, it is important to note that alcohol may also have causal effects that are positive, not negative. For example, drinkers earn more than abstainers, and part of this may reflect a causal effect of drinking (plausibly related to social interactions in certain types of occupations). Similarly, very large observational studies in public health have shown that moderate alcohol consumption is associated with reduced risk of heart disease mortality, giving rise to the oft-cited benefits of a glass of wine per day. This too may reflect a causal beneficial effect of alcohol on health (biological mechanisms include the possibility that alcohol reduces plaque deposits in the arteries and reduces the risk of blood clots). Economics research on these plausible benefits of drinking is much less complete than on the costs of drinking, in part perhaps because the types of designs that can provide relatively compelling evidence on causality are better suited to well-measured acute events such as deaths and arrests (as opposed to longevity or earnings, which are more likely the product of a series of important decisions and outcomes). Understanding whether and to what extent alcohol has causal effects on beneficial outcomes is an important area for research.

Conclusion

Economists have contributed greatly to the study of alcohol availability, alcohol consumption, and alcohol regulation. Key to the economics framework is a complete accounting of both the costs and the benefits of drinking, which has important implications for government intervention to correct negative externalities associated with alcohol consumption. Economists have also distinguished themselves among the social and public health sciences by advancing methodological rigor with respect to causal inference. Arguably the strongest consistent finding in

the broad economics literature on alcohol is that demand curves for alcohol slope downward: increases in the price of alcohol (broadly defined to include increases in both monetary prices and other nonmonetary costs of drinking) are negatively associated with the probability and frequency of drinking and with the quantity of alcohol consumed. Research has also credibly demonstrated that alcohol availability and alcohol consumption are causally related to increased risk of premature death, and there is growing evidence that drinking also causes individuals to be at increased risk for nonfatal injury, crime, and risky sexual behavior. More work is needed to understand whether and to what extent alcohol may have causal effects of improving (rather than harming) some health and social outcomes, as well as to understand the extent and nature of heterogeneity in the effects of alcohol control policies on drinking and health outcomes.

Ambulance and Patient Transport Services

Elizabeth T Wilde, Columbia University, New York, NY, USA

Introduction

Ambulance and Patient Transport Services include Emergency Medical Services (EMS) and private ambulance services, which supply emergency prehospital care, including basic medical support and roadside transport to hospitals for patients experiencing medical emergencies. In recent years, a number of economists have written thoughtful and careful papers on EMS; this article will summarize their work and the work of others who write on EMS topics of interest to economists. Sections Taxonomy of Ambulance and Patient Transport Services and US Emergency Medical Services contain an introduction to EMS. Section Private Provision of Emergency Medical Services, describes the work analyzing the decision to outsource EMS. Section Factors Affecting Quality of Care, summarizes the existing evidence on supply side factors affecting the quality of care. Section Quality of Care and Health Outcomes describes research on the relationship between quality of care and health outcomes. Section Demand for Emergency Medical Services explores factors predicting demand. Section Cost-Effectiveness/Cost–Benefit Analyses includes a description of cost-effectiveness and cost–benefit analyses. Section Conclusion concludes.

Taxonomy of Ambulance and Patient Transport Services

EMS are rival and excludable – only one patient can use an ambulance at a time and patients can be barred from service. In practice, however, access to EMS is frequently available to all, not only to those with the ability to pay. This makes EMS an impure local public good. EMS could also be considered an option good; patients frequently pay through taxes for the option of having EMS available when needed. As EMS systems are built to address urgent, unpredictable needs, there may be excess capacity most of the time.

EMS systems vary tremendously throughout the world. In Japan, EMS are provided by Emergency Life Support Technicians who have limited roles – they can provide cardiopulmonary resuscitation (CPR), defibrillate patients, and insert an airway, but are prohibited from distributing drugs. In Germany, EMS is regulated and organized at the 'Lander' or state level; the German population has the right and guarantee of prehospital emergency medical care either through a physician available through 24 h house call or via EMS. A person calling for EMS in Germany would reach a central dispatcher and then, most likely, would be served by a two-tiered system including a physician-staffed ALS. In 1998, EMS in Russia was two-tiered and staffed by physicians, with nurses dispatching ambulances from a central location and treatment initiated in the field; many patients are treated by physicians and then not transported to the hospital, unlike in the US system, for example, where transport is required for compensation. In general, European prehospital care is more likely to include care from a physician or a nurse in addition to a paramedic compared with American ambulances that do not have personnel with more than paramedic training; for a description, by country, of prehospital care arrangements (organization of EMS system, ambulance staffing, and helicopter availability), see Lethbridge (2009).

In low- and middle-income countries, prehospital care is frequently unavailable; if it exists, it is concentrated in urban areas, likely to be privately provided (and only available to those with the ability to pay), of uneven quality and largely unregulated, even though trauma, particularly as a result of car accidents, represents an increasingly significant and growing source of disability and mortality in developing countries. In Islamabad, Pakistan, police officers as well as physicians staff ambulances provided through a public–private partnership; members of the community, including Non Government Organizations subsidize physician salaries, equipment, and ongoing operational costs other than police salaries. In Turkey in the late 1990s, no personnel or equipment standards existed for prehospital care; in a typical city, Izmir, ambulances were staffed with a medical doctor with limited training and a driver without medical expertise, and it was unusual when the ambulance arrived before the patient had been transported by other means to the hospital. In 1997, Vietnam had no organized prehospital system; ambulances may be used for transport, but most often prehospital care relied on bystanders' transporting patients. In 1998, consistent with many other developing countries, there was no centralized prehospital care system in Thailand; approximately 30 pick up trucks staffed by volunteers picked up residents around Bangkok. Drivers have limited first-aid training. A water rescue boat must travel first from the hospital to the river, decreasing its usefulness significantly. Despite a large and increasing number of traffic accidents, prehospital care in India is largely nonexistent; with no centralized regulating body and the ambulance services only provided in only a few large cities where they are largely privately funded, most Indians lack access to trauma care of any kind. What is provided is of uneven quality; few programs exist to train paramedics and Emergency Medical Technicians (EMTs), and no certification or accreditation exists for professionals or programs. These characteristics define prehospital care throughout Southeast Asia (Bangladesh, India, Nepal, Pakistan, Bhutan, Maldives, and Sri Lanka); disproportionately concentrated in urban areas, serving those of higher socioeconomic status, frequently privately provided, without regulation or certification requirements, and limited in capabilities.

US Emergency Medical Services

In a typical EMS call in the US, a patient calls 911. A dispatcher at a local call center asks the patient a series of questions, evaluating the situation and eliminating false calls. The

dispatcher may also give the patient medical instructions over the phone while simultaneously activating the local EMS response. In urban areas, first responders typically arrive first at the scene. A first responder captures vital signs, determines the patient's medical history, and provides CPR. Meanwhile, the EMS response team composed of basic or intermediate EMTs or paramedics (advanced EMTs) travels to the scene by helicopter or by ground ambulance. Although the particular responsibilities of each type of personnel differ by state, EMTs supply more advanced care to patients than first-aid trained first responders. After arriving at the scene, assessing the situation, and providing initial care, the EMT or paramedic loads the patient into an ambulance or a helicopter and takes the patient to a hospital. In some cases, a medical director instructs and authorizes treatments en route. After transferring the patient to the care of physicians within the hospital, the EMS personnel collect billing information and fill out a call log with demographic and incident characteristics. In rural areas, the ambulance would likely be staffed by volunteers capable of delivering Basic Life Support services.

Most large cities in the US publicly provide EMS; in nearly half of all communities, EMS are organized and delivered through the fire department. Although first responders are almost always employed by a local government, either public or private ambulance or helicopter services may transfer patients. Many communities outsource emergency transport to for-profit ambulance agencies (more than 3000 in the US) or to hospital-based companies (approximately 7% of systems). In a hospital-based EMS system, the ambulance might park at the hospital in between calls and might be encouraged to bring patients to the affiliated hospital. With a private agency (hospital-based or other), the provider would likely own the infrastructure including the ambulance.

Revenues collected from private and public insurance for patient transports provide the majority of funding for EMS, potentially encouraging agencies to transport patients for whom the trip to the hospital is unnecessary. State and local taxes frequently supplement fees collected through insurance, along with grants from the state and the federal government. A variety of mechanisms, including government grants, fundraising, and donations, fund volunteer ambulance services.

Rather than being transported by ground ambulance, some patients may travel by medical helicopters. As of 2006, more than 650 medical helicopters operated within the US, run by private for-profit providers, hospitals, government agencies, or the military. More expensive to operate than traditional ambulances, helicopters may be no faster than ground ambulances, except in rural areas far from hospitals or in places where a ground ambulance cannot travel. Many patients transported by helicopter could have safely been transported by ground ambulance at considerably less expense without any survival loss. Using a helicopter may also limit the set of hospitals that a patient can be transported to.

Private Provision of Emergency Medical Services

When do some communities choose to outsource patient transport? In a 2009 paper, Holian hypothesizes that a vote maximizing politician will outsource patient transport when it will increase her votes. In his model of private provision, as the proportion of the elderly, who consume a disproportionate amount of EMS rises, service levels change. Empirical work suggests an inverted U-shaped relationship between the proportion of the voting population which is elderly and the proportion of privately provided ambulance services.

Communities might outsource their EMS for many reasons. In 2009, David and Chiang found that although fire departments may have lower EMS transportation costs because they can take advantage of the existing firehouse infrastructure to get closer to patients, it may be cheaper for private agencies, which can spread costs across multiple communities – to introduce technology which improves the quality of care (such as Geographic Information System). Arguably, then, the decision to privatize depends on several factors including the distance to other cities, the population, and the number of hospitals in the city (all but the former negatively associated with private provision). Among the ten largest and ten smallest cities in the US, larger cities, with older, less healthy populations, a higher chance of disasters, more crime, less geographically dispersed fire stations and trauma centers, and strong unions, tend to be less likely to contract with private providers.

A related question not yet evaluated empirically is whether public or private agencies are better providers. Some hypothesize that private ambulances may provide EMS care more efficiently than public ambulances, because private paramedics frequently earn lower salaries than paramedics employed directly by state and local governments, even as they appear to have more sophisticated equipment and greater flexibility.

Factors Affecting Quality of Care

Unfortunately, there are no nationally or internationally agreed-upon measures of EMS quality. However, response time, defined as the difference between the time of the initial call and the time of arrival at the scene, is one commonly used metric. Other metrics commonly used include total call time. Such metrics have not been systematically used by communities or states in the US to assess the quality of their EMS because a large proportion of states do not systematically collect response time data.

Many factors appear to be correlated with response times. In one southern state, Mississippi, whites appear to have higher response times than blacks, but these differences are eliminated after controlling for a county-level measure of population density. Others have found that distance, evening rush hour, patient being of Native American or Pacific Islander race, and gender predict longer total response times and that these factors plus bypass, neighborhood population density and percentage of white population are associated with delays of more than 15 min. Other factors including population density, the age of the housing stock, per-capita income, and first responders per square mile seem to be negatively correlated with mean response times, with area being positively correlated with mean response times.

It appears that incentives also affect response times – or at least the reported response times. One program in England profiled by Bevan and Hamblin (2009) publicly rewarded

agencies meeting response time targets with gold stars. After the program was introduced, the proportion of agencies meeting performance targets increased, but the gains were illusory – response times were systematically shaved and calls recategorized as less severe to satisfy requirements.

Worker fatigue, experience, human capital depreciation, and turnover also affect response times. In a 2009 article, David and Brachet used the detailed call level data from Mississippi to measure the relationship between experience and time out of hospital or at the scene. They construct person-specific and firm-specific measures of experience, and control for individual fixed effects and a lengthy set of covariates. A one standard deviation increase in the number of trauma runs conducted by an individual in a given quarter is associated with a reduction of 35 s in out-of-hospital time and 10 s on scene. Brachet *et al.* (2010) compare the performance of paramedics working late at night in 24 h shifts with those same paramedics working late at night on 12 h shifts. They observed that paramedics on 24 h shifts have significantly longer response times and take longer to transport patients to the hospital and perform fewer procedures. David and Brachet's (2011) article uses incident level data to measure the impact of human capital depreciation and turnover on time out of hospital. Turnover among EMS personnel is a significant problem for all EMS agencies, both paid staff and volunteers; one estimate puts the annual turnover among EMS personnel as high as 10%, with a median cost to agencies of over US$70 000. Partitioning experience into the human capital of those who work at the firm, those who have left the firm, and those who are joining the firm; David and Brachet derived an expression for firm-level experience and construct a measure of the relative contribution of turnover and human capital depreciation to organizational forgetting. Their reduced form estimates of organizational forgetting suggest that a quarter of the stock of experience existing at the beginning of the year survives to the end. When experience is separated into human capital accrued by individuals in the firm and those who have left the firm, they find the turnover to be a larger source of organizational forgetting (twice as large) than human capital depreciation.

Quality of Care and Health Outcomes

How do factors which affect response time affect health? Although there are many studies that look at factors that affect the quality of EMS care, few evaluate the relationship between quality of care and health outcomes largely because of the challenges in linking prehospital records to mortality and hospital records and in finding a credible nonexperimental identification strategies in a context where experiments may not be feasible.

Athey and Stern's (2002) work uses a differences-in-differences approach to determine the impact of the introduction of the new 911 technology on health outcomes. They model health as a function of response time and initial incident severity; they find that the introduction of Enhanced 911 in Pennsylvania improves the intermediate health measures for patients suffering from cardiac emergencies, as well as improving mortality measured 6 and 48 h after the initial incident. Enhanced 911 also reduces hospital costs for cardiac emergency patients. Wilde takes a different approach in her 2008 paper; she uses distance to the closest EMS agency as an instrument for EMS response time to account for the potential endogeneity of response time to patient severity. She finds that response time matters for mortality, but not health care utilization.

Shen and Hsia investigated the impact of bypass or diversion by EMS providers on mortality after acute myocardial infarction in a 2011 JAMA paper – an event which is arguably unrelated to the characteristics of the patient. Diversion may affect outcomes by affecting EMS response times (when the nearest hospital is on diversion, patients must be transported to hospitals that are farther away); it may mean that patients are transported to poorer quality hospitals or hospitals less capable of providing adequate care; it may also be an indicator for the quality of care for patients within the hospital experiencing the diversion (more crowded hospitals may provide worse care). Patients whose closest emergency department is on diversion for more than 12 h on the day of the incident experience higher mortality 30 days, 90 days, 9 months, and 1 year after the initial incident.

An example of work that explores a key policy question in EMS without a natural experiment or randomized controlled trial is that of a 2008 work by Concannon *et al.* who conducted a simulation of different EMS treatment choices for patients with acute ST-segment elevation myocardial infarctions. Patients can either be transported to the closest available hospital, transported only to hospitals with the capability of providing primary percutaneous coronary intervention (PCI) and treated with PCI or thrombolytic therapy, or be evaluated by EMS or by personnel at the local thrombolytic therapy-only hospital and then transported for PCI. Concannon *et al.* observed that selecting high-benefit patients for transport to PCI-capable hospitals reduces mortality without major shifts in hospital volumes.

Demand for Emergency Medical Services

What affects the use of EMS? There appears to be distinct EMS usage patterns by day (more calls between 10.00 a.m. and 8.00 p.m.) and the day of week (more calls on Friday and Saturday). Age and race/ethnicity also predict usage: people over the age of 85 years call more than 3 times the rate of those between 45 and 64 years of age and are transported at more than 4 times the rate of patients between 45 and 64 years of age. African Americans also call at a much higher rate than non-Hispanic whites.

In an intriguing analysis, Ringburg *et al.* conducted a discrete choice experiment in the Netherlands and found that households were willing to pay much higher amounts than would actually be necessary to provide 24 h helicopter emergency medical service as described in a 2009 paper. It appears that even if helicopter services are not cost-effective, households are willing to pay for them.

Many researchers in the field of operations research and applied mathematics have tackled questions regarding the optimal design of EMS systems, including identifying the optimal ambulance and helicopter station location and the

optimal response time threshold for performance measurement, in addition to building models to forecast demand. That research is beyond the scope of this work.

Cost-Effectiveness/Cost–Benefit Analyses

Most existing cost analyses compare the costs and benefits of particular intervention or mode of care. For example, in their 2002 paper Athey and Stern calculate the costs and benefits from introducing Enhanced 911, a service that helps dispatchers to identify caller locations. They find that improvements in outcomes for cardiac issues cover 85% of the costs of implementing Enhanced 911, making the policy almost certain to be beneficial. Wilde conducts a cost–benefit analysis of a reduction in response times caused by eliminating mutual aid – a policy whereby communities share resources to cover excess demand – and finds that the per life year cost of a 9.5 s reduction in response times would be considerably less than US$50 000.

Evidence on the cost-effectiveness of air transport is mixed. One study that determined the costs of operating a local air ambulance service, supplemented with hospital costs for trauma survivors, estimated the cost of air transport per life year saved as US$2454. Another study collected microlevel costs, surveyed patients two years after their initial trauma incident, and estimated the incremental cost per quality-adjusted life-year (QALY) of helicopter use at more than 28 000 Euros. Several other studies looked retrospectively at patient records and concluded that there were few benefits for patients from air transport, and considerable costs to the health care system. Unfortunately, many of these studies fail to identify the perspective (societal or other), the year the costs were gathered in, fail to include comprehensive costs, and are inconsistent in their assessment of effectiveness making it difficult to draw concrete conclusions (QALY or mortality).

Conclusion

In recent years, there has been an increase in the literature written by or for economists on EMS. Nevertheless, many key clinical and policy questions remain unanswered, providing scope for further research. Economists have much to offer in the field of EMS: by asking different types of questions (i.e., on private vs. public provision, or cost-effectiveness) and using different techniques. Given the growing recognition of EMS as an essential part of emergency care, such research should only increase in the coming years.

Analysing Heterogeneity to Support Decision Making

MA Espinoza, Pontificia Universidad Católica de Chile, Santiago, Chile, and Institute of Public Health of Chile, Santiago, Chile
MJ Sculpher and A Manca, University of York, York, UK
A Basu, University of Washington, Seattle, WA, USA

Glossary

Complete information Refers to the knowledge of the set of covariates that explain differences in outcomes between all individuals.
Essential heterogeneity It corresponds to the unobserved heterogeneity when the selection of treatment depends on these unobserved characteristics.
Ex-ante choices Decisions that a data analyst expects the patients to make based on some of the observed patient characteristics but without access to other relevant information.
Ex-post choices Decision resulting from the interaction of the patient with health professionals, relatives, and other sources of information that are relevant for the treatment selection, but were unobserved to the data analyst trying to predict these choices.
Expected value of individualized care It represents the expected cost of omitting information about individuals when making decisions based on the average estimates.
Nonessential heterogeneity It corresponds to the unobserved heterogeneity when the selection of treatment does not depend on these unobserved characteristics.
Observed heterogeneity Proportion of the variability that can be explained by a set of observed (known) characteristics.
Perfect information Refers to the knowledge of the true mean effect of a particular covariate on the health outcome. It implies 100% precision and/or 100% accuracy, and therefore, no remaining uncertainty.
Preferences In the context of cost-effectiveness analysis (CEA), preferences refer to the rational element of judgement that guides individuals in their task of ranking health states in a particular order to reveal the relative value of such states.
Stratification Process whereby individuals are categorized in different subgroups.
Subgroups Subset of patients whose membership is defined by one or more individual characteristics.
Variability Differences in outcomes between individuals, which can be explained by observed and unobserved characteristics.

Introduction

The flow of new medical technologies is a response to several factors including an ageing population, changes in environmental conditions creating new epidemiological profiles and scientific development. This impacts on health care systems which, to satisfy increased demand for medical technologies, are faced with the need to increase expenditure on healthcare or to disinvest in other services to release resources. Regardless of the type of healthcare system, the problem of deciding which new technologies to fund is unavoidable. As policy makers are increasingly held accountable for these decisions, many are adopting explicit and evidence-based approaches to the allocation of limited resources. This needs, at the very least, information about which interventions work and the value of such technologies.

In a growing proportion of jurisdictions 'value' is defined in terms of cost-effectiveness, where the incremental cost of a new technology per additional health outcome relative to alternative interventions for a given patient group is assessed. This incremental cost-effectiveness ratio is then compared with a maximum (or threshold) value of a unit of health gain which is based either on an estimate of the health forgone as a result of displacing existing services to fund the new technology, administrative rule of thumb or an estimate of society's willingness to forgo consumption in exchange for health improvement. Both effectiveness and cost-effectiveness are usually considered as average estimates relating to a target population. This approach has been largely justified by the fact that it is impossible to observe the effect of alternative treatments in the same individual at the same time, a problem known as the 'fundamental problem of causal inference'. Average treatment effects derived from randomized controlled clinical trials are unbiased estimates when the groups being compared have, on average, similar characteristics, so that the differences in the outcomes are attributable to the treatment received by patients in each group. This causal statement is possible because randomization is expected to balance observed or unobserved confounding factors.

Although the focus on average treatment effects is widespread, this is essentially pragmatic given the challenges in estimating individual treatment effects. The promise of genetic testing is that patient management can more appropriately be tailored to the characteristics of the individual – a technological approach to understanding between-patient heterogeneity in treatment effects. However, in jurisdictions using formal cost-effectiveness analysis to inform resource allocation decisions, as well as those that are unwilling or unable to consider costs explicitly (e.g., comparative effectiveness research in the US), there is a recognized need to understand heterogeneity using existing data on predictors of patients' outcomes following alternative interventions. The focus on the average patient leads to dichotomous decisions – accept or reject a given intervention for all patients in a given population. In contrast, understanding of heterogeneity in costs, effects and cost-effectiveness between patients within the

population facilitates decisions which may guide the use of the intervention toward those patients in whom it is (cost-) effective. This targeted, rather than general, funding of interventions frees-up resources for more (cost-) effective alternatives, leading to an improvement in the overall population health from a given budget allocation. In principal, a full understanding of heterogeneity allows decisions to reflect the characteristics of the individual patient, so the gains from reflecting heterogeneity are maximized.

Interest in heterogeneity for decision-making takes various forms. From a biomedical perspective, reflecting heterogeneity in decisions has been promoted as a means of achieving personalized medicine, which requires the identification of measurable parameters (e.g., based on molecular biomarkers) that allow doctors to prescribe treatments according to specific individual characteristics. Even without such testing, many clinical specialties use existing clinical individual level information to maximize a patient's absolute benefit from treatment compared to its potential harms. An example of this is the use of easily accessible prognostic models for decisions about the choice of adjuvant chemotherapy in breast cancer. Those healthcare systems that use cost-effectiveness analysis to inform decisions increasingly take a step further in seeking to identify the groups of patients for whom absolute health benefit gains justify the relevant cost. Furthermore, despite being financed through taxation, social insurance or private insurance, many collectively funded jurisdictions have recognized the role for individual patient choice in healthcare decisions. There are several reasons for such a policy, and one of these is the potential role for patient choice as a vehicle for characterising unobserved heterogeneity in the costs and benefits of medical interventions.

This article reviews the key elements of the discussion about how heterogeneity should be examined, exploited and analysed for the purposes of decision-making about healthcare interventions. In terms of the methods for economic analysis, it focuses on the role of understanding heterogeneity as a source of value to achieve greater health. The remaining of the article is in four sections. The first section seeks to review standard approaches to the assessment of heterogeneity. The next explores methods developed to represent the value of considering heterogeneity in healthcare decision-making. The third describes the role of patients' choices and preferences in understanding heterogeneity. Finally, the authors conclude by summarizing the key messages of the article highlighting the opportunities for further research.

Standard Approaches to Assess Heterogeneity in Evaluation of Healthcare Technologies

The term 'variability' is used to express the differences in outcomes between individuals. They can be explained by both observed and unobserved characteristics. 'Heterogeneity' has been defined as the proportion of the variability that can be explained by a set of observed (known) characteristics at the time of analysis. In general terms, the set of characteristics that explain the total variability can be further divided in the knowable and the unknowable. In practice, only a portion of the knowable factors can be identified and observed, mainly because of the lack of data and limits on the conduct of further research (e.g., funding and human resources). These knowable only in principle characteristics go with the other unknowable characteristics in the general category of unobserved characteristics. In this article the authors consider unobserved variability or unobserved heterogeneity synonymous. This unobserved part is also referred as stochastic uncertainty or first-order uncertainty.

'Complete information' refers to knowledge of the set of covariates that are able to explain differences in outcomes between all individuals in the population (total variability or total heterogeneity). This is a theoretical concept that is reached when all the covariates needed to explain differences between individuals are revealed. 'Perfect information' refers to the knowledge of the true mean effect of a particular covariate (and its correlation with others) on the health outcome. Likewise, perfect information also refers to the knowledge of the true value of a particular covariate in one individual (e.g., the presence of a genetic characteristic with 100% accuracy). From a decision-making point of view, the main challenge is to take into account as much information about individual-level characteristics as possible. The aim for health researchers is, therefore, to achieve a full characterization of total heterogeneity, i.e., not only to convert the knowable characteristics into observed measurable variables, but also to make some prediction of the expected individual outcomes considering unobserved heterogeneity.

The literature in different areas provides alternative nomenclatures in the study of heterogeneity. For example, epidemiology and biostatistics emphasize the importance of distinguishing between moderators, mediators or nonspecific predictors of treatment outcomes. Variables considered as moderators inform for whom and under which conditions the treatment works. Mediators, in contrast, indicate potential mechanisms that explain the causal effect. Nonspecific predictors are variables that show an effect on the outcome without interacting with the treatment. These distinctions are relevant in understanding the underlying causal model of the health problem. In the context of the evaluation problem in econometrics, unobserved heterogeneity has been termed 'nonessential heterogeneity' when the selection of treatment does not depend on these unobserved characteristics. When treatment selection depends on the unobserved expected gains, this is called 'essential heterogeneity'. In the context of epidemiology and biostatistics, essential heterogeneity indicates that there are knowable moderators of treatment effect that are unobserved in the data. More generally, terms such as observable or measurable heterogeneity are broadly used across the sciences. Figure 1 synthesizes these terms, making a parallel correspondence between them. For example, observable heterogeneity includes, on one side, mediators, moderators and nonspecific predictors. However, it includes known and knowable heterogeneity. Unobserved heterogeneity, also called first order uncertainty or stochastic uncertainty, includes part of the observable heterogeneity (the part that has yet to be revealed) and the unobservable (or unknowable) heterogeneity.

In clinical epidemiology and economic evaluation, exploration of heterogeneity has classically been driven by subgroup analysis. Usually, the dimensions explored correspond

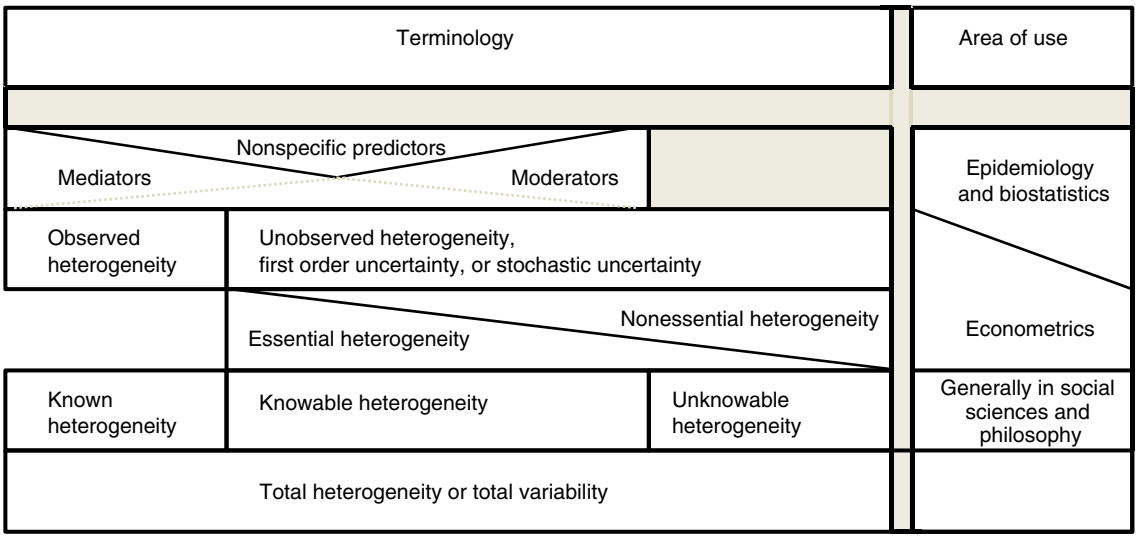

Figure 1 Terminology in the study of heterogeneity. Relationship between different terms and the field where it is used.

to baseline (or underlying) risk and treatment effect heterogeneity. Heterogeneity in baseline risk refers to the set of characteristics that predict a particular a priori probability of presenting the health outcome under standard care or without intervention (natural history). This probability may influence the effect of a new intervention relative to standard care, where the relative treatment effect might be expressed as, for example, a relative risk, odds ratio, or hazard ratio. However, even in the case where the relative treatment effect is the same across individuals, the absolute value of the health outcome can vary across patients if they are expected to have different baseline risk profiles.

Treatment effect heterogeneity, however, exists when a set of patient characteristics predict different relative treatment effects among a population of patients. In statistical terms, this corresponds to the interaction between the treatment effect and the covariate that defines the individual's membership of a particular subgroup. Treatment effect heterogeneity can be categorized as a quantitative interaction (differences between subgroups are in the same direction but they vary in terms of their magnitude), effect concentration (the treatment effect is only seen in one subgroup) and qualitative interaction (the treatment effect varies not only in magnitude but also in direction between subgroups). It is important to stress that both baseline risk and relative treatment effect heterogeneity are defined on the basis of one or more observed characteristics at baseline, assessed on the basis of health outcome(s).

Dealing with heterogeneity in economic evaluation may also relate to costs and preferences. Heterogeneity in costs typically takes the form of a set of patient characteristics predicting differences in the use of healthcare resources. For example, age might be expected to explain a large proportion of the variation in length of hospital stay for common procedures such as hip and knee replacement and heart failure. Heterogeneity in preferences is considered in detail below.

So far the discussion has focussed on heterogeneity at the level of the individual patient. Geographical variation has also been a matter for attention, particularly in cost-effectiveness analysis. This has been explored mostly in the context of countries, although this type of heterogeneity could also be important between localities or jurisdictions within a country, with specific characteristics that affect, for example, the incidence or prevalence of a particular condition. These differences can be explained by several elements of the health system, clinicians, patients or wider socioeconomic factors. For example, the relative prices of resources may vary across jurisdictions as well as the opportunity cost imposed on health outcome through additional costs falling on the system. Similarly, it is known that teaching and specialized hospitals incur higher expenditure than general hospitals, with marked differences within the same jurisdiction. Further, better trained health professionals might generate better clinical results and incur fewer costs as a result of more efficient care (e.g., quicker diagnostics and lower complication rates in surgical procedures).

Despite the growing interest in considering heterogeneity as part of decision-making in healthcare, researchers face some constraints in using these methods due to the orthodox adherence to classical methods of statistical inference. The first of these follows from the fact that most clinical trials are designed to find statistically significant average treatment effects and their sample sizes are determined accordingly, any attempt to make inference on subsets of the sample faces the problem of loss of power (i.e., increase in type-2 error). It can be shown, however, that using prespecified (baseline) covariates in a regression framework increases statistical power, something that can be explained by the magnitude of the prognostic effect of the covariate on the outcome. A second concern relates to the fact that, when additional testing is performed on the same data, there is a higher probability of finding statistically significant differences between groups explained by chance, a problem known as multiplicity (i.e., leading to greater false positives or an increase in type-1 error).

A third problem concerns the requirement of an interaction test to prove treatment effect heterogeneity in clinical studies. If heterogeneity in a treatment effect is shown to be

statistically significant, authors usually report both baseline and treatment effect heterogeneity. In contrast, if there is no statistical significance, information about (significant) baseline risk heterogeneity might be omitted. Although from a clinical point of view only treatment effect heterogeneity might be considered important, systematic variation between patients in baseline risk is also a relevant source of heterogeneity from a decision-making perspective. Indeed, between patient heterogeneity in baseline risk – even in the presence of a homogeneous relative treatment effect – yields heterogeneous absolute treatment effects, which interests policy makers because it has implications both for budget impact and equity concerns.

A further issue is that, although these tests reflect a genuine interest in achieving reliable and precise estimates of treatment effect differences in subgroups, they have been demonstrated to have low power and a high rate of false negatives. Finally, loss of balance between arms of a trial has also been raised as a concern in estimating treatment effects for subgroups.

All these concerns are relevant for clinical studies and they do not necessarily apply in a similar way to cost-effectiveness analysis. Although inference about treatment effects is mainly based on the magnitude of probability of error (errors type-1 and -2), decision rules should also consider the consequences of those errors. Thus, economic analysis in healthcare is focused on the correct characterization of uncertainty rather than inferential decision rules (e.g., taking *p*-value equal to .05 as a rule of thumb). However, even in the case of decisions that follow these principles, there are some constraints on the study of heterogeneity. For example, characteristics used to explain differences in (cost)-effectiveness between individuals may be constrained by equity considerations. The National Institute for Health and Clinical Excellence (NICE) for England and Wales, for instance, states that subgroup analysis based purely on differences in treatment costs is not relevant to their decisions. Furthermore, transaction costs involved in the operationalization of decisions at an individual level or in different subgroups need to be explicitly considered in the analysis.

Value of Heterogeneity

The consideration of heterogeneity has value for the healthcare system because greater population health can be achieved from a finite budget by conditioning treatment decisions on those factors responsible for such between-patient heterogeneity. Subgroup analysis has been the most common approach to explore heterogeneity in the context of health technology assessment. Coyle *et al.* (2003) represented the value of considering subgroups as the incremental net benefits (INB) that can be gained from a 'stratified' analysis for the case where two interventions are compared. If policy makers restrict the adoption of technologies to those subgroups with positive INB, then the gain derived from making different decisions for different subgroups is the difference between the sum of the positive INB, also termed TINB_S (total INB considering subgroups) and the total INB (TINB, including positive and negative INB). In other words, it is the absolute value of the sum of the INB in those subgroups where the INB is negative. Using an alternative notation, the value of stratification can be expressed as Δ_STINB:

$$\Delta_s TINB = INB_S - TINB = -\sum_{s=1}^{S} INB_S w_S, \quad \forall_S \text{ where } INB_S < 0$$

where $w_s \in (0,1)$ is a weight indicating the proportion of the total population represented by subgroup s and $\sum_{S=1}^{S} w_s = 1$.

Basu and Meltzer (2007) developed a framework for estimating the value of eliciting information at patient level to make individualized decisions. They introduced the concept of expected value of individualized care (EVIC), a metric that reflects the population net benefits (NBs) forgone because of the ignorance of heterogeneity in preferences when decisions are made based on the average estimates. EVIC is calculated as the difference between the average of the maximum NBs in each patient (individual NBs (*i*NBs)) and the maximum of the average NBs of the alternative treatments across patients. This formulation of EVIC has been termed 'with cost-internalization,' in the sense that the decision takes into account the opportunity cost of an alternative resource allocation. According to the original definition, EVIC can be expressed as:

$$EVIC = \int_{\theta \in \Theta} \left\{ \max_j NB(\theta) p(\theta) d\theta \right\} - \max_j \int_{\theta \in \Theta} NB(\theta) p(\theta) d\theta$$

The authors point out that, although EVIC was initially estimated for patient preferences, it can also be estimated for any other (set of) parameter(s) of interest in the decision model. Indeed, a total EVIC captures all parameters of interest and should be interpreted as the expected gains that could be attained if individual information about every patient is considered when estimating the outcome of interest.

EVIC can also be expressed as 'without cost-internalization.' In this case, the decision at individual level follows the rule of maximising expected health benefits instead of net health benefits (i.e., without accounting for opportunity costs). In their first application of EVIC to real data, the authors demonstrate how the value of individualized information can be affected by the decision rule applied. Using an illustrative example of alternative treatments for prostate cancer, the estimated EVIC with cost-internalization was greater than US$70 million, this value fell to US$0.9 million without cost-internalization, suggesting that efforts to elicit individualized information is much more valuable if doctors (and patients) internalize costs when making their decisions. Basu and Meltzer also presented parameter-specific EVIC ($\text{EVIC}_{\theta i}$), which is analogous to the expected value of perfect information for parameters. An advantage of this metric is that by ranking parameters according to $\text{EVIC}_{\theta i}$ the most valuable information for individualized decisions can be identified.

These recent methodological developments provide an adequate representation of the potential health that can be gained if heterogeneity is taken into account in decision-making. It is important to highlight that EVIC (total and for specific parameters) is conditional to the structure of and evidence within the decision model. Thus, if the model fails to capture an important source of heterogeneity, the estimate of EVIC may be unreliable. EVIC can be estimated from individual patient data or from aggregate data.

Current approaches to express the value of heterogeneity estimate the expected value of the health that could be gained by considering heterogeneity. However, sampling uncertainty must also be considered as part of the same characterization. For example, if EVIC for the parameter 'polymorphism A' represents the value of conducting a pharmacogenetic test to reveal whether the patient has such a polymorphism, then the estimate of EVIC implicitly assumes that the effect of having the polymorphism on the outcome is known with total precision, and also that the test is 100% accurate. Thus, EVIC provides an estimate only of the potential value of making different decision for patients with and without the polymorphism, but it does not provide any information about the probability that such alternative decisions are wrong. Consequently, an important issue that needs to be addressed is the role of decision uncertainty when heterogeneity is taken into account.

Preferences and Choice as Sources of Heterogeneity

Preferences and choices are concepts with important implications for the study of heterogeneity across individuals.

Preferences as a Source of Heterogeneity

Preferences have been central to how health outcomes have been valued in CEA, where the primary objective is to maximize health gain subject to a budget constraint. CEA often uses quality adjusted life years (QALYs) as a measure of health gain. Although the QALY can only be assumed to accord with individual preferences under very strong assumptions, quality of life weights are generally taken as reflecting the preferences of the relevant group of responders (typically patients or the public). Indeed, some methods used to elicit quality of life weights for QALYs have a strong basis in preference theory (e.g., the standard gamble method is derived from expected utility theory). These methods estimate a relative value of descriptive health states, which are a representation of a particular level of health related quality of life (HRQoL).

Although heterogeneity in preferences was an important part of the development of the concept of EVIC by Basu and Meltzer, relatively few studies have addressed the idea of considering heterogeneity in patients' preferences. Nease and Owens (1994) introduced the idea of estimating individualized expected health benefits to realize the value of a guideline that considers individual patients' preferences. Using a decision model for mild hypertension, they showed that decisions guided on the basis of individualized preference assessment should be considered cost-effective compared to average preference estimates. Sculpher (1998) compared different preference-based approaches to treatment allocation (based on expected individual health, expected individual cost-effectiveness and free treatment choice by the patient), revealing that decisions based on expected individual QALYs and net QALYs are not well correlated with treatment choice. This probably reflects the limited link between QALYs and individual preferences. In other words, patients were basing their treatment choices on criteria not reflected in the derivation of the QALY.

Choice as a Source of Heterogeneity

An optimal (treatment) choice for an individual patient is one that maximizes the individual's welfare, utility or health depending on the elements in his/her objective function. In the context of healthcare, ex-ante choices are the decisions that a data analyst expects the patients to make based on some of the observed patient characteristics but without access to other relevant information and points of views that patients may face while making actual decisions. This view contrasts with the notion of treatment selection (or revealed choices or ex-post choices) which is the individual's decision resulting from the interaction of the patient with health professionals, relatives and other sources of information that are relevant for the decision, but were unobserved to the data analyst trying to predict these choices. This can be operationalized in the context of, for example, a shared decision-making model, where patients and health professionals share information about alternative diagnostic and treatment options as well as outcome preferences with the aim of making the best choice among the alternative courses of action. Ex-post choices can also be driven by anticipated gains and losses. To the extent that these anticipations are not completely unfounded and they deviate from the average gain and loss from a treatment, ex-ante prediction of choices can be substantially different from ex-post choices. This has implications for policy making.

A policy concern for many healthcare systems is that patients' preferences and choices should be taken into consideration in the decision-making process. NICE, for example, recognizes this argument as part of its social value statement, but it also highlights the importance of making adequate judgments to ensure good use of the limited resources. Less clear, however, is the extent to which patients' unconstrained treatment choices can be consistent with the social objective of maximising health gain subject to finite resources. One possibility is that patients' choices can provide some information about the expected potential health gains from a particular treatment. In other words, choices provide information on the extent to which a patient expects (or is expected) to benefit from an intervention.

In the clinical trials literature it has been reported that when patients are allocated to their preferred treatments, their outcomes are affected positively without effect on attrition rates. This might indicate that treatment works better in patients who would choose it, irrespective of the causes that explain loss in follow-up. If ex-ante choices can be used to predict outcomes, then they could help select treatment as a form of subgroup analysis. However, findings indicating that ex-ante choices are not good predictors have also been reported. Although the role of ex-ante choices as predictors is not clear, this might not be the case for ex-post choices. Given the process needed to reveal those choices, they are likely to be more predictive of health outcomes than ex-ante choices. If so, revealed choices might correlate strongly with many other unobserved covariates that explain variability in health outcomes. Thus, by using appropriate statistical techniques,

individual treatment effects could be estimated and their heterogeneity at individual level characterized, producing a better understanding of the joint distribution of potential health outcomes (potential outcomes are defined, according to the Rubin's causality model, as the observed consequences (Y) of alternative treatments ($t=0,1$) in one particular individual (i), i.e., the outcome observed *de facto* and the counterfactual (unobservable), which defines the joint distribution as $G[Y_{0i}, Y_{1i}]$). A research agenda for understanding heterogeneity should include new approaches to reveal individual choices and their role in explaining variability in health outcomes. This should address alternative study designs and analytical techniques.

Some governments and health systems value providing patients with (at least some) unconstrained choices over the healthcare they receive regardless of the impact on their ultimate health outcome. This principle of patient autonomy may, however, clash with an efficiency objective of maximising health across population from available resources. That is, owing to resource limitations, one patient's choice can be another patient's health loss. To the extent that social decision makers have a more complex objective function which includes population health and patient autonomy, then economic evaluation will need to establish how one objective is valued against the other.

Conclusions

In conclusion, heterogeneity in decision-making is occupying an important place in the health research agenda, not only because there is an intrinsic value for individualization of care but also because it is consistent with the objectives of maximizing health under limited budgets. Important conceptual and methods contributions have made in the past few years; however, there are still several gaps that require further research. Future investigation should examine the need to produce a more systematic approach to exploring heterogeneity (e.g., through subgroup analysis), the incorporation of parameter uncertainty in a more integrative framework with heterogeneity and the exploration of the role of patient choices in explaining variation in health outcomes.

Biopharmaceutical and Medical Equipment Industries, Economics of

PM Danzon, University of Pennsylvania, Philadelphia, PA, USA

Introduction

The biopharmaceutical industry (including small molecule drugs, biologics, and vaccines) and the medical equipment industry (including implantable medical devices, diagnostic imaging, and other diagnostics) have been major contributors to both rising healthcare spending and improved quality and quantity of life globally over the past four decades. Global spending on biopharmaceuticals reached one trillion dollars in 2012. Biopharmaceuticals account for between 10% and 20% of healthcare spending in most Organization for Economic Cooperation and Development countries, and often a higher share in developing countries that spend relatively less on hospital and physician services. The medical equipment sector is both conceptually less precisely defined and empirically harder to measure. Industry revenues are estimated at $332 billion (Ernst and Young, 2012), or roughly one-third of biopharmaceutical industry revenues.

The US remains by far the largest single market for these industries. For biopharmaceuticals, the US share of global sales was 34% in 2011, down from 45% in 2000 (Table 1). Over the past decade growth of biopharmaceutical sales has slowed to low, single-digit annual growth rates in North America and Europe, due to patent expiries and genericization of many major drugs and slower growth of new drugs. This contrasts with double-digit growth of biopharmaceutical spending in many emerging markets, particularly China, Brazil, India, and some other countries of Asia, Africa, and Latin America, reflecting their rising incomes and increased spending on health care. For medical equipment, the US share is roughly 45% of global sales.

The economics literature has focused much more heavily on biopharmaceuticals than on medical devices and diagnostics, reflecting both the greater expenditure share of biopharmaceuticals and the greater availability of data. Economic analysis focuses on features that differentiate these industries from other health services or consumer goods industries, in particular: high research and development (R&D) intensity; heavy regulation of all business functions, including R&D, market access, pricing and marketing; and complex market environments due to physicians and payers being major customers, in addition to patients. Economic analysis has taken both a social welfare/policy perspective and a firm or industry perspective. From the policy perspective, key issues related to biopharmaceuticals are the design of intellectual property (IP) rights, regulatory and reimbursement systems to provide appropriate incentives for R&D, and to assure appropriate utilization and prices for drugs, devices, and diagnostics, such that they deliver value for money. From the firm or industry perspective, key issues include understanding the causes of declining R&D productivity and optimal strategic responses; measurement and demonstration of incremental value of new compounds to regulators and payers; and development of effective entry and sales strategies for emerging markets. Because regulation of market access, pricing, and reimbursement are decided by each country separately, global policy and strategy must consider the interaction of policies adopted in different countries, in particular, the many challenges related to segmentation and differential pricing when selling global products in markets that differ vastly in regulation, IP, and ability and willingness to pay.

This overview article on the economics of these industries lays out the theoretical issues and major empirical findings, focusing first on issues related to R&D and then turning to markets, reimbursement and pricing, promotion, and specific issues related to vaccines, personalized medicine, and biosimilars. Although this article focuses on biopharmaceuticals, reflecting the much larger literature, it also describes ways in

Table 1 World pharmaceutical markets

Region	*Pharmaceutical sales (US$ billion)*			*Percentage of worldwide sales (%)*		
	2006	*2011*	*2016 (estimate)*	*2006*	*2011*	*2016 (estimate)*
US	269.78	325.04	368.9	41	34	31
Canada	13.16	19.12	23.8	2	2	2
EU5	125.02	162.52	154.7	19	17	13

which medical equipment is similar and different. Other articles in this volume provide greater depth on various issues.

R&D: Costs, Regulation, and IP

R&D Costs and Regulation

The biopharmaceutical industry is unusually research intensive. The US research-based industry invests approximately 15% of its sales in R&D, compared with approximately 4% for US industry in general and 8% for the US-based medical device industry. The R&D cost of bringing a new medical entity (NME) to market is currently estimated to be approximately $1.5 billion (Mestre-Ferrandiz *et al.*, 2012) and take 5–12 years from discovery through development, clinical trials, and regulatory approval. New drugs must meet stringent standards of safety, efficacy, and manufacturing quality before receiving market access approval. Large and lengthy clinical trials to demonstrate safety and efficacy, with high failure rates, are major drivers of the high cost per approved NME. Throughout the 1970s, 1980s, and 1990s, the cost per approved new drug increased by seven to eight percentage points per year above general price inflation. Factors contributing to rising cost per NME include not only rising clinical trial costs but also, more recently, higher failure rates. The evidence suggests that of drugs entering human clinical trials, only one in seven or eight reaches approval, compared to one in five in the 1990s. Rising failure rates reflect both safety, efficacy, and economic factors. Recent scientific advances have enabled development of novel therapies, but predictability remains imperfect. Further, because good treatments already exist for easier diseases, new drugs must now either provide significant incremental value relative to existing drugs that are available as low-priced generics, or tackle diseases that pose tougher scientific challenges, such as Alzheimer's disease and cancer, or target diseases that were previously ignored due to small populations. Most recently approved drugs target either specialty conditions (complex, relatively uncommon diseases treated by specialists) or even small orphan indications (defined in the US as affecting less than 200 000 patients per year). In the US in 2010 and 2011, one-third of new active substances approved had orphan designation. This reflects the intended incentives provided by the Orphan Drug Act, which provides special tax credits and market exclusivities for drugs that receive orphan status, as well as the very high prices realized by some orphan drugs, now more than $400 000 per patient per year for some drugs. It also reflects the granting of orphan status for small indications for drugs that may subsequently be approved for other, larger indications – for example, many cancer drugs serve both orphan and nonorphan indications.

The cost of developing a new drug includes the out-of-pocket expenses incurred by firms from discovery through first approval on the successful compound and related failures, because failures are an unavoidable part of the process. The full, capitalized cost per approved NME also includes the opportunity cost of capital invested, because investors must recoup their opportunity cost in order to continue investing in R&D. This cost of capital is about half the total cost (Di Masi and Grabowski, 2007). Although the mean cost is estimated at US$1.5 billion (Mestre-Ferrandiz *et al.*, 2012), there is significant variation with lower costs for rare diseases that necessarily have smaller trials, and relatively high costs for drugs to treat high-volume, chronic diseases that require large and long trials.

R&D expense for medical devices is much lower than that for drugs. Devices are classified into classes I through III, based on risk to patients and device novelty. The US Food and Drug Administration (FDA) has oversight over device safety, efficacy, and quality, but clinical trials are usually required only for novel devices classified as class III. Most devices are incremental modifications of existing products and can be approved by showing 'substantial similarity' to an existing device, without clinical trials. The EU's CE mark system authorizes either state or private oversight bodies to review safety and quality, and proof of efficacy is not required. Devices are therefore often launched earlier in the EU than the US, in contrast to drugs for which EU launch is often delayed by reimbursement requirements.

Safety: Benefits and Costs

Market access regulation that requires demonstration of safety and efficacy entails costs as well as benefits. The appropriate extent and structure of this regulation has been debated in the academic and policy literatures. The main economic focus has been whether the current regulatory approach to drug approval provides an optimal trade-off between safety and delay. The benefits of regulation include preventing unsafe and ineffective drugs from being sold and requiring the production of unbiased information about drug outcomes, including risks, benefits, and contraindications as demonstrated in controlled trials. The statistically significant findings from clinical trials form the basis for the product label and approved promotional messages. By revealing the true expected benefits and risks from drugs before launch, such information reduces the risk of adverse outcomes and drug withdrawals for safety reasons.

The costs of market access regulation include increased development costs, which may keep some potential drugs off the market, and delay in consumer access to new drugs. The FDA User Fees (which fund the hiring of additional reviewers) and the Fast Track and Priority Review regulatory initiatives have accelerated the review process of new drugs and provided mechanisms for approval based on surrogate endpoints, with postlaunch follow-up. Despite some mixed evidence that more rapid reviews have resulted in more postlaunch adverse events and drug withdrawals, on balance the evidence from pharmaceuticals suggests that these initiatives have increased consumer welfare. For medical devices, the appropriate structure and requirements for review are still under debate in the US. Delays in approval relative to the EU are a concern, but so is the number of recalls of devices approved through the accelerated process. Future economic research is needed on the optimal structure of market access regulation for medical devices.

Patents, Exclusivities, and Other Research and Development Incentives

The high cost of R&D for biopharmaceuticals (and, to a lesser extent, medical devices) implies a cost structure with high fixed costs that can benefit consumers globally but are sunk at launch, with low marginal cost per pill. Investment in the costly and risky process of pharmaceutical R&D therefore requires some mechanism to assure a return on successful investments for originator firms. The standard approach is patents which grant the innovator a monopoly for the duration of the patent by barring identical copies. Defining appropriate patent terms and criteria for postpatent generic entry are critical policy issues. All countries that are members of the World Trade Organization must recognize 20-year product patents, running from date of filing, for all products that meet requirements of novelty and utility, not just pharmaceuticals.

In addition to this basic patent protection that applies to all types of goods, the US and many other countries have added regulatory provisions that define certain exclusivity protections for qualifying originator pharmaceuticals, partially make-up for patent term lost before launch due to the lengthy R&D process, and also define entry conditions for generics. In the US, the 1984 Hatch–Waxman Patent Restoration and Generic Competition Act extended patent terms and defined regulatory exclusivities for originators, and eased entry requirements for generic versions of small molecule drugs. Specifically, Hatch–Waxman provided originator drugs with up to 5 years of patent restoration to compensate for patent life lost during R&D and regulatory review, and 5 years of exclusivity for originator data before generics can reference the data. For generics, Hatch–Waxman provided an Abbreviated New Drug Approval (ANDA) pathway that enables generics to be approved without doing new safety and efficacy trials, provided they can show bioequivalence to the originator drug and reference the originator safety and efficacy data. Paragraph IV provides a 180-day market exclusivity for the first ANDA generic that successfully challenges originator patents, to incentivize challenge to dubious patents.

The ANDA provisions greatly reduced the regulatory costs of approval for generics and facilitated the growth of generics in the US. The 180-day exclusivity period has led to successful challenges of many patents, and hence speeded generic entry. Generics now account for more than 80% of all prescriptions dispensed in the US, and a higher percentage for compounds for which generics are available. Unsurprisingly, because patentability requires that an invention be new, useful, and nonobvious, original composition-of-matter patents that apply to new molecules have generally withstood generic challenge in the US, whereas additional patents filed later on ancillary features or new delivery systems have more frequently been successfully challenged for failing to meet requirements of novelty and nonobviousness. The requirements for proof of novelty and nonobviousness differ across countries. This has led to some products that are patented in the US being denied patents in countries such as India.

Given the experience of patent litigation and uncertainty under the Hatch–Waxman Act, the 2010 Affordable Care Act (ACA) provisions for a new regulatory approval pathway for follow-on biologics (biosimilars) has focused on the regulatory exclusivity period for originator data. This is currently set at 12 years from the first licensing of the referenced biologic, in contrast to 5-year data exclusivity for chemical drugs in the US. Whether this much longer exclusivity period, combined with more favorable reimbursement for biologics, potentially distorts R&D choices toward biologics, despite their lower convenience and higher cost for consumers, is an important topic for future research. In contrast to these discrepant US data exclusivity periods, the EU grants 10 years of data exclusivity for both chemical and biologic drugs.

More generally, regulatory exclusivities offer more flexibility of duration and more certainty of enforcement, compared to patents that must run for 20 years from filing but may be challenged. However, this flexibility may make regulatory exclusivities more subject to manipulation by special interests. Given the vastly different costs involved in different types of biopharmaceutical and medical technology R&D, use of both patents and the more flexible exclusivities seems optimal.

For medical devices, patents are important but in general create weaker and less durable market power than for pharmaceuticals, because it is relatively easy to invent around a medical device patent using a slightly different product design. Moreover, entry of incrementally improved, follow-on devices renders the original design obsolete within a few years, even if the 20-year patent nominally remains valid.

Although patents are in some respects an efficient and effective mechanism to incentivize R&D, patents have other disadvantages besides the inflexible term and uncertain validity already mentioned. In particular, patents operate by limiting competition and enabling innovator firms to charge prices above marginal cost, which can lead to suboptimal use of drugs in the absence of insurance. High price–marginal cost margins also create strong incentives for promotion. Several alternatives to patents have been proposed for pharmaceuticals, including both 'push' programs that provide subsidies to reduce the cost of R&D and 'pull' programs that increase and/or guarantee revenues for companies that bring new drugs to market, including prizes, patent buyouts, and advance market commitments. Some of these alternatives have been applied to R&D for 'neglected' diseases with prevalence predominantly in low-income countries, including the advance market commitment for the pneumococcal vaccine.

Further research is needed on the optimal mix of IP alternatives, including patents, exclusivities, and others, for specific R&D contexts related to drugs, devices, and other technologies, in order to appropriately reward innovation without granting inefficient barriers to entry. Such research should consider how the optimal mix of protections might differ across countries at different levels of development. Because the goal of IP or other protections is to provide an appropriate financial reward to innovators, the optimal type and duration of IP should ideally also consider the pricing and reimbursement environment, which determines the prices and revenues that can be earned during the protection period. More on this below.

Mergers, Alliances, and Organization of R&D

The basic and translational science underlying many new drugs is developed in academic institutions, often supported by government research grants. The traditional mechanism for developing and commercializing such technologies has been the creation of start-up companies, usually with venture capital funding, taking advantage of the Bayh–Dole Act that encourages private commercialization of publicly funded research. Over the past two decades, thousands of start-up firms have been formed, many have been acquired by larger, established firms, some have failed, and a few have grown to become fully integrated biotechnology companies. Over time, the share of new approved drugs that originated with small firms has grown.

As large pharmaceutical firms have experienced declining returns on their internal R&D, they are increasingly using product licensing alliances and outright acquisition of small firms to source new compounds externally. For the small firms, such alliances with established biopharmaceutical firms provide an important source of R&D financing, as well as regulatory and commercial experience and expertise. The terms of these alliances and acquisitions are structured to align incentives and share risk, through payments that are triggered only if the product achieves certain goals. These contingent payments include R&D milestone payments, tiered sales royalties, opt-in options for the licensee in alliances, and contingent valuation rights linked to sales in acquisitions.

The theoretical literature has hypothesized that formation of product development alliances may be hampered by asymmetric information. However, contingent payments in the deal structure are designed to address both adverse selection and moral hazard risks. The empirical literature is mixed, but in general finds that in-licensed products have a higher probability of success than internally developed products, which supports the notion that the stringent due diligence process of alliance formation is more rigorous at weeding out compounds that will ultimately fail, compared to internal R&D review processes within large firms.

In addition to alliances with small firms, several large firms have recently reorganized their drug discovery divisions into small units that attempt to mimic the entrepreneurial spirit and incentives of small firms. The compounds that are produced by these internal units must compete with externally sourced compounds for scarce resources to fund clinical trials. Other attempts to increase R&D productivity within large firms include changes in personnel and organizational structure, and changes in compensation schemes. Despite all these attempts to improve R&D productivity, several large pharmaceutical companies have cut their R&D budgets recently for the first time in decades and instituted share buy-back programs, in response to shareholder concerns about the low return on R&D investment.

Small firms are not immune to the rising costs of R&D and high failure rates. Longer and riskier investment cycles and uncertainty of exit through either acquisition or an initial public offering have also slowed the flow of venture capital into formation of early-stage biotechnology companies. This decline in private equity and venture funding for start-ups has been partially offset by an increase in alliances directly between large pharmaceutical firms and academic institutions and a growth in funding through the corporate venture capital arms of large biopharma firms. These and other creative financing developments suggest that there may be efficiency gains from facilitating mechanisms to finance the development of new products without the formation of new start-up companies around each idea.

Markets for Biopharmaceuticals and Medical Technology

Principles of Optimal Insurance

The market for pharmaceuticals in any country depends on the extent of insurance and on the rules of reimbursement used by payers to control the effects of insurance on prices and utilization. Insurance protects consumers against the financial risk of high drug spending but also makes consumers insensitive to drug prices. Demand-side price sensitivity is further undermined by the fact that physicians who prescribe drugs often lack the information and incentives to make price-sensitive choices. Inelastic demand of insured consumers creates incentives for firms to charge higher prices than they would if consumers were informed decision-makers facing full prices. To address this insurance-induced price insensitivity, insurers in most countries use a range of strategies to control prices and utilization of prescription drugs.

The optimal design of insurance coverage is a critical policy issue that affects patients' access and financial exposure, innovation incentives for firms, and budget impact for taxpayers and consumers. In theory, insurance coverage and eligibility should be designed to encourage optimal utilization of existing drugs (static efficiency) and optimal incentives for R&D investment for new drugs (dynamic efficiency) and provide reasonable financial protection for patients. One proposed approach to achieving these three goals is that copayments should be set at marginal cost while the health insurer pays a top-up payment to the biopharmaceutical firm to reward innovation (Lackdawalla and Sood, 2009). In practice, both marginal cost and appropriate top-up payments are difficult to observe, and this approach ignores appropriate financial protection for patients.

An alternative approach, that could in theory achieve second-best static and dynamic efficiency and appropriate financial protection for patients, is for each payer to make reimbursement of a drug conditional on meeting an incremental cost-effectiveness ratio (ICER) threshold – for example, $50 000 per quality-adjusted life-year (QALY) – that reflects the willingness-to-pay for health gain of that payer's enrollees or citizens (Danzon *et al.* 2012). The firm would be permitted to price up to the ICER threshold, but this implies that the price premium would be constrained by the new drug's incremental benefit relative to the comparator or standard of care. The payer would also define coverage eligibility to assure access for patients for whom the drug is cost-effective at the price charged. Copayments would be modest, to collect some revenue but assure affordability. This approach encourages appropriate innovation, by paying a premium for new drugs

that is based on their incremental value, and assures access for patients. If all countries with comprehensive insurance set ICER thresholds unilaterally, based on their willingness to pay for health, manufacturers would have incentives to set prices that differ across countries, reflecting countries' willingness and ability to pay. This result is broadly consistent with Ramsey pricing principles applied to R&D as a joint cost.

In practice, pharmaceutical pricing and reimbursement regulation differs across countries but follows four broad prototypes: (1) the USA exemplifies free pricing in a pluralistic insurance market with competing health plans; (2) Europe exemplifies several approaches to setting price and reimbursement in universal insurance systems; (3) Japan exemplifies price regulation in a market where physicians traditionally dispensed drugs; and (4) many emerging markets illustrate predominantly self-pay markets for drugs. The following sections describe key economic issues in each of these prototypical markets.

Free Pricing with Competing Payers: The US

In the pluralistic US healthcare system, no single payer has sufficient market power to significantly influence prices. Payers rely primarily on tiered formularies and costsharing to preserve some patient price-sensitivity and to enable payers to negotiate discounts in return for preferred formulary status. Although list prices are unconstrained, tiered formularies have achieved significant discounts in therapeutic classes with close therapeutic substitutes. However, in classes with few and/or differentiated products, which includes most specialty drugs and biologics, payers have not used tiered formularies aggressively to attempt to extract discounts. Rather, they rely increasingly on specialty tiers with 20–30% coinsurance rates. However, most patients are protected by catastrophic limits on costsharing or manufacturer copay coupons, which provides appropriate financial protection but leaves little if any constraint on prices. Launch prices for new drugs therefore continue to rise, with several more than $100 000 per year or per treatment course. Similarly, for physician-dispensed biologics, the reimbursement rules create incentives for high launch prices, with little constraint from patient costsharing.

By contrast, generic markets in the US are highly price competitive. High rates of generic entry and penetration, combined with low generic prices, reflect not only the Hatch–Waxman provisions requiring bioequivalence with low entry costs, but also pharmacy substitution and reimbursement rules that assure price-conscious dispensing choices by pharmacies and patient acceptance of generics. Over the past 15 years, patent expiration on many originator drugs has enabled a massive shift toward generics. In 2012, more than 80% of prescriptions were dispensed generically, up from 47% in 2000, but generics account for only approximately 30% of sales by value, due to their low prices. Generic penetration rates are higher and generic prices are absolutely lower in the US than in many other countries (Danzon and Furukawa, 2011). This has provided significant savings to consumers and created budget headroom for high-priced new drugs. As the flow of new generics declines, attention may shift to better ways to assure value for money while preserving access to new pharmaceuticals in the US.

Effects of cost sharing

Patient cost sharing is an important feature of health-insurance design, particularly in the US. In theory, optimal cost sharing balances financial protection of patients against deterring overuse of services and excessive pricing. If other constraints on pricing or use are also used, then optimal cost sharing can be lower. Conversely, Garber *et al.* (2006) show that at levels of cost sharing that are optimal for patient protection, prices would exceed levels needed to incentivize optimal R&D, assuming current patent design is optimal. Unsurprisingly, cost-sharing levels are highest and studies of cost-sharing effects are most numerous in the US.

Because details of cost-sharing structure, levels, stop-loss, and other controls differ across contexts, generalizations are problematic. With that caveat, the evidence confirms that tiered cost sharing affects choices between drugs. Even modest cost sharing affects utilization and compliance. Recent studies have focused on the interconnection between utilization of drugs and utilization of other services, which may be complements (a physician visit may be necessary to get a prescription) or substitutes (compliance with medications may reduce disease flare-ups and emergency visits). Evidence that even modest cost sharing for some chronic medications can significantly affect utilization of more costly medical services has generated great interest in 'value-based insurance design,' which would take these complementarities into account in designing cost sharing. Further research is needed into how optimal cost-sharing structures differ across disease states and drug types, and how their effects in practice are modified by stop-loss limits, manufacturer coupons, and other offsets.

Price and Reimbursement Regulation: The EU

In most industrialized countries with comprehensive insurance, payers control prices and utilization of biopharmaceuticals, with a view to maintaining access while managing within fixed health budgets. Price regulatory systems use three prototypical approaches to setting prices, and some countries use variants of multiple approaches.

Internal referencing

Internal referencing compares the health outcomes with the new drug relative to one or more existing drugs and grants a price premium only if the new drug demonstrates superior safety, efficacy, or other benefits. In principle, this approach rewards innovation that produces measurable incremental value. It is usually applied only at launch. Postlaunch price increases are generally not allowed, and price decreases may be mandated if total expenditure for a drug exceeds the payer's target based on the expected number of eligible patients. These 'volume-price offsets' reduce the price in proportion to the expenditure overrun. This not only keeps expenditure within target but also deters promotion beyond the target population.

A special case of internal referencing is 'reference price reimbursement,' as implemented in Germany and the

Netherlands, in which the payer groups drugs based on similarity of indication, therapeutic effects, and sometimes mechanism of action. The reference price is the maximum reimbursement price for all drugs in the group, and if the actual price is higher, the patient must pay the excess. The reference price is usually based on a low-priced drug within the group, which could be a generic. If classes are broadly defined and ignore significant differences between drugs, this approach can undermine incentives for incremental innovation within a class. In Germany's post-2010 approach to drug pricing, the first step is a formal review of the new drug, relative to comparators. If the new drug is deemed to offer no significant improvement it is assigned to a reference pricing group and is reimbursed at the prevailing reference price. If it is deemed significantly superior, then a new price is negotiated or determined by arbitration. Thus this approach recognizes the importance of benefit evaluation before assigning a drug to reference pricing.

External referencing

With external referencing, the price of the new drug in country X is set at the mean, median, or minimum price of the same drug in a specified set of other countries. This approach is widely used in the EU, and the external reference may be the EU average price. This approach undermines the firm's ability to maintain price differentials between countries although, as noted earlier, such differentials are consistent with Ramsey pricing principles applied to paying for the joint costs of R&D. Further, external referencing creates incentives for firms to delay or not launch drugs in small, low-priced countries, if these prices might undermine potentially higher prices in other countries. Several studies have found evidence of such delays and nonlaunch due to referencing within the EU. Thus, external referencing by one country can lead to spill-over reductions in access and presumably social welfare in referenced countries.

Parallel trade

Although parallel trade is not a form of direct price regulation, it has effects similar to external referencing, but on a more limited scale. Parallel trade (also called commercial drug importation) permits commercial third parties – usually pharmacies and wholesalers – in one country to import drugs purchased in other, lower-priced countries, effectively arbitraging the price differences. The EU authorizes parallel trade between EU member countries as part of the general policy of free movement of goods within the EU.

Although economic theory generally concludes that free trade increases social welfare by enabling consumers to source products from lower cost producers and benefit from the savings, these conditions are generally not met for parallel trade in drugs. Price differentials for drugs between EU countries reflect differences in income and regulatory systems, not differences in production costs, hence there is no resource efficiency gain from such trade. On the contrary, parallel traded goods often require repackaging or relabeling which adds to resource costs. Further, the savings from arbitraging differences in exmanufacturer prices are largely captured by middlemen and are not transferred to consumers/payers. If the net effect of parallel trade is revenue redistribution from manufacturers to distributors that results in reduced incentives for R&D, then the efficiency effect of parallel trade is likely negative.

Cost-effectiveness review

An indirect approach to price control results when the payer reviews the incremental cost-effectiveness of a new drug, relative to standard of care, as a condition of reimbursement. The UK's National Institute for Clinical Excellence exemplifies this approach, with detailed methodological requirements and an explicit threshold cost per QALY. Other countries, including Australia, Canada, and Sweden use similar approaches. If the manufacturer is permitted to set a price up to the maximum at which the new drug meets the ICER threshold, then this approach acts as an indirect control on price that rewards innovation and enables the manufacturer to capture the benefits produced, as required for dynamic efficiency, but without the payer having to directly regulate the price.

Conceptually, it is a simple step to convert cost-effectiveness analysis (CEA) review into an explicit value-based pricing (VBP) regime. VBP would allow a new drug a price premium over current treatment commensurate with its incremental value, which includes both incremental health benefits plus any cost savings. This VBP might be adjusted postlaunch, if the evidence on incremental benefits changes. Whether the VBP should be adjusted if the price of the comparator changes due, for example, to generic entry, is an important policy question that requires further research.

Measurement of Value

If payers are concerned to get maximum value from their expenditures on medical care, then measurement of value of health gain, using CEA and other approaches, is essential. CEA is used as part of broader health technology assessment (HTA) programs to evaluate the incremental health-related effects and costs of new technologies, including drugs, relative to existing technologies. This approach was adopted in the 1990s in Australia, New Zealand, the UK, and Canada, and variants have since been adopted in an increasing number of countries in Europe and more recently in Asia and Latin America. In the US, there is growing interest in comparative-effectiveness research, but with political reluctance to explicitly use cost per QALY or other outcome measures to make reimbursement decisions. CEA grew out of more general HTA, as payers sought more systematic, evidence-based approaches to resource allocation and adoption of costly new technologies within limited budgets.

Implementing value measurement raises both theoretical and practical issues that are being worked out as payers attempt to apply CEA to regulation of pharmaceutical use and prices. Practical questions include what types of evidence to use and how to deal with the inevitable gaps in evidence, especially at launch; use of risk- or cost-sharing contracts when evidence is uncertain; and use of CEA as one among several criteria considered by decision makers. Considerable progress has been made over the past two decades in both theory and measurement of value, primarily using QALYs. Although many

criticisms remain, similar and other criticisms are likely to apply to any alternative metric that attempts to provide a unidimensional measure of value that can compare outcomes across different health interventions. Until superior alternatives are developed, QALYs are likely to remain widely used.

Physician Dispensing

Pharmaceutical reimbursement raises unique issues in countries with physician dispensing. Japan, Taiwan, and South Korea have traditionally exemplified this approach, but each has recently taken steps to separate prescribing and dispensing, in contrast to China where most drugs are still prescribed and dispensed in hospitals and clinics. Simple economic theory and casual observation suggest that where physicians dispense the drugs that they prescribe and can profit from the margin between a drug's acquisition cost and their reimbursement, manufacturers will offer discounts in order to increase this profit margin. The financial incentives of physicians may, therefore, lead to excessive prescribing and bias toward high-margin drugs. Japan traditionally mitigated this effect by biennial review of acquisition prices and downward revision of reimbursement prices to squeeze the margin.

Since 2000, Japan, South Korea, and Taiwan have all taken steps to encourage switching to pharmacy dispensing. The fundamental challenge is that if dispensing income is a significant fraction of total income for physicians, then payers are under pressure to increase other payments to physicians, in addition to now paying pharmacy dispensing fees, which may increase total expenditures. Japan took a gradual, incentive-based approach, paying increased prescription issuance fees for physicians and dispensing fees for pharmacists. The share of prescriptions dispensed through pharmacies has increased to more than 60% in 2011, but cost savings are uncertain because of the additional fees. Korea abruptly required that physicians cease dispensing drugs, which led to physician protests, increased fees, and apparently a shift to higher priced drugs. In response to physician protests, Taiwan allowed clinics affiliated with physician offices to continue dispensing as long as they hired a pharmacist and paid additional fees. Hence, again there has been no reduction in total medical expenditures. Thus, although the evidence suggests that physician prescribing does distort utilization, changing this is not easy and may lead to higher, not lower expenditures, at least in the short run.

Promotion

Biopharmaceuticals

Because the potential benefits and risks of pharmaceuticals are intrinsically nonobvious, providing information to physicians and consumers about a drug's potential effects is critical to its appropriate use. Such information dissemination is provided and financed largely by pharmaceutical firms, through detailing of physicians, journal advertising, distribution of free samples, and direct-to-consumer advertising (permitted only in the US and New Zealand), subject to regulations that differ across countries. The economic and policy issues raised by such types of pharmaceutical promotion are discussed in another part of this encyclopedia. Estimates of the advertising-to-sales ratio in the US range from 6.7% to 18%. The highest estimates include samples valued at retail prices, which significantly overestimate the cost of samples to firms. High advertising-to-sales ratios reflect both the fact of multiple customers – physicians, patients, and payers – and the incentives created by inelastic demand resulting from extensive insurance coverage and high price-to-marginal cost ratios.

The economic literature on promotion is mainly from the US. It suggests that advertising may be both informative and persuasive, and both characteristics apply to some pharmaceutical advertising. Implications for public health and welfare depend on whether or how far advertising raises brand-specific versus industry-wide demand, impacts drug costs, and impacts competition and prices. Empirical evidence is mixed but suggests that consumer advertising is more effective at enlarging the general market, through more physician contact, expanded treatment, etc., whereas physician advertising is primarily persuasive, although the informative role is likely to be greater early in a drug's lifecycle. There is no strong evidence that either consumer or physician-directed promotion raises prices. An overall welfare assessment would require a balancing of complex benefits and costs, and conclusions may depend on type of drug, stage of lifecycle, and other factors that affect the relative magnitude and value of information versus persuasion.

Medical devices

Promotion of medical devices and equipment varies by sector, depending on the user/decision-maker, usually a hospital. However, for complex, implantable devices such as hips or stents, the surgeons who insert the devices may also be major customers because their ease of use with a device affects their time required and willingness to use a device. Such devices require promotion by technically qualified, skilled salespersons who may also play an important role in training the surgeons on how to use the devices. The empirical evidence suggests significant economies of scale in device marketing. This is plausible, because larger firms that produce a full range of products for a particular medical specialty, for example, orthopedics, can spread the fixed costs of hiring and training a dedicated salesforce that promotes only their products, whereas smaller firms that produce only one product may have to rely on general distributors who handle competitors' products. Such economies of scale in marketing are plausibly one factor accounting for the general pattern that small-device firms with good products are usually acquired by larger firms, rather than attempting to seek external financing to grow as independent competitors. Comprehensive data on promotion, sales, and pricing are not available for devices as it is for drugs, hence this remains an important area for future research.

Emerging Markets: Self-Pay for Pharmaceuticals

Pharmaceutical markets in developing countries differ from those of industrialized countries in that insurance coverage

for drugs is very limited, with most people paying directly out-of-pocket, especially those at lower income levels. Theory suggests that manufacturers might seek to practice price discrimination – charging lower prices in these countries than in higher-income countries – if they were assured that the drugs would not be exported to, or their lower prices would not be referenced by, higher-income countries. Similarly, price discrimination between rich and poor consumers within these countries would also increase sales for companies and access for consumers, if it were feasible. However, government policies, distribution systems, and other factors undermine market segmentation in developing countries, although corporate strategies such as dual branding, direct distribution to providers, and consumer coupons can be effective for some drugs. Inefficient distribution systems also pay a role in raising retail prices to consumers, regardless of prices charged by manufacturers in many developing countries.

The global nature of pharmaceutical R&D raises issues of appropriate cross-national price differentials to share the joint costs. Theoretical models of monopoly pricing using either price discrimination or uniform pricing and models of Ramsey pricing applied to payment for the joint costs of R&D suggest that differential pricing is welfare superior to uniform pricing across countries. Assuming that higher-income countries have more inelastic demand, this implies that richer countries should pay higher prices than poorer countries, and this is consistent with most norms of equity. The principle of differential pricing between the richest and poorest nations is widely accepted in policy debates. However, in practice, consensus breaks down on appropriate price differentials and absolute price levels, particularly for middle-income countries with emerging middle classes but large poor populations.

The evidence suggests that drug prices are higher, relative to average per capita income, in low- and middle-income countries. This applies to generics as well as on-patent drugs. Relatively high prices in low- and middle-income countries partly reflects the highly skewed income distributions, which create incentives for firms to target the more affluent segment (Flynn *et al.*, 2006). Further, because regulatory systems in these countries do not require that generic copies be bioequivalent to the originator, quality uncertainty leads producers to compete on brand, using both brand and high price as a proxy for quality (Danzon *et al.*, 2011). In such markets, only the lowest-quality firms compete on price. However, regulatory requirements for bioequivalence of all generics would likely put many local firms out of business. Thus, the obstacles to reform are primarily political.

Vaccines

Preventive vaccines are biologics but differ from other biopharmaceuticals in important aspects. The external costs of infectious diseases imply external benefits from effective vaccines, and this has motivated public mandates, purchasing, and subsidies for vaccines in most countries and government subsidies to supply for particular products, such as Project Bioshield in the US. Relatively small market size and concentrated purchasing have contributed to the existence of few or sole suppliers of most individual vaccines in the US, which has resulted in shortages when the sole supplier experiences production problems.

A considerable literature has examined the cost-effectiveness of different vaccines in different contexts spanning both developed and developing countries, and appropriate policy responses to both suboptimal private demand and sole supplier markets. Policies to promote investment in vaccine R&D include push and pull incentives for the private sector, public production, and the no-fault Vaccine Injury Compensation Program that was implemented in the US in 1986.

After decades of being considered a neglected R&D sector, the past decade has seen a resurgence of interest in vaccines, with several large pharmaceutical companies and many smaller companies entering the US and EU markets, and several WHO-qualified suppliers of vaccines, from India and South Korea, now selling the majority of vaccines to emerging and middle-income countries. Thus, future research must consider factors that differentiate vaccines from other biologics and are common across all or most vaccines and market contexts versus factors that are specific to a particular vaccine or market context. The conditions for purchasing and supplying vaccines differ significantly across countries. Identifying these differences and their effects is a necessary part of generalizing about vaccine economics and appropriate vaccine policy.

Diagnostic Imaging

Like biopharmaceuticals, diagnostic imaging, including computed tomography, magnetic resonance imaging, positron emission tomography, and other technologies, poses challenges related to achieving appropriate use, pricing, and R&D incentives. However, the context and solutions are very different because these are durable machines with high fixed costs but low marginal cost to hospital or physician purchasers. Although a hospital may own the machine, the decision to order a scan is usually made by a physician who is not the same as the radiologist who interprets the scan and is reimbursed. These basic economic issues related to imaging are discussed in another article, focusing on the USA. Another article reviews the reimbursement approaches used in different countries and then discusses the empirical evidence on differences across countries in number of scanners, rates of scans, and expenditures as a percentage of healthcare spending are described in another part of this encyclopedia. These articles establish a foundation and some interesting facts but point out the need for more research in this important area.

Conclusion

The biopharmaceutical and medical equipment industries pose many interesting economic questions that are different from the textbook economic industries or the health services sectors. Like health services, the role of insurance is fundamental in affecting demand. However, because these are research-intensive

industries, optimal insurance and reimbursement design must consider effects on producers' incentives, short and long run, as well as effects on consumer protection. Much progress has been made in understanding the economics of R&D, effects of regulation, promotion, and pricing and reimbursement, particularly for biopharmaceuticals. But this remains a fertile field for future research.

Biosimilars

H Grabowski, Duke University, Durham, NC, USA
G Long and R Mortimer, Analysis Group, Inc., Boston, MA, USA

Introduction

Although the biotech industry is a relatively new source of medical therapies – its first new drug approvals came in the early 1980s – it has recently become a major source of drug industry growth and innovation. New biological entities (NBEs) have a significantly higher likelihood of being a first-in-class or novel introduction compared with other new drug entities (Grabowski and Wang, 2006). For example, the oncology class has experienced the introduction of breakthrough monoclonal antibodies and targeted biological agents resulting from increased knowledge of the molecular mechanisms for cancer (DiMasi and Grabowski, 2007a). Substantial improvements in survival, morbidity, and patients' quality of life have been documented in diseases previously resistant to successful treatment, such as aggressive HER-2 positive breast cancer (Smith *et al.*, 2007) and disability associated with rheumatoid arthritis (Weaver, 2004).

Although NBEs have been an important source of biopharmaceutical innovation, they have also accounted for a rising share of overall drug expenditures in the US and worldwide. They now account for approximately one-quarter of all the US expenditures on pharmaceuticals and represent approximately half of all products in clinical testing (Trusheim *et al.*, 2010). NBEs for oncology patients and other indications also can cost tens of thousands of dollars per course of treatment. They are also frequently targeted to life-threatening and disabling diseases. These facts and trends have made biological entities an increasing focus of attention for policymakers and payers grappling with rising healthcare costs and budgets.

A recent development in Europe and the US is the establishment of an abbreviated pathway for the so-called biosimilars – biological products that are similar to, but not identical with, a reference biological product in terms of quality, safety, and efficacy. Biologics are typically more complex molecules than small-molecule chemical drugs. Biologics are manufactured not through chemical synthesis but through biological processes involving manipulation of genetic material and large-scale cultures of living cells, where even small changes to the manufacturing process may lead to clinically significant and unintended changes in safety and efficacy. As a result, establishing that a biosimilar is 'similar enough' to achieve comparable therapeutic effects in patients is a much more challenging task for companies and regulators than establishing bioequivalence for generic chemical drugs. Biosimilars generally require analytical studies, animal testing data, and some clinical trial evidence on safety and efficacy to gain approval. Biosimilars can provide an important new source of competition to established biological entities. A key issue at the present time is how this competition is likely to develop and how it will influence expenditures for biopharmaceuticals by payers and consumers, investment in innovation, and the research, development, and marketing processes for manufacturers.

The EU has had a framework in place for approving biosimilars since 2005. The European Medicines Agency (EMA) has issued general and class-specific guidelines in six classes and has approved biosimilars in three product classes – somatropins, erythropoietins, and granulocyte colony-stimulating factors (G-CSFs). The experience of biosimilars in various European countries is considered later in this article.

In March 2010, as part of the overall Patient Protection and Affordable Care Act, the US Congress created an abbreviated pathway to approve biosimilars. The Food and Drug Administration (FDA) is in the process of implementing the law, including consulting with potential entrants and developing and releasing for public comment draft guidelines. The US situation is of particular interest as it has been the center of biotech innovation and the country with the largest expenditures on biological products. Although the US has a strong history of generic drug utilization, until the 2010 Act, there was no corresponding pathway for biosimilar entry.

In this article, the authors first discuss regulatory, reimbursement, and economic factors that will affect how competition between branded biologics and biosimilars may evolve. These factors are based on current market dynamics including initial European biosimilar experiences, the provisions of the new US law enacted in 2010, and the US experiences under the Hatch-Waxman Act. Taking into account the scientific, manufacturing, and other differences between biologics and chemically synthesized drugs, and between the regulatory frameworks governing each, expected biosimilar competition is then compared and contrasted with generic competition. Finally, the likely impact of biosimilars on cost savings is briefly assessed and potential impacts on innovation incentives in the biopharmaceutical industry is discussed.

Biosimilar Experience in the European Union

The EU has had in place a well-defined regulatory pathway for biosimilars for several years. In October 2005, the European Commission adopted an EMA framework for the approval of biosimilars. The framework includes an overarching set of principles; general guidelines on quality, safety, and efficacy; and guidelines specific to product classes. To date, the EMA has issued guidelines in six therapeutic classes. Guidance is under development for three other major types of biologics: monoclonal antibodies, recombinant follicle-stimulating hormone, and recombinant interferon beta. Other countries have used a European-like approach, including Canada (where biosimilars are termed 'subsequent entry biologics' (SEBs)) and Japan. Australia adopted the EU guidelines in August 2008.

 doi:10.1016/B978-0-12-375678-7.01208-6

The EMA has required at least one Phase II or III clinical trial for biosimilars to demonstrate similar safety and efficacy to their reference molecules. As opposed to the legislative biosimilar framework in the US, in which the FDA approves applications as biosimilars or interchangeable biosimilars, the EMA framework does not result in any findings of interchangeability, and questions of substitution are left to the member states to regulate. Local substitution laws differ across the EU member states, with some including explicit prohibitions on automatic substitution for biologics (such as Spain and France).

Since 2006, 14 biosimilar products in three therapeutic classes – erythropoietins, somatropin, and granulocyte colony-stimulating factors (G-CSFs) – have been approved, referencing four innovative products, and 13 are currently marketed in Europe. Three applications for biosimilar human insulin (with different formulations) were withdrawn in December 2007, based on failure to demonstrate comparability, and one approved product was later withdrawn (Table 1).

Empirical Evidence from Biosimilars in the European Union

Germany has exhibited the highest level of aggregate demand and market share for any biosimilar product (erythropoietin). To date, Germany's Federal Healthcare Committee, which decides which products and services are reimbursed, has embraced biosimilars wholeheartedly. In addition to a reference pricing system in place for biosimilars, Germany has specific targets or quotas for physician and sickness funds for biosimilars that vary by region. Furthermore, Germany is a main source of biosimilar manufacturing in Europe, and biosimilar companies generally enjoy strong reputations with healthcare providers.

Uptake in other European countries has been slower. In some cases, this reflects later biosimilar entry dates and the timing of reimbursement approval by government payers. Although evidence from experiences in Germany or other European countries with biosimilar substitution are not directly applicable to other markets, given differences in the markets and pricing, access, and reimbursement systems, they nevertheless suggest that over time, payers, physicians, and patients will accept biosimilars.

Table 2 summarizes biosimilar shares in five large European countries: France, Germany, Italy, Spain, and the UK, for the therapies somatropin, erythropoietin alpha, and G-CSF from 2007 to 2009. The extent of biosimilar penetration varied substantially both across therapies within a country and across countries for the same therapy. In Germany, the biosimilar erythropoietin alpha accounted for 62% of total biosimilar and innovator product units sold in 2009, within 2 years of its launch; by contrast, in France, Italy, Spain, and the UK, biosimilar erythropoietin alpha had less than a 5% share in 2009. Biosimilar market shares for G-CSF in 2009 ranged from 21% (UK) to 7% (Spain). However, there is evidence that biosimilar G-CSF shares have grown rapidly in several European countries since 2009 (Grabowski *et al.*, 2012). In particular, a study undertaken by IMS Health found that biosimilars in the G-CSF class had shares more than 50% in Germany, France, and the UK by the third year after launch, and characterized the market for this class in these counties as being commodity-like and mainly controlled by payers (IMS, 2011a). In contrast, the shares for somatropin are lower than the other two classes in most European countries, reflecting conservative physician prescribing and a differentiated market with competition based on price, promotion, and delivery device-based patient convenience.

Biosimilar market development (and share uptake) may differ between European countries and the US, given the differences between their healthcare systems. For example, the US is more litigious than Europe; thus, the FDA may decide to proceed more cautiously and require more clinical data than the EMA has in the past. This broad generalization may not always hold true; however, in the US, the FDA approved Sandoz's enoxaparin sodium abbreviated new drug application (ANDA) as a fully substitutable generic (referencing Lovenox®) requiring no clinical evidence. In contrast, the EMA requires clinical data to approve a biosimilar application for a low molecular weight heparin. Future research comparing biosimilar market attitudes and experience in European countries, countries with a European-like approach (e.g., Australia, Japan, and Canada), the US, and other nations (e.g., the so-called 'BRIC' nations of Brazil, Russia, India, and China) is needed. Given the significant differences in the regulatory, medical delivery, and reimbursement systems between less-developed and more-developed nations, the pattern of biosimilar competition may also be very different.

The United States Biologics Price Competition and Innovation Act

The Biologics Price Competition and Innovation Act of 2009 (BPCIA), enacted as part of the Patient Protection and Affordable Care Act of 2010 (PPACA), created an abbreviated pathway for the FDA to approve biosimilars. This legislation complements the 28-year-old Drug Price Competition and Patent Term Restoration Act of 1984 (generally referred to as the Hatch-Waxman Act), which provides a clear path for generic drug entry in the case of new chemical entities (NCEs) approved under the Food, Drug, and Cosmetic Act (FD&C Act) through the ANDA process. Through that process, generic drugs demonstrated to be bioequivalent to off-patent reference drugs may be approved without the submission of clinical trial data on efficacy and safety. ANDA approval requires a finding that the generic drug is bioequivalent to its reference drug and has the same active ingredient(s), route of administration, dosage form and strength, previously approved conditions of use, and labeling (with some exceptions). Some initially marketed biologic products were approved under the FD&C Act, such as human growth hormones. However, most large molecule biologic medicines were approved under the Public Health Service Act and have not been subject to generic competition under the ANDA process of the Hatch-Waxman Act. Biologic medicines approved under the Public Health Service Act will now be subject to competition from products coming to market through an expedited biosimilar approval process – relying at least in part on the innovator's package of

Table1 European biosimilar regulatory reviews and current marketing status

Trade name	*Active substance*	*Biosimilar sponsor*	*Reference product*	*Therapeutic area*	*Biosimilar decision and date*	
Omnitrope	Somatropin	Sandoz	Genotropin	Turner syndrome, pituitary dwarfism, and Prader–Willi syndrome	Approve	12 April 2006

Filgrastim Hexal	GCSF	Hexal	Neupogen	Cancer, hematopoietic stem cell transplantation, and neutropenia	Approve	6 February 2009
Filgrastim Zarzio	GCSF	Sandoz	Neupogen	Cancer, hematopoietic stem cell transplantation, and neutropenia	Approve	6 February 2009
Nivestim	GCSF	Hospira	Neupogen	Cancer, hematopoietic stem cell transplantation, and neutropenia	Approve	8 June 2010

Abbreviation: GCSF, granulocyte colony-stimulating factor.

Table 2 Initial biosimilar competition in selected EU countries: Market share evidence

	Biosimilar unit share of the molecular entity				
	France	*Germany*	*Italy*	*Spain*	*UK*
Somatropin					
2007	2%	3%	6%	1%	0%
2008	10%	6%	17%	1%	0%
2009	16%	8%	27%	5%	1%
Erythropoietin alpha					
2007	0%	0%	0%	0%	0%
2008	0%	35%	0%	0%	0%
2009	4%	62%	0%	4%	1%
GCSF					
2007	–	–	–	–	–
2008	0%	1%	0%	0%	2%
2009	7%	17%	N/A	9%	21%

Note: Biosimilar share of unit sales are measured based on Defined Daily Dose. Biosimilar G-CSF was not launched until 2008, so biosimilar shares for 2007 are not reported in Table 3. For G-CSF in Italy in 2009, the biosimilar share is recorded as N/A to reflect insufficient data for calculating a biosimilar share – fewer than 5000 DDDs were reported in the data for combined innovator and biosimilar unit sales in Italy that year.

data or a prior FDA approval – for the first time as a result of the BPCIA.

The key provisions of the new legislation establishing an abbreviated pathway for the FDA to approve a biosimilar are:

- Biosimilarity: A biosimilar does not have to be chemically identical to its reference product but must be "highly similar to the reference product notwithstanding minor differences in clinically inactive components" and there must be "no clinically meaningful differences, in terms of safety, purity, and potency." (PPACA, Section 7002 (b)(3))
- Interchangeability: The FDA may deem a biosimilar interchangeable with its reference product if it can be shown that it "can be expected to produce the same clinical result as the reference product in any given patient" and that "the risk in terms of safety or diminished efficacy of alternating or switching between use of the biological product and the reference product is not greater than the risk of using the reference product without such alternation or switch." (PPACA, Section 7002 (k)(4)) The first biosimilar shown to be interchangeable is entitled to a 1-year exclusivity period during which no other product may be deemed interchangeable with the same reference product.
- Regulatory review: The FDA will determine whether a product is biosimilar to a reference product based on stepwise consideration of analytical, animal-based, and clinical studies (including the assessment of immunogenicity and pharmacokinetics or pharmacodynamics). In February 2012, the FDA released the first three documents in a set of guidance documents for the development of biosimilars under BPCIA.
- Regulatory Exclusivity for the innovative biologic: Biosimilar applications may be submitted beginning 4 years after FDA approval of the reference innovative product. Before the FDA can approve a biosimilar using the abbreviated pathway, there is a 12-year period of exclusivity following FDA approval of the innovative biologic. An additional 6 months of exclusivity is available for the reference innovative biologic if pediatric-study requirements are met, which applies to both the 4- and 12-year exclusivity periods. The most important (and contentious) of these exclusivity provisions is the 12 years of exclusivity for an innovative biologic before a biosimilar can enter using an abbreviated application. This 12-year exclusivity term is referred to as regulatory exclusivity in distinction from the exclusivity afforded through patents granted by the US Patent and Trademark Office.
- Limitations on 12-year exclusivity: Several types of licensures or approvals are not eligible for 12-year exclusivity, including: (1) a supplemental biologics license application (sBLA) for the reference biologic; (2) a subsequent BLA filed by the same sponsor, manufacturer, or other related entity as the reference biologic product that does not include structural changes in a biologic's formulation (e.g., a new indication, route of administration, dosing schedule, dosage form, delivery system, delivery device, or strength); or (3) a subsequent BLA filed by the same sponsor, manufacturer, or other related entity as the reference biologic product and that includes structural changes in a biologic's formulation but does not result in improved safety, purity, or potency.
- Reimbursement: A potential disincentive for biosimilar adoption is mitigated by setting the reimbursement for a biosimilar under Medicare Part B at the sum of its Average Selling Price (ASP) and 6% of the ASP of the reference biologic.
- Patent provisions: The BPCIA requires a series of potentially complex private information exchanges between the biosimilar applicant and reference product sponsor, followed by negotiations and litigation, if necessary. In contrast to the patent provisions for NCEs under the Hatch-Waxman Act, there is no public patent listing akin to the Orange Book, no 30-month stay when a patent infringement suit is brought, and no 180-day exclusivity awarded to the first firm to file an abbreviated application and achieve a successful Paragraph IV patent challenge.

Food and Drug Administration Regulations and the Costs of Developing a Biosimilar

The new law authorizing biosimilars gives broad latitude to the FDA to define the process and standards for approval. FDA decisions will affect both the demand for and the supply of biosimilars:

- The level of evidence required will affect the costs of market entry, the number of biosimilar entrants, and the assets and capabilities required to compete successfully.
- The level of clinical trials and other evidence required to establish interchangeability or similarity will also potentially affect the level of market adoption, as greater levels of evidence may increase physicians', payers', and patients' confidence in a biosimilar medicine.

- Naming conventions and pharmacovigilance requirements for biosimilars will affect market entry and perceptions of substitutability by physicians, payers, and patients, as well as safety monitoring after launch.
- Whether data on one indication can be extrapolated to others – absent additional clinical trials in that patient population will have an impact on entry decisions, perceptions of substitutability, and biosimilar market uptake.
- Definitions of what constitutes changes in 'safety, purity, or potency,' as they are applied to determine whether a 12-year exclusivity is to be authorized for next-generation products will affect biotech investor incentives.

Criteria for Establishing Biosimilarity

The initial draft guidance documents released by the FDA in February 2012 state that "FDA intends to consider the totality of the evidence provided by a sponsor to support a demonstration of biosimilarity" (emphasis added). For a given biosimilar application, the FDA draft guidance notes that "(t)he scope and magnitude of clinical studies will depend on the extent of residual uncertainty about the biosimilarity of the two products after conducting structural and functional characterizations and possible animal studies." (Food and Drug Administration (FDA), 2012a, pp. 2, 12). Theoretically, this could encompass, at one extreme, only a bioequivalence study (similar to what is required for generic approval under Hatch-Waxman) or, at the other extreme, when science and experience require more data, a full program of clinical studies equivalent to that included in a biologic's license application.

FDA officials, in a New England Journal of Medicine publication, had previously stated that "[a]lthough additional animal and clinical studies will generally be needed for protein biosimilars for the foreseeable future, the scope and extent of such studies may be reduced further if more extensive fingerprint-like characterization is used." (Kozlowski *et al.*, 2011, p. 386) In the future, the agency hypothesizes, the current state-of-the-art for analytic characterizations may advance to allow highly sensitive evaluations of relevant product attributes and permit a 'fingerprint-like' identification of very similar patterns in two different products (such strategies were cited in the FDA's approval of the Sandoz ANDA for enoxaparin sodium, a complex mixture, mentioned later in this article.)

The costs of an FDA submission for the US approval could be lower for biosimilars already on the market in Europe if the biosimilar can rely on previously undertaken European clinical trials, at least for some products. In its draft guidance documents released in February 2012, the FDA noted it will accept clinical studies undertaken for approval in other jurisdictions under certain circumstances, when justified scientifically and when accompanied by 'bridging' data. However, it also noted, "[a]t this time, as a scientific matter, it is unlikely that clinical comparisons with a non-US-licensed product would be an adequate basis to support the additional criteria required for a determination of interchangeability with the US-licensed reference product," and the specific data requirements for products will be determined by the FDA on a case-by-case basis. (Food and Drug Administration (FDA), 2012b, p. 8.)

If the FDA requires significant clinical trial evidence, approvals for biosimilars, as compared with generics, will require a much bigger investment. The cost for biosimilar approval will depend on the number and size of the necessary clinical trials, the number of indications involved, and other specific FDA requirements. The current requirement for a BLA is typically two large-scale Phase III pivotal trials. If the FDA requires at least one Phase II/III type study comparable to those undertaken by innovators, then the out-of-pocket costs will likely be in the range of US$20 million to US$40 million for the studies alone. In addition, the preclinical costs associated with biosimilars may in some cases be higher for biosimilars than for innovative products, as they entail modifying the production process to achieve a specific profile that very closely approximates the reference product without the benefit of the innovator's experience. Others have estimated that for very complex biologics such as some monoclonal antibodies, biosimilar development costs could total US$100 million to US$200 million and take 8 or more years to bring a product to market (Kambhammettu, 2008). In contrast, the cost of completing bioequivalence studies for generic drugs is estimated to be only US$1 million to US$2 million.

Regulatory Requirements for an Interchangeability Designation

Another key regulatory issue will be the analytical and clinical evidence required to deem a biosimilar interchangeable with its reference product, thus enabling automatic substitution without physician approval, subject to relevant state laws. Under the BPCIA, for products used more than once by patients (the majority of biologics), the biosimilar sponsor will need to demonstrate that switching between the biosimilar and reference product poses no additional risk of reduced safety or efficacy beyond that posed by the reference product alone. Postapproval interchangeability assessments may require a strong postmarketing system and evaluation of postmarketing data.

Achieving an FDA finding of interchangeability may be associated with far greater development costs than achieving a determination of biosimilarity, so it may be limited initially to a select few examples where molecules meet certain tests for establishing 'sameness' through differentiated characterization or other available technology. For instance, the availability of differentiated analytical characterization technology supported the FDA's approval of Sandoz's ANDA for generic enoxaparin sodium (referencing Lovenox®). Although not a biosimilar (Lovenox®, a chemically synthesized product derived from natural sources, has been described as a complex mixture), the factors that the FDA cited in its approval may give some insight into the Agency's current approach and how continued technological change could influence the evidence necessary to establish interchangeability in the future.

For classes of more complex biologics, applications for biosimilarity will likely require some clinical trial data in order to be approved and costly switching trial data in order to be deemed interchangeable. Many firms may elect not to make the investments necessary to pursue interchangeability initially, given the current state of scientific knowledge regarding

biosimilars and high levels of regulatory uncertainty. This is in contrast to small-molecule generic drugs, where an 'A' rating by the FDA recognizes the products as therapeutically equivalent and eligible for substitution by pharmacists without physician approval, subject to state substitution laws, thus driving rapid share loss by the branded reference product.

Manufacturing Costs

The ongoing cost of manufacturing biological entities is also significantly higher than for chemical entities. Biosimilar manufacturers may need to construct expensive plants or obtain long-term lease or purchase agreements with third parties that have an FDA-approved facility if they do not already have excess suitable manufacturing capacity. In any event, the cost of entry for biosimilars in terms of plant capacity is likely to be an order of magnitude higher than for generic drug products (which may total only US$1 to US$2 million) and may be closer to two orders of magnitude higher. The high costs of entry – particularly the substantial capital requirements – are likely to restrict the number and types of biosimilar entrants, at least initially. Furthermore, initial entry is likely to be limited to the biologics with the largest revenues and those where scientific and market feasibility have been demonstrated in Europe.

The Perspectives of Healthcare Payers, Providers, and Patients

Reimbursement and Payer Considerations

Payer reimbursement policies and access control mechanisms also can substantially affect the extent and speed of biosimilar uptake. Consistent with relevant local laws, regulations, and practices, payers will develop coverage and reimbursement policies and make individual pricing, reimbursement, and access decisions for biosimilars and their branded reference products.

Cost sensitivity and willingness to encourage the use of biosimilars in place of their reference therapies may vary across different payers, including private insurers and public payers. Payer controls that restrict patient and physician therapy choice and access may also vary according to the setting in which care occurs (e.g., inpatient hospital or physician office), whether the biosimilar is rated interchangeable, the therapeutic indication and disease severity (e.g., oncology or growth disorders), as well as other factors.

Private insurers

Historically, in the US, managed care plans have been reluctant to restrict access or pursue aggressive cost-control measures because many biologic therapies are: (1) targeted to life-threatening illnesses such as cancer or other diseases that involve serious disability and (2) often lack close substitutes. In addition, biologics that are dispensed by physicians are often managed within plans as medical benefits rather than pharmacy benefits and are typically less subject to centralized controls or formulary restrictions. This has been changing over the past several years, particularly in indications where there is a choice between multiple brand name biologics. The introduction of biosimilars can be expected to accelerate these trends toward more active management of biologic choice, costs, and utilization.

Medicare

Medicare reimburses biologics under either the Part B or the Part D program, depending on the mode of administration. Many biologic drugs are currently dispensed in a physician's office, clinic, or hospital as infused agents. The use of these biologics for Medicare patients is covered under the Medicare Part B program, whereas self-injectable biologics dispensed in pharmacies (including by specialty pharmacy or mail-order programs) are covered by the Part D program.

Medicare Part B

In designing the new abbreviated pathway for biosimilars, Congress acknowledged that the Medicare rules for reimbursement of drugs administered under Part B could provide inadequate financial incentives for providers to utilize lower priced biosimilars. Part B drugs have historically been purchased through a 'buy and bill' approach by providers who also make decisions about which therapies are appropriate for a given patient. The provider is reimbursed by Medicare for administering a Part B drug, and the level of reimbursement is based on the manufacturer's weighted ASP for the category to which the drug belongs (defined by a unique code), plus 6%. When generics are assigned to the same code as their reference new chemical entity, physicians receive the same level of reimbursement, the volume-weighted average ASP for all manufacturers' products, for using either the generic or the reference product. Thus, physicians generally have a strong incentive to utilize the lower cost generic product, (although the physician's choice of generic or reference product also depends on the net acquisition cost of both products to the physician, based on any contracts that may be in place with the brand manufacturer as well as the pricing strategy of the generic entrant).

Because biosimilars are unlikely to be deemed interchangeable by the FDA, at least initially, to the degree they are thus unlikely to be assigned to the same code as the brand product, physicians may have an incentive to utilize the more expensive (higher ASP) reference product for patients, as reimbursement is based on ASP plus 6%. To mitigate potential financial disincentives for physicians to adopt biosimilars, the new legislation sets biosimilar reimbursement under Medicare Part B at the sum of the biosimilar's ASP and 6% of the ASP of the reference biologic product. The reference biologic product will continue to be reimbursed at its own ASP plus 6%. By basing the 6% payment to providers on the reference brand's ASP, the legislation seeks to mitigate provider disincentives to adopt lower cost biosimilars when they are not deemed to be interchangeable and are placed in separate codes. Whether this reimbursement provision will be sufficient to overcome physician experience and loyalty to the reference biologic, as well as other financial incentives, is an open question.

Medicare Part D

Privately offered Medicare Part D drug programs cover drugs available at retail or via mail order, including self-injectable biologics. Biologics accounted for only 6% of total

prescription drug costs in the Medicare Part D program in 2007 (Sokolovsky and Miller, 2009); however, spending for biologics within the Part D program is expected to increase rapidly in the coming years. Between 2007 and 2008, MedPac estimates indicate that prices paid for drugs on specialty tiers (including biologics) in the Part D program grew by 18%, compared with 9% for all Part D drugs. Expenditures for self-injected biologics are expected to continue to grow rapidly as these agents are increasingly used to treat a range of diseases, from rheumatoid arthritis to multiple sclerosis to human growth deficiency, and a large number of new biologics are currently under development. The high price of self-injected biologics relative to traditional NCEs also suggests that biologics will comprise an increasing share of Part D expenditures. This shift may lead payers to pursue pharmacy management techniques aimed at controlling utilization of these biologics.

Many Medicare Part D plan designs include a specialty drug tier, with median coinsurance rates increasing from 25% in 2006 to 30% in 2010 for stand-alone prescription drug plans and to 33% in 2010 for drug plans offered as a part of Medicare Advantage (Hargrave *et al.*, 2010). Coinsurance plan designs could produce strong incentives to utilize biosimilars if substantial discounts emerge for biologic products with expensive courses of treatment for patients. Preferred specialty drugs might be subject to lower rates of coinsurance, to a copayment rather than to coinsurance, or to lower patient out-of-pocket costs at the same coinsurance rate.

One limiting factor to formulary incentives for biologics in Medicare Part D is that enrollees with low-income subsidies make up a disproportionately large share of the market for biologics under the Part D program. Given that these individuals are subject to limited cost sharing, other instruments such as step therapy and prior authorization may be employed to provide incentives for the use of biosimilars.

Medicaid

Medicaid Preferred Drug Lists (PDLs) reflect preferred biologic products in a number of therapeutic categories. Preferred drugs can be dispensed without the access controls (e.g., prior authorization) applied to nonpreferred drugs. For example, online PDLs for Florida, Illinois, New York, Ohio, Pennsylvania, and Texas indicate that rheumatoid arthritis (RA), hepatitis C (HCV), and human growth hormone formularies in these six large states preferred two or three RA agents (of six), one or two HCV agents (of five), and between two and five human growth hormones (of nine agents/forms). Medicaid programs can be expected to encourage biosimilars through PDLs and other medical management instruments. States with managed Medicaid programs apply formulary and access management techniques common in commercial insurance plans, and such managed programs are becoming more common.

Hospitals

Hospitals typically bear the costs of all drugs, including biologics, used during inpatient hospital stays as part of a fixed diagnosis-related group-based reimbursement per admission (DRG) that includes all services and products used during the episode of care. Consequently, these hospitals have incentives to implement formularies of preferred drugs and other mechanisms that encourage the use of lower priced products, possibly including biosimilars. As a result, for biologics that are generally used in hospital settings, hospitals will play a larger role than insurance companies in determining the demand for biosimilars. In the hospital sector, Pharmacy and Therapeutics (P&T) committees review the drugs that are stocked, on standing order forms, and which can be used by physicians. Hospitals also rely on Group Purchasing Organizations (GPOs) to gain leverage in negotiating discounts from suppliers, including biologic manufacturers. Because the hospital GPO market is highly concentrated, favorable contracts with a handful of suppliers can affect product selection. In addition, fixed reimbursement creates strong incentives for input cost reductions. To the degree that biologics used in the inpatient hospital setting are included in the DRG, depending on how significant a portion of spending they represent, hospitals may be more aggressive in implementing access controls to favor the utilization of some biosimilars, if biosimilar prices are not countered by originator manufacturer discounts.

United States healthcare reform initiatives

More widespread adoption of comparative- and cost-effectiveness analyses across the US healthcare system could also influence adoption of biosimilars. Formal cost-effectiveness reviews by payers have been well established in countries outside the US in the form of Health Technology Assessments (HTAs). In the UK, for example, the National Institute for Health and Clinical Excellence's (NICE) coverage recommendations have been based on strict reviews of cost-effectiveness calculations relative to current treatment, with an implied threshold value of an acceptable incremental cost per quality-adjusted life-year (QALY).

Finally, long-term changes in reimbursement policies may also shift financial incentives toward the use of biosimilars. For example, the adoption of global payment strategies, rather than fee-for-service reimbursement, or some form of shared savings, could strengthen the link between physician and/or hospital compensation and the use of lower priced biologics. Global payment strategies provide incentives for the adoption of lower cost treatments (and potentially encourage greater price competition) by setting a fixed payment level for a patient/episode of care, with all or some portion of the cost savings accruing to the care providers. Several states are considering implementing global payment strategies, and it has been suggested that government programs such as Medicaid could be the first to implement these strategies.

Patient and Physician Perspectives

The rate of biosimilar penetration is expected to vary by disease indication, patient type, physician specialty, and other factors. As noted, rates of patient and physician acceptance of biosimilars are expected to be lower when the biosimilar lacks an interchangeability rating. In addition, rates of biosimilar acceptance may vary according to such physician and patient-focused factors as: Whether the physician specialty is historically more price-sensitive or demonstrates greater levels of brand loyalty in therapy choice (for instance, allergists vs. rheumatologists); whether the biosimilars will be used long-term

as maintenance therapy or only once or twice (particularly if long-term clinical data are not available); whether the indication is life threatening or the implications of therapeutic nonresponse or adverse reactions are perceived to be very serious; or whether the difference in ease-of-use or out-of-pocket cost to the patient of the brand instead of the biosimilar is expected to be high.

When patients are stable on a given maintenance therapy, biosimilar substitution may tend to be concentrated among new patient starts. (The same is true of 'switches' between one branded drug and another.) As a result, the penetration of biosimilars for indications with a low rate of turnover in the patient populations may be limited if products are not interchangeable. The degree of biosimilar uptake will also depend on cost differences and the financial incentives to utilize biosimilars employed by managed care and government payers. These incentives, however, are likely to be tempered if existing patients are responding well to an established therapy. Other factors such as specialists' brand loyalty, clinically vulnerable patient populations, and physician conservatism in switching stable patients to new therapies are also likely to keep rates of biosimilar uptake for current patients below those for new patients.

Another important demand-side factor is the perspective of specialist physicians and patient groups concerning biosimilars. Physicians who have years of experience with the reference biologic may be reluctant to substitute a biosimilar even for new patients until sufficient experience has been accumulated in clinical practice settings, as opposed to in clinical trials. To stimulate demand, it may be necessary for biosimilar firms to establish 'reputation bonds' with physicians through strategies similar to those employed by branded firms that communicate information to establish brand value through physician detailing, publications, advertising, and education programs. In addition, patient assistance programs and contracts with health plans, pharmacy benefit managers (PBMs), hospitals, or provider groups, which exercise control over therapy choice, may be used in a targeted way to affect the economic proposition associated with biosimilar adoption. These measures will increase the cost of drug distribution and marketing for biosimilars compared with small-molecule generic drugs, where such marketing and sales costs are minimal and demand is purely driven by lower price and pharmacy contracts for availability.

Biosimilar Competition versus Generic Competition

Since the passage of Hatch-Waxman 28 years ago, generic entry has become a principal instrument of competition in the US pharmaceutical market. Generic products in 2010 accounted for 78% of all the US retail prescriptions, (IMS, 2011b) compared with only 19% in 1984 (Federal Trade Commission, 2002). As discussed, the growth of generic utilization has been accelerated by various formulary and utilization management techniques such as tiered formularies, prior authorization and step therapy requirements, higher reimbursements to pharmacies for dispensing generics, and maximum allowable cost (MAC) programs.

A distinctive pattern of generic competition has been observed in numerous economic studies (Grabowski, 2007). There is a strong positive relationship both between a product's market sales and the likelihood of a patent challenge and between the number of generic entrants and the intensity of generic price competition once the exclusivity period has expired. An increasing number of products are now subject to patent challenges earlier in their product life cycle, as generic firms seek out the 180-day exclusivity period awarded to the first firm to file an ANDA with a successful Paragraph IV challenge. Successful products typically experience multiple entrants within the first several months after patent expiration, and generic price levels drop toward marginal costs rapidly as generic entry increases.

Theoretical Models of Biosimilar Competition

Given the much higher costs of entry for biosimilars compared with generic drugs, as well as the other demand- and supply-side factors discussed in the section Food and Drug Administration Regulations and the Costs of Developing a Biosimilar, the pattern of biosimilar competition is expected to differ from current generic competition. In particular, fewer entrants and less intensive price discounting are expected and competition may resemble branded competition more than generic competition (Grabowski *et al.*, 2006). This is currently the case in the human growth hormone market, where eight products compete both through price, patient support, and product delivery differentiation. In 2006, Sandoz entered the human growth hormone market with Omnitrope® (which referenced Pfizer's Genotropin®, via the section 505(b)(2) pathway of the Hatch-Waxman Act). Omnitrope® has struggled to gain market share. Initially, it was reported to have priced at a 30% discount based on wholesale acquisition cost (WAC) compared with the most widely used biologic in this class, Genotropin®. By 2008, Omnitrope®'s discount had increased to 40% (Heldman, 2008). Despite these discounts, its share of somatropin use remained below 5%. These outcomes may not be reflective of the pattern of substitution for biosimilars generally, given that the human growth hormone market was a mature one with a number of competitors, and also given the differentiation by established brands via sophisticated pen- or needle-free delivery systems in this product class. With the approval of a pen delivery device system, and a strategy that includes physician detailing and patient support services, Omnitrope®'s share of prescriptions dispensed increased to 19% in September 2012.

To date, some theoretical analyses have attempted to model the likely scenarios for biosimilar competition in the US market. One paper implements a simulation approach and projects that the relatively high cost of biosimilar entry will result in relatively small number of entrants even for larger selling biologic products and more modest discounts on biosimilars than in the case of generics (Grabowski *et al.*, 2007). Other research relies on a segmented model of biosimilar competition, where biosimilars would be utilized significantly in price-sensitive segments of the market but less so in the nonprice-sensitive segments (given the reluctance of many providers to utilize biosimilars until considerable

Table 3 Biosimilar competition US market share and price discount economic analyses

Source	*Peak biosimilar penetration*	*Biosimilar discount to preentry brand price*	*Basis*
Grabowski (2007)	10–45%	10–30% (year 1)	Higher estimates correspond to complex small molecules
Congressional Budget Office (CBO) (2008)	10% (year 1) 35% (year 4)	20% (year 1) 40% (year 4)	Similar market situations
Express Scripts (2007)	49%	25% (year 1)	Therapeutic alternatives
Avalere Health (2007)	60%	20% (year 1) 51% (year 3)	Average small-molecule generic drug penetration rates

clinical experience has accumulated) (Chauhan *et al.*, 2008). In this model, average price discounts depend on the relative size of these market segments. The findings indicate that, given a relatively small number of branded biosimilar competitors, the innovator will discount prices from preentry levels but not as much as the biosimilar entrants. This is in contrast to generic competition where branded firms typically do not lower prices postentry but may license an authorized generic when only a small number of generic competitors are expected as a result of a successful paragraph IV entry with a 180-day exclusivity award (Berndt *et al.*, 2007).

Empirical Studies of Generic Drug Analogs

Another line of research attempts to predict how biosimilar competition will emerge by considering analogous situations, including the US generic market for certain products which share some characteristics suggestive of biologics. In one example of this research, small-molecule drugs are divided into two classes, noncomplex and complex, with complex drugs being those that meet two of the following criteria: black box warnings, narrow therapeutic index, prescribed by specialists, oncology products, or manufacturing technology that is available to only a limited number of firms (Grabowski *et al.*, 2011a). Price and quantity data from IMS Health Inc. were analyzed for 35 conventional (nonbiologic) drugs that experienced generic entry between 1997 and 2003, and those drugs classified as complex were found to have significantly lower levels of generic share and price discounts. Furthermore, complex drugs faced only 2.5 generic entrants 1 year following initial generic entry, whereas noncomplex drugs faced an average of 8.5 generic entrants.

Although data from conventional small-molecule generics should not be directly applied to estimate biosimilar shares following market entry, they suggest that uptake rates for biosimilars may be likely to be significantly lower than those for generics, at least initially. Furthermore, these more complex generic drugs are rated therapeutically equivalent (that is, they have an FDA rating of A) and, therefore, benefit from some automatic substitution. To avoid substitution, physicians need to specify in 'do not substitute' orders that prescriptions are to be dispensed as written. At least initially, most biosimilars will not be rated therapeutically equivalent and, therefore, will not be subject to automatic substitution.

Table 3 summarizes other market share and price discount analyses generally based on selective aspects of the US generic market. Most notably, as part of the evaluation of the proposed legislation regarding biosimilars, the Congressional Budget Office (CBO) predicted a penetration rate of 35% with price discounts by biosimilars of 40%. Other estimates of market penetration from a pharmacy benefit management firm, Express Scripts, as well as by Avalere Health, a consulting firm, tend to be somewhat higher than either the Grabowski (2007) or the CBO values, with penetration in the 50–60% range, and somewhat higher discounts in the case of the Avalere study (50% by year 3).

The FDA approval of generic enoxaparin sodium, rated as therapeutically equivalent (having an A-rating) to branded Lovenox®, provides important data about competitive pricing strategy and market acceptance of generics for a complex, 'biologic-like' product. Other notable attributes of Lovenox® include large expenditures by payers (pregeneric entry sales of more than US$2 billion) and a complicated manufacturing process. Currently, the FDA has approved generic enoxaparin applications from two third-party manufacturers, Sandoz (partnered with Momenta) and Amphastar (partnered with Watson), although the latter is the subject of patent litigation. In addition, there had been for a time an 'authorized generic' supplied by Sanofi, the branded manufacturer of Lovenox®. Sales of generic enoxaparin have been robust and there has been rapid erosion of Lovenox®'s revenues and market share.

Projected Savings to United States Consumers

The CBO estimated that the provisions in the current health care law establishing a biosimilar pathway would reduce federal budget deficits by US$7 billion over the 2010–2019 period. This finding is consistent with a 2008 CBO study of a similar Senate bill, which estimated a reduction in federal budget deficits of US$6.6 billion and a reduction in biologic drug spending of US$25 billion for the 2009–18 period. Over the full 10-year period, the US$25 billion in reduced biologic drug spending would represent roughly 0.5% of national spending on prescription drugs, valued at wholesale prices. The bulk of these estimated savings accrue in the last 5 years of the 10-year time ranges analyzed. Savings beyond the 10-year period may increase substantially as more biologics lose patent and 12-year exclusivity protections and as scientific advances reduce the cost of developing and producing biosimilars.

A number of the largest-selling biologic products may face losses of some key patent or 12-year exclusivity protections in the coming years. Determining the effective patent-expiry date

for any given biologic is fraught with uncertainty because of unknowns such as which patents comprise the portfolio protecting an individual biologic, of which there may be many; the strength of those patents in the face of challenges; and the ability of biosimilar manufacturers to work around existing patents. In November 2011, for example, Amgen announced that it had been issued a patent for the fusion protein etanercept (Enbrel®) that could block biosimilar competition until 2028 (the term is 17 years from the date of award, rather than 20 years from the date of application, due to the date of the patent application). Previously, many public sources had anticipated biosimilar entry exposure for Enbrel® as early as 2012. Based on a review of patent-expiry information disclosed in manufacturers' financial reports and supplemented with additional public information from academic literature, research reports, patent filings, and court documents, the earliest publicly reported potential patent-expiry dates for a set of top-selling biologics occur in a timeframe between 2013 and 2018. These biologics include Epogen®/Procrit®, Neulasta®, Remicade®, Rituxan®, and Humira® (all products having multibillion dollar US sales in 2011). The date when these biologics may actually experience biosimilar market entry under BPCIA depends on many technical, market, regulatory, and legal factors, such as whether entry will be at risk, and the outcome of the patent litigation that is likely to ensue.

The extent of biosimilar cost savings will depend on the timing and number of biosimilar entrants, their market share and price discounts relative to the originator's product, and the potential competition from the introduction of 'biobetters' or next generation products in particular product classes. There is likely to be considerable variation in how competition evolves across biological products reflecting molecule complexity, regulatory criteria, the originating firm's patent estates, patient populations and physician specialties, as well as changing reimbursement systems and procedures. In contrast to small-molecule generic competition, there is unlikely to be a 'one-size-fits-all' pattern for biosimilar competition for the foreseeable future.

Innovation Incentives

As it did with Hatch-Waxman, Congress has attempted to balance the objectives of achieving cost savings from an abbreviated pathway for biosimilars with preserving innovation incentives for new biologics. As discussed earlier, NBEs have been an important source of novel and therapeutically significant medicines. Major advances have occurred for several oncology indications, multiple sclerosis, rheumatoid arthritis, and other life-threatening and disabling illnesses. BPCIA differs from Hatch-Waxman in the term of the data exclusivity period for innovators: BPCIA establishes 12-years data exclusivity period for innovative biologics, whereas Hatch-Waxman establishes a 5-year exclusivity period for NCEs. (The FDA cannot approve an abbreviated application relying on the innovator's data until these exclusivity periods expire.) Furthermore, as mentioned earlier, the private information exchange process for resolving patent disputes is very different for biologics under the BPCIA than the 'Orange Book' public disclosure and Paragraph IV challenge framework for NCEs under Hatch-Waxman.

Regulatory Exclusivity and Patent Protection

The process of discovering and developing a new biologic is a long, costly, and risky venture. DiMasi and Grabowski have estimated that the cost to develop a new FDA-approved biopharmaceutical is US$1.2 billion in risk-adjusted costs, capitalized to 2005 dollars using an 11.5% discount rate (DiMasi and Grabowski, 2007b). DiMasi and Grabowski found that NBEs cost more in the discovery phase, take longer to develop, and require greater capital investment in manufacturing plants than NCEs. They found that the probability of success is higher for biologics than for NCEs, but biologics that fail do so later in the Research and Development (R&D) life cycle. After adjustment for inflation and the different time periods studied, the cost of developing an NBE and an NCE are roughly comparable in value.

Intellectual property protection in the form of patents and regulatory exclusivity are the primary policy instruments by which governments encourages risky investment in R&D for new medicines (together with any tax subsidies or direct financial investment programs that may apply). Regulatory exclusivity and patents have separate but complementary roles. The US government awards patents for inventions based on well-known criteria: novelty, utility, and nonobviousness. A regulatory exclusivity period, however, is needed because after invention a long, risky, and costly R&D process remains for the development of new medicines. Effective patent life is often uncertain because significant patent time elapses before FDA approval and because there is uncertainty associated with the resolution of any patent challenges. As a result, regulatory exclusivity provides a more predictable period of protection. It essentially acts as an 'insurance policy' in instances where patents are narrow, uncertain, or near expiry.

The protection afforded by regulatory exclusivity may be particularly important for innovation incentives in biologics to the degree that patents in biologics are narrower in scope than those for small-molecule drugs and more likely to be successfully challenged or circumvented. This may be true to the degree that biologics rely more on process patents, for instance. Given that a biosimilar will be slightly different in its composition and/or manufacturing process, a court may determine that it does not infringe the innovator's patent. This has the potential to lead to a seemingly contradictory outcome where a biosimilar may be 'different enough' not to infringe the innovator's patents but still 'similar enough' to qualify for approval through an abbreviated approval pathway.

As discussed, the BPCIA grants 12 years of exclusivity for innovative biologics during which the FDA may not approve biosimilars referencing them, compared with 5 years of exclusivity for NCEs under the Hatch-Waxman Act, during which an abbrevaited application referencing them cannot be submitted (plus a stay on generic entry for up to 30 months when there is a patent challenge to allow for resolution of litigation). In contrast, the EU has harmonized across member states an '8 + 2 + 1'approach for both NCEs and NBEs (consisting of 8 years of data exclusivity, during which generic competitors may not reference the innovator's data in their applications; 2 years of market exclusivity during which generic marketing authorizations cannot be approved; and a potential additional 1 year of protection for new indications that

demonstrate significant clinical benefits over existing therapies that are approved within the first 8 years after the original molecule's approval).

Economic Analyses of the 12-Year Exclusivity Period

The US 12-year exclusivity period for innovative biologics was the focus of substantial debate by legislators. The 111th Congress considered bills with exclusivity periods ranging from 5 to 14 years. To provide economic analysis to the legislators, Grabowski (2008) developed a breakeven financial analysis using historical data on R&D costs and revenues for new biologics and the risk-adjusted market return on investment in the industry. Under this model, a representative portfolio of biologic candidates would be expected to 'break even' (or recover the average costs of development, manufacturing, promotion, and the industry's cost of capital) between 12.9 and 16.2 years after launch.

A recently published Monte Carlo simulation model examines the interaction between regulatory exclusivity terms and patent protection periods under different scenarios to highlight the circumstances where each is important in maintaining innovation incentives (Grabowski *et al.*, 2011c). The results of this analysis are generally consistent with Congress' determination that a regulatory exclusivity period of 12 years appropriately balances objectives for potential cost savings from biosimilar price competition with long-run incentives for investment in innovative biologics. This study finds that when biologic patents are relatively less certain and expected to have shorter effective lifetimes, an exclusivity period of 12 years greatly enhances investment incentives. However, if biologic patents provide relatively strong protection with significant effective patent life remaining at approval, patents alone will be sufficient to maintain investment incentives in most cases. In those instances, however, the 12-year exclusivity period has only a minimal effect on the timing of potential biosimilar entry and consequently on healthcare costs.

It remains unclear whether the longer exclusivity periods for biologics compared with chemical entities will tilt R&D incentives toward large molecules and whether Congress will consider harmonizing these periods, as is currently the case in the EU.

The Resolution of Patent Challenges

Hatch-Waxman also featured Paragraph IV 180-day exclusivity provisions, under which generic manufacturers could challenge the legitimacy of branded manufacturers' patents or claim that generic entry would not infringe them. Over time, as the law and economic benefits to generics were established, the likelihood of Paragraph IV challenges increased and most drugs became subject to challenges (Berndt *et al.*, 2007; Grabowski *et al.*, 2011a). This has led to uncertainty regarding the effective patent term for new drug introductions, as well as substantial litigation costs early in the product life cycle.

Under the BPCIA, an abbreviated application for a biosimilar can be filed after 4 years. The filing of an application triggers a series of potentially complex private information exchanges between the biosimilar applicant and reference product innovator. These exchanges are followed by negotiations and a process for instituting litigation on the core patents, when necessary. Congress has crafted these patent provisions while eliminating the incentive for litigation associated with a 180-day exclusivity period for the first filer in a successful challenge, as well as the automatic 30-month stay on entry under Hatch-Waxman. By instituting this potentially complex structured process for biologics, legislators hoped that patent disputes would be resolved before the expiration of the 12-year exclusivity period so that biosimilars can enter in a timely fashion. Generic manufacturers have raised concerns about the need to divulge proprietary information, and whether these rules will achieve their intended effects remains unknown.

Firms pursuing a biosimilar strategy could also choose to file a full BLA rather than an abbreviated application. Under the patent resolution provisions of the BPCIA, firms filing an abbreviated biosimilar application are required to disclose information about their manufacturing process and identify potential patent conflicts. By choosing instead to file a full BLA, the biosimilar firm would avoid this disclosure requirement, and, if approved, also be able to enter before the expiration of the 12-year exclusivity period. However, the firm needs to weigh these benefits against the additional investment of expenditures and time associated with filing a full BLA for a biosimilar product. Several firms apparently are considering this strategic option. Teva recently relied on a full BLA filing for its G-CSF filgrastim product, although the original submission to the FDA predated the establishment of a biosimilar pathway in the US. In Europe, the same Teva product is marketed under the name Tevagrastim® and was approved through an abbreviated biosimilar application for the reference product Neupogen® (**Table 1**). The product is scheduled to be launched in the US in late 2013 under a patent settlement with Amgen.

Summary and Conclusion

Biologics have accounted for a significant number of innovative medicines over the past three decades. At the same time, they account for a growing share of drug expenditures in some countries. Policymakers have anticipated the introduction of biosimilars mitigating these cost pressures. Biosimilars have been introduced in various EU countries beginning in 2007. The extent of biosimilar penetration for the biological entities, erythropoietin, G-CSF, and somatropin has varied substantially across therapies within a country and across countries for the same therapy. Germany has experienced the greatest initial uptake of biosimilars reflecting targeted incentives quotas and related factors.

The new US law is designed to balance the objectives of achieving cost savings in the current period and preserving incentives for continued innovation in the future. A number of leading biologic products with significant sales in the US are expected to experience some patent expiration in the next decade, so cost savings could grow significantly over time, depending on how other factors such as regulation, reimbursement, and intellectual property litigation evolve over this period.

In terms of maintaining incentives for future innovation, the US law provides for a 12-year exclusivity period after an innovator's product is approved before a biosimilar referencing can be approved utilizing an abbreviated pathway. This 12-year exclusivity period provides an important 'insurance policy' to the patent system and could be important in the case of biologics where patents may prove to provide less certain protection than those for NCEs. Analysis of a portfolio of representative biological products indicates that 12 years or more of exclusivity from patents or regulatory provisions is generally consistent with achieving breakeven returns that provide a risk-adjusted return on capital and R&D investments.

A number of important issues remain for future research, including how the new law will affect industry structure and incentives for undertaking R&D for biologics versus NCEs. As was the case with Hatch-Waxman, change may be gradual at first, but over time the new law could lead to profound changes in the economics and organization of the biopharmaceutical industry.

Introduction

As healthcare costs increase because of the aging population and technological developments in healthcare, the need by healthcare decision makers for economic evaluations of new healthcare interventions becomes more important. A comprehensive economic evaluation of a new healthcare intervention requires an analysis of both the efficiency of the intervention compared with current treatment patterns and the annual budget impact of the new intervention. An analysis of the annual budget impact might be used to determine affordability of the new intervention, given healthcare budget constraints, or as an implementation tool for newly reimbursed interventions.

A budget-impact analysis typically first identifies, in a national or local health plan, the treated population for the indication for which the new intervention is approved. The analysis then estimates the annual change in healthcare expenditures for the treated population with and without the new intervention in the treatment mix for different rates of uptake of the new intervention. Unlike a cost-effectiveness analysis, which compares the new intervention with a standard of care, the comparison in a budget-impact analysis is between the mix of treatments before the new intervention is reimbursed and the mix of treatments after the new intervention is reimbursed, taking into account the rate of uptake of the new intervention.

There are several published guidelines for budget-impact analyses. These guidelines have been developed either by the health technology assessment (HTA) agencies that require a budget-impact analysis as part of a reimbursement submission (e.g., Pharmaceutical Benefits Advisory Committee (Australia), Canada, Taiwan, and the National Institute for Health and Clinical Excellence (NICE) in the UK) or by independent organizations (e.g., the International Society for Pharmacoeconomics and Outcomes Research). These guidelines describe the estimation framework and data sources that are recommended for performing budget-impact analyses.

Key Elements of a Budget-Impact Analysis

Budget-impact analyses have six primary elements, irrespective of the modeling framework used to derive the estimates: (1) treated population size, (2) time horizon, (3) treatment mix, (4) intervention costs, (5) other healthcare costs, and (6) presentation of results. In addition to these six primary elements, budget-impact analyses generally include sensitivity analyses to test the impact on budget estimates of the uncertainty in the input values used in the analysis or the variability of these inputs among health plans or health systems. Issues that should be considered for each of these elements are described in the following paragraphs.

The first step in a budget-impact analysis is to determine the population currently being treated for the disease indication of interest using epidemiological data. It is critical to estimate not only the size of the treated population but also the mix of disease severity in the population because treatments and disease-related healthcare expenditures may vary with disease severity. For example, individuals with schizophrenia that is refractory to treatment with standard care will have higher annual costs and will use a different mix of treatments than individuals who are responsive to treatment. It also is important to consider a possible 'woodwork' effect with a new intervention, that is, more patients with the indicated condition presenting for treatment when a better treatment becomes available. Finally, for a new intervention that reduces mortality, slows disease progression, and/or changes treatment patterns, changes in the treated population size and the distribution of the population by disease severity must be estimated on the basis of the assumed uptake rates for the new intervention.

The second element, the time horizon for the budget-impact analysis, typically is chosen on the basis of the requirements of the healthcare decision maker, rather than on the duration of the impact of the new treatment (as for a cost-effectiveness analysis). Because healthcare budget holders generally have a short planning horizon, time horizons of

 doi:10.1016/B978-0-12-375678-7.01423-1

3–5 years are usual. With such short time horizons, offsetting cost savings many years in the future from slowed disease progression of chronic diseases or prevention of future cases of the disease or its complications are not captured. But this is an accurate reflection of the costs incurred over the typical planning horizon.

The third element in a budget-impact analysis is the determination of the mix of interventions currently used for the indication and the predicted change in that mix if the new intervention is made available. Unlike cost-effectiveness analyses, which compare the outcomes when taking the new intervention with the outcomes with a standard-of-care intervention, a budget-impact analysis does not assume immediate switch by all patients to the new intervention. Rather, the new intervention is assumed to alter the mix of interventions used for the indication, using estimated or observed uptake data. The budget impact will be higher if the new intervention is used in place of a generic drug than if the new intervention is used in place of another branded drug or a surgical procedure. Also, the budget impact will be higher if the new intervention is combined with current treatments instead of substituted for them.

The costs associated with the current and new interventions should include some or all of the following, depending on the type of intervention: acquisition, administration or labor, other equipment, monitoring, and adverse-event or complication costs. For drugs, generally, wholesale acquisition costs (in the US) or national formulary costs are used as the default values, although the analysis should be designed so that discounts and copays can be subtracted from these costs to provide more accurate estimates of the healthcare decision makers' costs. For devices, wholesale prices should be used; for procedures, standard labor costs should be used. All of these costs are used to reflect the expected costs of current and new interventions to the decision maker for each year of the budget-impact analysis time horizon.

The fifth element, an estimate of the impact of the new intervention on other indication-related costs, excluding intervention costs, is generally but not always included in budget-impact analyses. A simple calculation can be used, based on clinical trial data, for example, to estimate these costs for acute conditions and for those chronic conditions where the full impact on indication-related costs happens within a short period of time or is not likely to change over the model time horizon. Alternatively, changes in indication-related costs for a chronic illness may be estimated by adapting the disease progression model (used to estimate the cost-effectiveness ratios) to calculate annual indication-related costs after reimbursement has been approved for the new treatment. This adaptation involves running the cost-effectiveness model in 'prevalence' mode where the model adds a newly treated cohort each subsequent year, in addition to tracking the starting cohort.

The sixth element in budget-impact analysis is the presentation of the results. Unlike cost-effectiveness analysis, where there may be a societal perspective that can be used as the reference case, there is no reference case in budget-impact analysis. The appropriate perspective for the analysis varies with each decision maker's budget responsibilities, which may range from a pharmacy or department budget to an entire hospital or outpatient clinic budget to countrywide healthcare services. Thus, the model needs to be programed in such a way that it can generate the budget impact from these multiple perspectives. In general, the results are presented undiscounted for year 1, 2, 3, etc. after the new intervention is made available to the decision maker's population. Cumulative, multiyear results also may be presented either discounted or undiscounted.

Clearly, in any budget-impact analysis, there is uncertainty about both model assumptions and input parameter values. In cost-effectiveness analysis, one-way and probabilistic sensitivity analyses are the recommended approaches for presenting the impact of the input parameter uncertainty. For budget-impact analyses, the more common approach to uncertainty analysis is to present a series of scenario analyses, changing input parameter values either one at a time or several at a time to create different scenarios that are meaningful to the decision maker; for example, changing intervention uptake rates and/or expected effectiveness in the decision maker's population. The decision maker may also enter values for input parameters that may vary among health plans or health systems but be known with certainty to each decision maker, such as drug costs, treated population size (based on size of population served and local incidence or prevalence rates), disease severity mix, and patient age distributions. Scenario analyses, which include alternate combinations of uncertain and variable input parameters, provide decision makers with more credible information about the range of possible results, given the specifics of their health plan or health system.

Categorization of Budget-Impact Modeling Approaches

There are three main budget-impact modeling approaches that have been used by HTA agencies and/or in published studies: (1) cost calculator, (2) Markov or state transition model, and (3) Monte-Carlo or discrete-event simulation model. The simplest approach, a cost calculator, is typically used for acute indications and for chronic indications where a static analysis is appropriate; Markov models and discrete-event simulation models are used for chronic indications where a dynamic approach is needed to capture the changes in treated population size, indication severity mix, or treatment patterns.

Budget-Impact Analysis: Cost Calculator Approach

For each drug recommended for reimbursement by the National Health Service (NHS) in England, NICE prepares a costing template for the drug's recommended use where budget impact is assessed to be greater than £1 million or more than 300 patients are affected. The costing template is presented on the NICE web site as a guide to budget planning for decision makers implementing the recommendation in the UK. These costing templates provide excellent examples of static models using a cost calculator approach. The NICE costing templates estimate the expected impact on the NHS budget of the new drug's predicted market uptake over the

next 3–5 years, after considering the current and new drug acquisition costs and associated administration, monitoring, and adverse-event costs. Where credible clinical data are available, the costing templates also estimate changes in disease-related costs associated with the use of the new drug. One-way sensitivity analyses, based on variations in the input parameter values, also are included in the more recent costing templates.

An example of an NICE costing template for prasugrel is presented here to illustrate the cost calculator approach for performing a budget-impact analysis. Prasugrel, when coadministered with acetylsalicylic acid, is indicated in the UK for the prevention of atherothrombotic events in patients with acute coronary syndrome (ACS) (that is, unstable angina, nonST segment elevation myocardial infarction (NSTEMI) or ST segment elevation myocardial infarction (STEMI)) who undergo primary or delayed percutaneous coronary intervention. However, prasugrel was recommended by NICE for reimbursement by the NHS as a treatment option for only a subset of the UK-indicated population: those with STEMI, those with STEMI or NSTEMI and stent thrombosis while taking clopidogrel, and those with NSTEMI and diabetes. The NICE costing template is presented in **Table 1** and includes the six key elements of a budget-impact analysis estimation of the population size, time horizon (1 year), current and projected treatment mix, drug costs, offsetting disease-related cost savings, and presentation of results. The footnotes to the NICE analysis table provided details of the data sources used in the costing template.

In the prasugrel example, because both drugs included in the analysis are oral drugs, there were no costs estimated for administration. Monitoring costs were also not included. Side effect costs, specifically those associated with bleeding events, were included in the rehospitalization rate. The prasugrel costing template included estimates of savings from a reduced rate of rehospitalization in the first year after the ACS

Table 1 Cost calculator model: The NICE costing template for prasugrel

Note	*Description*	*Unit costs*	*Units*	*Total cost*

For people aged 75 years of age and more than HES 2007–08 data used (codes I20.0–I22.9) to calculate incidence.
3. Age-related incidence from Main, C., Palmer, S., Griffin, S. *et al.* (2004). Clopidogrel used in combination with aspirin compared with aspirin alone in the treatment of nonST segment elevation acute coronary syndromes (ACS). *Health Technology Assessment* 8 (40). ACS incidence significant for age groups from 35 upward. The over 75s category reflects different license indications for the drugs in respect of this age group.
4. Estimate from British cardiovascular intervention society returns (2007) – 53.72% of patients undergoing percutaneous coronary intervention have acute coronary syndrome (nonST segment elevation myocardial infarction (MI)/Unstable Angina and ST segment elevation MI). Total patients 69 677 × 53.72% = 37 430 patients. This is equal to 16% of the total acute coronary syndrome patients per year.
5. Prasugrel-specific product characteristics exclude patients with prior TIA/stroke. This is estimated to be 4% on the basis of the TRITOM TIMI 38 study – Wivott (2007).
6. British cardiovascular intervention society audit returns (2007). Figures taken from manufacturers submission.
7. Results taken from TRITON-TIMI 38 trial included in Evidence review group report (2009). The proportion of patients receiving stents where stent thrombosis has occurred during clopidogrel treatment. Appendix 3 Table 9.6. It has been assumed this proportion applies to nonST segment elevation myocardial infarction patients receiving clopidogrel treatment.
8. Estimate based on expert opinion. Please enter own estimates.
9. British cardiovascular intervention society audit returns (2007). Figures taken from manufacturers' submission.
10. British cardiovascular intervention society audit returns (2007). The figure has been adjusted for people in whom stent thrombosis has occurred during clopidogrel treatment as this group would be recommended prasugrel.
11. Price of clopidogrel: British national formulary 57 edn. (2009). Price of prasugrel as in manufacturers' submission (2009). Proportion is based on annual incidence numbers for people aged 35–74 years of age.
12. Please adjust proportion to reflect local estimates. Where not all people aged 75 years of age and more receive prasugrel for its indicated use, it is assumed that these people would be treated in line with current practice and therefore no incremental cost is likely to be incurred.
13. Daiichi-Sankyo (2009) Eli Lilly and Company Ltd STA submission: Prasugrel for the treatment of acute coronary artery syndromes with coronary intervention. Table 34: TRITON-TIMI rehospitalizations summarized by category with UK NHS reference costs and adjusted to reflect Table 36 – UK rehospitalization rates. The calculated figure for the number of rehospitalizations avoided in the cost per 100 000 columns has been rounded to the nearest whole number which is 1. For smaller populations, savings may not be significant or robust due to the randomness of events. For larger populations, saving results are scaled in the normal way, i.e., rounded to the nearest 1.
14. Reduction in rate of rehospitalizations taken from Table 36 manufacturers submission relating to UK reduction rate. Rehospitalization categories mapped to NHS mandatory tariff 2009/10 and reference costs 2007–08 (where no mandatory tariff). HRG codes used are: AA21Z; AA09Z; AA15Z; EB10Z; EA31Z–34Z; EA14Z–16Z; EA40Z–42Z. Reference cost code used FZ38A.

episode that was observed in a large head-to-head clinical trial with clopidogrel.

This NICE costing template for prasugrel also included an extensive one-way sensitivity analysis, using maximum and minimum values for the following input parameter values:

- The annual incidence, by age group.
- The proportion of patients with ACS in whom immediate percutaneous coronary intervention is needed.
- The proportion of patients with STEMI.
- The uptake rate in the STEMI population.
- The proportion of the ACS population with NSTEMI.
- The proportion of NSTEMI population with stent thrombosis on clopidogrel.
- The proportion of the NSTEMI population with diabetes.
- The uptake rate of prasugrel in the NSTEMI population.
- The proportion of patients receiving prasugrel who are more than 75 years of age.
- The cost of clopidogrel per patient per year.
- The reduction in rate of rehospitalizations.
- The weighted average cost of rehospitalizations.

The rationale for the selection of the minimum and maximum values for the sensitivity analysis is not provided in the costing template.

Budget-impact analyses using a cost calculator approach have also been published in peer-reviewed journals. For example, in an article by Chang and Sung, the budget impact of using pimecrolimus cream for atopic dermatitis or eczema was estimated using estimates of the number of people seeking care for this condition each year and the average number of physician visits for the condition each year. Chang and Sung used data from a clinical trial of pimecrolimus to estimate likely reductions in follow-up physician visits for those patients who were treated with pimecrolimus. Although the condition is chronic, it is not progressive or life threatening. Therefore, the use of a static cost calculator approach is appropriate. Chang and Sung estimated the budget impact for a single year, on the basis of observed market share for the first year the drug was introduced, but tested the impact of changes in market uptake in a sensitivity analysis.

Using a static cost calculator approach to budget impact analysis for chronic progressive and/or life-threatening diseases may underestimate the budget impact. For example, Smith and colleagues used a static approach to estimate the budget impact of valsartan for the treatment of patients with heart failure. The authors' estimates were based on the number of enrollees with heart failure in a US health plan and on the average number of hospitalizations each year for these patients. The authors used data from a clinical trial of valsartan that showed a reduction in the number of hospitalizations and in the length of hospital stay for patients treated with valsartan. However, annual mortality rates with heart failure are significant, and the valsartan clinical trial also estimated a reduction in mortality for patients on valsartan. Such a reduction in mortality would result in an increased number of patients being treated for heart failure at any one time and an associated increase in treatment and monitoring costs for the health plan. This increase in the population size being treated was not included in the Smith and colleagues' budget-impact analysis. A dynamic disease progression model could have been used to estimate the change in the size of the prevalent population over time, given the reduction in mortality rates. Alternately, estimates of the change in life expectancy with valsartan could have been derived from the clinical trial data and used to estimate the change in the treated population size at steady state and used in the cost calculator approach.

A budget-impact analysis by Dee and colleagues estimated the budget impact of natalizumab over a 3 year time horizon for multiple sclerosis, a slowly progressing chronic disease. In this analysis, the authors explicitly captured the budget impact of the increasing uptake of natalizumab over time. The budget-impact estimates in the Dee and colleagues' study were based on the reduced costs for treating relapses of multiple sclerosis and the increased drug costs for natalizumab, including administration costs and monitoring for serious side effects such as progressive multifocal leukoencephalopathy. The authors also considered different payer perspectives and adjusted the budget impact depending on which payer perspective was considered. However, this static cost calculator approach ignored the impact on multiple sclerosis treatment costs of slowing the rate of disease progression that is associated with natalizumab treatment.

In the Smith and colleagues' study, the estimated budget impact of the new treatment did not include the additional drug-related and disease monitoring and symptomatic treatment costs in the extra months of life for the patient. But for patients with heart failure in these studies, the additional life expectancy may be short and the impact on the size of the treated population relatively small. Similarly, the budget impact of slowing disease progression in multiple sclerosis, omitted from the Dee and colleagues' study, is likely to be small within the time horizon of the budget-impact analysis. But in other chronic conditions, the impact on life expectancy could be significant, for example, for human immunodeficiency virus (HIV) infection. In this case, a dynamic budget-impact model, using either a Markov model or simulation approach, might be more appropriate.

Budget-Impact Analysis: Markov Model Approach

A study by Mauskopf demonstrated how a Markov model can be used to develop both cost-effectiveness and budget-impact estimates for a hypothetical new treatment for HIV infection. To develop the budget-impact estimates, it was first necessary to understand the current distribution of HIV patients among different HIV health states, measured in terms of ranges of CD4 cell counts. This distribution was obtained for a cohort of patients who were not treated, using natural history data that provided estimates of the time spent in each health state. Using these estimates and the number of new patients diagnosed and their CD4 cell-count distribution, the Markov model was run, adding a newly diagnosed cohort each year, until a steady state was reached for the number of patients in each health state without treatment. The introduction of the hypothetical antiretroviral therapy drug regimen was assumed to shift the CD4 cell-count up by one CD4 cell-count range for all patients in the treated cohort and to hold the cohort there for 4 years before disease progression resumed. The Markov model was rerun with the hypothetical antiretroviral drug

regimen. For each cycle of the model, the number of individuals alive in each health state was generated. A new steady state was reached in 10–20 years. For each health state, treatment costs, rates of opportunistic infections, and days in the hospital were estimated. Population estimates for all of these outcomes were generated for each year after introduction of the antiretroviral drug regimen.

A Markov budget-impact model can be programed to capture only the budget impact for newly entering cohorts cumulatively in each year after a new drug becomes available; alternatively, the model can be programed to assume that all prevalent patients also immediately switch to the new treatment or that a certain proportion of the prevalent patients switch each year. In the Mauskopf model, there were 10 680 persons alive in the UK with HIV in 1994 and an incident cohort of 1258 persons per year. The treatment regimens compared were no antiretroviral treatment and a hypothetical antiretroviral drug regimen that was assumed to stop disease progression for 4 years but to be taken for 6 years. All persons alive with HIV were assumed to switch immediately to the antiretroviral drug regimen, as were those individuals newly diagnosed during the model time horizon. Selected model inputs and outcomes are shown in Tables 2 and 3, respectively.

In this model, the impact of antiretroviral therapy (ART) on life expectancy for people with HIV infection was large, resulting in a significant increase in the number of individuals living with acquired immune deficiency syndromes (AIDS) and HIV infection and a shift to less severe disease stages. In this analysis, other outcomes that are of importance to patients and health planners were estimated, including the number of cases of opportunistic infections, illustrated in Table 3 by the number of cases of CMV infection, as well as the number of hospital days used by individuals with HIV infection. This latter value can be very useful for planning for hospital care for those with HIV infection.

Mar and colleagues presented a similar approach to budget-impact analysis using a Markov model for a Basque population to estimate the impact of the use of thrombolysis for patients with stroke on the prevalence of different degrees of residual disability in patients with stroke and the associated budget impact. In their study, the current prevalent population in different poststroke health states (death, disability, autonomous, and recurrent stroke) without thrombolysis was estimated using data on stroke incidence stratified by age and sex, all-cause mortality rates, stroke excess mortality risk, and disability outcomes from stroke. The budget impact associated with the use of thrombolysis was estimated using trial data indicating that the percentage of patients with residual disability was lower when thrombolysis was used than when it was not used. Thus, the Markov model was run over a 15 year time horizon with the two different rates of disability, as well as changing numbers of strokes due to the aging population. The results for the Basque population are shown in Table 4. In the Mar's study, the current population health state prevalence rates, as estimated by the Markov model for patients

without thrombolysis, were validated on the basis of population registry data and an alternative modeling approach for estimating poststroke life expectancy.

Two other published studies illustrate the use of Markov models to capture the dynamic aspects of budget-impact analysis. In the budget-impact analysis for trastuzumab in early breast cancer by Purmonen and colleagues, a 4 year time horizon was modeled using a state transition model with two health states: free of distant recurrence and with distant recurrence. The budget impact was estimated as the difference in cumulative undiscounted 1, 2, 3, and 4 year costs for all cohorts starting treatment during the model time period with or without the use of adjuvant trastuzumab. The model was based on the number of early breast cancer patients, human epidermal growth factor positive (HER2 +) prevalence, length and cost of adjuvant treatment, and the effectiveness of the treatment. All HER2 + patients were assumed to be treated with trastuzumab. Sensitivity analyses included a scenario analysis that looked at different treatment patterns, prevalence of HER2 +, and treatment costs. In addition, a probabilistic sensitivity analysis was included that estimated the impact of the following uncertain or variable parameter inputs: number of early breast cancer patients, HER2 + prevalence in those with early breast cancer, disease-related transition probabilities, and treatment costs. The results of the probabilistic sensitivity analysis were presented as an affordability curve in which the probability of the budget impact being below different budget constraints was presented (see **Figure 1**).

In a combination of cost-utility and budget-impact analysis of third-generation aromatase inhibitors for advanced breast cancer, Marchetti and colleagues used a state transition model to estimate the life expectancy and lifetime costs for a single annual cohort of patients newly diagnosed with advanced breast cancer and starting treatment with or without the use of anastrozole or letrozole. The authors estimated the budget impact for a single cohort under the assumption that all

patients in the cohort are treated with either anastrozole or letrozole. This focus on a single cohort and assumption of 100% uptake is typical for cost-effectiveness analyses but is less often used for budget-impact analyses.

Budget-Impact Analysis: Simulation Model Approach

Another type of disease model frequently used in cost-effectiveness analyses of new treatments is Monte Carlo or discrete-event simulation. In simulation models, the disease pathway is simulated for a group of individual patients with different characteristics for the duration of the disease episode or for lifetime (for chronic diseases). This approach to disease modeling has several advantages over a deterministic Markov approach: variability among patients in disease outcomes and in the impact of the treatment is captured explicitly; all relevant patient, system, and treatment characteristics can be captured without requiring an expansion of health states; disease and treatment history over time can be accounted for in the analysis; and multiple events can occur at the same time. Discrete-event simulation models track patients on the basis of the time to the next event, whereas Monte Carlo simulation models typically track the patients at specific time points. The disadvantage of the simulation approach is that it generally requires additional data inputs and additional computation time compared with the Markov modeling approach.

As with Markov modeling, the discrete-event simulation approach can be used to generate budget-impact as well as cost-effectiveness estimates by simulating a prevalent population rather than a single population cohort. Martin and colleagues presented the results of a budget-impact analysis for expanded screening for HIV in the US, using a Monte Carlo simulation model that included screening and treatment for HIV infection. This model has been used extensively for cost-effectiveness analyses of alternative management strategies for HIV infection. In their publication of the simulation model's results, the authors estimated the number of prevalent cases of HIV infection that were currently undetected and the annual number of new cases of HIV infection, using national prevalence and incidence data. Using a series of published studies and reports, the authors also estimated the proportion of these individuals that would be eligible for government-sponsored HIV screening, as well as the CD4 cell-count and viral load distributions for those persons unaware of their HIV status. The authors then entered this patient population into the screening module of their Monte Carlo simulation model and tracked costs over a 5 year time frame, with and without the introduction of a new screening program. Martin and colleagues presented the additional number of cases identified from expanded screening each year for 5 years and the undiscounted budget impact of expanded screening and the associated earlier treatment by discretionary and entitlement programs (see **Tables 5** and **6**; **Figure 2**).

Discrete-event simulation models also have been used to estimate budget impact of drug treatments, tracking both the prevalent and incident populations to determine the annual budget impact. Caro and colleagues used a discrete-event simulation model to estimate the budget impact over 100 days for alternative treatments of bipolar-associated mania, using estimates of changes in response to therapy in the Young Mania Rating Scale over time. Mar and colleagues used a discrete-event simulation model to estimate the budget impact of thrombolysis in patients with stroke, using estimates of a reduced number of patients with residual disability after stroke in those patients given thrombolysis treatment. In both

models, prediction equations were estimated by using patient-level data to estimate time to the primary events included in the model.

The advantages of using Monte Carlo or discrete-event simulation models to estimate budget impact of alternative disease management strategies are that, generally such models have been previously validated for the cost-effectiveness analyses and the inputs are consistent for both types of estimates. In addition, changes in disease severity and life expectancy over time can be included in the model. This is very important for HIV infection or stroke, where alternative screening or treatment strategies can have a major impact on the treated population size and/or severity mix, and thus on healthcare decision makers' budgets.

Conclusions and Where Next

As illustrated in this article, budget-impact models can be developed using a variety of approaches: a cost calculator approach or disease progression modeling approaches using either Markov or simulation models. Generally, the simpler approach is preferred by healthcare decision makers because such an approach is more transparent and can more readily be run using individual health plan characteristics. The cost-calculator approach can be used for acute illnesses, as well as for chronic illness where changes in disease severity, life expectancy, or treatment patterns (1) do not occur, (2) occur very rapidly and can readily be captured in a cost-calculator model, or (3) occur beyond the time horizon of the budget-impact analysis. In instances where the changes in disease severity, life expectancy, and/or treatment patterns cannot be credibly captured in a cost-calculator model, a disease progression modeling approach might be needed.

A disease progression modeling approach may be more desirable when an integrated cost-effectiveness and budget-impact model is desired. However, care needs to be taken to ensure that the budget-impact estimates are generated for the prevalent population rather than for the single-disease cohort that is typically used for cost-effectiveness analysis. The budget-impact model should also compare a mix of current and future treatments rather than a simple comparison of all patients treated with either a current treatment or a new treatment, as is typically seen in a cost-effectiveness analysis. In addition, the appropriate costs for the budget holder are their actual prices paid net of discounts and copays while opportunity costs are more appropriately used for cost-effectiveness analyses.

The question of how to reflect the uncertainty or variability in the inputs to a budget-impact analysis is also important. There are several different types of uncertainty or variability that can be present in the input parameter values, uncertainty about the estimates of the efficacy of the new and current interventions, variability in patient characteristics and current treatment patterns in different healthcare settings, and both uncertainty and variability in the changes in expected treatment patterns with the availability of the new intervention. Because these analyses are aimed to help healthcare decision makers understand the budget impact on the population for which the decision makers have responsibility, budget-impact analyses most commonly include either one-way sensitivity analyses, using ranges of both uncertain efficacy inputs and differences in patient characteristics and current and future treatment patterns (e.g., NICE cost calculators), or scenario analyses where several of these input parameter values may be changed to produce a scenario that most closely matches the healthcare decision maker's population. Probabilistic sensitivity analyses are sometimes included in published budget-impact analyses, but these are probably not very useful for healthcare decision makers because the sensitivity of the budget-impact analyses results to parameter uncertainty may be less than the sensitivity of the budget-impact analysis to variabilities in the healthcare decision maker's population characteristics and treatment patterns. The concept of the

affordability curve for different budget constraints as used in Purmonen and colleagues' article may be a useful way to present the results of a probabilistic sensitivity analysis. However, the probabilistic sensitivity analysis presented in Purmonen and colleagues' study included both uncertain parameters (HER2+ prevalence and transition probabilities reflecting efficacy) and variable parameters that would probably be known with certainty by the decision maker (price of trastuzumab and number of patients), thus reducing the value of their probabilistic sensitivity analysis.

Although the primary purpose of a budget-impact model is to estimate the annual impact on a health plan budget after a new intervention is reimbursed for the health plan's covered population, a budget-impact models may also generate estimates of the associated changes in population health outcomes during the same time period. These estimates may be used in the budget-impact analysis to estimate the changes in disease-related costs, but the population health estimates also can provide useful information for healthcare decision makers. For example, estimates of changes in disease cases or hospital days may be useful for health services planners. These population-based estimates of these outcome changes should be presented for each year after introduction of the new intervention along with the budget-impact estimates.

Collective Purchasing of Health Care

M Chalkley and I Sanchez, University of York, Heslington, York, UK

The term collective purchasing is often used interchangeably with cooperative purchasing, group purchasing and collaborative purchasing and sundry other expressions. A fuller list of terms is set out by Schotanus and Telgen (2007) and Tella and Virolainen (2005) who provide a useful starting point for investigating the wider use of these arrangements.

There are a number of notions of collective purchasing in health care and here three are considered: collective purchasing of health-care inputs, collective purchasing of health insurance, and collective purchasing of health-care treatments or interventions. The details are set out below.

Collective Purchasing of Health-Care Inputs

In the first notion of collective purchasing, health-care providers cooperate in respect of their purchasing of medical supplies. Nollet and Beaulieu (2005) provide a useful overview of these arrangements between health-care providers, which often mirror those that arise in other settings. The central idea is that a number of independent organizations, or more colloquially firms, agree amongst themselves to negotiate collectively with the suppliers of their inputs.

Advantages and Disadvantages

The motivation for such arrangements is primarily seen as being to reduce costs, by some combination of negotiating a lower price, reducing administration, or economizing on utilization. Studies of such collective purchasers typically report that they achieve price reductions in the order of 10–15%. Economists would argue that this is probably a consequence of the purchasing collective representing countervailing monopoly power and thus reducing the economic rents of their suppliers. Reductions in administrative costs will result from conventional sources such as economies of scale and scope and consolidation of the purchasing function. Some studies, for example, Schneller, 2000, report savings of as much as 40% in this respect but it is not clear that all costs are being recorded. Exactly how a purchasing collective might reduce utilization of inputs is less clear. One idea is that the collective standardizes its purchases and thus avoids unnecessary duplication of inputs. It is difficult to obtain hard evidence of this in practice and it should be noted that standardization requires coordination but not necessarily cooperative purchasing. In terms of problems of collective purchasing, the usually cited limitations of these arrangements are the problems of reflecting the potential diverse objectives of the members of the collective and the possible antitrust implications of collective action. As suggested above there are a number of sources of further reading on this use of collective purchasing in health care and it corresponds to a broad literature on supply chain management.

Collective Purchasing of Health Insurance

The second notion of collective purchasing arises specifically in the US health-care sector and originates from a system in which health insurance is often provided as a part of employment. Small employers who have to purchase health insurance on behalf of their employees may be at a disadvantage relative to larger employers in terms of dealing with the providers of health insurance. By forming health insurance purchasing cooperatives they might be able to redress this disadvantage. Wicks (2002) provides a good starting point for further reading in respect of these arrangements; their purported advantages and their potential problems. More recently the term health insurance purchasing cooperative has also been applied to any collective of individuals, as distinct from companies, seeking to purchase health insurance as a group. Moreover, there is contemporary policy debate concerning whether such arrangements can increase the coverage of health insurance.

Advantages and Caveats

If employee benefits are considered to be simply another input into production, then this second notion of the term collective purchasing is very closely related to the first use described in Section Collective Purchasing of Health-Care Inputs. By cooperating, small employers may achieve a lower price or achieve scale economies in their purchase of health insurance coverage. The literature on supply chain management referred to above again provides the details. But it can be argued that health insurance is a sufficiently idiosyncratic 'input' that additional issues arise in terms of benefits of forming a collective. The most often discussed issue – and again Wicks (2002) is the best starting point for further investigation – is that of risk pooling. A purchasing cooperative may help to balance high- and low-risk individuals and thus achieve coverage for some employees who might otherwise be precluded by their high-risk premiums. This idea is, however, contentious. If health insurers can discriminate between high and low risks they have an incentive to offer better rates to the lower risk types. So if two employers, one with a high-risk group of employees and the other with a low-risk group of employee form a cooperative to purchase insurance, there is a good chance that the low-risk employer would be offered better terms outside of the purchasing cooperative; the purchasing cooperative will fail. In reviewing the evidence regarding the effect of health insurance purchasing cooperatives, Wicks (2002) draws attention to the greater choice that individuals are faced with when a purchasing cooperative is in place. This is an interesting contrast with the more usual outcome of collective purchasing – greater standardization.

Collective Purchasing of Health-Care Treatments: The Role of Insurers

Although the first two notions of collective purchasing described in Sections Collective Purchasing of Health-Care Inputs and Collective Purchasing of Health Insurance arise in particular jurisdictions or in particular institutional settings, the third notion is close to ubiquitous in health-care markets. Although physicians or health-care organizations are the supplier of care and individuals in need of that care are the recipients, for most individuals in most circumstances the terms under which their care is provided – how much will be paid for it under various scenarios – is determined as a part of an agreement entered into by their insurer with health-care providers. This concept of collective purchasing seems to have been first exposited in relation to public-health insurance by Evans (1987) but, as one will see, can equally be argued to apply increasingly to private insurance. To understand this notion of collective purchasing, and just how substantially the consumer of health care differs from the consumer of apples or pears, it is useful to start by reconsidering the usual concept of purchasing (demand) in economics. This supposes that there is a defined good or service, a price that is specified by the seller, and a consumer whose role it is to specify the quantity they wish to purchase. Almost none of this applies in health-care markets. The services that constitute health care are many and varied and patients are more interested in getting better than in receiving those services *per se*. Service is not well-defined up until delivery (treatment) and suppliers do not compete in the conventional sense of offering a known product at a given price. The quantity that a person wants is 'enough to make me better.' And pertinent to a discussion of collective purchasing, consumers seldom act unilaterally because health-care insurance often involves insurers reimbursing health-care suppliers directly. The topic of health insurance is a vast one and its emergence and growth in health-care provision a substantial area of study, but the interested reader can consult McGuire (2011) or Pauly (2011) for recent overviews. A crucial element of insurance is that it makes the insurer a third-party purchaser of health care and this element of health-care provision gives rise to a number of concerns, especially in terms of the lack of incentives that the recipients of services have to regulate or monitor suppliers. This is another substantial topic for which Stinchcombe (1984) and Enthoven (1994) provide an entry point for further reading.

Alternatives to Collective Purchasing under an Insurance Scheme

Following Section Collective Purchasing of Health-Care Treatments: The Role of Insurers, the intermediation of insurance seems to make collective purchasing of health-care treatments commonplace. That does not need to be the case; traditional arrangements termed indemnity insurance allow insured individuals free reign to choose their health-care supplier, with the insurer reimbursing, subject to rules regarding copayment, stop-losses, etc., the provider of treatment. However, increasingly fewer private insurance arrangements allow consumers to unrestrictedly choose their supplier, or permit suppliers to dictate the price of a service, preferring instead to manage the treatment pathway by selectively contracting with specific providers or even integrating providers into the organization through employment contracts. Under managed care arrangements, as described by Dranove (2000), Newhouse (2002), and Baker (2011), insurers enter into various arrangements with providers on behalf of their enrollees. This kind of management of treatment provision, where the insurer collectively purchases on behalf of their enrollees is, if anything, more prolific in the realm of public-health insurance which conditions treatment on contracts with health-care providers with terms and conditions set on behalf of all covered patients/consumers (Blomqvist, 2011). Thus collective purchasing and health insurance would seem to go hand in hand; insurers collectively purchase health care on behalf individuals and the extent of such arrangements can vary according to the number of consumers covered (from employees in a single company, to all members of the population of a region or even a nation) or the services covered (from a single health-care intervention to an integrated treatment system) and may encompass many different payment mechanisms (from fixed price per treatment item, to price per illness of a fee per patient).

Advantages and Caveats of Health-Care Insurance

A first approach to explaining the above phenomenon might be to consider the same motives for collective purchasing as described in the first two notions of that term described above; by seeking to purchase on behalf of a large population the insurer might be able to negotiate lower prices and save resources relative to what each individual would have to expend in dealing with their own provider. One key problem is that providers of health-care have informational advantages and third-party arrangements such as insurance mean that even the limited information that patients have may not available to the payer. This results in a lack of information, incentives, and buying power on the demand side of health-care markets. The result is effective monopoly power on the part of service suppliers and one interpretation of collective purchasing arrangements by insurers is that they provide some countervailing buyer power. In simple terms, a single patient, consumer, or even small insurer may be at the mercy of a health-care provider who dictates a high price; a purchasing collective may achieve a lower price. This mirrors the traditional role of collective purchasing in other contexts except that in health care a need for countervailing market power may by more pervasive; it is not only lack of competing suppliers that creates seller power, it is lack of buyer information.

The previous approach does not, however, recognize the very distinctive features of health-care provision regarding which a large literature has developed in health economics and which can begin to rationalize the third notion of collective purchasing much more convincingly. Elsewhere in this volume there are extensive discussions of agency, imperfect information, and transactions costs and the implications of these for health-care delivery and understanding these concepts is central to appreciating a long tradition in health economics focusing on the consequence of insurance in terms of the extent that

consumers who are insulated from cost will not have incentives to control the cost of their treatment. It thus becomes important for insurers to contain costs but, given the general lack of information that patients and consumers have it is also important to maintain incentives for a good quality of service.

In this setting, collective purchasing of health treatments becomes a method of dealing with multiple agency issues. One approach emphasizes selective contracting, the purchaser's decision about which providers to contract as suppliers. By limiting the set of suppliers, the purchaser generates bargaining power that may counteract market power of sellers or allow a buyer to influence the cost and/or quality of care. A second possibly complementary approach focuses on contract design. Rather than just negotiating on price, in their role as collective purchasers of health-care insurers may dictate the form of contract that the health care is provided under and thereby seek to influence, through the design of appropriate incentives the cost and quality of health care that patients receive. Viewed in this context a collective purchasing contract is a means of trying to align the incentives of health-care suppliers with those of the purchaser of health care. A great deal of attention has, for example, been directed at the question of whether a simple fixed-price arrangement as embodied in the Medicare Prospective Payment System in 1983, and much emulated since, can achieve both cost control and appropriate quality of care. A recent summary of the extensive adoption of such systems in Europe and the claims that are made in terms of cost control are documented in Brusse *et al.* (2011). This transition from purchasing through reimbursement of costs to determining an *ex ante* fixed price gives perhaps the best illustration of the potential of collective purchasing to effect change in a health-care system.

Agency theory also highlights how difficult it might be in practice to design good collective purchasing contracts for health care. As one problem is resolved so others may materialize. One concern that has developed is that while moving toward predetermined prices based on a particular characterization of a patients' medical condition (so called prospective price contracts) may drive down costs, it may also give rise to attempts to select easier to treat patients – cream skimming – or avoid expensive ones. Thus for a collective purchaser the design of appropriate contracts can be very complex matter.

Summary

In many areas of economic activity, purchasers find it in their interests to act collectively to get a 'good deal' from their supplier. Traditional explanations of collective purchasing rely on the concept of buyers achieving some monopsony power to offset the monopoly power of sellers, or on the achievement of scale economies in purchasing. These explanations apply equally well in health care in regard to supply chain management in health-care organizations such as hospitals, who cooperate to purchase medical supplies, and can be extended to understand health insurance purchasing cooperatives. The possible disadvantages of these arrangements are that they fail to correctly reflect the diversity of preferences of their constituent members, or that they may run foul of the law in terms of antitrust or anticompetitive practices. But there is another notion of collective purchasing in health care that is more prolific and requires a rather more involved explanation. Individual consumers of health care do not for the most part act unilaterally in dealing with a health-care supplier – insurers, both public and private, act as intermediaries and very often as the collective purchaser. This manifestation of collective purchasing is intricately linked with the prevalence of health insurance, which is an arrangement concerned with insulating individuals from the costs of their health care and where individuals are so insulated agency problems arises. Insurers may try and contain costs and ensure adequate quality by setting terms and conditions for the supply of health treatments and thus act as collective purchasers. These sorts of arrangements go under different names such as managed care or health-care contracts depending in part on whether they are instigated by private or public insurers, but they are in essence collective purchasing.

Comparative Performance Evaluation: Quality

E Fichera, S Nikolova, and M Sutton, University of Manchester, Manchester, UK

Glossary

Agency relationship The relationship between an agent and a principal. Classically in health care, the role of a physician or other health professional in determining the patient's (or other client's) best interest and acting in a fashion consistent with it. The patient or client is the principal and the professional is the agent. More generally, the agent is anyone acting on behalf of a principal, usually because of asymmetry of information. In health care, other examples include health managers acting as agents for their principals such as owners of firms or ministers, regulators as agents for politically accountable ministers, ministers as agents for the electorate. In health care, the situation can become even more complicated by virtue of the facts, first, that the professional thereby has an important role in determining the demand for a service as well as its supply and, second, that doctors are expected (in many systems) to act not only for the 'patient' but also for 'society' in the form, say, of other patients or of an organization with wider societal responsibilities (like a managed health care organization), or taxpayers, or all potential patients. There can be much ambiguity, as in seeking to understand the agency relationships in overseas aid giving and management, and as in establishing the extent to which formal contracts can enhance efficiency.

Incentive contracts The contracts between insurers or other third party payers and the providers of health care that embody incentives and penalties (both usually financial) for failing to meet particular conditions.

Yardstick competition An industrial regulatory procedure under which the regulated price is set at the average of the estimated marginal costs of the firms in the industry.

Zeckhauser's dilemma A problem with incentive contracts when those who are incentivized to behave in particular ways cannot fully control the consequences of their actions. They then require compensation in some form to offset this increase in the risk they face of failure, which raises the cost of the contract relative to the benefits anticipated by the principal.

Introduction

Health care purchasers and regulators often make comparisons between providers on indicators of quality. In this article the rationale for such comparisons is described, the options for this form of monitoring are considered and how this type of evaluation has evolved over time is outlined. Then, using a recent example of a quality program that links financial rewards to comparative performance in the UK, the key issues with this kind of performance evaluation are highlighted.

Principal–Agent Problems

The health care sector is characterized by a series of agency relationships. Patients delegate decision-making to doctors and payers give responsibility for supplying health care to providers. This delegation of decision-making or provision would be unproblematic if there was symmetric information and identical objectives were shared between the parties. In reality, two general problems are suggested by the principal–agent analysis. First, the task itself (i.e., delivering health care) is only partially observable or verifiable. This is called the moral hazard or hidden action problem. Second, the agent's capabilities are unknown to the principal but are known to the agent before the parties enter into the contract. This may adversely affect the principal's payoff and is called the adverse selection or hidden information problem.

The solution adopted in practice is to use a set of performance indicators to measure the output of the agent. However, this is only a partial solution because the information problems persist when the correlation between such indicators and the agent's effort is noisy and determined by a random component that often varies across agents. The extent to which the agent is in control of such variation is also unknown to the principal. The principal must therefore design a contract or system of incentives that elicits a second-best outcome from the agent.

Problems with Incentive Contracts in Healthcare

It is often claimed that the design of incentive contracts is more difficult in the health care sector than in other sectors. This is particularly the case when the principal's problem of ensuring that the agent delivers a high quality service is considered. There are five problems that are germane:

1. One of the best known concerns about incentive contracts is the trade-off between incentives and risk (so-called Zeckhauser's dilemma). Theoretically, incentive contracts impose a risk on agents and risk-averse agents will require a higher mean level of compensation. This premium will increase with the riskiness of the environment. Although empirical research has not found convincing evidence that higher incentives are given in riskier environments, health care providers provide an uncertain output (the well-being of the patient) which is only partially dependent on their actions.
2. When multiple actions are substitutes, incentive schemes may cause diversion of effort. For instance, an incentive

scheme focused on observable indicators will induce health care providers to game the system and reduce their effort on unobservable dimensions.
3. Because patients differ in their expected health outcomes and the agent has more information on the expected health outcomes than the principal, the agent may engage in 'cherry-picking' of patients, providing care only to patients at low risk of adverse outcomes.
4. As health care provision often requires input from more than one agent, the aggregation of agents into groups (for example, hospital teams) for incentive contracts creates externalities. These externalities may be positive (through monitoring of effort by close peers) or negative (caused by free-riding on others' efforts).
5. Health care providers have a social role and are trained to adopt professional ethics. Their utility functions are typically assumed to contain an altruism component that values the benefits to their patients. Incentives have the danger of crowding-out this intrinsic motivation.

Information on Quality

Quality assessment in health care is bedeviled with measurement problems. The measurement of output, or more strictly the agent's effort in producing output, is particularly difficult. Quality can be measured in terms of the quality of inputs, processes, or outcomes. Input quality measurement, for example, would involve assessing the capabilities and training of the labor force, the standard of the capital facilities and equipment, and the input mix. Such an approach is often taken by health care regulators seeking to maintain a register of qualified providers. Process quality measurement, however, would involve assessing whether agents are performing actions that are most likely to generate good quality outputs. In health care, this might involve assessing whether providers are adhering to best-practice guidelines and offering patients effective treatment regimes. Finally, quality output measurement would focus on the benefits that have been achieved for patients, regardless of how they have been achieved. Such benefits should include gains in survival and quality of life and increasingly capture patients' experience of using health care services.

The difficulty for the principal is to know which type of quality measurement offers the most accurate information on the agents' efforts. Quality inputs are a necessary but not sufficient condition for quality outputs. When assessing the quality of processes, principals are frequently forced to rely on agents' reports of their processes. These may be deliberately misreported, or may be applied to the least-costly patients who may be less likely to gain substantial benefits. The main problem with direct measurement of the quality of the agent's outputs is that these are noisy signals of their effort because patient outcomes reflect historical events, the patient's own actions, and the actions of other agencies. These are largely unobservable and contain a substantial random element.

For these reasons, principals often adopt a portfolio of quality indicators across each of these levels. This reduces, but does not eliminate, the problems with each of the individual indicators. However, it generates new problems of how the agent's performance on each indicator should be aggregated to form an overall signal of their effort.

Comparative Performance Evaluation

Broadly speaking, incentive contracts can be classified into two types of performance measurements: (1) absolute and (2) comparative performance. Under absolute performance, the agent is set standards on performance measures that must be achieved, for example, 80% compliance with a care guideline. Under a comparative performance scheme, the agent's performance is benchmarked against a relative standard.

The relative standard in comparative performance evaluation can be set on two dimensions: time and reference group. The time dimension of comparative performance can be implemented in a static or in a dynamic setting (i.e., current or historical performance). The reference group dimension of comparative performance can be implemented across groups of agents within or between health care organizations. Although dynamic comparative performance may or may not be implemented across reference groups, static comparative performance is always relative to a reference group.

To set an absolute performance standard, the principal needs to have good information on the effort that the agent will need to make to reach that standard. Setting a relative standard based on the agent's own historical performance ensures that the agent improves quality (and thereby increases effort) period-on-period but can fall foul of secular trends and does not seek to induce equal effort across agents. Use of a static reference group benchmark isolates performance measurement from (common) secular trends, but relies on choice of an appropriate reference group and places the agent at higher risk.

If the reference group approach is selected, comparative evaluation can involve two broad types of comparisons against the other agents. It can involve comparison to the average (which is called benchmarking) or it can involve the construction of league tables (known as a rank-order tournament in the sport sector).

Benchmarking versus Rank-Order Tournaments

The primary purpose of relative performance evaluation is to mitigate the principal's imperfect information. However, comparative performance evaluation has a 'yardstick competition' effect as well as an information effect. Because rank-order tournaments will increase competition more than benchmarking, the latter is a lower-powered incentive whereas the former provides sharper incentives. Previous research has shown that wider variation in levels of performance will be induced by rank-order tournaments. The risk of such tournament-based incentives is that contestants who think they have little chance to earn a prize are not motivated by the scheme and wider variations in performance are created.

Comparative performance evaluation is optimal only when all agents face common challenges. When this is the case, the performance of one agent allows the principal to infer information about another agent's performance. However, if worse health conditions adversely affect performance and these are concentrated in specific areas, then these factors should be filtered out by comparing providers within the same area. However, an agent's rank-order within an area contains less information on the performance of an individual agent and will not generally represent an efficient use of information. Instead, aggregate measures like averages of similar organizations are more efficient because they provide sufficient information about common challenges.

Benchmarking is able to reduce the 'feedback' and the 'ratchet' effects of the reward mechanism. Feedback occurs whenever one agent's action affects the incentive scheme and thus changes the agent's own reward as well as the reward for other agents. As the number of agents affecting the overall standard is higher under benchmarking, the feedback effect will be lower than in the case of rank-order tournaments. The ratchet effect is in essence the dynamic counterpart of the feedback effect. Good agents may be better off by hiding or misreporting their 'true' performance for fear that the principal may raise the current target on the basis of past performance. Unless collusion between agents occurs, this gaming is mitigated by benchmarking.

More fundamentally, any judgment on which type of relative performance evaluation is most effective depends on the goals the principal is trying to achieve. The principal may be primarily concerned with maximizing efficiency or with minimizing inequity. If the principal is mainly concerned with increasing the efficiency of health care provision then they will seek to use comparative performance evaluation to increase the average level of performance and will likely adopt a rank-order tournament. Alternatively, the principal may be motivated by the distribution of agents' performance levels as they care most about equity of health care provision. In this case, they will seek to use comparative performance evaluation to close the gap between outstanding and poorly performing health care providers. In this case, the principal may be reluctant to use rank-order tournaments as this may increase the gap in performance between agents at the top and the bottom of the league.

The Development of Comparative Performance Evaluation

Comparative performance evaluation began as an informal exercise in the private sector and became more structured in the late 1970s in response to Japanese competition in the copier market. It typically took the form of rank-order tournaments as the extent of market competition was high.

More recently, benchmarking has been used in the public sector. For example, from April 1996 the Cabinet Office and HM Revenue and Customs in the UK have run a project, the Public Sector Benchmarking Service, to promote benchmarking and the exchange of good practice in the public sector.

Box 1 shows some key definitions of benchmarking. It highlights the competitive definition of benchmarking by the private company Xerox and the less competitive definition of benchmarking, focused on learning from comparisons, by the public sector.

These developments have been mirrored in the health care sector. Initially, governments in their roles as payers and regulators, made use of the availability of electronic information to give feedback to providers on their relative performance. These initiatives were frequently undertaken under the auspices of professional bodies and the focus was deliberately on information-sharing and supporting intrinsic motivation. Providers were often given data on their own performance and the performance of the average provider or their rank in the distribution of performance over anonymized providers.

Later, these data were deanonymized and sometimes publicly reported. This was viewed as a natural progression. Once providers were content that the information on their performance was accurately recorded and consistently collected across providers, the public could be reassured that quality in the public health care sector was consistently high.

However, when quality first became linked to penalties and rewards, it was typical to use absolute performance standards. The introduction of waiting time targets in the UK National Health Service (NHS), associated with stringent monitoring and strong personal penalties, for example, was enforced using absolute maximum standards. These were frequently criticized for distorting priorities and inducing gaming, though the empirical evidence on patient reprioritization is scant and previous research finds no support for gaming. Similarly, the introduction of highly powered financial incentives for UK general practices in the form of the Quality and Outcomes Framework were based on absolute standards. The lack of data on baseline performance meant that these standards were set too low and that only modest gains in quality were delivered, some of which have been shown to be due to gaming of the self-reported performance information.

The second generation of financial incentives for improving quality in the UK NHS make greater use of comparative performance evaluation. There are a number of national schemes that emphasize local flexibility and payment for quality improvement rather than achievement of absolute standards. The forerunner to these was introduced in one region in England

Box 1 Definitions of benchmarking

The Public Sector Benchmarking Service defines benchmarking as: 'Improving ourselves by learning from others.'

The Cabinet Office calls benchmarking: 'The process of comparing practices and performance levels between organizations (or divisions) to gain new insights and to identify opportunities for making continuous improvements.'

The European Benchmarking Code of Conduct states that: 'Benchmarking is simply about making comparisons with other organizations and then learning the lessons that those comparisons throw up'.

Xerox, a pioneer of private sector benchmarking in the copier market says that it is: 'The continuous process of measuring products, services and practices against the toughest competitors or those companies recognized as industry leaders.'

and provides a good example of the limitations of using financial incentives linked to comparative performance evaluation. This scheme is described in the next section.

The Advancing Quality Program

The Advancing Quality (AQ) program was launched in October 2008 for 24 acute hospital trusts in the North West of England. Trust performance is summarized by an aggregate measure of quality – the composite quality score – within each of five clinical domains. The five incentivized clinical conditions are acute myocardial infarction, coronary artery bypass graft surgery, hip and knee replacements, heart failure, and pneumonia. The composite quality scores are derived by equally weighing achievement on a range of quality metrics which include process and outcome measures. Table 1 lists the quality metrics used in AQ.

Table 1 Quality measures used in the advancing quality program

Patients with acute myocardial infarction
Aspirin at arrival
Aspirin prescribed at discharge
ACEI[a] or ARB[b] for LVSD[c]
Adult smoking cessation advice/counseling
Beta blocker prescribed at discharge
Beta blocker at arrival
Fibrinolytic therapy received within 30 min of hospital arrival
Primary PCI[d] received within 90 min of hospital arrival
Standardized survival index
Patients with heart failure
Evaluation of left ventricular function
ACEI or ARB for LVSD
Discharge instructions
Adult smoking cessation advice/counselling
Patients receiving coronary artery bypass grafting
Aspirin prescribed discharge
Prophylactic antibiotic received within 1 h before surgical incision
Prophylactic antibiotic selection for surgical patients
Prophylactic antibiotics discontinued within 48 h after surgery end time
Patients receiving hip and knee replacements
Prophylactic antibiotic received within 1 h before surgical incision
Prophylactic antibiotic selection for surgical patients
Prophylactic antibiotics discontinued within 48 h after surgery end time
Recommended venous thromboembolism prophylaxis ordered
Received appropriate venous thromboembolism prophylaxis within 24 h of surgery
Readmission avoidance rate – 28 days post discharge
Patients with pneumonia
Oxygenation assessment
Initial antibiotic selection for immunocompetent patients
Blood culture performed in A&E before initial antibiotics received in hospital
Initial antibiotic received within 6 h of hospital arrival
Adult smoking cessation advice/counseling

[a]Angiotension converting enzyme inhibitor.
[b]Anguitensin receptor blocker.
[c]Left ventricular systolic dysfunction.
[d]Percutaneous coronary intervention.

The AQ scheme is similar to the Hospital Quality Incentive Demonstration (HQID) in the US. Both schemes started as pure rank-order tournament systems. At the end of the first year, hospitals in the top quartile received a bonus payment equal to 4% of the revenue they received under the national tariff for the associated activity. For trusts in the second quartile, the bonus was 2% of the revenue. For the next two quarters, the reward system changed to the same structure that was adopted by HQID after 4 years; bonuses were earned by all hospitals performing above the median score from the previous year and hospitals could earn additional bonuses for improving their performance or achieving top or second quartile performance. There was no threat of penalties for the poorest performers at any stage.

Evidence from HQID and AQ initiatives suggests that providers quickly converge to similar values on the process metrics and differences in performance must be measured at a very high level of precision to discriminate among providers. In addition, on some of the process measures most providers scored (close to) maximum scores. Because of the small variability in the measures and these ceiling effects, the schemes end up rewarding trusts based on small differences in performance.

Under the HQID and AQ scoring mechanisms, all of the targeted indicators are given equal weight regardless of their underlying difficulty. Thus, the quality score methodology involves a risk that providers will divert effort away from more difficult tasks toward easier tasks. However, despite the clear incentive to do so, research from the US suggests no consistent evidence that providers engaged in such behavior.

From the perspective of public health and policy making, the more important question, however, is whether health outcomes have changed as a result of the introduction of HQID and AQ initiatives. Here, the US and UK experiences are contradictory. A comprehensive US study found no evidence that HQID had affected patient mortality or costs. The first evidence from the UK shows that the introduction of AQ initiative was associated with a clinically significant reduction in mortality.

In both countries, studies have found weak links between process measures and patient mortality and ruled out causal effects on the health outcome. This appears to show that improved performance on the process measures alone could not explain the association with reduced mortality in the North West.

The critical questions now are how and why AQ scheme was associated with robustly estimated mortality reductions when similar studies have found little evidence of an effect of process metrics on patient outcome.

The qualitative evaluation of the AQ scheme found that participating hospitals adopted a range of quality improvement strategies in response to the program. These included employing specialist nurses and developing new and/or improved data collection systems linked to regular feedback of performance to participating clinical teams.

Compared to HQID, the larger size and greater probability of earning bonuses in AQ may explain why hospitals made such substantial investments. The largest bonuses were 4% in AQ compared to 2% in HQID and the proportion of hospitals

earning the highest bonuses was 25% in AQ compared to 10% in HQID.

In addition, the participation process may be important. To participate in HQID, hospitals had to (1) be subscribers to Premier's quality-benchmarking database, (2) agree to participate, and (3) not withdraw from the scheme within 30 days of the results being announced. The 255 hospitals that participated represented just 5% of the total 4691 acute care hospitals across the US. In contrast, the English scheme was a regional initiative with participation of all NHS hospitals in the region. This eliminated the possibility of participation by a self-selected group that might already consist of high performers or be more motivated to improve. Further experiments would be required to identify whether pay for performance schemes are more effective when participation is mandatory or targeted at poor performers.

Despite the 'tournament' style of the program, staff from all AQ participating hospitals met face-to-face at regular intervals to share problems and learning, particularly in relation to pneumonia and heart failure, where compliance with clinical pathways presented particular challenges and where the largest mortality rate reduction can be found. Similar shared learning events were run as 'webinars' for HQID. The face to face communication, regional focus, and smaller size of the scheme in England may have made interaction at these events more productive.

The fact that a scheme that appeared similar to a US initiative was associated with different results in England reinforces the message from the rest of the literature that details of the implementation of incentive schemes and the context in which they are introduced have an important bearing on their effects.

Concluding Remarks

To summarize, the asymmetry of information between the principal and the agent is particularly acute in the case of information on quality. Principals design incentive contracts under these circumstances to induce agents to increase their effort. One way in which principals can retrieve information on the efforts being made by agents is through comparisons of performance across time and/or across agents. Such comparative performance evaluation can involve comparison to own historical achievements or a reference group's achievements. The principal can benchmark agents to the average or create a rank-order tournament.

Although both types of comparative performance evaluation can improve efficiency by reducing the principal's information problem, rank-order tournaments are more likely to increase the gap between performance at the top and the bottom of the league. Benchmarking minimizes feedback and ratchet effects, but it can also weaken competition between agents. Ultimately, the choice between benchmarking and rank-order tournaments depends on the objectives of the principal.

In practice, comparative performance evaluation for improving quality was used quite widely and with little controversy when it appealed only to intrinsic motivation. Linkage of comparative performance evaluation to financial rewards, however, has led to a sharper focus on its limitations. In this regard, the experiences with the HQID and AQ initiatives display many of the conundrums of using comparative performance evaluation. There is a great deal of uncertainty over, and little empirical evidence to support, the choice of comparator. The frequently adopted strategy of using a portfolio of indicators leads to problems of appropriately weighing the calculation of overall performance to avoid re-prioritization of effort. Finally, incentivization of improvements in the quality of processes reported by agents does not in itself lead to outcome improvements.

Overall, the evidence base on the effects of comparative performance evaluation is weak. Although there has been a great deal of (well-intentioned) experimentation, these initiatives have been adapted too frequently and have not been rigorously evaluated. Ultimately, the main challenges for principals considering the use of comparative performance evaluation are how to measure hospital quality, how to identify similar agents to make accurate comparisons, whether to appeal to extrinsic or intrinsic motivation, and how to devise and implement the pay-for-performance initiative given the context in which it is introduced.

Competition on the Hospital Sector

Z Cooper, Yale University, New Haven, CT, USA
A McGuire, LSE Health, London, UK

Glossary

Concentration The degree to which a given number of producers (in this case hospitals) share the total level of output (treatments) in a given geographical area.
30-Day AMI mortality A death from acute myocardial infarction (AMI) within 30 days of admission to hospital.
Hospital competition Hospital behavior that arises when hospitals are contesting for patients due to incentive mechanisms imposed by funding bodies. Hospitals might compete on the basis of lowering prices or increasing quality of care, or a combination of the two, to attract patients and funding. Quality competition under fixed prices currently is predominant.
Hospital prices The charges either set by the hospital or by the funder or the regulator for the treatments and other services provided. The level of hospital costs are one determinant of prices; other factors include the degree of competition, the level of unsecured costs (e.g., to compensate for teaching provision, charitable provision, or new innovation), and the type of financial return sought (e.g., whether the hospital is for-profit or not-for-profit).
Hospital quality The quality of service provision attained by a hospital. Quality may be judged across many different dimensions and measured in different ways (ranging, e.g., from in-hospital mortality rates to level of overall patient satisfaction).
Market power The ability of any individual producer to control a dimension of the market it operates in. Within the hospital sector market power is normally related to the degree to which a hospital is able to capture potential patients. The higher the concentration of patients treated within a given geographic region by a given hospital tends to form the basis of the measurement of hospital power.

Introduction

A range of specific policies designed to increase both patient choice and hospital competition has been introduced in, amongst other countries, England, Denmark, Sweden, Norway, and the Netherlands. A primary concern arising from such reforms is the effectiveness of hospital competition to provide improvements in quality, responsiveness, and efficiency. Theory would suggest that if hospital prices are not fixed but endogenously determined by the hospitals themselves, and quality is not easily observed or verifiable, then hospitals may react to increased competition for funds by offering lower quality at a given price, thus chiseling on quality, attracting higher volume and funding but producing lower quality output. Competition may be introduced, but it may not produce the desired effect.

Theory also suggests, however, that if prices are set exogenously increased competition will lead to higher quality, although, it has also been noted that, if provider preferences are sufficiently altruistic, high quality provision can also occur within a restricted competitive environment. Indeed, theoretically, if altruism is sufficiently high there may be a negative relationship between competition and quality provision. Thus examination of the incentive structures and the environment into which these are introduced is critical. This has been the subject of debate, at the core of which is the notion that, given a regime of fixed prices, hospitals will compete for patients and therefore revenue, through improving the quality of care offered. Fixed hospital prices are essentially associated with Diagnostic Related Group (DRG) prices for predefined case groupings. Those in favor of hospital competition argue that with fixed price competition for patients, efficiency and quality improve as hospitals increase their performance or risk losing their market share. Those against competition argue that such market-based reforms can destabilize hospitals, increase transaction costs, and possibly even harm patients.

This article examines the empirical evidence on patient choice and hospital competition to consider whether competition is associated with an improvement in hospital quality and patient outcomes. To do so, the general literature that considers hospital competition and quality is assessed. Before this examination of the literature however, the conceptual difficulties of measuring competition in this sector are discussed.

Issues in Measuring Competition

To assess the impact that hospital competition has on clinical quality there has to be an agreed definition of market power. The major challenge is the estimation of the size of the competitive market and the power exercised by individual hospitals. It is obvious that incorrect definition of the potential market would result in biased assessment of the impact of competition.

In product markets price relationships, in particular own-price and cross-price elasticities, may be examined to aid definition of the relevant market. In the hospital sector this is not relevant as prices, even if known, are highly regulated. Typically, investigators calculate hospital market size through concentrating on the definition of geographic area instead and do so in one of three ways. First, geographic market area may be defined as based on a fixed radius, defined by a largely arbitrary distance that creates a circular market of radius *r*. Investigators then calculate the degree of competition inside that market. Fixed radius measures have the possibility of both

overestimating and underestimating the actual size of the market. The shortcomings of such fixed radius measures is that they do not take account of potential demand when they estimate market size. As a result, the fixed radius measures may suffer from urban density bias and overestimate competition in urban areas. However, an advantage of this type of fixed radius market definition is that the market size tends not to be endogenous to any other factors, such as hospital quality.

A second option is to create a variable radius market where the radius *r* that dictates the size of the market varies according to preexisting referral patterns, actual patient flows, or hospital catchment areas. For instance, a variable radius *r* could be set at a length that captures the home addresses of 75% of patients at a particular hospital. Variable radius measures tend not to be as affected by urban density bias but some argue that, when the radius *r* that defines the size of the market is based on existing referral patters or hospital catchment areas, the market size they estimate may again be biased. For example, a high performing hospital may have a larger catchment area than a lower quality competitor.

A third option is to create a radius that varies according to travel distance. An example of a travel-based radius would be to define radius *r* as the distance that captures the hospitals within a 30-min travel time from a particular patient's home address. Market definitions based on existing referral patterns may be related to the real or perceived quality of local hospitals, but can suffer from referral patterns reflecting quality. Some argue that any estimates of competition that rely on actual patient flows may still be biased. Rather than using actual patient flows, predictions of patient flows to specific hospitals may be used to reduce this bias. Some studies have used predicted demand to estimate market size, based on travel distance for patients, arguing that their method mitigates the problems of traditional fixed and variable market measures of competition. However, in practice, sizes of markets defined using radii derived from travel distances tend to be highly correlated with the sizes of fixed radius markets. Because the two market definitions produce results, which are so closely correlated, they both tend to be affected by urban density bias. The key issue with both market definitions is that they require a largely arbitrary definition of the size of the market, such as 30 km for fixed measure and a 30-min travel time for time variable measure. Both market definitions may therefore either overestimate or underestimate the true size of the market depending on how the upper boundary of the market is set by researchers.

All three approaches have been applied to the hospital market; none is perfect. Each measure has its own strengths, weaknesses, and inherent bias. A practical approach in considering which method to employ is to assess the compatibility of the data with the various measures, to trade-off the inherent bias contained in each method by comparisons across a number of measures and to explore the use of instrumental variables to overcome any endogeniety.

General Evidence on the Relationship between Hospital Competition and Clinical Quality

The largest volume of literature assessing the relationship between hospital competition and quality comes from the USA (see Gaynor, 2006 for an overall review). The bulk of the existing US literature has investigated the relationship between competition, prices, and capacity and is rather out of date. There is a related small, but growing literature in the US that looks directly at the impact of hospital competition on clinical performance. A number of studies consider endogenous price environments and, unsurprisingly, the general finding with respect to the influence of increased competition on outcome quality is ambiguous.

A smaller number of recent studies on competition and quality tends to the conclusion that, under exogenously determined fixed-price competition, higher levels of competition generally lead to improvements in clinical performance. The bulk of this US literature on hospital competition and clinical quality examines the outcomes of Medicare beneficiaries and within the timeframe of these studies Medicare operated an exogenously determined DRG pricing scheme. Findings generally support a positive relationship between in-hospital mortality and increased hospital concentration (Kessler and McClellan (2000) is a prime example). One study found that competition was associated not only with improved outcomes in the Medicare population but also with more intensive treatment for sicker patients and less intensive treatment for healthier patients who needed less care.

The literature outside the US is smaller but supports the general findings. There is a growing, recent literature on hospital competition within the National Health Service (NHS) in England, for example. It is based on the introduction of a purchaser–provider split, where GP practices purchased secondary hospital care on behalf of their patients. As initially introduced, these reforms were said to have created an internal market in health care. They were based on various contractual arrangements. Hospital prices were generally not fixed and can therefore be assumed endogenous. There is a wide consensus that the internal market never created high-powered incentives for hospitals or developed a significant degree of competition. Notwithstanding this criticism, there is some evidence that prices fell during the internal market. One study also found that, during the initial phase of the internal market, higher competition was not associated with lower quality.

Examination of the impact of the NHS internal market on patient waiting times and length of stay for hip replacement from 1991 to 1994/5, using survival analysis to look at hospital level data during the internal market reform period, found that waiting times for hip replacements fell and so did patients' average length of stay. This study found that, after the internal market was introduced, patients were more likely to be transferred to another facility rather than remaining in the hospital where they had the surgery until they were ready to be discharged home.

The strongest evidence on the impact of hospital competition on patient quality in the NHS comes from a number of English studies. This article considers various aspects of increased competition on hospital quality. The dominant quality measure, 30-day AMI mortality, was chosen because, being tied to an emergency treatment and largely associated with in-hospital mortality, it is not easily manipulated by hospital admission policies. The mechanism through which AMI-mortality may be used as a proxy for general hospital quality is not always made explicit, but hinges on the

presumed correlation between the management of AMI treatment and wider hospital practices. One study of the impact of the internal market (presumed competitive) on hospital quality as it had been before 1999, i.e., a period before the fixing of hospital prices, used a 30-min drive time from ward centers as the competitiveness measure. Using hospital-level data and controlling for hospital and local area characteristics, it was found that the internal market led to a small but statistically significant increase in 30-day AMI mortality, the adopted measure of quality (Propper, 1996).

A further study (Propper *et al.*, 2008) used a longer time period to assess whether more competitive areas had higher or lower AMI mortality over the period 1991–1999. Once again this is a period of endogenously determined prices. Similar to the findings from their previous work, the report that higher competition during periods of competition was associated with higher AMI mortality, i.e., higher competition is associated with lower hospital quality in this dimension. They argue that it is not credible that hospitals deliberately sought to curtail quality in this manner – hospitals did not deliberately worsen 30-day AMI mortality. Rather it is suggested that as the internal market increased competitive pressures hospital resources were shifted from quality domains that were not fully observable and verifiable such as the impact of hospital care on health outcomes, to those, such as waiting times for elective procedures that were easily measured and were being targeted.

The introduction of DRG-type prices into the English NHS in 2005/06 fixed hospital tariffs at the same time as competition within the NHS was strengthened. Two recent studies have used difference-in-difference estimators to examine the impact of this increase in competition on hospital quality using 30-day AMI as the measure of hospital quality. Cooper *et al.* (2011) found that AMI mortality decreased more quickly for patients living in more competitive areas than that in less competitive areas. Specifically in the three-year period after the reforms were introduced, a one standard deviation increase in hospital competition was associated with approximately a 1% decrease in AMI mortality. Gaynor *et al.* (2010) found a similar impact of the increase in competition on hospital quality, again measured through 30-day AMI death rates, over the period 2003 to 2007. Both studies, therefore, find that increased competition under a fixed price regime within the English NHS over the period 2002–8 improved hospital quality even though a different aggregation of data and different methods are used.

There is also a small empirical literature that considers the impact of increased hospital competition on equity and patient access. The hypothesis is that competition may have a detrimental effect on equality of access for NHS patients. Waiting times for patients having an elective hip replacement, knee replacement and cataract repair over the period 1997 and 2007 in England seem to have generally decreased as competition increased, with the variation in waiting times for those procedures across socioeconomic groups also greatly reduced. Cookson *et al.* (2010) examined the impact of the internal market on equity, measured as the association between patient deprivation and hospital utilization. They compared competitive and noncompetitive areas, where competition was measured using a Herfindahl–Hirschman (HHI) index in a fixed radius market and also found that there was no evidence that competition had a worsening effect on socioeconomic health care inequality.

Conclusions

This short review has confirmed what was to be expected from theory: Under exogenous fixed-price regimes health care reforms, which increase competition among hospital providers, can lead to improved outcome of quality. There is not a large volume of empirical evidence that can be used to test this theoretical conclusion but what does exist is rather robust. The methods used tend to be similar and reliant on robust estimation procedures, including difference-in-difference estimation and large data sets. One criticism of these findings is that a large number of studies use a similar proxy measure of hospital quality: 30-day AMI mortality. There are justifiable reasons for the choice of this measure: It is associated with an emergency admissions and treatment, which is difficult to manipulate by the hospital providers. It is nonetheless a one-dimensional measure of quality and the generalizability of the empirical findings rest on a belief that there is a strong correlation between this dimension and other less verifiable dimensions of hospital quality. It is perhaps not too difficult to buy into the belief that if hospitals have good management structures all dimensions of quality will trend in a similar manner. Other empirical research has indeed found that hospitals with better overall management skills had lower mortality from AMI. Moreover, recent studies show that this measure of hospital quality (30-day AMI mortality) is indeed correlated with other hospital outcome measures. The policy implications appear clear that with a fixed price regime competition can be improving. That this is not found when prices are set endogenously is perhaps an unsurprising lesson.

Cost Function Estimates

K Carey, Boston University School of Public Health, Boston, MA, USA

Glossary

Average cost Total cost divided by the rate of output.
Behavioral cost function A cost function that includes amongst its determinants not only the cost of inputs but also things such as length of stay, case-mix, and quality of care.
Cost function A mathematical relationship between the costs of inputs in the production process and the rate of output.
Economies of scale Also known as increasing returns to scale: The amount of resources used per unit of output falls at higher output rates.
Economies of scope Also known as 'scope effects.' Economies of scope enable a firm to produce several goods or services jointly more cheaply than producing them separately. The simultaneous production of hospital care and medical teaching is an example.
Fixed cost A cost that does not vary with output either because input prices are constant or because decision makers have decided not to vary the input in question. Few, if any, inputs are technically fixed in the sense of being unalterable.
Long run A period of time in which all inputs are treated as variable.
Marginal cost The additional cost incurred if the output rate is increased by a small amount.
Production function A technical relationship between 'inputs' and the maximum 'outputs' or 'outcomes' of any procedure or process. Also sometimes referred to as the 'technology matrix'. Thus a production function may relate the maximum number of patients that can be treated in a hospital over a period of time to a variety of input flows like doctor- and nurse-hours, and beds.
Short run A period of time in which one or more inputs are treated as fixed.
Stochastic frontier cost function An empirical method of estimating the maximum outputs obtainable from given resources and, hence, the degree to which actual operations fall short of the most efficient way or operating.

The Economic Cost Function: Foundations

Microeconomics contains a theoretically based framework that describes how an individual business enterprise chooses to optimize production and cost efficiency, given existing technologies and prices of inputs. Within this supply side structure, the production function models the relationship between outputs produced and inputs used in the process, and the cost function models the relationship between the production cost of different levels of output accounting for input prices. The two functions are related in the sense that the production function shows the various ways of combining inputs to produce outputs, given the state of technology, and the cost function shows how to do it at minimum cost. Given certain basic mathematical properties, a duality or one-to-one correspondence exists between a set of production possibilities and the respective minimum cost function. In modeling the provision of health care services, economists often prefer the cost function to the production function because input prices are plausibly assumed to be determined outside of the model of firm behavior, whereas the selection of inputs in the production process are not.

The cost function is a powerful tool in the econometric application of the theory of production. In health economics, the preponderance of cost function estimation studies have focused on the hospital, which lies at the nexus of health care services and is the foremost component of health care spending. A number of issues involved in cost function estimation in health care have been addressed in empirical studies of US hospital costs. The remainder of this article will highlight the key issues involved in cost function estimation largely in that context.

Approaches to Cost Function Estimation

Short-Run Versus Long-Run Cost Functions

In any cost function estimation, a fundamental determination facing the researcher is whether to adopt the short-run or the long-run perspective. The distinction lies in assumptions regarding the state of equilibrium, or whether the firm has set all its inputs at their cost-minimizing levels. A variable cost function assumes the short-run scenario in which a firm's capital costs are fixed, whereas a total cost function takes the long-run perspective, in which all costs are variable and inputs have been chosen such that total costs are minimized. In the short-run variable cost function specification, the dependent variable measuring costs does not include capital costs; however, the fixed measure of capital is included as an explanatory variable. In the long-run total cost function, the dependent variable includes capital costs.

The appropriate choice of the short-run versus the long-run approach draws on both theoretical and practical considerations. If the firms are believed to be employing all inputs at the cost minimizing levels, then the long-run total cost function is indicated by theory. However, if firms cannot adjust their capital stock quickly in response to changing output

levels or input prices, a short-run variable cost function is the preferable specification. From a practical perspective, estimation of a long-run cost function requires a measure of capital costs, which are often difficult to observe. In addition, the long-run cost function should include measures of all input prices including those of capital, which in most applications can be achieved only as rough approximations.

In hospital studies, it is generally agreed that capital stocks are adjusted over time horizons exceeding the periods of study included in most datasets. Moreover, the industry has experienced considerable organizational, regulatory, and demand side changes over recent decades. These factors, together with the challenges of measuring capital costs and capital input prices, generally have led economists to estimate short-run variable cost functions for hospital studies. This specification does require reliable measures of fixed inputs. It also assumes that those inputs are exogenous, or that hospitals do not have the opportunity to significantly adjust their physical plant size.

Structural Versus Behavioral Cost Functions

In pure theoretical form, costs are modeled solely as a function of output levels and prices of inputs, controlling for fixed inputs or capital in the case of the short-run variable cost function. However, in empirical applications, cost functions generally incorporate other observable factors that have been found both conceptually and empirically to account for significant variation in the costs of producing specific products or services. This is particularly important in the health services literature where such cost estimations are alternatively referred to as behavioral cost functions or hybrid cost functions as opposed to structural or pure theoretic cost functions.

In the hospital literature, variables included in behavioral cost functions may not have a particular role in the microeconomic theory of the firm, but they incorporate real world differences in hospitals and reflect patterns of variation found in actual hospital cost data. Typically, hospital cost functions contain a primary measure of output such as number of admissions, one or more measures of input prices, and a measure of fixed capital such as the number of beds or the amount of total fixed assets. Admissions alone do not capture variation in hospital output. Other product descriptor variables commonly included are average length of inpatient stay, a case-mix index that is usually based on the relative costliness of the diagnosis-related groups assigned to admitted Medicare patients, and the number of hospital outpatient visits.

Other key variables that have been demonstrated to account for variation in hospital costs and are often included as controls in the cost function are measures of local market competition, ownership status (for-profit, not-for-profit, or government), and the presence of a teaching mission. Market competition is often measured using a Herfindahl–Hirschman index of market concentration. The index, calculated as the sum of the squared market shares of individual firms competing in the same market, is a function of the number of competitors and the distribution of their relative market shares. Its values fall in the range of 0–1 where lower measures signify many hospitals competing within the market and higher measures indicate fewer hospitals. Teaching hospitals are more costly because of the extra resources involved in performing an educational, in addition to a therapeutic, mission. These costs are sometimes captured by a binary variable such as membership in the Council of Teaching Hospitals or alternatively by a continuous variable measuring the number of medical residents affiliated with the hospital.

Challenges in Cost Function Estimation

Measuring Output: The Multiproduct Cost Function

Health care provision is highly complex, and measuring the output of a firm that supplies health care services is often complicated. For example, a typical general hospital treats patients with a large number of diverse conditions using thousands of different medical procedures. Resource utilization for surgical inpatients is greater than for medical inpatients, and inpatients are more resource intensive than outpatients. In physician practices, office visits for established patients have cost implications that are unlike those driven by visits with new patients, emergency room visits, or hospital visits. Nursing homes provide distinct levels of care for their residents, and skilled nursing patient days have different cost implications than intermediate care or other patient days.

Most health care cost estimations rely on the multiproduct cost function (also referred to as the multiple output cost function), which defines the cost of producing more than one type of output assuming that all inputs are used efficiently. Incorporating more than a single output into the cost function adds realism to the model. The multiple output specification also allows for a richer set of theoretical constructs useful in applications of cost function results. However, greater output complexity also introduces additional challenges in capturing unit costs of production. These issues are discussed in further detail in the section on Average Costs.

Controlling for Quality

Microeconomic theory assumes that the firm minimizes cost in choosing inputs to the production process to produce outputs at a given level of quality. Although measurement of firm cost is generally straightforward and measures of output are usually feasible, the quality of health care service provision is multidimensional and difficult to quantify. Yet, it has long been established that if quality of service is not controlled in a cost function, biases result.

Variation in quality levels also complicates the theoretical modeling of health care cost. In the case of hospitals, high nurse staffing ratios, the extra resources required by teaching hospitals, sophisticated information systems, and/or innovative high technology services are cost increasing features that have been found to be associated with higher observed hospital quality. Yet, low quality also can be cost increasing if it is related to lapses leading to preventable adverse events or postoperative complications that require additional services. These dynamics are interrelated. For instance, higher nurse staffing levels and/or sophisticated information systems not only have a direct and positive impact on costs but also reduce the probability of expensive adverse events, thereby simultaneously having an

indirect effect that is cost reducing. Overall, the theoretical relationship between costs and quality is complex, consisting of the joint effects of many different factors operating simultaneously.

Quality of health care also has presented repeated problems of measurement and data availability. Consequently, many cost function studies have not included explicit quality measures, confounding the impact of cost containment policies. In the absence of observed measures, some hospital cost functions have incorporated unobserved quality by building on the economic theory or by exploiting the structure of the error term in regression models. Studies that have included observed quality controls have relied heavily on structural measures of hospital quality such as teaching activity. There is widespread agreement that quality of care tends to be higher in teaching hospitals, which have access to the newest technologies. Yet, patient satisfaction and continuity of care are often worse in teaching hospitals and reports of resident exhaustion not uncommon. Teaching *per se* also represents the specific hospital output of medical education so that teaching is at best a proxy variable for hospital quality. Other structural measures include the presence of high-technology services, board certification of staff, hospital accreditation, and registered nurses as a percentage of full-time nursing staff. Finally, process measures such as outpatient follow-up to inpatient care, or outcome measures such as readmission, mortality, or adverse event rates have been used as quality controls.

The Profit Maximization Assumption in Health Care

The empirically estimated cost function derives from a theoretical framework, which assumes that the firm's fundamental goal is profit maximization. However, it generally is agreed that producers of health care services are often motivated by other objectives. For-profit enterprises constitute a minority of general hospitals in developed countries, and a large percentage of nursing homes are nonprofit organizations. Although a number of theoretical models have been developed in order to explain the objectives of nonprofit firms in the health sector, the empirical cost function literature on hospitals does not find that ownership drives cost differences. Growing competition in the hospital industry may force nonprofit hospitals to behave much like for-profit hospitals to remain viable.

Useful Constructs

The magnitudes of coefficients on independent variables generated by the cost function are not in themselves meaningful. However, a number of constructs fundamental to the theory of the firm can be determined using the cost function estimates. Key measures include marginal cost, average cost, economies of scale, and economies of scope. These represent a highly constructive set of tools that frequently are used in cost function applications to research and policy.

Marginal Costs

Marginal cost is the increment in cost that occurs when the output produced is increased by one unit. More formally, it is the derivative of the total cost function with respect to output. Marginal costs are important because economic decisions are made at the margin. For example, the economic decision of a physician practice to expand or reduce a particular service in response to a change in fixed payment rates will depend on the marginal cost of producing that service.

Average Costs

Average cost is defined as the total cost of production divided by the number of output units. Although a conceptually simple construct, calculation of average costs is complicated in health care cost functions. Because of the multiproduct nature of production, it is difficult to describe output in a single utilization measure. The American Hospital Association Annual Survey Database contains measures of 'adjusted' discharges and patient days where these outputs are inflated by the ratio of total (inpatient plus outpatient) revenues to inpatient revenues. These measures are widely accepted and used in hospital cost function estimations; however, it is recognized that they are biased to the extent that hospitals cross-subsidize across inpatient and outpatient services. Although the ratio of costs rather than revenues would be a more accurate economic adjustment, separation of costs in this way is not generally available in hospital accounting systems.

Economies of Scale

Economies of scale refer to the notion that average cost falls as the firm expands. Conversely, diseconomies of scale occur when expansion incurs increasing average costs. From a technical standpoint, a measure of economies of scale is equivalent to the ratio of marginal to average costs. This is because if cost at the margin is lower than average cost, then average cost will fall with increased output.

In the multiproduct context, there are two distinct economies of scale concepts. Product specific economies of scale characterize the cost effects of expanding each output separately while holding production levels of other outputs constant. The alternative adaptation is ray scale economies, which assumes a proportional increase in cost resulting from a simultaneous proportional increase in all outputs. Either construct may be appropriate; the choice depends on the context involved in the specific analysis.

Economies of Scope

The nature of multiproduct cost functions also gives rise to the related concept of economies of scope. Typically, a health care enterprise will produce more than one product because sharing of resources generally means that it is cheaper to produce products together than to produce them separately. Economies of scope refer to the savings incurred as a result of joint production.

Functional Form of the Cost Function

The cost function is not derived from a specific production technology; hence, no particular functional form is called for

in estimation. Yet, because the functional form of the minimum cost function is unknown to the researcher, there is a risk of misspecification, in which the model may yield poor or even erroneous predictions. Some judgment is called for in selecting a functional form for the cost function, and the econometrician practices a degree of art as well as science in formulating the econometric model.

A variety of specifications are employed in practice. The most commonly used in the health industries is the translog, a 'flexible functional form,' which represents a local second-order Taylor approximation to any true differential function. The translog involves logarithmic transformation of the dependent and independent variables and includes squared terms as well as interactions among outputs as independent variables. An important drawback to the translog that estimates a large number of parameters is the problem of multicollinearity among its many terms so that some precision of the estimates is sacrificed for functional flexibility, a trade-off that may or may not be warranted depending on the size of the dataset being used and the objectives of the particular research question. The problem is exacerbated in multiproduct cost functions and increases with finer disaggregation of outputs.

An alternative to the translog that often has been adopted in hospital and nursing home studies is a model that is logarithmic in costs with cubic polynomials on output. Although less flexible than the translog, the cubic specification is consistent with the classic U-shaped average cost function. It is particularly useful when the focus of the research is on marginal effects. There are other functional forms that have been used to estimate hospital cost functions. Of particular mention are the generalized translog, which often is used for multiproduct cost functions in cases where an output takes a value of 0 for some firms, and the generalized Leontief, which is useful in studies where the determination of input substitutability is of particular interest.

Some Applications

Health economists have used the cost function approach to address an extensive array of research questions. A description of the full range is beyond the scope of this narrative. However, this section highlights several notable issues that have been explored using cost function estimates. The purpose is to provide insight into the usefulness of the cost function approach in addressing important health policy concerns.

An economic question that lies at the core of the theory of the firm is optimization of firm size and the related issue of scale economies. The importance of economies of scale as a determinant of industry structure underlies economic arguments that have been put forth as justification for various forms of hospital regulation. A wave of hospital mergers in the 1980s and 1990s, for example, led the US federal antitrust authorities to develop guidelines for hospital mergers that allowed for demonstration of economic efficiency stemming from economies of scale. Economists have used the cost function to estimate the optimal hospital size, measured in patient days, or alternatively in number of beds. More recent policy concern has been over rapid growth of small physician-owned specialty hospitals. The economic cost function approach has been used to address the question of whether these hospitals are large enough to capture scale and scope efficiencies.

The cost function approach also has been applied to changes occurring in the internal organization of hospitals over the past two decades. Steep declines in the length of hospital inpatient stays began in the 1980s in response to insurer and government payer pressures on hospitals to absorb greater financial risk in their treatment decisions. The cost function has been used to examine the marginal cost of patient days over the course of a hospital stay. If the marginal cost of a patient day is relatively small, because the patient is in the recuperation stage and resource utilization is relatively low, then shortening the stay may or may not be an effective cost containment strategy.

An interesting policy question relating to the production of physician services is whether physician payments reflect marginal costs. For example, the Resource-Based Relative Value System through which US physicians are paid under the Medicare system was designed to reimburse at cost; however, the formulae used by Medicare is based on accounting cost systems that may not accurately reflect true production costs. A multiple output physician cost function is a tool that can more accurately reveal how marginal costs of production vary across different physician services that may be reimbursed at the same rate under administered pricing or privately negotiated rates.

The multiproduct cost function is well suited to empirical analysis of the US nursing home industry, which serves residents under explicitly distinct payment mechanisms: Rates received for Medicaid patients covered under various state programs for the poor are known to be considerably lower than those charged to self-paying patients. The cost function is a useful tool for exploring a number of policy questions. Are Medicaid rates paid by states to nursing homes for providing care for their poor elderly populations equal to the cost of treatment? Conversely, do higher rates charged to self-paying patients cross-subsidize Medicaid patients?

Stochastic Frontier Cost Function Estimation: Measuring Inefficiency

As expenditures on health care in developed countries have mounted in recent years, the goal of improving efficiency in health care provision has become a central objective for policy makers. At the same time, the demand for improved capability in measuring provider performance has stimulated the development of frontier analysis, which generates empirically based inefficiency measures at the provider level. Frontier studies define inefficiency as the extent to which an organization's performance exceeds the optimum (or frontier) as predicted by either production function or cost function estimates.

Within this empirical framework, the stochastic frontier cost function is the principal econometric technique for identifying the cost inefficiency of an individual provider. In contrast to a typical cost function that fits the average level that best fits the data, the stochastic frontier cost function traces out the least cost locus econometrically for varying output

levels and in that sense is more consistent with the theoretical concept of cost minimization. Inefficiency is inherently unobservable and assumed to be absorbed in the residual term. Allowing for unobserved firm-specific random shocks, the technique identifies an inefficiency term according to the deviation of the firm's actual cost to the least possible cost as determined by the cost function. Focus on the inefficiency term in stochastic frontier cost function analysis differs from traditional cost function analysis, in which interest is centered on estimated coefficients. In examining the performance of hospitals over the past decade, stochastic frontier analysis has been more prevalent in the literature than traditional cost function estimation.

A particular challenge for stochastic frontier cost function estimation is the ongoing difficulty in adequately controlling for quality. In hospital studies, for example, if quality is cost increasing overall, failure to account for it will result in confounding the inefficiency measures because it is not possible to differentiate between higher residual costs resulting from unobserved superior quality and higher costs resulting from managerial inefficiency or slack.

Cost Shifting

MA Morrisey, University of Alabama at Birmingham, Birmingham, AL, USA

Cost Shifting

Cost shifting exists when a hospital, physician group, or other provider raises prices for one set of buyers because it has lowered prices for some other buyer. The term has also been applied to managed care firms that are similarly said to have raised premiums for one set of purchasers because it had to lower premiums for some other set. Cost shifting is often confused with price discrimination. Health service providers commonly price discriminate; that is, they charge different prices from different payers. However, such differential pricing strategies are not evidence of cost shifting.

Cost shifting frequently enters into debates over government payment polices for Medicare and Medicaid and is prominent in health-care reform debates. Some have argued, for example, that efforts to reduce Medicare expenditures by lowering payments to hospitals under the Medicare Prospective Payment System or through the encouragement of Medicare managed care plans may save money for Medicare, but it will increase expenditures by private payers. This is said to occur because hospitals simply raise their prices to private insurers to make up the difference. Insurers, facing higher hospital prices, will then tell employers that they have to raise health insurance premiums because they are 'being cost-shifted against' by hospitals.

Analogously, proponents of health-care reform will often argue that systemwide reforms are needed because efforts to control government expenditures will simply increase private expenditures. It is argued that private payers should support coverage for the uninsured because the costs of the subsidy will be less than they appear because the hidden cost shift will be eliminated. Any piecemeal effort to control costs will ultimately be eroded by increases in costs for some other payer with the result that costs are not controlled. Subsidizing care for the uninsured and reforming the health-care system are important goals, but cost shifting is unlikely to be a serious component of the underlying economics.

The Economics of Cost Shifting

Morrisey (1994) used the Frank Capra movie *It's a Wonderful Life* as a vehicle to describe the economics of cost shifting. In the movie, Mr. Potter owned most of the town of Bedford Falls and he was the meanest man in town. He charged high rents on his apartments and high interest rates on loans from his bank. Suppose he also owned and operated Potter Hospital, the only hospital in town.

As a profit-maximizing old man, Potter would charge the most people would be willing to pay for each hospital day. He would determine the extra revenue and extra costs associated with each day of hospital care and produce the number of hospital days for which the extra revenue just equaled the extra costs. If he produced less, he was giving up profit he could have had; if he produced more, he would lose money because the extra cost was greater than the extra revenue.

Suppose Potter had two sets of hospital service buyers. The first set includes private purchasers who are willing to pay according to their downward-sloping demand curves. At lower prices they will buy more hospital days. The second set comprises government-sponsored patients who pay only the amount set by the government. They cannot pay more and the government will not pay less. To keep the story simple, suppose that each group of patients costs the same to treat and that marginal costs increase over the relevant range of output.

Potter faces two questions: first, should he provide any care to government-sponsored patients, and second, if so, what price should he charge private patients. The answers are straightforward business economics. The objective is to extract as much profit out of each market segment as possible. On the government side, he will admit patients until the extra revenue, the government fee, is just equal to the extra cost of care. On the private side, things are a bit more complicated. He can charge only a single price in this market. A lower price implies more units sold, but he can collect the lower price only from people who would have paid more. So Potter must find the price at which the extra revenue is just equal to the extra costs of treating these patients. And that extra revenue can be no lower than what he could get from a government-sponsored patient. The result of these calculations is that Potter will admit patients until the marginal revenue from private patients is equal to the marginal revenue from government-sponsored patients and is equal to the marginal cost of care.

This is shown graphically in **Figure 1**. The analysis is a simple case of price discrimination on the part of a monopolist with two buyers. The government price ($P_{Gov't}$) is fixed by government fiat and the hospital can get all the government patients it wants; thus, the government demand curve is also the government market marginal revenue. The private market yields a downward-sloping demand curve and its associated marginal revenue curve. The profit-maximizing hospital would (conceptually) trace out the envelope of the highest marginal revenue available from each market for every unit of service. This yields the kinked dark line that incorporates parts of each of the private and government marginal revenue lines in the figure.

Potter Hospital would produce hospital services to the point where marginal cost equals the envelope marginal revenue. That is, it would supply the quantity Q_T. Potter would sell the amount between Q^* and Q_T to the government because the marginal revenue from the government is greater than that from the private market. He would sell the private market the quantity from the origin to Q^* because over this range the marginal revenue from the private payers is greater than that offered by the government. Notice that, like a good monopolist, Potter charges the private market the most it will pay for the quantity up to Q^*. That is shown by the private demand curve with the price $P_{Private}$.

 doi:10.1016/B978-0-12-375678-7.00927-5

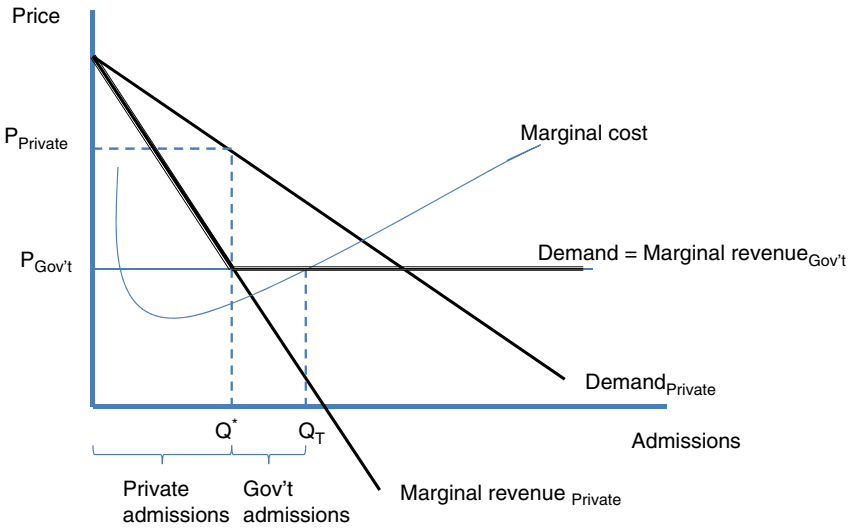

Figure 1 Monopoly price discrimination with two buyers.

Thus, because he has market power, Potter can charge different prices to different purchasers. This is classic price discrimination. A firm with market power will charge different prices to different purchasers as long as the purchasers have different degrees of price sensitivity and as long as one group cannot resell to the other. Thus, Potter charges a higher price to private purchasers (who have less price sensitivity) and a lower price to government-sponsored buyers (who are not allowed to pay even a dollar more than the government rate). Similarly, airlines charge higher prices to those who have to travel on specific dates and lower prices to those who have flexible schedules.

Now suppose the government lowers the price it will pay for hospital care. The cost-shifting argument says that Potter would accept the lower government price and 'make it up' by charging more in the private market. The economics imply the contrary. A lower government price signals that government patents are less profitable. Potter immediately sees that some private patients are willing to pay more than the new lower government rate. He shifts some hospital capacity to the private market. But to sell these services he has to lower the private price to everyone. Thus, government action lowering its price does not lead to higher private prices; rather lower private prices result as a profit-maximizing provider tries to shift capacity to the private segment of the market. Thus, standard theory indicates that cost shifting will not occur.

Graphically, the result is easily shown. See **Figure 2**, which adds a new lower government payment level to the earlier discussion. Note that the envelope of marginal revenue shifts down in its second segment. Potter Hospital reduces its total output from the old Q_T^1 to Q_T^2 to reflect the lower price available. The smaller quantity is now reallocated with more going to private patients and less to government-sponsored patients. However, the only way that Potter can sell the extra private services is to lower the price, as the figure indicates, from P^1_{Private} to P^2_{Private}.

Suppose the hospital were nonprofit and therefore did not 'maximize profits.' To see this, consider George Bailey from the *Wonderful Life* movie. He has a good heart and wants to help people. Suppose he ran the hospital in Bedford Falls. In particular, suppose George wanted to have the newest technology and to provide care to the indigent who are not eligible for the government care and cannot pay for private care. Note that if these things paid, Mr. Potter would have provided them as well.

If the hospital is to be all it can be, George has to generate as much 'surplus' as he can. Surplus, of course, is just another word for profits. The business problem is exactly the same for George Bailey as it was for Mr. Potter. If the hospital wants to provide as much charity care and new technology as it can, it must charge what the traffic will bear in each of its markets. The only difference between the two is how they spend the 'surplus.' Thus, when the government cut its price, George would shift capacity to the private market segment and lower its price as well. Potter ended up with fewer profits, and George Bailey ended up being able to provide less charity care and less new technology. Again, no cost shifting is predicted.

Cost shifting requires that a hospital or provider, more generally, raises its price for the private patient when the government price is reduced. This result can be consistent with standard economics, but it requires some special circumstances. First, the provider has to have market power. Without it, it cannot charge different prices. Second, it has to 'favor' paying patients. This means it has to charge them prices that are below the profit-maximizing price. Another way to say this is that the provider has to have 'unexploited market power.' Some commentators have described nonprofit hospital boards as not permitting charges to be set at levels above that needed to provide quality. This could be construed as favoring paying patients with prices below 'surplus maximizing' levels.

Under this scenario the hospital could be thought of as spending surpluses it could have had on lower prices to paying patients. Then, when the government lowers its price, the hospital has less surplus to subsidize its paying patients and raises its private price. This is cost shifting as envisioned by its proponents.

Several hypotheses emerge from this analysis. First, market power is a necessary condition for cost shifting. If health-care

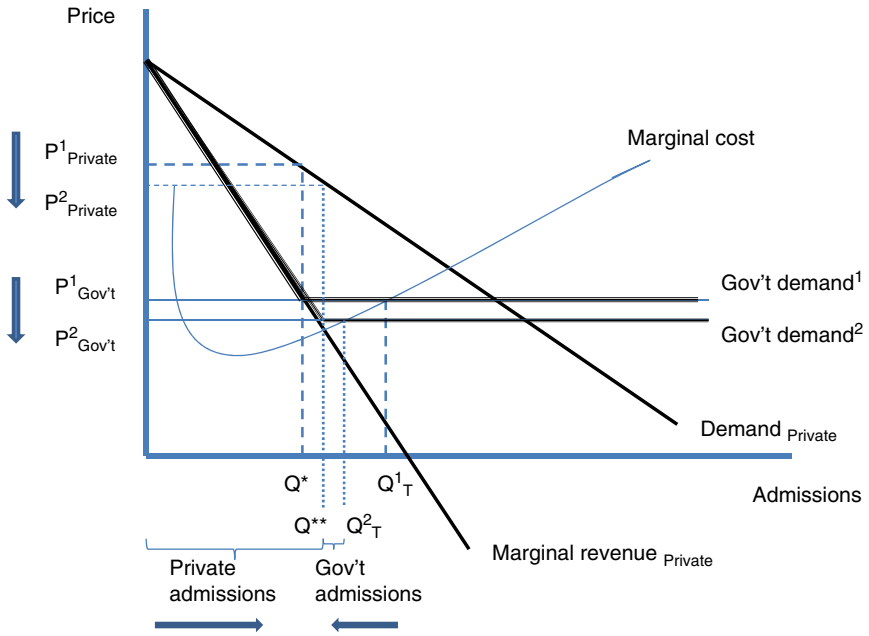

Figure 2 Effect of lowering of the government price.

markets are competitive, then cost shifting cannot exist because efforts to raise prices to one market segment would be thwarted by a willingness of others in the market to provide services at the old price.

Second, profit maximization implies no cost shifting. If a provider is indeed maximizing profits, by definition it has no unexploited market power. As a consequence, if investor-owned hospitals are profit maximizers, one would not expect to see them engaged in cost shifting.

Third, nonprofit status with market power by itself does not imply the ability to cost shift. The issue is the objectives of the organization. Cost shifting requires that the organization value setting prices to private patients at levels below those that would maximize profits.

Fourth, the model implies that cost-shifting behavior is limited. Once a provider exploits its unexploited market power, it has no further ability to cost shift.

Empirical Evidence on Cost Shifting

Ultimately the existence and magnitude of cost shifting is an empirical issue. The empirical evidence with respect to cost shifting has been mixed, but the rigorous research largely concludes that if it exists, its magnitude is modest at best. Unfortunately, much of the work simply misses the point because it seeks to show that different payers pay different prices for essentially the same services. This is true, but price discrimination is not cost shifting. Other work tries to use cross-sectional comparisons to test for the presence of cost shifting. This is difficult to achieve because cost shifting is a dynamic phenomenon. However, there have been five relatively recent papers that test for cost shifting using hospital behavior over time. See Morrisey (1994 and 1996) and Frakt (2011) for detailed reviews of the literature.

Hadley *et al.* (1996) used a national sample of hospitals over the 1987–89 period to examine the effects of financial pressure and competition on the change in hospital revenues, costs, and profitability, among other things. They found that hospitals with lower base-year profits increased costs less and increased their efficiency. With respect to cost shifting, "[w]e found no evidence to suggest that cost shifting strategies that might protect hospital revenues in the face of financial pressure were undertaken successfully" (Hadley *et al.*, 1996, p. 217).

It is also noteworthy that this study, and all of those reviewed here, control for hospital ownership status, but do not formally test for differences in behavior by ownership type. This is a lost opportunity. The exception is the work by Zwanziger *et al.* (2000).

Dranove and White (1998) used 1983 and 1992 California hospital data to examine the effects of reductions in Medicaid and Medicare volume on changes in price–cost margins (i.e., net price minus average costs all divided by net price) of privately insured patients in Medicaid-dependent hospitals. They found "no evidence that Medicaid-dependent hospitals raised prices to private patients in response to Medicaid (or Medicare) cutbacks; if anything, they lowered them" (p. 163). They also found that service levels fell for Medicaid (and Medicare) patients relative to privately insured patients and fell by more in Medicaid-dependent hospitals.

Zwanziger *et al.* (2000) used California hospital data from the same source over the full time period 1983 through 1991 and reached decidedly different conclusions. They computed the average price per discharge for Medicare, Medicaid, and privately insured patients. Controlling for average costs in a two-stage model, they found that lower Medicare and Medicaid prices were associated with higher private prices. A one percentage point decrease in the Medicare average price was estimated to increase private prices at nonprofit hospitals by 0.23–0.59 percentage points. The larger price increases were

found in markets with less hospital competition. They also found evidence that investor-owned facilities also engaged in cost shifting. Similar analysis by Zwanziger and Bamezai (2006) for the 1993–2001 period concluded that "cost shifting from Medicare and Medicaid to private payers accounted for 12.3 percent of the total increase in private payers' prices from 1997 to 2001" (p. 197).

Cutler (1998) examined whether lower Medicare payments led hospitals to greater cost cutting or cost shifting. Using data from Medicare cost reports over the 1885–1990 and 1990–95 periods, he found that in the early period, hospitals shifted costs dollar for dollar to private payers – an effect larger even than the Zwanziger *et al*. study. However, over the later period he found no evidence of cost shifting. Cutler attributes the difference in the results to the advent of selective contracting in the early 1990s that increased the extent of price competition among hospitals.

The most extensive analysis of cost shifting undertaken to date is that of Wu (2010). She uses Medicare data to examine the long period from 1996 to 2000 focusing on the effects of the effect of the Balanced Budget Act on Medicare hospital prices. Unlike earlier work, she treats the Medicare variable as endogenous. Wu finds that hospitals shifted approximately 21 cents of each Medicare dollar lost to private payers. Cost shifting varied by the bargaining power of the hospital. When a hospital had more power vis-à-vis insurers; it was able to shift more costs.

Conclusions

The most rigorous of the studies conducted in the past decade provide mixed evidence of the existence and magnitude of cost shifting in hospitals. Taken as a whole, the evidence does not support the claims of its proponents that cost shifting is a large and pervasive feature of US health-care markets. Only an early analysis by Cutler (1998) finds dollar-for-dollar increases in private prices as a result of lower Medicare payments. Even this finding is contained to a single short-run period. At best, one can argue that cost shifting, over the 15–20 years covered by the recent analyses, resulted in perhaps one-fifth of Medicare payment reductions being passed on to private payers. At worst, the majority of the rigorous studies found no evidence of cost shifting.

The theoretical literature strongly suggests that cost shifting can take place only if providers have unexploited market power. Once exploited, this avenue of response to changes in government payment policies disappears. This, together with the empirical findings, has three implications. First, policy advocates should worry much less about cost shifting. Although it can exist, other factors appear to be much more important in determining provider pricing. Second, the bulk of burden of reductions in government programs are borne by public patients. The consequences of such decisions cannot be shuffled off to private payers. Finally, health-care competition matters. One should look for evidence of cost shifting in markets and times that are characterized by provider concentration. If one is worried about cost shifting, encourage greater competition among hospitals, physicians, and insurers.

Cost-Effectiveness Modeling Using Health State Utility Values

R Ara and J Brazier, University of Sheffield, Sheffield, UK

Glossary

Cost-effectiveness analysis A method of comparing the opportunity costs of various alternative health or social care interventions having the same benefit in terms of a common unit of output, outcome, or other measure of accomplishment.

Cost-effectiveness threshold The maximum incremental cost-effectiveness ratio that is acceptable to a decision-maker. A rational community health-maximizing decision maker judges this threshold in terms of the health forgone elsewhere in the system if resources were to be devoted to one particular purpose rather than being available elsewhere in the system – the opportunity cost in terms of health.

Genomics The science of the function and structure of genomes, i.e., the DNA within a single cell of an organism.

Incremental cost-effectiveness ratio The ratio of the difference between the costs of two alternatives and its effectiveness or outcomes.

Meta-analysis A statistical technique for combining data from multiple studies used to identify the overall estimate of treatment effect.

Opportunity cost The value of a resource in its most highly valued alternative use. In a world of competitive markets, in which all goods are traded and where there are no market imperfections, opportunity cost is revealed by the prices of resources: the alternative costs forgone in order to pursue a certain action.

Introduction

There has been a growing use of quality-adjusted life-years (QALYs) in the assessment of the cost-effectiveness of healthcare interventions. There are now many agencies around the world using evidence on the incremental cost per QALY to inform reimbursement decisions or clinical guidelines. The QALY provides a metric for valuing the impact of healthcare interventions on survival and health-related quality of life (HRQL) on a common scale. It achieves this by assigning a utility value for each health state on a scale where 1 is for full health and 0 for dead, with the possibility of negative values for states regarded as worse than dead. There are many different ways for deriving such health state utility values (HSUVs). At the same time, there has been an increasing use of decision-analytic models to provide the main vehicle for conducting the assessment of cost-effectiveness. These overcome the limitations of relying on single clinical trials, which often do not use measures for generating HSUVs, have a limited sample size (particularly for some rare events), insufficient follow-up periods, an unrealistic protocol and setting, and may be difficult to generalize from. Models provide a means of combining evidence from a variety of sources on the clinical efficacy of the interventions, resource use, costs of resources, and HSUVs in a way that addresses the decision problem in a more relevant way than a clinical trial. HSUVs are a key parameter in such models. There is a separate article on the derivation of HSUVs and the different instruments used. This article is concerned with the methodological issues associated with using HSUVs in cost-effectiveness models.

There are many different types of models used to assess cost-effectiveness including decision trees, Markov models, and discrete event simulation. All seek to represent reality in terms of health states likely to be experienced by patients in the decision problem, transition probabilities between the states, and costs and utility value associated with each state. The states may be defined in different ways including whether a patient has a condition, severity of condition, key events (e.g., fractures in the case of osteoporosis), adverse events, and various comorbidities. These events may occur multiple times and there may be cases of multiple conditions. This article addresses four sets of methodological issues around the use of HSUVs to populate such cost-effectiveness models. (1) The selection of the measure for generating the HSUVs that best meets the requirements of policy makers and measurement criteria like validity. (2) The source of HSUV data such as the main clinical efficacy trials or whether to seek more relevant values for the model population from observational datasets, or to search, review, and synthesize an ever-growing literature. (3) Suitable utility data using the required measure may not be available from relevant studies, and in these cases regression techniques may be used to map from various health or clinical measures onto the selected utility measure. (4) Technical problems in using HSUVs in cost-effectiveness models, including how to adjust values over time, estimate values for those not in the condition of interest, and estimate the impact of conditions (comorbidities) or adverse events. This article considers the technical issues alongside the common requirements of policy makers around the world. Many of the decisions are not technical ones alone but involve normative judgments that in many cases will be made by policy makers requiring cost-effectiveness evidence. This is intended to be a practical guide aimed at analysts who are building cost-effectiveness models.

What Measures Should be Used?

There are four broad approaches for generating HSUVs: Generic preference-based measures (also known as multiattribute utility instrument), condition-specific preference-based measures, bespoke vignettes, and patient's own valuation. The most

 doi:10.1016/B978-0-12-375678-7.01411-5

widely used of these in recent years has been the generic preference-based measure of health. These measures have two components. One is a descriptive system that is composed of several multilevel dimensions. For example, the EQ-5D has five dimensions (mobility, self-care, usual activities, pain and discomfort, and anxiety and depression) each with three levels (a five-level version has recently been developed) and defines 243 health states. Each one of these states has a value on the QALY scale that was obtained by interviewing a sample of the general population. This descriptive system is usually completed by patients or their proxies in clinical studies and so provides a direct link between QALY estimates and the reported experiences of patients. By collecting EQ-5D or some other measures over time, it is possible to calculate the QALY gain in a trial setting (as the area under the curve) or to value states used in the model from observing patients in different clinical states.

These generic measures are designed for use in all conditions and patients. However, there are concerns that no one measure is sensitive or relevant to all conditions or patient groups. For this reason condition-specific preference-based measures have been developed by Brazier and colleagues. The problem with condition-specific measures is a concern with the lack of comparability between different instruments. This will be a problem where the model contains states from different conditions, as is often the case, and where the policymaker is making resource allocation decisions between conditions. Another approach has been to develop specific vignettes where there is no patient-reported information on the impact of a condition or its treatment. These vignettes can be specifically designed to describe the states in the model. However, in addition to the concern about comparability, vignettes do not have a direct link to evidence on patient experience that is achieved by the other two approaches, because they are not based on patient completion of a descriptive system but usually involve the views of experts (all be it informed by patient experience). The final approach avoids having to describe health states altogether and instead ask patients to value their own state using one of the preference elicitation techniques, such as time trade-off. Most agencies prefer health states to be described by patients and then valued by members of the general public, but one or two have specifically requested valuations directly from patients and this approach continues to be used.

A key problem is that these different approaches to valuing health produce different values. Indeed, different generic instruments have been shown to generate HSUVs that differ to a significant degree. The selection of instrument will have important implications for the incremental cost-effectiveness ratio. There is a literature on how to select the right measure in a given case, and this considers issues around the validity of the descriptive system for the condition, valuation methods, and source of the values. The decision about the right measure should not only consider these issues but will also be constrained in some cases by the policy makers to whom the model is going to be submitted. Some agencies have adopted a reference case that includes a preferred measure or approach. The most prescriptive has been the National Institute for Health and Clinical Excellence (NICE) in England who state a preference for the EQ-5D, and those submitting evidence need to demonstrate the EQ-5D is not appropriate in order to submit cost-effectiveness models using HSUVs from other measures. In some other countries, there is merely a preference for a generic measure. In others still, there is no preference expressed as to which type of measure should be used.

The final choice of measure used to derive the HSUVs will depend on some combination of the requirements of the policymaker, psychometric and other criteria, and also availability. In many cases, there is very limited evidence on HSUVs from a preferred measure or approach, and the analyst must make best use of available evidence. This may include the use of nonreference-based measures of health or clinical measures through the use of mapping (see Section Predicting Health State Utility Values When Preference-Based Data are Not Available). It will increasingly involve reviewing a range of possible sources including trials, observational and routine datasets, and the literature.

Source of Health State Utility Values

Clinical Trials

An appropriate source for the data on HSUVs may be the main clinical trial(s) used to inform the evidence on effectiveness. This enables the trial data to be used directly within the analysis of HRQL, eliminates concerns about the applicability of the health data to populations from which the effectiveness estimates are obtained and enables all the effects of treatment to be included directly in the estimate, including any side effects of treatment, without the need for adjustment. However, there may be concerns about the generalizability of effectiveness and/or HRQL data to the population in the model. There may be other circumstances where health state utility data are not best collected within the clinical trials, for example, if adverse events related to the condition or treatment are rare and not likely to be captured in the trials, or where the outcomes of interest are too long-term to be captured in a typical trial duration, or when the trial does not reflect common practice. In these circumstances observational studies may be more appropriate for capturing the impact of the event on HRQL.

Observational

HSUVs are often sourced from observational sources conducted for the purpose. Such tailored studies have the advantage of being designed for the purpose of populating a specific model and so can be designed to value the specific states defined in the model. However, this will often not be possible. Another data source is routine datasets such as general population health surveys (e.g., Medical Expenditure Panel Survey in USA and Health Survey for England in England) or routine surveys of patient-reported outcomes (e.g., the UK Patient Reported Outcome Measures program). For any observational source a key concern will be the extent to which HSUVs are caused by the condition. Patients who had a recent fracture, for example, have a lower score than those who do not. However, the differences found from cross-sectional observational studies tend to exaggerate the impact of hip

fracture because they often do not take into account their prefracture health status. As for evidence on efficacy, longitudinal evidence is better evidence than cross-sectional, as the impact of specific events or disease onset can be controlled for covariates.

Reviewing the Literature

There are published lists of HSUVs for a wide range of conditions and this literature is growing all the time. There is a risk that model builders will be tempted to use the first suitable value or even use those values that support the cost-effectiveness argument that is being made in a submission to a reimbursement authority. The larger the literature, the more prone the selection of values is to bias. For this reason, it is beholden on analysts to justify their selection of values. This implies a need for HSUVs, like other important model parameter values, be obtained from a systematic review of the literature in order to minimize bias and through appropriate synthesis of available values, capture the uncertainty, and improve the precision in the values used.

There are rarely the resources available to do a full systematic review in searching, reviewing, and synthesizing the evidence. Furthermore, reviewing HSUV studies is different from the conventional hierarchy of evidence used for clinical effectiveness. Simply looking for HSUVs from a search for efficacy evidence will fail to retrieve many, if not most, published HSUVs for the health states in the model because randomized controlled trial are often not the main important source for HSUVs and the models may include other conditions and adverse events. A model examining the cost-effectiveness of strategies for managing osteoporosis had states for various factures (e.g., hip, vertebra, and shoulder), breast cancer, coronary heart disease, and no event. A systematic literature review by Peasgood and others on the impact of osteoporosis fractures identified 27 articles from an initial set of 1000 papers reporting potentially relevant HSUVs for the model. As can be seen in Figure 1, there is a substantial difference in the HSUVs reported for the same time periods and although there is a trend for recovery following hip fracture, none achieve the prefracture values, and one study reported a decline in HSUVs over a period of 4–17 months.

The key considerations in searching and reviewing HSUVs are: (1) Do the HSUVs meet the methodological requirements of the policymaker – in the case of NICE, the focus may be on obtaining EQ-5D values (using the UK tariff of values), (2) have the HSUVs been obtained from a population relevant to the population in the model (e.g., in terms of severity of condition, age, and gender), and (3) what is the quality of the study including recruitment and response rates? These considerations do not operate in a dichotomous way because the analyst is looking for the best estimates and not necessarily the perfect ones, and these requirements may be relaxed depending on the available evidence base. Concerns about the relevance or quality of data should be fully explored in the cost-effectiveness model through the use of sensitivity analyses.

There are a number of search strategies for identifying HSUVs. However, a full search of the literature may yield many hundreds of values, and so the reviewer may wish to use more focused search strategies limited to identifying existing reviews or key papers and following up references in those articles, as described by Papaioannou.

For many conditions, there are a large number of HSUVs available in the literature and considerable variation in the values for what seem to be similar states. A review of values for use in a cost-effectiveness model of osteoporosis, for example, found values for hip fracture to vary from 0.28 to 0.72 and

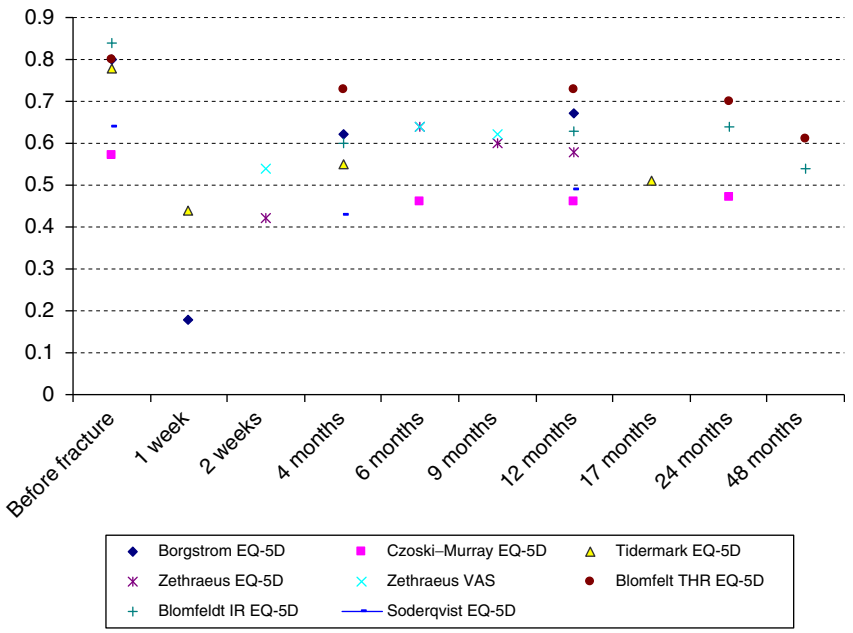

Figure 1 EQ-5D and EQ-VAS for hip fracture over time. Reproduced from Peasgood, T., Herrmann, K., Kanis, J. A. and Brazier, J. (2009). Figure 2 Mapping or crosswalking exercise.

vertebral fracture from 0.31 to 0.8. This leaves considerable scope for discretion in the selection of values for an economic model. The variation was partly due to differences in methods. In this example, the values were limited to EQ-5D for populating the cost-effectiveness model because the submission was for NICE. The values still varied considerably between studies. This may have been due to the different source countries, with much of the data coming from Sweden. It may also have been due to the very low response rate in some studies. There has been little research into the synthesis of HSUVs using techniques similar to those used for clinical efficacy including simple pooling or metaregression, but such work is at an early stage and the number of studies available for given conditions tend to be too small and heterogeneous. For this reason, current practice often involves selecting the study, which provides the most relevant values.

In practice, there may be little or no relevant HSUVs available for the cost-effectiveness model, but there may be trials or observational datasets that have collected HRQL or clinical data on relevant patients. The next section considers an increasingly used solution to this problem of mapping the relationship between the HRQL or clinical measure and the required preference-based measure.

Predicting Health State Utility Values When Preference-Based Data are Not Available

When the required preference-based utility measure is not collected in the clinical effectiveness studies or any relevant observational source, a mapping exercise can be undertaken to predict the required values (e.g., EQ-5D) from an alternative HRQL or clinical measure collected in the key study or studies. This exercise (Figure 2) requires an external dataset, which includes both the preferred preference-based data (the dependent variable (DV)) and at least one other variable (the independent variable (IV)) that is also available from the key clinical effectiveness or observational study. The data in the external dataset are used to obtain a statistical relationship, known as a statistical regression model, which can then be used to predict the required preference-based utility scores using the data available from the clinical effectiveness study.

The statistical regression model can take many different forms depending on the relationship between the variables and the underlying distributions of the data. The simplest model is a straight linear function ($y=\alpha+\beta x+\varepsilon$) where y is the DV (the preference-based HSUVs), α is the intercept, β is the vector of coefficients for the IVs, and ε is the error term. These regression models can be used to predict the DV in any datasets, which include the IVs. If some of the IVs are missing from the second dataset, the mean values from the external dataset used to obtain the statistical relationship can be used as proxies.

Using Clinical Variables and Progressive Conditions

Statistical regression models are also used to determine relationships between clinical variables and preference-based utility values when the cost-effectiveness models are driven by clinical variables, which represent stages or progression in the primary health condition. In these instances it may be that, although the clinical effectiveness study collects the required preference-based data, the distribution of patients across disease severity is such that the subgroup sizes are too small to determine HSUVs for each of the individual stages of the condition. For example, ankylosing spondylitis is a chronic progressive condition, and the severity of the condition is described using two clinical measures: the Bath Ankylosing Spondylitis Disease Activity Index (BASDAI) and the Bath Ankylosing Spondylitis Functional Index (BASFI). Both measures range from 0 to 10, which represent no disease activity or functional impairment and maximum disease activity or functional impairment, respectively. Figure 3 shows how the preference-based utility values (the EQ-5D) vary by BASDAI and BASFI scores using the function: EQ-5D = 0.9235 − 0.0402 ∗ BASDAI − 0.0432 ∗ BASFI, which was obtained using ordinary least square regressions.

Figure 4 shows the BASDAI/BASFI profile (primary *y*-axis) and the corresponding EQ-5D values (secondary *y*-axis) plotted over time (*x*-axis) as would be used in a cost-effectiveness model. The figure shows individuals enter the model with average BASDAI/BASFI scores of seven units at baseline (time = 0). They initially respond to treatment, and their BASDAI/BASFI score improves to an average score of 4. After 4 years they stop responding to treatment and their BASDAI/BASFI scores revert to the baseline score of 7. These scores gradually worsen as the condition progresses until reaching the maximum possible score (BASDAI/BASFI equals 10) at 17 years. The BASDAI/BASFI scores remain at these levels until the patient dies (time = 26 years). Using the function described earlier to predict EQ-5D values from the BASDAI and BASFI scores, the predicted EQ-5D values are 0.241 (0.544, 0.241, − 0.062, and 0) at baseline (4–7 years, 17 years, 26 years, and after 26 years).

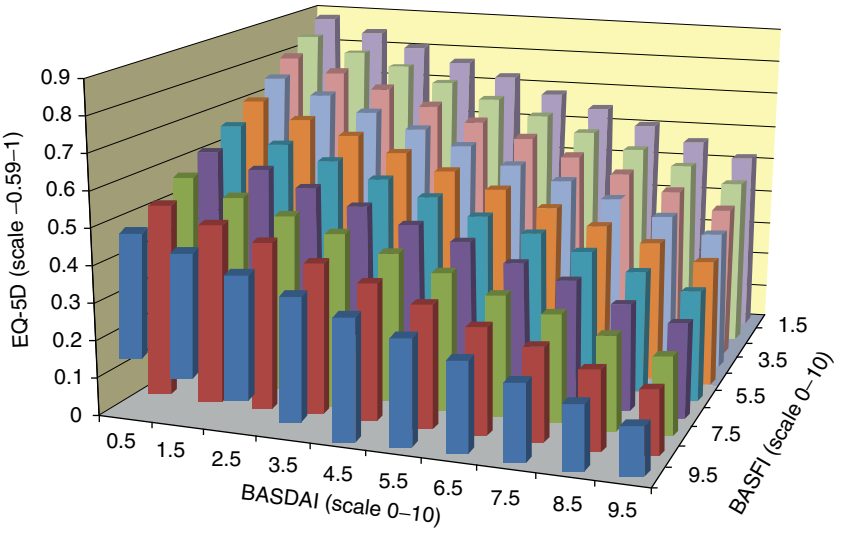

Figure 3 Plot of EQ-5D against BASDAI and BASFI.

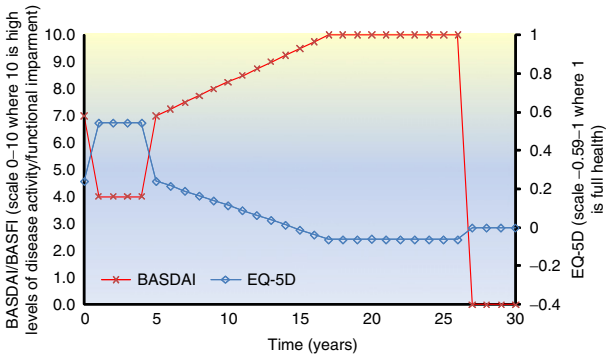

Figure 4 Patient's BASDAI/BASFI profile and associated EQ-5D scores over time.

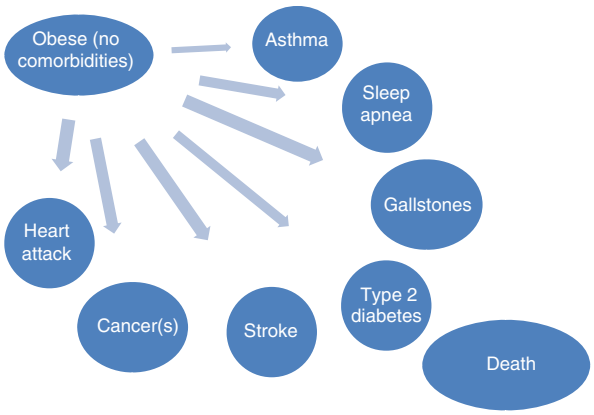

Figure 5 Possible health states in a cost-effectiveness model in obesity.

Multiple Health States

For a simple cost-effectiveness model involving few health states, the mean (and variance) preference-based utility values for each of the health states may be sufficient to describe the average HRQL and associated uncertainty for the health condition. However, when the cost-effectiveness model includes numerous distinct health states and additional predictors of health status, a statistical regression model and associated covariance matrix can be used to ensure correlations between preference-based utility values and are maintained when exploring uncertainty in the probabilistic sensitivity analyses.

One example is a cost-effectiveness model exploring the potential benefits of pharmaceutical interventions used to induce weight loss in obese patients. Obese patients are at increased risk of comorbidities (e.g., type 2 diabetes, cancer(s), heart attacks, strokes, etc. Figure 5) and the effectiveness of interventions are quantified in terms of changes in body mass index. To model this, analysts would need HSUVs for each of the comorbidities differentiated by body mass index and potentially age and/or gender. It is unlikely that this level of detailed information for each of the different subgroups would be available from clinical effectiveness studies. In this case, a statistical regression model obtained from a large external dataset could be used to predict the values required for each of the health states in the cost-effectiveness model.

Double Mapping

There are occasions when it is not possible to obtain an external dataset which includes both the required preference-based utility measure and one or more of the variables collected in the clinical study. In these instances, although not ideal, it is possible to obtain preference-based utility values using a process known as 'double mapping'. Double mapping involves the use of two external datasets and one statistical regression model obtained from each of these.

For example, in patients with psoriatic arthritis, a chronic progressive condition, the clinical study did not collect HRQL data but did collect information on demography (age, gender, and current and previous pharmaceutical treatments). In

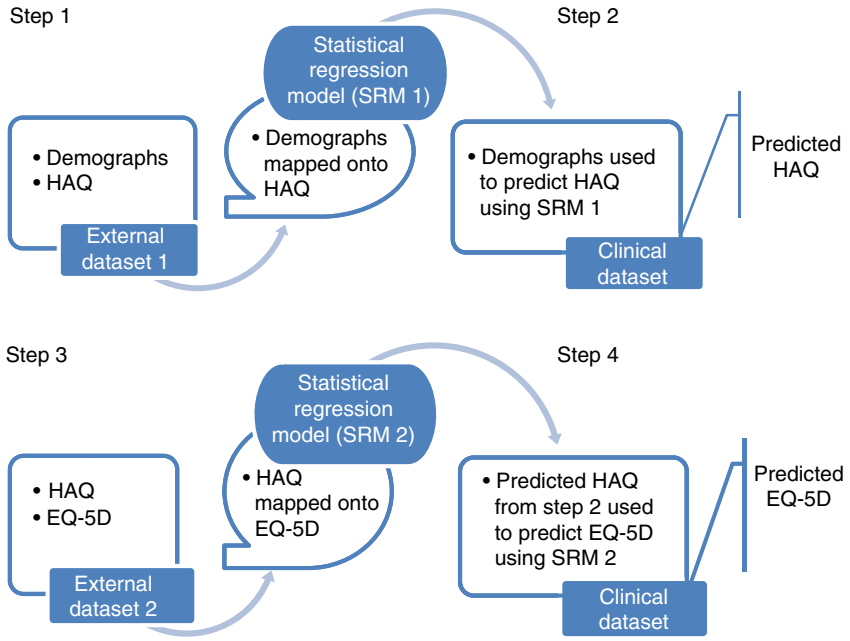

Figure 6 Double mapping exercise in psoriatic arthritis.

the cost-effectiveness model, the Health Assessment Questionnaire (HAQ: range 0–3, 3 = worse) was used to describe both the initial benefits of treatment and the long-term progression of the condition. Two external datasets were available (Figure 6). The first dataset (external dataset 1) had data on demography (age, gender, and current and previous pharmaceutical treatments) and HAQ but did not have any HRQL data. The second dataset (external dataset 2) had HAQ and the required preference-based data (EQ-5D) but did not have data on demography. The cost-effectiveness model required a relationship, which would link HRQL data to HAQ, the clinical variable, which would describe the benefits of treatment and long-term progression of the condition.

The process used to predict EQ-5D scores in the cost-effectiveness model is described in Figure 6. Step 1: External dataset 1 was used to obtain a statistical regression model 1 mapping demography (age, gender, and pharmaceutical treatments) onto HAQ. Step 2: The statistical regression model 1 was used to predict HAQ using the data on demography (age, gender, and pharmaceutical treatments) in the clinical study. Step 3: External dataset 2 was used to obtain the statistical regression model 2 mapping HAQ onto EQ-5D. Step 4: The predicted HAQ scores from the clinical study were used to predict EQ-5D in the cost-effectiveness model using the statistical regression model 2.

Predictive Ability

Ideally, any statistical model would be validated in an external dataset before use in a cost-effectiveness model. However, in the majority of cases, regressions are performed because the actual data are not available in a particular group, and therefore it is not possible to validate results in this way. Regression models, which have HRQL measures as the DV, typically underestimate and overestimate values at the top and bottom of the index, respectively. Consequently, it is important to demonstrate the accuracy in the predicted values across the full range of the index. If the objective of the regression is to obtain a model to predict values in cost-effectiveness model, then it is also useful to assess the ability of the regression model to predict incremental values accurately. The predicted values are typically assessed using the mean absolute error and root mean squared error. However, these summary scores can mask inaccuracies at the extremes of the index, and the predicted values should be assessed by subgrouping across the range of actual values.

Applying Health State Utility Values in Cost-Effectiveness Models

Baseline or Counterfactual Health States

Decision-analytic models in healthcare typically assess the benefits of interventions in terms of the incremental QALY gain associated with alleviating a health condition or avoiding a clinical event. To calculate this, in addition to requiring the HSUVs associated with the condition or event, the analyst will also need the baseline or counterfactual HSUVs to represent the HRQL associated with not having the particular health condition or event. For example, if modeling the benefits of introducing a screening program for breast cancer, analysts would require the mean HSUVs from a cohort with a history of breast cancer (including longer term data to model any potential changes in HRQL as the condition progresses) and the mean HSUVs for patients who do not have breast cancer. Similarly, when modeling an intervention that has the potential to avoid

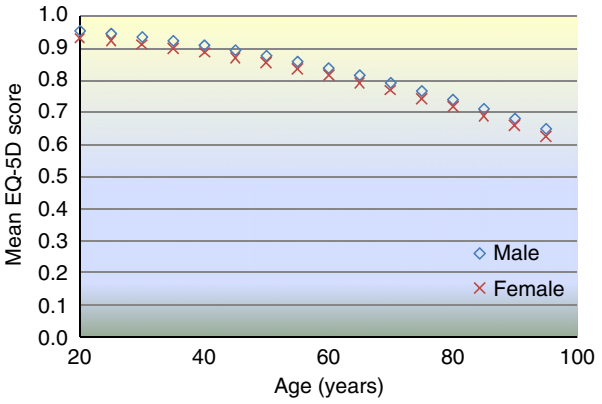

Figure 7 HSUVs by age and gender from the general population.

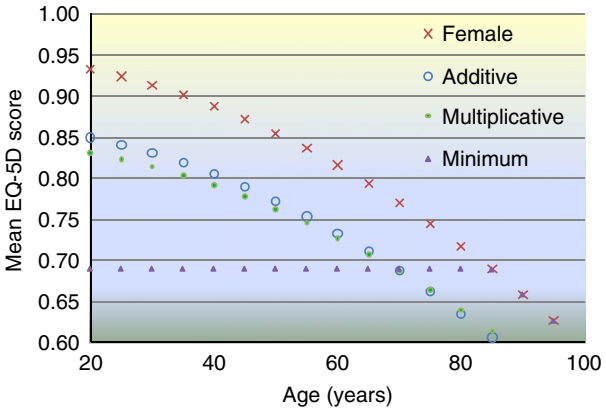

Figure 8 Combining HSUVs using the additive, multiplicative, and minimum methods.

subsequent cardiovascular events in patients with acute coronary syndrome, for example, a stroke, the analyst would need to know the mean HSUV for patients who have experienced a stroke and the mean HSUVs for individuals who have not experienced a stroke but have a history of acute coronary syndrome.

A patient without a particular condition is unlikely to have an HSUV of one. A better approach would be to use a normative dataset. Furthermore, the values of those with a condition are likely to change over time. HSUVs from the general population, for example, show a negative relationship with age (i.e., as age increases, the average HRQL decreases, Figure 7). This is due to several factors such as general decline in health directly attributable to age and an increase in prevalent health conditions, which are in general correlated with age. As many cost-effectiveness models use a lifetime horizon to accrue the costs and QALYs associated with interventions, it is reasonable to assume that the baseline or counterfactual HSUVs within the model may not remain constant over the full horizon modeled. Although there is a substantial volume of HSUVs in the literature describing the HRQL for specific health conditions, corresponding data for individuals without a specific health condition are more difficult to obtain without access to huge datasets. Unless the health condition is particularly prevalent, or unless it has a substantial effect on HRQL, removing a cohort who has a specific health condition will not have a substantial effect on the mean HSUVs obtained from the general population. In many instances, if the condition-specific baseline data are not available, it is possible to use data from the general population as proxy scores to represent the baseline or counterfactual HSUVs in the decision-analytic model.

Adjusting or Combining Health States

Healthcare decision-analytic models depict the typical clinical pathway followed by patients in normal clinical practice. As such they can become quite complex involving multiple health states, which represent the primary health condition with additional health states representing either comorbidities (e.g., when an additional condition exists concurrently alongside the primary condition), or an adverse event associated with the intervention or treatment (e.g., nausea is a side effect of treatments for cancer, whereas patients receiving aspirin for hypertension are at increased risk of hemorrhagic strokes). Ideally, each individual health state within a decision-analytic model would be populated with HSUVs obtained from cohorts with the exact condition defined by the health state. For example, it has been demonstrated that statins, which are typically given to manage cholesterol levels in patients with or at high risk of cardiovascular disease, have a beneficial effect on inflammation, thus may provide an additional benefit in patients with rheumatoid arthritis. To assess the benefits of statin treatment in a cohort with both cardiovascular disease and rheumatoid arthritis, the analyst would need HSUVs obtained from patients with both these conditions. However, many clinical effectiveness studies use very strict exclusion criteria relating to comorbidities and/or concurrent medications. As a consequence, the people who represent typical patients with comorbidities are excluded from studies, and analysts frequently combine the mean data obtained from cohorts with the single conditions to estimate the mean HSUVs for a cohort with more than one condition.

The methods used to combine the data can have a substantial effect on the results generated from decision-analytic models, and it has been shown that the result can vary to such an extent that they could potentially influence a policy decision, which is based on a cost per QALY threshold. There are a number of different ways to estimate the mean HSUV for the combined health condition using the mean HSUVs from the single health conditions. Traditional techniques include the additive, multiplicative, and minimum methods. The first two apply a constant absolute and relative effect respectively, whereas the latter ignores any additional effect on HRQL associated with the second health condition, using the minimum of the mean HSUVs obtained from cohorts with the single conditions as shown in Figure 8. Additional methods that have recently been tested include exploring the possibility of regressing the mean HSUVs from cohorts with single conditions onto the mean HSUVs from cohorts with comorbidities using ordinary least square regressions. Although this research is in its infancy, the early results look promising. However, based on the current evidence base, researchers recommend that the multiplicative method is used to estimate HSUVs for comorbidities, using an age-adjusted baseline as a minimum when calculating the multiplier used.

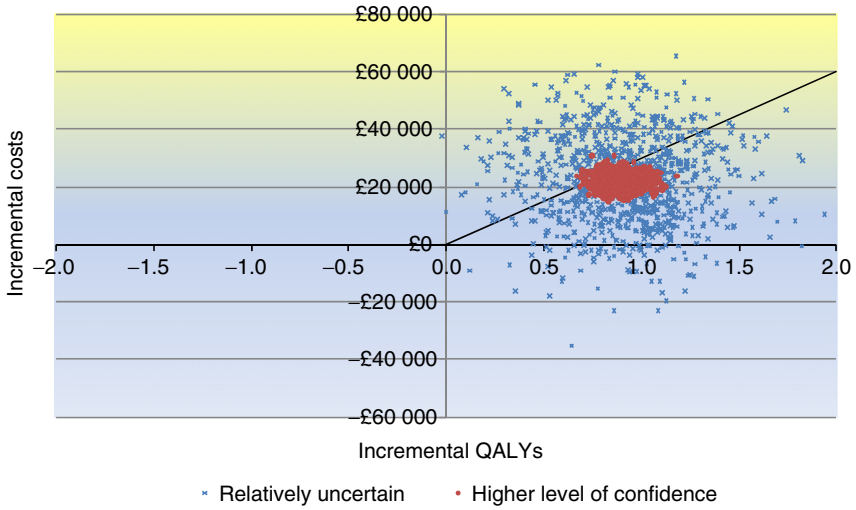

Figure 9 Cost-effectiveness scatter plane.

Worked Example

Females with condition A have a mean EQ-5D score of 0.69 and a mean age of 73 years, and females with condition B have a mean EQ-5D score of 0.70 and a mean age of 80 years. Using the data from the general population (Figure 8) as the baseline, these data are combined to determine what the EQ-5D score is for females with both condition A and condition B. Using data from the general population, at the age of 73 years and 80 years, the mean EQ-5D score for females is 0.7550 and 0.7177, respectively. The multipliers for conditions A and B are 0.9138 (=0.69/0.7550) and 0.9754 (=0.70/0.7177). The baseline data are then adjusted using these multipliers to estimate the age-adjusted EQ-5D score for the combined conditions A and B as shown in Figure 8.

Adverse Events

When considering adverse events for inclusion in cost-effectiveness models, it is important to distinguish between acute events and chronic sequelae. Although the inclusion of decrements on HRQL associated with grade 3–4 adverse events is particularly important, the cohort used for the main HSUVs may have included a proportion of patients who had experienced grade 1–2 adverse events and care should be taken to ensure these are not double counted. As in the preceding section, treating the decrement associated with the adverse event as a constant value may be inappropriate and based on the current evidence, the HSUVs should be multiplied (adjusting for age wherever possible) when combining these data.

Uncertainty

All results generated from cost-effectiveness models used to inform policy decision making in healthcare are subject to uncertainty. The uncertainty is examined and reported using sensitivity analyses. One-way sensitivity analysis is a procedure in which the central estimates for key parameters in the model are varied one at a time (generally using the 95% confidence intervals) and inform readers which variables drive the results generated by the model. Probabilistic sensitivity analysis is a method of varying all variables simultaneously to assess the overall uncertainty in the model. The individual Monte Carlo simulations (e.g., 5000) are generated using random numbers to sample from the distributions of the parameters. New results are generated by the model and each of the 5000 results stored. The recorded results are then used to illustrate the overall variability in the model results.

Figure 9 shows a scatter plot of the incremental costs (y-axis) and incremental QALYs (x-axis) generated from a cost-effectiveness model. The red points represent the individual results generated when there is relatively little uncertainty in the parameters used in the model. The blue symbols represent the individual results generated when there is considerable uncertainty and thus cover a broader area. The mean results (£24 500 per QALY) are the same in the results that are relatively uncertain and the results that are associated with a higher level of confidence. Using a cost per QALY threshold of £30 000 per QALY (the diagonal line), 41% of results from the model, which has a high level of uncertainty, are greater than this threshold, compared to just 7% of results from the model with a smaller level of uncertainty.

When looking at the uncertainty associated with the HSUVs, the distribution used to characterize the variables for the probabilistic sensitivity analyses should be chosen to represent the available evidence as opposed to selected arbitrarily. HRQL data, in particular the preference-based utility data, are generally not normally distributed. They are typically skewed, bimodal or trimodal, bounded by the limits of the preference-based index, and can involve negative values representing health states consider to be worse than death. Despite this, in the majority of decision-analytic models, the uncertainty in the mean HSUV can be adequately described by sampling from a normal distribution. Exceptions to this rule include when conducting patient-level simulation models using data from cohorts with wide variations in HSUVs and a relatively low or high mean value. In these cases an alternative approach would be to describe the

utility values as decrements from full health (i.e., 1 minus the HSUV) and then sample from a log normal or gamma distribution, which would give a sampled utility decrement on the interval $(0, \infty)$. If a lower constraint is required (i.e., -0.594 for the UK EQ-5D index), the standard beta distribution could be scaled upwards using a height parameter (λ) producing a distribution on a $(0, \lambda)$ scale.

Conclusions

The use of HSUVs in cost-effectiveness models has not received much attention in the literature. However, there are often no relevant HSUVs to be found in the literature, observational sources, or even trials. This article has provided practical guidance to those seeking to build cost-effectiveness models. In the near future, it is expected that there will be further developments in the field including methods of mapping, the synthesis for HSUVs across studies, and in the measures themselves. Policymaker's requirements may also change over time.

Cost–Value Analysis

E Nord, Norwegian Institute of Public Health, Oslo, Norway, and The University of Oslo, Oslo, Norway

Introduction

Cost–value analysis (CVA) is a type of formal economic evaluation that can be used to inform decision makers in a public health service about the value to the public of different health technologies and what ought to be the public health service's maximum willingness to pay for them. In estimating value and limits to willingness to pay, CVA takes into account that in most countries with a public health service, citizens and societal decision makers hold concerns for both efficiency and equity. The concern for efficiency means that value – and thus willingness to pay – increases with the size of the health benefit provided by the technology – measured, for instance, in terms of the number of quality-adjusted life-years (QALYs) produced. Equity concerns may, for instance, mean that for a given health benefit, value and willingness to pay increase with the severity of the condition that is addressed. Other equity concerns may also be relevant (see History and Value Basis).

CVA has features in common with cost–utility analysis. Costs are estimated in the same way, and health benefits are expressed in QALYs. The difference is that concerns for equity are included in the determination of value. The replacement of the term 'utility' with the term 'value' in the name of the analysis serves to emphasize this difference. Whereas 'utility' refers to individuals' personal valuations, 'value' in 'cost–value analysis' refers to a broader societal concept. The basic premise of CVA is that simple aggregations of QALYs do not yield reliable estimates of citizen's overall valuation of different programs, because concerns for equity are not included in such simple aggregations.

Example

In CVA, the value of a program can either be expressed in equity-weighted QALYs (EQALYs) or in a public health care service's willingness to pay for QALY gains, given the context in which the gains occur and the characteristics of the patients who receive them. A simple example is as follows: Assume a scale of individual utility of health states from 0 to 1. Assume that intervention 'A' takes one type of patient from utility level 0.4 to level 0.6 for 1 year at a cost of EUR 10 000, whereas intervention 'B' takes another type of patient from level 0.8 to level 1.0 for 1 year at the same cost. The two interventions are equally cost effective (because the QALY gain and the cost is the same). But the societal appreciation (value) of the 0.2 QALYs in intervention A may be, say three times as high as that in intervention B, given the much greater severity of the pre-intervention condition in A and thus the much greater need in this type of patient. The cost–value ratio of intervention A would then be better than that of intervention B, namely $10\,000/(0.2 \times 3) = €16\,700$ EUR per EQALY versus $10\,000/0.2 = €50\,000$ EUR per EQALY, which suggests that A should be given priority among the two if a choice had to be made. To put it differently, it suggests that, in a society where such a concern for severity prevails, the public health care system should have a three times higher willingness to pay for intervention A than for intervention B, in spite of B producing the same amount of QALYs. CVA thus supports context-dependent, graded willingness to pay for QALYs.

History and Value Basis

The term 'cost–value analysis' was first introduced by Nord in 1993. It may be used in a general sense, that is, about any evaluation that takes into account relevant concerns for fairness (equity) in the weighting of individual benefits, whatever these concerns may be. However, in the development of CVA hitherto, some concerns have been treated as particularly salient. Based on a review in 1999 of existing materials in Australia, the Netherlands, New Zealand, Norway, Spain, Sweden, the UK, and the USA, Nord suggested that ethicists' and policy makers' reflections, and results from public preference measurements, seem to converge on the following points:

A. Society demands that medical interventions satisfy a minimum requirement of effectiveness for resource use to be justified.
B. Society's appreciation (valuation) of medical interventions increases strongly with increasing severity of the patients' condition. (This is often referred to as a 'concern for the worse off.')
C. Life saving or life extending procedures are particularly highly valued, and significantly more highly than interventions even for patients with severe chronic conditions.
D. When the minimum requirement of effectiveness is satisfied (see point A), society worries less about differences in the size of the health benefits provided by treatment programs for different patient groups, the underlying attitude being that people are entitled to realizing their potential for health, whether that be large or moderate, given the state-of-art in different areas of medicine.
E. As a special case of point D, society in most cases does not wish to discriminate between people with different potentials for health in decisions about life saving or life extension. For instance, society regards the prevention of premature death in people with chronic disease as equally worthy of funding as the prevention of premature death in otherwise healthy people. (Life extending interventions for people in vegetative states or states of very low subjectively perceived quality of life is an exception from this rule.)

Work on CVA hitherto has aimed at incorporating the specific ethical concerns above in formal valuation models (Nord *et al.*, 1999; Nord, 2001). The term 'cost–value analysis' is thus mostly used in this specific operational meaning rather than in the more general sense noted earlier.

Preference Measurements

To incorporate the above concerns in a numerical valuation model, data are needed on the strength of preferences for equity. The strength of societal concerns for severity and realization of potentials has been studied in samples of the general public in several ways. The most widely used technique is the person trade-off, which was introduced by Patrick, Bush, and Chen in 1973 under the name 'equivalence of numbers' and was given its present name by Nord in 1995. Typically, samples of the general public are presented with pairs of programs targeting two groups of patients that differ on one characteristic. The subjects are presented with numbers of beneficiaries in the two programs and asked to judge at what ratio between the numbers of beneficiaries they find the two programs equally worthy of funding. For instance, program A provides an improvement in utility from 0.4 to 0.6 for 100 people, whereas program B provides an improvement from 0.8 to 1.0 for a larger number of people. How large must the latter number be for the two programs to be deemed equally worthy of funding? The stronger the concern for the worse off (those in program A), the higher will the stated 'equivalence number' in program B be.

Person trade-off responses that take into account special concerns for severity may be represented by values for health states on the 0–1 scale from dead to full health used for QALYs. For instance, a program A prevents death in 10 people and allows them to live in full health. Program B averts an illness that leads to nonfatal state S. Assume that people consider 100 averted cases in program B to be equally worthy of funding as 10 averted deaths in program A. The value of S is then given by $1-(10/100)=0.9$. Person trade-off-based values for health states are typically higher than utilities obtained for the same states by techniques ordinarily used in the QALY field.

Other possible approaches to measuring public preferences for equity include questions about willingness to pay and questions formulated by Paul Dolan about how large a health benefit for one group of patients needs to be relative to a given health benefit for another group of patients for the two benefits to be deemed equally valuable from a societal perspective.

Modeling

Technically, there are various ways of incorporating data about concerns for equity in formal evaluation models. They may all be seen as modifications of the QALY approach that lead to evaluation in terms of EQALYs.

One modification, suggested by Nord *et al.* in 1999, is to count as one all gained life years, even if they are in less than full health, as long as they are good enough to be desired by the individuals concerned. The purpose of this is to avert discrimination against the chronically ill or disabled in valuations of interventions that extend life (confer (cfr) point E in the section 'History and value basis'). A second modification proposed by the same researchers is to place less weight than the QALY approach does on the duration of health benefits in comparisons of programs for patients with different life expectancies (cfr point D in the section 'History and value basis'). This may, for instance, be done by discounting distant health gains more strongly than at the 3–5% annual rate that is customary in conventional cost-effectiveness analysis, or by disregarding benefits that lie beyond a certain point in time. A third modification is to multiply utility gains as estimated by conventional QALY tools with explicit equity weights reflecting the severity of the preintervention condition and the degree to which health potentials are realized (cfr points B–D in the section 'History and value basis'). Alternatively, one may transform conventional utilities into societal values as illustrated in Figure 1. A transformation curve that is convex to the *Y*-axis and has strong upper end compression can, in principle, accommodate concerns for both severity and realization of potentials. For instance, in the figure the curve transforms conventional utilities of 0.4 and 0.7 to societal values of 0.8 and 0.95. If one replaces utilities from the *X*-axis with the values from the *Y*-axis, the value, for instance, of a cure of A relative to B increases from 2:1 to 4:1 (concern for severity), whereas the value, for instance, of taking someone from A to B relative to from A to healthy increases from one-half to three-fourth (concern for reduced potential).

Tentative transformation functions of the kind in Figure 1 were published by Nord in 2001 for utilities from various multiattribute utility instruments commonly used in QALY calculations. Table 1 contains the same type of information. Based on meta-analysis of policy documents and public preference measurements in several countries, the table shows a set of values for health states that purports to reflect the structure of societal concerns for severity and realization of potentials, using limitations in mobility as an example. The table is included as a potentially helpful analytical tool in guidelines for pharmacoeconomic evaluations in Norway.

Consider first the columns 1–3 in the table. The examples of states on the 8-level scale in column 1 were chosen with a view to making any one step move upwards on the scale to be roughly of the same importance from the viewpoint of affected individuals. In other words, the scale purports to be an equal interval scale in terms of individual utility. This suggests an even distribution of the 8 levels over the 0–1 utility space, i.e., utility scores for the various levels, roughly as in column 2. The numbers in column 3 are societal values. Concerns for

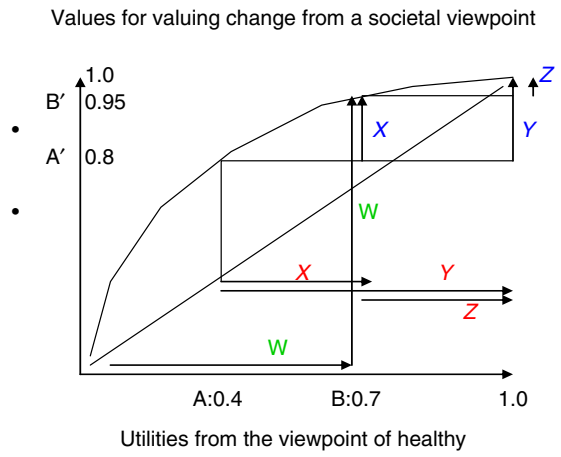

Figure 1 Utilities versus societal values for priority setting.

Table 1 Health state values encapsulating concerns for severity and realization of potential. Implied public willingness to pay (WTP) assuming WTP of €10 000 EUR for saving a life year

[a]Values adjusted after original publication.

Abbreviation: QALY, quality-adjusted life year.

Source: Adapted from Nord, E., Pinto, J. L., Richardson, J., Menzel, P. and Ubel, P. (1999). Incorporating societal concerns for fairness in numerical valuations of health programs. *Health Economics* **8**, 25–39.

Examples at levels 2–7:

2. Can move about anywhere, but has difficulties with walking more than 2 km.
3. Can move about without difficulty at home, but has difficulties in stairs and outdoors.
4. Moves about without difficulty at home. Needs assistance in stairs and outdoors.
5. Can sit. Needs help to move about – both at home and outdoors.
6. To some degree bedridden. Can sit in a chair part of the day if helped by others.
7. Permanently bedridden.

severity are reflected in the fact that movements one step upwards on the scale are assigned more value the lower the start point. Concerns for not discriminating too strongly against groups with reduced potentials for health are reflected in the fact that from any given start point, improvements of different size (i.e., consisting in different numbers of steps on the scale) do not differ as much in value as they do in terms of individual utility gains calculated from column 2.

Health state values with a pattern as that in column 3 may be used to weight life years and improvements in health status in the same way as is done in QALY calculations. But valuations of outcomes are then in terms of EQALYs rather than conventional ones. They may be related to costs in cost–value ratios that in theory indicate value for money of different interventions in a broader way than cost–utility ratios do.

An alternative to calculating EQALYs by using numbers like those in column 3 is to keep QALYs themselves untouched and instead practice context-dependent willingness to pay for QALYs. Consider columns 4–6 in **Table 1**. The figures in columns 4(a) and 4(b) follow from columns 2 to 3, respectively. The figures in column 5 presuppose an anchoring value for willingness to pay. If, for instance, the willingness to pay to save a life year in normal health is €100 000 EUR, the rest of the figures in column 5 follow by rescaling the figures in column 4(b) by a factor of 100 000. The column shows that willingness to pay increases much more than proportionally to the severity of the start point. As a consequence, the willingness to pay for a QALY increases with the severity of the start point (column 6).

This can be developed further. One may, in principle, construct a hierarchical set of priority classes that takes into account various equity concerns that society deems relevant in priority setting. For each class, a maximum societal willingness to pay for a QALY is decided, such that the higher the priority class, the higher is the willingness to pay. Any outcome in terms of QALYs is assigned to its appropriate class, which will be higher in the hierarchy the more the outcome has equity concerns counting in its favor. The cost of the QALY gain will then be compared to the maximum willingness to pay for a QALY in that class. For instance, QALYs gained in people with severe conditions will, all else equal, be placed in higher classes than QALYs gained in people with moderate conditions and thus justify higher costs. An approach of this kind is considered for implementation in the Netherlands, with a social willingness to pay for a QALY ranging from roughly €10 000 EUR to 80 000 depending on preintervention severity.

Although technically different, a scheme consisting of priority classes and context-dependent willingness to pay is in its actual content equivalent to a system in which QALYs themselves are weighted and compared to a uniform willingness to pay for a QALY. In both approaches, judgments need to be made regarding how much weight the QALYs in question deserve to be given. In one approach, the chosen weight is connected to willingness to pay by assignment to priority class, in the other approach the same weight is connected to the QALY gains themselves and thus indirectly to willingness to pay. Preference data that have been elicited by means of the person trade-off or other methods in order to determine equity weights for QALYs may thus also be relevant in determining the gradient of willingness to pay in a hierarchy of priority classes. To judge whether the cost per QALY of a given intervention is within the willingness to pay for QALYs in the priority class in question may thus be seen as a variant of CVA in the general sense of the term.

Alan Williams suggested in 1997 that QALYs should be assigned more value the more the beneficiaries' expected

health over the whole life time falls short of a normal amount of health (including longevity) over a whole life. This fair innings approach is essentially a proposal to include a societal concern for equity in the formal economic evaluation. The fair innings approach to weighting QALYs for equity may thus be seen as yet another variant of CVA in the general sense of that term.

Issues

Population preference data to support CVA are presently not satisfactory. Data on what would be reasonable separate equity weights are almost nonexisting. This also applies to the fair innings approach. For the values in Table 1, column 3, the empirical basis in preference measurements is substantial, but the values are the result of an informal meta-analysis of the relevant preference literature conducted by one researcher. As noted in a review by Shah in 2009, other researchers could reach different conclusions.

Another current limitation is that Table 1 refers to health problems in terms of reduced mobility. This is because so much of the existing societal preference data pertain to this particular dimension. To apply the numbers to other kinds of health problems, one needs to know where they belong on the severity scale of Table 1. This may be judged by judging the effect on quality of life of those other problems compared to the effects on quality of life of the various mobility problems indicated in the table. Alternatively one may regard columns 2 and 3 as roughly indicating the relationship in general between individual utilities and societal values. So for instance, if one has utilities from the multi-attribute utility instrument EQ-5D columns 2 and 3 may be used to roughly estimate corresponding societal values.

One common criticism of societal value numbers is that people's responses to numerical preference questions in mailed questionnaires are unreflective and unreliable. This is to some extent true. However, researchers have also collected preference data in more high quality ways, for instance, in focus groups that discuss ethical issues carefully before each participant gives their responses to specific quantitative questions.

Finally, the idea of incorporating concerns for fairness in a numerical valuation model is controversial. Some researchers, for instance, Dolan and Olsen (2003), are concerned that such incorporation may overload the model and perhaps makes it more difficult to understand and less reliable. The alternative is to leave it to decision makers to take concerns for fairness into account informally when dealing with the results of cost-effectiveness analyses. This is an important practical issue for continued debate. It is also a theme for further research. At the end of the day, it is an empirical question whether decision makers feel helped or not by CVA, or feel more helped when provided with such analyses in addition to conventional cost-effectiveness analyses.

Cross-National Evidence on Use of Radiology

NR Mehta, Riddle Hospital, Media, PA, USA, and University of Pennsylvania, Philadelphia, PA, USA
S Jha and AS Wilmot, University of Pennsylvania, Philadelphia, PA, USA

Introduction

The specialty of radiology, diagnostic imaging, has revolutionized the practice of medicine across the globe. No other form of diagnostic medicine has had such a dramatic impact on disease detection and mapping progression of treatment in the preceding decades. In a 2001 survey of physicians, magnetic resonance imaging (MRI) and computed tomography (CT) scanning ranked number 1 amongst 30 medical innovations of the last 25 years, beating cholesterol-lowering HmG-CoA reductase inhibitors (statins), coronary arterial bypass graft, and newer generation antibiotics (Fuchs and Sox, 2001).

With the diagnostic imaging technological revolution has come the inherent increased costs of the technology itself. With CT scanners and MRI scanners costing upward of $3 million (US), the utilization of these machines at an ever increasing pace has helped drive up the medical bills of patients everywhere.

One of the benefits to having diagnostic imaging technology disseminated throughout the world is to provide a window into how the differing health care delivery systems tackle this issue of managing cost and utilization in the face of limited resources. In this article, four countries are studied: the US, the UK National Health Service (excluding Scotland), Canada, and Japan. The US provides a window into their blend of private and government-sponsored health care systems. The UK and Canada allow a glimpse into two variants of government-run health care. Japan allows for an analysis of their social insurance health care system, which has the highest per capita number of CT and MRI scanners of the comparison countries. As can be seen from **Tables 1** and **2**, these countries differ substantially in their numbers of advanced diagnostic equipment (CT and MRI scanners) as well as radiologists per capita. This article will document these differences and provide some suggestions of possible contributing factors. More rigorous analysis of determinants of cross-national differences in technology uptake and their effects on health outcomes remains an important subject for future research.

United States

Health care in the US is a mix of private and government-sponsored methods of financing and care delivery. Insurance coverage largely depends upon age, income, and employment. For the majority of the adult population under the age of 65, private insurance is obtained through the workplace. Employer-sponsorship of health insurance takes advantage of tax preferences, facilitates contract negotiation for employees, and creates an insurable pool of enrollees. Those who are not employed or who do not have employer-sponsored health care (sole business owners, independent contractors), can buy insurance directly from insurance companies in what is known as the individual market. Much of the *Patient Protection and Affordable Care Act of 2010* is devoted to reforming this individual market, such as removing preexisting condition exclusions, setting medical-loss ratios for insurance companies, and creating health insurance exchanges to provide information and subsidies to individuals who purchase these policies.

For senior citizens over the age of 65, there is government-sponsored Medicare. This program, which is administered by private carriers, sets provider payments for hospitals and physicians nationally, including reimbursement for radiology. The program is funded by a combination of payroll taxes on workers, general revenues and premiums paid by beneficiaries. Finally, a subset of people below the poverty line are eligible for Medicaid. Medicaid is government-sponsored by both Federal and state governments. Provider payments are set on a state-by-state basis and the program is funded via taxes. People who fall outside of these public and private programs remain uninsured, except for minor additional programs. Private insurance programs (employer-sponsored and individual) for those under the age of 65 tend to follow the national fee structure provided by Medicare.

Among the four countries considered, the US has the most radiologists per capita. In addition, the US has the second highest number of MRI and CT scanners compared with the other countries. The high number of scanners can in large part be attributed to the fee-for-service system, a system that rewards doing more per patient. The majority of the country has no limits regarding the number of scans performed or the number of scanners in operation, with only a few state-based exceptions where a certificate of need is required prior to the purchase of a scanner. For every scan performed, a fee is collected, and thus the incentive to perform higher volume of scans. The higher volume of scans translates to a higher volume of scanners.

Payment for imaging services in the US is, in general (driven by Medicare), split into two categories: technical fee and professional fee. The technical fee is that which goes to the owner of the imaging equipment. The professional fee goes to the radiologist for interpretation of the study. Typically, the professional component is much less than the technical component, reflecting the relatively high equipment costs. In 2011, for example, a CT scan of the head carried a professional fee around $40, as compared to the technical fee of around $150.

A major legislation undertaken by the Federal government to curb cost and growth in imaging was enacted in the Deficit Reduction Act of 2005 (DRA 2005). This legislation reduced the technical fee payment for contiguous body part scanning. Hence, a CT scan of three contiguous body parts, such as the chest, abdomen, and pelvis, where the reimbursed technical fee was 100% for each, became 100% for the chest and 50%

for the abdomen and pelvis (Moser, 2006). In 2012, Medicare further reduced payments to radiologists by decreasing the professional fee on a second body part for patients scanned on the same day by 25%. Although these changes primarily impact Medicare patients, insurance carriers tend to follow Medicare rates, giving this legislation tremendous impact. Indeed, Medicare rates indirectly serve as a 'national fee schedule.' As a result of the DRA 2005, imaging volumes in radiology offices decreased 2.0% between 2006 and 2007, as compared to yearly increases of 8.4% between 2002 and 2006 (Levin *et al.*, 2009).

The Organization for Economic Development and Cooperation (OECD) data indicate that the US, as compared to UK, Canada, and Japan, has the highest total health expenditure on imaging as a percent of gross domestic product (GDP) (**Table 1**). The US ranks second among this group in terms of number of CT and MR scanners per million, with Japan taking the top spot. The US also has by far the highest number of scans – both MRI and CT – per capita population, implying that there is a relatively high level of access to imaging technology in the US. However, when utilization per scanner is estimated (number of scans per scanner), the country falls to the second to last in terms of MR and CT utilization, indicating a relative under utilization of imaging equipment compared to other countries. Indeed, the US and Japan are the only high-income countries in the world, which allow for essentially unrestricted acquisition of high-technology scanners in a fee-for-service environment (Cutler and Ly, 2011). It is, therefore, not surprising that both of these countries have more scanners and lower utilization of scanners compared to the UK and Canada.

The number of radiologists practicing in the US is around 100 per million population (**Table 2**), the highest of the analyzed countries. In contrast to the relatively low scanner utilization in the US, the radiologist utilization is the highest, indicating that the US radiologist is reading more studies per year than their peers in other countries. Thus the overall evidence shows that the US has a relatively high number of scanners, radiologists, and scans per capita, which is consistent with it having relatively few controls on investment in new equipment and on licensure of new radiologists.

According to the Center for Medicare and Medicaid Services and Blue Cross Blue Shield Association, expenditure on diagnostic imaging has been approximately 5% of total expenditure on health care. The total amount of money spent on diagnostic imaging in the US in the year 2000 was approximately $75 billion. In 2000, the national health expenditure was $1.377 trillion, making imaging costs 5.4% of total health care expenditure. The total cost of diagnostic imaging for 2005 was estimated to be $100 billion. In 2005, the national health expenditure was $2.029 trillion, making imaging costs approximately 4.9% of total expenditure on health care.

Between 1998 and 2005, the annual growth rate in diagnostic imaging in the Medicare population was 4.1%. This has slowed down in recent years, likely as a result of a combination of cost-containment strategies from the government as well as the economic slowdown. Between 2005 and 2008, the annual growth rate of imaging in the Medicare population was 1.4% (Levin *et al.*, 2011).

United Kingdom/England

England has a universal public health care system (National Health Service, NHS) with a supplementary private insurance

system. Taxes are used to fund the NHS, where most care is provided at no cost to the patient at the point of service. Patients register with and go to a general practitioner (GP) who then serves as a gatekeeper between them and the hospitals/specialists, including radiologists who normally are employed in radiology departments within hospitals. Supplementary private insurance is purchased by about 12% of the population. It mostly pays for quicker access to specialists and elective surgeries, which may be performed in private hospitals or private beds in NHS hospitals. Anecdotally, private insurance provides a greater degree of access to imaging than the NHS. The private system is staffed largely by the same physicians who serve in the NHS.

In general, over the preceding decades, radiology in the NHS has been characterized by limited quantity of radiology equipment, limited number of radiologists, and waiting lists for patients. These issues have been tackled and have steadily improved.

While the density of radiology equipment per capita in England remains far lower than in the US, there has been a substantial upgrading of imaging equipment in England over the past decade. According to the UK Department of Health, during 2000–07 the NHS spent £564 million (£80 million per year) on CT, MRI, and LINAC (linear accelerator, for radiotherapy) machines in inflation-adjusted currency. The estimated cost to replace this equipment over the next decade is £1 billion, noting yearly NHS annual budgets of around £100 billion.

In 2001, there were 1586 consultant radiologists. In 2010, the number of full-time equivalent radiologists was 2194, representing an approximate 38% increase over the decade. This translates to approximately 45 full-time equivalent radiologists per million of population. Despite this increase, it is still below the Royal College of Radiologists recommendation of eight full-time equivalent radiologists per 100 000 of population, according to a December 2012 Center for Workplace Intelligence report. Universal evening and weekend coverage is not prevalent as is the case in the US. There is a drive toward longer hours, and 12–14 h days per radiologist, working 7 days per week has been implemented at Royal Sussex County Hospital in Brighton with reported success. In order to provide around the clock coverage, 24 h a day and 7 days per week, the number of radiologists would need to increase to 6000, which implies roughly doubling the current number.

In addition to high case volume, radiologists in England face additional work pressures. The NHS Cancer Plan requires that a radiologist be present at multidisciplinary meetings, which have increased in duration and frequency since 2007. These, on average, occupy 10% of the radiologists' clinical time. In contrast, this is not a requirement in countries such as the US, where it is occasionally provided as a voluntary effort. This results in additional radiologist time taken away from reading films, exacerbating shortages. As in the US, an aging population and increasingly complex imaging examinations with an increased number of images per study, have also increased the clinical burden on radiologists. A Center for Workplace Intelligence report from August 2011 reports on burn out resulting in radiologists leaving the work force for sick leave or early retirement, as well as an increased rate of mistakes such as overlooked lung cancers on radiographs. A study from the Royal College of Surgeons of Ireland in March 2011 surveying Irish radiologists describes understaffing issues in a system in which radiologist numbers are centrally controlled by government agencies. The authors argue that current methods of determining radiologist productivity are outdated and do not give adequate weighting to responsibilities such as teaching, procedures, double reading, and interpreting outside films.

Private practice radiology does exist on a more limited scale than the US, providing 10–15% of radiology services, as per a July 2002 Audit Commission report. Fees for diagnostic exams vary from provider to provider, but in general align with fees charged in the US.

England has made progress in terms of patient wait times for imaging. An audit commission report in 2002 found the average wait time for outpatient MRI services was 20 weeks, while for CT this was over 6 weeks. In 2004 the NHS contracted with an independent sector radiology provider, Alliance Medical, to provide 635 000 MRI scans to assist with MRI backlogs. This served as a short-term solution to the waiting lists. However, there is concern from within the NHS radiology departments as to direct competition with the independent sector for limited NHS funds. According to the Department of Health, as of 2009, wait times over 6 weeks for CT and MRI have been essentially eliminated.

The OECD data show that as of 2012, health care spending in England is lower than in the US, accounting for 9.8% of GDP compared to 17.4% in the US. However, rising health care costs have led to recent reforms in the NHS. As per the Department of Health spending review, the budget of the NHS for 2011 is £103.8 billion, and the current budget provides a 0.4% increase in real terms through 2015. Overall planned cost cutting include £20 billion in efficiency savings and a 33% decrease in administrative costs. Specific to radiology, there will be an expected £8 million in savings annually to be achieved by having some plain radiographs interpreted by radiographers (nonphysicians) rather than radiologists.

In 2008/2009, £1.1 billion was spent on radiology services, equating to 1.4% of the NHS budget. This is a smaller percentage when compared to the US (Grant *et al.*, 2012). About 38.8 million imaging examinations were performed in England in 2010, including 4 million CTs, 2.1 million MRIs, and 22.2 million radiographs, as per the Center for Workplace Intelligence. This volume amounts to approximately 73 imaging examinations per 100 population per year. There has been a rapid increase in volume of imaging in the UK, and between 1996 and 2010 there has been a 445% increase in MRI, 279% increase in CT, 94% increase in ultrasound, and a 16% increase in radiographs. As in the US, the increase has primarily involved the more advanced and expensive imaging modalities. Based upon calculations from the OECD health data, the US, in comparison, has had an increase of 208% in MRI, and 262% in CT.

Tables 1 and 2 show fewer CT and MRI scanners in the UK relative to the US. When accounting for the total number of scans performed, on average the UK seems to have a higher utilization of their imaging equipment. On a per radiologist basis, despite the aforementioned concerns of high case load and clinical burden, radiologists read on average less number

of CT and MRI cases per year than their US counterparts. The difference between the countries might in part be attributable to the differential payment structure of radiologists. In the US, there is a financial gain for reading more studies, while in the UK there is no such overt financial benefit in their salaried model.

Canada

Canada has a single-payer universal health care system paid for through taxation. Cost containing strategies, such as patient copayments, are effectively prohibited for 'medically necessary services' by federal mandates. The roots of the Canadian health care system date back to the Federal Health Insurance and Diagnostic Services Act of 1957. The act provided that provinces funded 50% of the health care cost with a federal match of 50%. Federal funding was contingent upon the provinces providing medically necessary care, portability of coverage, and universal coverage. In 1977, the open-ended federal funding of health care was replaced with a federal per capita block grant, meaning a fixed amount of money would be provided to provinces every year, initially with indexing to the GDP. In the early 1990s, the federal contribution was frozen at 1989 levels, making the provinces responsible for all growth of spending. By 1999, the federal share of health care costs had fallen to between 10% and 20%. Until 2005, the Canadian system banned private insurance from providing services covered by public health insurance. In 2005, the Quebec Supreme Court ruled in Chaoulli versus Quebec that Quebec's prohibition of private medical insurance in the face of long wait times for public federally mandated care violated 'rights to life' and 'security of person'in Quebec's charter. The provincial government has so far responded to this ruling by managing waiting times, rather than encouraging growth of private insurance.

The provincial contribution to health care is generally from income or payroll taxes that are not earmarked specifically for health care, and hence the amount of money individuals pay for health care is not obvious to the taxpayer. From 2001 to 2010, the rate of health care spending has increased at greater than three times the rate of inflation. Health care spending is projected to equal or exceed 50% of all revenue in 6 of 10 Canadian provinces by 2017 (Skinner and Rovere, 2011).

Every year the provincial government negotiates annual global budgets with the hospitals. The fixed budget covers all operating costs and is based on estimated volume of patients (occupied beds). New capital expenditures are allocated separately. There is a theoretical disincentive on the part of the hospitals to provide expensive services, unless this would result in increased revenue, which would typically only happen with a lag.

Physicians are primarily in solo practices (about 50% are GPs), and collect their revenues via a fee-for-service system but subject to an annual aggregate spending limit. Provinces and medical associations determine a uniform fee schedule that typically applies throughout the province. Expenditure and income caps per physician are put into place (varying from province to province), which are intended to prevent overutilization. After achieving a certain level of income (total fees), the physician is paid only a percentage of the remaining fees. Radiologists, in particular, are facing such 'clawbacks' proposed by provincial governments. Once total billings reach a certain level, the clawback reduces payment of subsequent services by a fixed percentage. A 2012 Ontario proposal reduces payment by 5% for billings above $400 000, 10% over $750 000, 25% for billings over $1 million, and 40% for billings over 2 million. This reduced marginal benefit attempts to balance the incentive of reading too many scans. The concern of the clawback scheme is the potential exacerbation of current waiting lists.

Canadian radiologists are paid primarily in a fee-for-service system. Based on data from the 2010 National Physician survey, 80% of diagnostic radiologists who responded received greater than 90% of their income from fee-for-service, while 10% received income from a blended source (which can include fee-for-service, salary, capitation, contract, on-call remuneration, etc.).

A small number of private radiology clinics do exist in Canada. As of 2007, there were 42 for-profit MRI/CT clinics in Canada. Traditionally these clinics have performed scans as a fee-for-service out of pocket payment and radiologists at these sites do not work in the public sector. Rates for scans in Alberta range between $500 and $800 per scan, while rates per scan in British Columbia range between $500 and $2200. To help combat public sector wait lists, they are now being used to help increase imaging capacity in the provinces via contracting with the public health service (Mehra, 2008).

As per 2010 data from the OECD, Canada spends 11.4% of its GDP on health care costs (**Table 1**). Estimated per capita spending for radiology in Canada is $55.29. This is closer to the spending of the UK, and considerably less than that of the US. According to the Canadian Association of Radiologists in 2012, costs of medical imaging in Canada (including maintenance of equipment and physician payment) is approximately $2.14 billion (US). Total health care expenditure is 11.4% of a GDP of $1.6 trillion (US), or $180.8 billion. Based on this, diagnostic imaging costs in Canada are approximately 1.2% of total health care expenditure. However, it should be noted that this does not include capital costs of scanner purchase. Taken at face value, the percentage is on par with the UK share of 1.4%, however much lower than the US share of 4.9%.

While a majority of Canadian citizens and physicians have an overall positive impression of the Canadian health care system, the system is not without criticisms. One criticism of the Canadian health care system has been with regard to long wait times. There is a low density of physicians in Canada that serves as one potential rate-limiting step with regard to overall health care spending. This holds true in radiology, with 67 radiologists per one million population, compared to 100 radiologists per million in the US. In addition to lower manpower availability, the density of expensive medical equipment such as MRI and CT scanners is also lower in Canada, potentially limiting access and resulting in long wait times. According to one survey released in 2009, the wait list for urgent MRIs ranged from 24 h to greater than 1 month, and the wait list for elective MRIs ranged from 28 days to 3 years. Other criticisms that have been raised in the past decade relate to slower adoption of new technology, which may in

some cases and in some parts of the country lead to patients undergoing diagnostic and interventional procedures performed with less modern equipment than would be possible with more resources. Furthermore, due to the single-payer system, diagnostics and procedures that are reimbursed at a low rate or not at all by the public health system may be difficult for patients to obtain. As noted in **Table 2**, the number of CT and MRI scans interpreted per radiologist is less than their US counterparts, whereas Canada ties with the UK in having the highest number of scans per scanner. This suggests that availability of scanners or budget allocation to pay for scans are on average more often the limiting factors on patient access, rather than manpower.

Comparison between the UK and Canada, both with single-payer health care systems, shows similarities in the percent of radiology expenditure as a share of total health expenditure, as well as the per capita expense of radiology services. There are also strong similarities in scanner utilization. These similarities are in place despite the difference in payment models to radiologists, with Canada being fee-for-service and the UK being a salary model. It might be surmised that radiologists are not, therefore, in the driver seat of imaging utilization, and that it is the organization of the health care system that plays a more critical role.

Japan

Japan has a universal health insurance system. Health insurance is mandatory, with individuals receiving insurance either via employer-sponsored plans or via one of several government-sponsored health insurance plans. Health care spending as a percent of GDP is low in Japan relative to other industrialized nations – largely a result of the government's tight regulation of health care prices. The system operates via a national fee schedule, reviewed biennially, which determines government reimbursement for all health care services. This single payment system has served as a remarkable control mechanism for costs.

Despite tight government control over reimbursement for imaging, there is no central government control on the installation of high-technology scanners in Japan. Japan has the most MRI and CT scanners per capita. The high density of MRI and CT scanners in Japan is an interesting phenomenon, because reimbursement for imaging in Japan is far lower compared to the US. For instance, the reimbursement for a CT scan in Japan in 2008 was equivalent to $80, with the reimbursement for an MRI equivalent to $155–180, these prices being approximately one-fifth to one-tenth of the reimbursement for the same studies in the US (Ehara *et al.*, 2008).

The low level of reimbursement begs the question as to why Japanese hospitals and clinics would purchase so many scanners and perform such a high volume of imaging, and whether imaging in Japan is profitable. The answer in part is cultural and relates to the expectation for rapid diffusion of medical technology in the Japanese society, which is quick to believe in its benefits even in the absence of clinical effectiveness data. Medical imaging in Japan is in fact not typically profitable, yet hospitals reportedly seek high-technology scanners so as to maintain their prestige and competitive edge. The prestige of having an MRI scanner may attract more patients and increase profits indirectly from margins on other services. Furthermore, while the government reimburses imaging at a low rate, it does provide subsidies for purchasing imaging equipment by major public hospitals and academic medical centers (Ikegami and Campbell, 2005). Outside of major academic centers, private sector imaging providers who do not receive any government support tend to operate with lower cost Japanese-made scanners. The cost of imaging equipment in Japan is significantly lower than in the US, which also helps to explain the high density of scanners. Toshiba, Hitachi, and Shimadzu produce less expensive models of imaging equipment for sale to Japanese providers (Kandatsu, 2002).

A 2001 survey of scanners in Japan by the Japan Radiological Society revealed that approximately 30% of MR scanners were high-field 1.5 T scanners. A survey from 2005 showed that 53% of installed MRI scanners were 1.0 T or less. In comparison, a 2006 IMV market research survey of the US reported 90% of MRI scanners at 1.5 T field strength or greater. The strength of the magnetic field in MRI is measured in Tesla units, and higher Tesla scanners are stronger scanners. This increased magnetic field strength in MRI results in higher signal-to-noise ratio (SNR) in the resulting image. With high SNR, smaller structures and finer details are more easily visualized, which theoretically improves diagnostic accuracy. When comparing costs between superconducting scanners, in 2004, a 0.3 T scanner can cost around 70 million Yen (approximately $753 000), while a 1.5 T scanner can run 120 million Yen (approximately $1.3 million) (Hayashi *et al.*, 2004).

Japanese fee schedules have been adjusted over time to reflect the increased use of MR and CT. As the volume of imaging increases, the government decreases reimbursement to control overall expenditures. For instance, in 2002 the reimbursement for an MRI brain exam was decreased from 16 600 Yen ($180 in US dollars, using early 2013 exchange rate) to 11 400 Yen ($124), an approximate 30% decrease. Over the past decade, there has been recognition that the higher cost of operation and the higher quality of imaging provided by higher field strength MRI scanners and multidetector CT deserves higher levels of reimbursement.

Other issues that distinguish the practice of radiology in Japan from that in the US, Canada, and England include the prevalence of interpretation of images by nonradiologists. In 1996, the government began offering higher reimbursement for studies interpreted by board-certified radiologists. While the proportion of studies interpreted by radiologists has increased since that time, only 40% of imaging examinations were interpreted by radiologists as of 2003 (Nakajima *et al.*, 2008).

Of all of the countries included in this article, Japan has the lowest density of radiologists, with 36 per one million of population as of 2004. Japanese radiologists worked an average of 63.3 h per week in 2006. Cases read per radiologist, or radiologist utilization, are on par with the US when accounting for the 40% radiology interpretation rate. A 2002 survey from the European Society of Radiologists of 14 European countries showed that essentially all CT and MR examinations are reported by radiologists.

Japan's total health expenditure is on the lower end of the spectrum when compared to the other countries analyzed in this article. In 2003, radiology costs were estimated to be approximately 5.2% of total health care expenditures (Imai, 2006). This is closer to the radiology share of spending in the US (4.9%), than in the UK and Canada.

Conclusion

Comparison of the four countries used in this study demonstrates important cross-national differences in the utilization of diagnostic imaging, both absolutely and as a percent of total health care spending.

On the side of total spending, the US and Japan have the highest percentage of total health expenditure utilized for radiology, at 4.9% and 5.2%, respectively. By contrast, the UK and Canada have the lowest percentage of total health expenditure utilized for radiology, at 1.4% and 1.2%. However, note that data for Canada do not include costs of scanner purchase, only operational costs. One of the major differences between these groups of countries is that the former (US and Japan) are not single public payer systems. And although the latter group (UK and Canada) do have a degree of private practice running alongside the single public payer, the public system is by far the dominant mode of health care delivery. Publicly owned providers are fundamentally not designed to make a profit on the delivery of care.

From the provider reimbursement standpoint, fee-for-service versus salaried model of radiologist pay does not, with this limited glance, account for significant differences. Canada is a fee-for-service system, while the UK is a salaried model, and both systems achieve a relatively low percentage of total health expenditure utilized for radiology.

In terms of access, Japan has the most scanners per capita but ranks second, after the US, in number of scans per capita. Utilization of equipment numbers, however, indicates that the UK and Canada use their equipment more intensively than the US and Japan, which is perhaps unsurprising given the former two countries' lower number of scanners per capita. Access to imaging is related to the percentage of total health expenditure utilized for radiology.

Ultimately, it might be surmised that an 'if you build it, they will come' mentality exists within health care, and that single-payer models serve as a better mechanism to limit both imaging access and costs. Both the UK and Canada have government budget constraints that can tightly control number of scanners in the market. And while Canada pays the radiologist a fee-for-service model for interpretation of the scan, the performance of the scan is not reimbursed in this manner. Therefore, a potential strategy for countries attempting to reign in radiology expenditures is the elimination of technical fee-for-service, while preserving current mechanisms of radiologist interpretation reimbursement. Simply reducing the technical component fee may not be enough, as Japan has shown with its reduced fee schedule. The market response in Japan has been to utilize lower cost scanners, and the country has continued high radiology costs as a percentage of total health expenditure.

Further research is needed into whether technical fee-for-service reimbursement is a causative factor for higher costs, not just for medical imaging, but also for health care as a whole. The removal of technical fee-for-services, not merely the reduction of fees, in laboratory services, surgical and clinical services, in addition to imaging services could serve as a future direction of health care cost containment and health care policy.

Decision Analysis: Eliciting Experts' Beliefs to Characterize Uncertainties

L Bojke and M Soares, University of York, York, UK

Glossary

Covariate A variable that is possibly related to the outcome under study.

Credible interval An estimate of the range of values possible within a specified degree of credibility, usually 95%.

Elicitation Method to obtain subjective beliefs from an individual.

Heuristics Experience-based techniques for problem solving, learning, and discovery such as rules of thumb.

Introduction

Decision-modeling is increasingly used or required by health technology funding/reimbursement agencies as a vehicle for economic evaluation. The process of developing and analyzing a decision analytic model as part of a health technology assessment (HTA) involves many uncertainties. Some relate to the assumptions and judgments regarding the conceptualization and structure of a model, others to the quality and relevance of data used in the model. Where data are absent or inadequate to inform model uncertainties, the decisionmaker is faced with the options of using whatever data are available, or commissioning and/or waiting for further research. Delaying a decision is not without negative consequences, however, as patients may not receive what is actually the most cost effective intervention and population health will be negatively affected. As an alternative to delaying decisions, eliciting expert opinion can be useful to generate or complement the missing evidence.

Elicitation can transform the subjective and implicit knowledge of experts into quantified and explicit data. Characterizing experts' uncertainty over the elicited values of parameters further used within a decision model, and assessing the consequential impact on decision uncertainty, is particularly important in HTA. It is also useful in exposing disagreements and different degrees of uncertainty among experts. By specifying the 'current level of expert knowledge' as distributions, these can be used to generate estimates of the value of conducting further research to resolve these uncertainties.

There are many possible uses for elicitation in HTA (Box 1). In general, it is relevant where otherwise less informed, implicit or explicit assumptions have to be made. Expert knowledge can, therefore, help to characterize uncertainties that otherwise might not be explored.

Techniques for eliciting uncertain quantities have received a lot of attention in Bayesian statistics. However, it is a relatively new technique in HTA and there are few examples of its use. This article attempts to distill a large literature so as to outline the methods available and their applicability to HTA, using relevant examples from the field. It is not intended to be a comprehensive summary but is instead a general guide with further reading for those wishing to dig deeper.

The stages of an elicitation are divided into: the design of the exercise, its conduct, methods for synthesizing data from multiple experts, and assessments of adequacy of the exercise.

Box 1 Uses of elicitation in HTA decision-modeling

The possible uses of elicitation in HTA decision-modeling include:

- Generating an appropriate set of comparators.
- Identifying appropriate patient pathways and relevant events.
- Describing parameters and their associated uncertainty.
- Quantifying the extent of bias, or improving generalizability from one context to another.
- Characterizing structural uncertainties either through generating differential weights for scenarios or by eliciting distributions of parameterized uncertainties.
- Validating or calibrating model estimates.

The Design Process

Decisions on what quantities to elicit and how to do it should be determined by the intended purpose. There are a number of issues to consider, and these can be categorized as: whose beliefs to collect, what and how to elicit, and specificities of elicit complex parameters such as beliefs regarding correlation.

Whose Beliefs?

There is a large literature on the selection of experts. The criteria range from citations in peer reviewed articles to membership of professional societies. There is no consensus on the best approach. It is generally agreed that an expert should be a substantive expert in the particular area. However, the issue of whether an expert should possess any particular elicitation skills (e.g., previous experience of elicitation) is less clear and will depend on the complexity of the task. Experts with statistical knowledge may be required for elicitation of quantities such as population moments or parameters of statistical distributions, though most experts can be assumed to provide reasonable estimates of observable quantities, such as proportions. In selecting experts, ideally only those without competing interests should be chosen so as to reduce motivational bias. Once the analyst has selected the expert group, one needs to decide how many experts to include in an exercise. Generally, multiple experts will provide more information than a single expert; however, there is a lack of guidance regarding the appropriate number of experts.

 doi:10.1016/B978-0-12-375678-7.01406-1

What to Elicit?

Although previous elicitations have often sought to elicit probabilities or numbers of events, costs, quality of life weights, and views on relative effectiveness can also be elicited. Once the analyst has decided on the parameters to elicit, the methods of doing so come to the fore. There are several methods available. When eliciting, for example, a transition probability, experts can be asked to indicate their beliefs regarding the probability itself, the time required for x% patients to experience the event, or the proportion of patients who would have had experienced the event after y amount of time. In other words, conditional on particular assumptions, evidence on each of these aspects can inform the same parameter. In selecting an appropriate method, there is a need to consider the compatibility of the format with that of other evidence in the model to be used jointly with the elicited judgments. Where multiple parameters are to be elicited, the analyst may promote some homogeneity in the quantities used, avoiding, for example, seeking judgments on transition probabilities by using proportions of patients for some parameters and the time required for x% patients having had experienced the event for others. It is also generally accepted that experts should neither be asked regarding unobservable quantities nor regarding moments of a distribution (except possibly, the first moment, the mean) or coefficients for covariates.

How to Elicit?

After choosing which quantities to elicit, the expert needs to be able to express his/her uncertainty over each. Previous applications of elicitation techniques have found that nonnumerical expressions of uncertain quantities can be useful. However, obtaining quantitative rather than qualitative judgments on the level of uncertainty is required in a decision model. This is usually done by asking experts to specify their beliefs over a manageable number of summaries characterizing their uncertainty surrounding the quantity of interest. Ideally, the focus should be on eliciting summaries with which the experts are familiar and it is generally agreed that experts do not perform well when asked directly to provide estimates of variance. It can also be useful to elicit quantities that are conditional on observed or hypothetical data.

Experts can be asked to reveal credible intervals directly (the range of values that an expert believes to be possible within a specified degree of credibility, usually 95%) or other percentiles of the distribution. Variable interval methods can be used, where percentiles are prespecified and the expert is asked to indicate intervals of values in accordance with their beliefs regarding the particular parameter. Alternatively, the fixed interval method, which is also based on percentiles, requires the analyst to specify a set of intervals that a specific quantity X can be contained within. The expert then gives the probability that X lies within each interval.

A method that has been applied previously in HTA is the histogram technique or probability grid. This is a graphical derivation of the fixed interval method where the expert is presented with possible values (or ranges of values) of the quantity of interest, displayed in a frequency chart on which he/she is asked to place a given number of crosses in the intervals or 'bins'. Histograms are appealing to even the least technical of experts (see **Box 2** for an example of this method in practice).

Eliciting Complex Parameters

Complex parameters include joint and conditional quantities, regression parameters, and correlation, and transitions in a multistate model (e.g., a Markov model). Perhaps the most common challenge arising with parameters that are interdependent is that a joint distribution may need to be elicited. The analyst can assess the model's sensitivity to variations in the correlation coefficient, or estimate the correlation as part of the elicitation exercise. There are a number of methods for eliciting correlations but no consensus regarding the most appropriate method. The methods include descriptions of likely strength of correlation, direct assessment, and the specification of a percentile for quantity X contingent on a specified percentile for quantity Y. However, the complexity of eliciting probability distributions that is conditional on other probability distributions is likely to be too cognitively difficult for many experts. In these circumstances, it may be appropriate to adopt a second best approach and elicit distributions conditional on means or best guesses. This was the approach used by Soares *et al.* (2011), where experts were first asked to record the probability (and uncertainty) of a patient's pressure ulcer being healed when they received treatment with hydrocolloid dressing. For experts who believed that the effectiveness of other treatments was different from the hydrocolloid dressing, the distribution of the relative treatment effects was elicited by asking experts to assume that the value they believe best represented their knowledge about the effectiveness of the comparator treatment, hydrocolloid dressing, was true (reference value). The reference value was the mode (or one of multiple modes, selected at random).

Conducting the Exercise

Explaining the Concept of Uncertainty

Eliciting measures of uncertainty can be complicated, particularly because one wants to ensure that data reflect uncertainty in the expected value rather than its variability or heterogeneity. This is largely a question of the format of the exercise; however, it can also be useful to present contrasting examples of uncertainty and variability to help the expert understand the key distinctions. Visual aids (such as the histogram) can be useful for the elicitation exercise and can help to reduce the burden on experts. It is also helpful to train them, especially when they have limited experience of elicitation. Experts will often respond better to questions and give more accurate assessments if they are familiar with the purpose and methods used in the elicitation exercise. Frequent feedback should also be given during the process and, if possible, experts should be allowed to revise their judgments.

Understanding the Impact of Bias and the Impact of Heuristics

It can be useful to understand how experts judge unknown quantities, in particular, whether they use specific principles or methods in order to make the assessment of probability

Box 2 Application of the histogram method (Soares *et al.*, 2011)

The histogram method is a fixed interval method. The range of values that the quantity may take is partitioned into intervals, and for each interval, information is collected on the probability of observing values. In an empirical application where uncertain quantities were elicited to inform a cost effectiveness model of negative pressure wound therapy for severe pressure ulceration, 23 nurses elicited 18 uncertain quantities. All uncertain quantities elicited were probabilities, thus a common scale was used (from zero to 100). A snapshot of the instrument used, to display the questions, is represented in **Figure 1**.

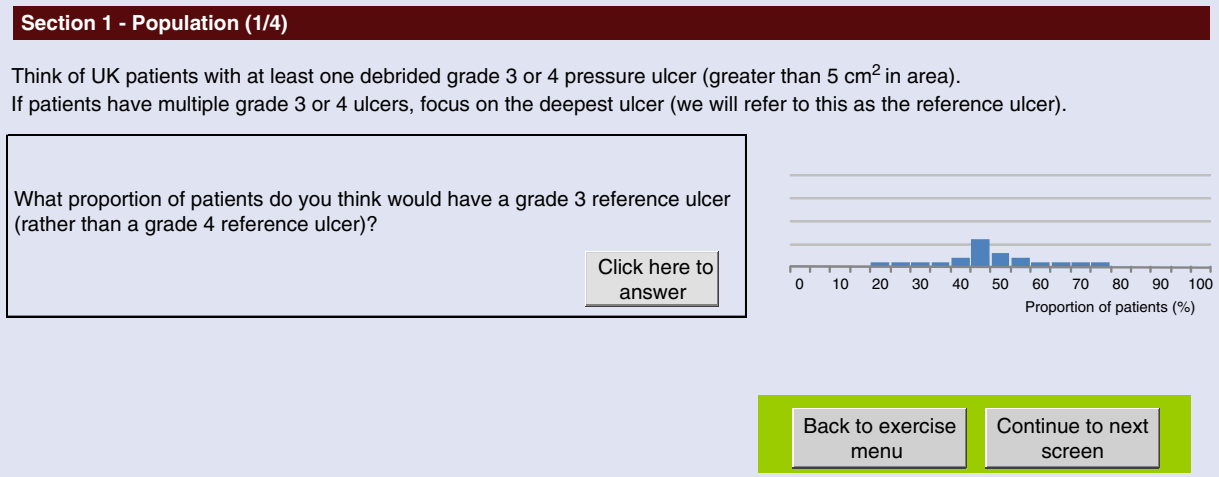

Figure 1 Graphic set-up of the instrument used in the elicitation exercise.

For each uncertain quantity, individual experts were asked to place 21 crosses on a grid defined to have 21×21 cells (**Figure 2**). Note that, for ease, the possible values that the quantity could take were made discrete (i.e., 0, 5, 10, …, 100). By placing the 21 crosses in the grid, the expert is effectively attributing a probability mass to each of the possible values, where each cross represents 4.765% probability. The expert can either express certainty by stacking all of the crosses in the same value (vertical column) or express the full certainty that a value is not possible by not attributing any crosses to it. By attributing one cross to each possible value, the expert is expressing the view that any value could be possible, i.e., full uncertainty.

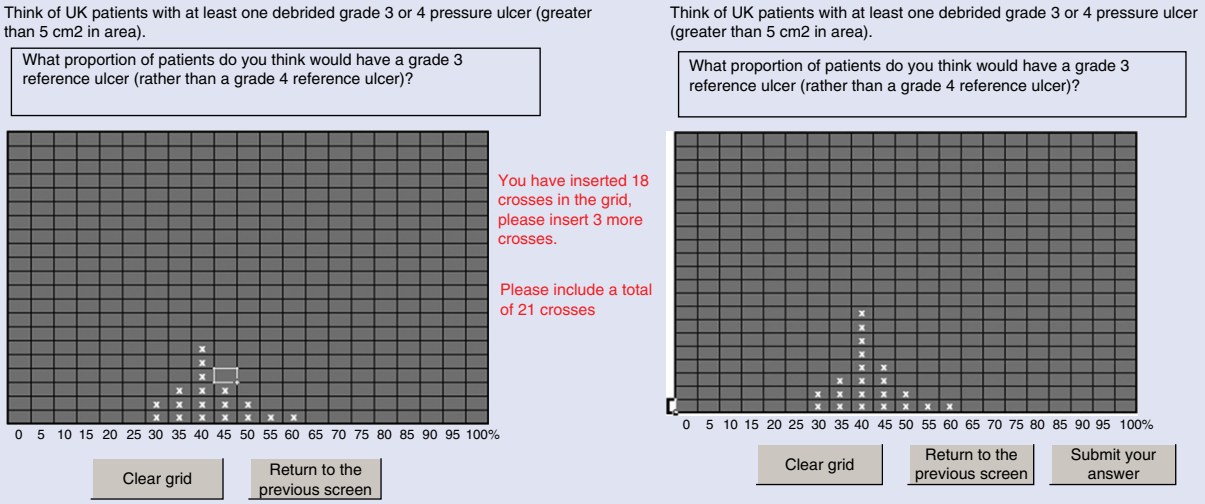

Figure 2 Graphic set up for the data capture histogram.

simpler. These heuristics are useful but can sometimes lead to systematic errors. Garthwaite *et al.* (2005) described the following heuristics: judgment by representativeness, judgment by availability, judgment by anchoring and adjustment, conservatism, and hindsight bias. All these issues should be considered when eliciting probabilities, as each can bias the assessments derived from experts, although the direction of bias is unlikely to be known. In addition, any motivational biases, bias from operational experience, and confirmation biases must be considered and appropriate measures taken to address their implications. Examples of biases in elicitation are described in Box 3.

Box 3 Examples of biases in elicitation

Biases in elicitation can include:

△ Biases associated with experts:

→ Motivation biases: for example, when experts have an incentive (e.g., financial) to reach a certain conclusion.

→ Cognitive biases: these commonly involve the use of heuristics to help reach decisions, solve problems, or form judgments quickly. Examples are:

Conjunction fallacy: When the probability of conjunction (combined) events is judged to be more likely than either of its constituents.

Availability: Where easy to recall events (like natural disasters) are judged to have high probabilities of occurring.

Hindsight bias: The tendency to overestimate the predictability of past events.

Anchoring effect: The tendency to rely on an anchor value that does not provide any information regarding the actual value.

△ Biases associated with elicitation methods:

→ Structuring elicitation questions: biases may arise from how the question is framed, for example, if relevant events have been omitted, experts are unlikely to consider them in replying. But biases can also occur when scales are used; for example, contraction bias occurs when the full range of a scale has not been presented to the expert.

→ Elicitation medium (e.g., interview or email survey) or aggregation method. Experts in group meetings (typically conducted when consensus aggregation methods are applied) tend to adopt a stronger position often resulting in overconfident statements.

Although it is not clear from the literature how most biases can be reduced/avoided, it is good practice to provide experts with an appropriate and comprehensive training session, which may make it clear what biases they might exhibit. The analyst can also attempt to avoid bias in designing the elicitation task, and avoid motivation biases in the selection of experts.

Synthesizing Multiple Elicited Beliefs

When judgments from several experts are required, it is often desirable to obtain a unique distribution that reflects the judgments of all of them. There are two broad methods for achieving this: behavioral and mathematical.

Behavioral approaches focus on achieving consensus. A group of experts is asked jointly to elicit its beliefs, as if it were a single expert, through the implicit synthesis of opinion and without aggregating individual opinions. In this approach, experts are encouraged to interact in order to achieve a level of agreement for a particular parameter. There are a number of behavioral aggregation techniques. The Delphi technique is probably the best known of these and it has been frequently applied to decision-making in healthcare. It involves sequential questionnaires interspersed by feedback and has characteristics that distinguish it from conventional face-to-face group interaction, namely, anonymity, iteration with controlled feedback and statistical response. The Nominal Group Technique is another popular consensus method. Here individuals express their own beliefs to the group before updating these on the basis of group discussion. The discussion is facilitated either by an expert on the topic or by a credible nonexpert. The process is repeated until a single value (or distribution) is produced.

However, there are problems with group consensus. First, consensus may not be easily achieved, and in some circumstances, there may be no value that all experts can agree on. Second, dominant individuals may so lead a group that they effectively determine the view of the whole group. Perhaps most importantly, however, is that a focus on achieving consensus means that behavioral approaches miss the inherent uncertainty in experts' beliefs regarding a parameter. There is a tendency for the group to be overconfident when reaching consensus regarding an unknown parameter.

Mathematical approaches to synthesizing multiple beliefs do not attempt to generate a consensus. Rather, they focus on combining individual beliefs to generate a single distribution using mathematical techniques. Aggregating individual experts' estimates into a single distribution is the preferred approach in applied studies. However, some studies have also used individual experts' assessments as separate scenarios for exploration. Synthesis of data from multiple experts often involves two steps: fitting probability distributions and combining probability distributions.

Fitting Probability Distributions

Fitting probability distributions to elicited data can be undertaken by the analyst either post elicitation or by asking the experts to assess fitting as part of the elicitation exercise. Parametric distributions can be fitted if an expert's estimates can be represented in such a way. The choice of parametric distribution is usually governed by the nature of the elicited quantities. If elicited priors are to be updated with sample information, then choosing conjugate distributions is advantageous for analytical simplicity. However, the development of computational methods has made it possible to choose nonconjugate distributions (i.e., distributions not from the same statistical family). Nonparametric methods can also be used. These do not assume that the data structure can be specified *a priori*; in effect, they have an unknown distribution.

Combining Probability Distributions

There are two main methods for combining probability distributions: weighted combination and Bayesian approaches. Weighted combination is referred to as opinion pooling, more specifically either linear opinion pooling or logarithmic opinion pooling. If $p(\theta)$ is the probability distribution for unknown parameter θ, in linear pooling, experts' probabilities are aggregated using the simple linear combination: $p(\theta) = \sum_i w_i \cdot p_i(\theta)$, where w_i represents a weight assigned to expert i. In logarithmic opinion pooling, averaging is undertaken using multiplicative averaging. These two methods can differ greatly, with the logarithmic method typically producing a narrower distribution for the parameter, implying less uncertainty in the estimate.

An example of the use of linear pooling is described by White *et al*. (2005), they have elicited expert opinion on treatment effects and the interaction between three trials. Experts are asked to assign a weight of belief (up to 100) to intervals of annual event rates. Experts' weights were

then combined by taking the arithmetic mean of individual assessments (linear pooling with equal weighting of experts).

More recently, there has been a move toward using Bayesian models for combining probabilities. Aggregation in a Bayesian model uses the experts' probability assessments to update the decisionmakers' own prior beliefs regarding an uncertain parameter. These methods have not yet been applied in HTA and the need for the decisionmakers' input is likely to be difficult to implement in practice.

If experts have been asked to express their beliefs regarding the value of an unknown quantity using a histogram, number of options are available for aggregation. Linear opinion pooling and Bayesian models can be used to aggregate parametric distributions, fitted to each expert's histogram. Alternatively, the empirical distributions derived can be combined to generate one overall empirical distribution.

Interdependence of Experts

Regardless of the method used to combine experts' probability distributions, an additional level of complexity is introduced when the assumption that experts provide independent beliefs is not sustainable. This is more likely if experts are chosen from the same professional organization or base their beliefs on shared experience or information. In this case, joint distributions should be used, incorporating the covariance matrix for the experts' assessments.

Assessing Adequacy

Four alternative measures have previously been described in the literature for assessing the adequacy of an elicitation: internal consistency, fitness for purpose, scoring rules, and calibration.

Internal Consistency

Internal consistency is particular relevant when eliciting probabilities. An expert's assessment of one (or more) unknown parameters should be consistent with the laws of probability. Achieving coherence may, however, involve more complex reasoning and, in the presence of such complexity, either incoherent judgments are transformed for further use or the exercise is constructed in order to minimize or eliminate incoherence. Qualitative feedback can also be useful in assessing internal consistency. Any discrepancies can be fed back to the experts and appropriate adjustments to assessments can be made.

Fitness for Purpose

Inevitably, some degree of imprecision will remain in elicited beliefs and their fitted distributions. Sensitivity analysis can be useful in discovering whether the ultimate results of the analysis change if alternative (but also plausible given the expert's knowledge) distributions are used. A commonly used sensitivity analysis in a Bayesian framework explores alternative prior distributions. If results do not change appreciably, then the distributions can be said to represent the experts' knowledge and are thus fit for purpose.

Scoring Rules

For parameters that are known or subsequently become known to analysts, comparisons can be made between elicited distributions and those known distributions. This provides an opportunity for assessing the 'closeness' of the elicited and actual distributions. The 'scoring rule' then attaches a reward (a score) to an expert using some measure of accuracy, with those gaining higher scores being regarded as performing better. Commonly used scoring rules are the quadratic, logarithmic, and spherical methods. In the example from Chaloner *et al.* (1993), elicitation was used to inform a model using the intermediate results of a randomized trial. On completion of the trial, comparisons were made between elicited estimates and those based on actual data. It was concluded that the elicitation exercise, although producing some thought-provoking results, did not necessarily predict trial outcomes with much accuracy. Although not done explicitly as part of the exercise, it would have been possible to score experts' beliefs retrospectively, possibly with a view to combining these with the experimental data.

Calibration

The most commonly used method for assessing the adequacy of elicitation is to measure experts' performance through calibration. The basic premise of calibration is that a perfectly calibrated expert should provide assessments of a quantity that are exactly equal to the frequency of that quantity. By asking experts to provide estimates of known parameters, their performance, in terms of distance between their estimates and the true value, can be determined. Unlike scoring rules, measures of performance such as calibration can then be used to adjust estimates of future unknown quantities. Alternatively, a recent example by Shabaruddin *et al.* (2010), used the mean number of relevant patients to derive a weighting for each expert. This was then used to generate weighted means in the linear pooling.

Discussion

Formally elicited evidence to parameterize HTA decision models is yet to be used widely. However, it has huge potential. Compared with many other forms, elicitation also constitutes a reasonably low cost source of evidence. However, the potential biases in elicited evidence cannot be ignored, and due to its infancy in HTA, there is little guidance to the analyst who wishes to conduct a formal elicitation exercise.

This article has summarized the main choices that an analyst will face when designing and conducting a formal elicitation exercise. There are a number of issues, of which the analyst should be particularly mindful, especially the need to characterize appropriately the uncertainty associated with model inputs and the fact that there are often numerous

parameters required, not all of which can be defined using the same quantities. This increases the need for the elicitation task to be as straightforward as possible for the expert to complete.

There are numerous methodological issues that need to be resolved when applying elicitation methods to HTA decision analysis. In choosing to use more complex methods of elicitation, it is also important to note that the complexity of many HTA decision models and the need to capture experts' beliefs, as inputs into these, creates a tension between generating unbiased elicited beliefs and populating a decision model with usable parameters. However, where experimental evidence is sparse, controversial, and difficult to collect, as far as emerging technologies, the need to explore the added value of elicited evidence seems particularly pressing.

Demand Cross Elasticities and 'Offset Effects'

J Glazer, Boston University, Boston, MA, USA, and Tel Aviv University, Tel Aviv, Israel
TG McGuire, Harvard Medical School, Boston, MA, USA

Glossary

Offset effects When use of one service 'offsets' or reduces use of another.

Sufficient statistic In welfare analysis, when a sufficient statistic is available, no data are informative about a welfare effect.

Introduction

The typical analysis of health insurance and service use considers coverage for a single aggregate commodity, 'health care.' It is natural to extend the analysis to more than one service, raising a number of issues in health insurance design. Fundamentally, two covered services can be substitutes or complements. 'Offset effects,' a term common in the empirical literature, refers to the substitute case, when use of one service 'offsets' or reduces use of another. The main insight regarding optimal insurance with multiple services is straightforward: When one service substitutes for another covered service, the increase in demand from insurance generates an efficiency gain from the decreased use of the other covered service. The reason for this is that the other service is itself insured and therefore to a degree 'overused.' The under appreciated subtlety in this result is the role of coverage for the 'other' service. Without coverage and overuse, there is no efficiency gain/loss with a change in demand for the other service. The role of coverage emerges in the analysis of multiple services, and has important implications for the way 'offset effects' should be measured and interpreted.

Concern about multiple services and substitutability and complementarity in insurance design need only be concerned with relationships with other covered services. Other services, if these are not part of the insurance plan even if they are health care services, are irrelevant for questions of optimal insurance. For example, suppose coverage for a certain prescription drug for pain offsets use of over-the-counter analgesics. Because these are not insured, there is no inefficiency associated with their use, and any 'offset' in the use of over-the-counter drugs is irrelevant for insurance design.

Coverage for the 'other good' plays a role in the empirical literature studying cross effects in demand. A large literature in health economics and health services research tests for 'offset effects.' The most active area for current research is on the cross effect of coverage for prescription drugs. Drug coverage is relatively new and variable. Furthermore, effective drug treatment for many, particularly chronic illnesses, might reasonably be expected to prevent/offset the need for other forms of care.

A related question is insurance coverage for 'prevention,' health care that affects the probability of illness. The argument for coverage for preventive services is similar to the offset argument, and rests on the presence of coverage of the service for the illness that would be prevented.

The article begins with a brief review of some of the empirical literature on offset effects, and then considers the issue from the standpoint of welfare economics and insurance design.

Empirical Literature Cross Elasticities

Much of the empirical research on cross elasticities in health care has focused on drugs. Ellison *et al.* (1997) studied cephalosporins, a class of anti-infectives, using IMS monthly time series data from 1985 to 1991, and found significant elasticities between some therapeutic substitutes. More recently, Ridley (2009) investigated cross-price elasticities for antiulcer drugs and drugs to treat migraines using data for 3 million people from a large pharmacy benefit manager (PBM) in the early 2000s. He found large effects on demand when drugs differed in the co-payment from other drugs in their class.

A particularly interesting case of a cross elasticity has emerged in statins, used to treat high cholesterol. In June 2006, the second largest-selling statin, Zocor, became available as generic simvastatin. Statin drugs had very high sales. In 2004, Zocor was the fifth largest selling drug worldwide in terms of dollar sales, and another statin, Lipitor, was the worldwide leader among all drugs from any class greater than $12 billion of sales annually. In response to the availability of generic simvastatin, managed care plans moved Lipitor to higher (less favorable) tiers (Aitken *et al.*, 2008 p. W157). One PBM moved Lipitor to tier 3 in January, 2006 in anticipation of generic simvastatin, and saw more than 40% of patients switch from Lipitor to a lower-tier statin (Cox *et al.*, 2007). Among those with co-payment differences of $21 or more, 80% switched.

It is typical in this literature to measure the 'offset effect' by the effect on total spending not just covered or plan spending on the 'other service.' For example, Shang and Goldman (2007) use Medicare Current Beneficiary Survey (MCBS) data from 1992 to 2000 to show that extra spending, measured by plan plus consumer medical costs, on drugs use induced by Medigap coverage, is more than offset by reductions in total health care spending. Hsu *et al.* (2006) compared medical spending for Medicare beneficiaries with a cap on drug coverage to those without a cap at Kaiser Permanente of Northern California before Medicare Part D. Drug spending was 28% less in the capped group but other

categories of expenditures were higher and total spending for all care was not significantly different between the groups, implying a near dollar-for-dollar offset in total costs. Gaynor *et al.* (2007) studied the effect of increases in co-payments charged for drugs among private employees on total (plan plus consumer) spending. Increases in nondrug spending, largely in outpatient care, offset $0.35 of each dollar saved in drug costs. An exception to the singular focus on total spending is the paper by Chandra *et al.* (2010), finding that the savings in costs due to higher co-payments for drugs were partly offset by higher spending on hospital services among retired state employees in California. They tracked offsets by payer because a primary (Medicare) and secondary (employer-provided supplemental) shared in offsets unequally. Approximately 20% of the cost savings from higher cost sharing for physician services and drugs was 'offset' by higher costs of hospitalization overall, with the offset concentrated among those with a chronic illness. Interestingly, as the authors point out, in the CalPERS case, this offset largely takes the form of a negative fiscal externality from the CalPERS supplemental policy (which saves from the elevated co-payments) to Medicare (which pays most of the costs of hospitalization).

The implicit logic in offset papers is that if total medical costs fall due to an increase in coverage, then the change in coverage is welfare improving (i.e., 'pays for itself'). This article argues that change in total medical spending, meaning the sum of plan and patient out-of-pocket spending, is not the right measure of the economic value (or cost) of a change in insurance coverage due to offset effects. Rather, changes in health plan costs alone measure the economic value of savings due to reductions in the use of other services. Applying methods reviewed by Chetty (2009) and Glazer and McGuire (2012) showed that a 'sufficient statistic' for evaluating the welfare effect of change in coverage for one that is good is the change in total plan-paid costs less the change in costs transferred to/from consumers. They derived an elasticity rule for when the offset effects of an improvement in coverage increases welfare.

A simple argument shows why total costs are not the right welfare measure of an offset effect. Suppose the plan covers just one service, 'health care,' and an increase in coverage of health care increases a consumer's total expenditures on health care. The consumer budget constraint implies that spending on some other noncovered services has to fall. This 'offset' says nothing about efficiency because coverage expansions are always exactly 'offset' in this trivial sense. What if the other affected spending were on another form of health care that was minimally covered in the plan, say for 1% of costs with consumers paying 99%? Logically, token coverage cannot imply that the full spending change as an offset should be counted.

A Model of Offsets in Health Insurance

Suppose a health plan covers services 1 and 2. Quantity of each received by a representative individual in the plan is x_1 and x_2 measured in dollars. Benefits to the individual are $B(x_1,x_2)$, where $B_i \geq 0$, $B_{ii} < 0$, $i=1,2$, with subscripts indicating partial derivatives. Letting c_i denote the co-payment charged for each unit of service i, then the individual demands service i to satisfy:

$$B_i(x_1,x_2) = c_i \quad i = 1,2 \qquad [1]$$

Let R denote the plan premium paid by the enrollee. Assuming the plan makes zero profit, the premium is

$$R(c_1,c_2) = (1-c_1)x_1 + (1-c_2)x_2 \qquad [2]$$

where (x_1,x_2) are given by eqn [1].

The individual's total utility from the plan is thus

$$U(c_1,c_2) = B(x_1,x_2) - c_1x_1 - c_2x_2 - R(c_1,c_2) \qquad [3a]$$

where (x_1,x_2) are from eqn [1] and R is from eqn [2]. Substituting for R to recognize that the individual pays for services by a combination of the cost sharing and the premium:

$$U(c_1,c_2) = B(x_1,x_2) - x_1 - x_2 \qquad [3b]$$

Consider now what happens to utility (welfare) eqn [3b] if the plan were to change the co-payment for service 2:

$$\frac{\partial U(c_1,c_2)}{\partial c_2} = (B_1-1)\frac{\partial x_1}{\partial c_2} + (B_2-1)\frac{\partial x_2}{\partial c_2}$$

$$= (c_1-1)\frac{\partial x_1}{\partial c_2} + (c_2-1)\frac{\partial x_2}{\partial c_2} \qquad [4]$$

The second equality follows from eqn [1].

Suppose co-payment for service 2 is reduced. If $\partial x_1/\partial c_2 > 0$, there is an offset effect and consumption of x_1 falls with this change. What happens to welfare? Equation [4] tells us how to value the offset. Reversing the sign of eqn [4] to get an expression in terms of plan shares, when co-payment for service 2 goes up (down), utility of the individual goes up (down) if and only if eqn [5] holds:

$$\left[\underbrace{(1-c_1)\frac{\partial x_1}{\partial c_2}}_{\text{Offset effect}} + \underbrace{(1-c_2)\frac{\partial x_2}{\partial c_2}}_{\text{Own-price effect}}\right] < 0 \qquad [5]$$

The intuition for this result is the following: The second term on the left-hand side of the inequality captures the inefficiency in consumption induced by the reduction in co-payment for service 2. With health insurance, the marginal benefit of health care is less than the marginal cost ($B_2 = c_2 < 1$), and the extra consumption of x_2 due to the reduction in co-pay creates additional welfare loss. In the conventional analysis of optimal health insurance, this welfare loss is weighted against the risk spreading gain to find the optimal co-payment, c_2. The first term on the left-hand side in eqn [5] is the offset effect due to the change in consumption (in this case reduction) of x_1. Just as with the own-price effect, benefits and costs both matter in valuing welfare of any offset effect. The $1(\partial x_1/\partial c_2)$ part is the reduction in total cost from the change in x_1 and, because $B_1 = c_1$, the $-c_1(\partial x_1/\partial c_2)$ part is the loss in benefits. Thus, the net welfare measure of offset effects is plan's savings: $(1-c_1)\partial x_1/\partial c_2$.

Changes in (consumer's) welfare to changes in plan costs can now be related. From eqn [2] it is known that when co-payment for service 2 changes, the change in the plan costs is

given by

$$\frac{\partial R(c_1,c_2)}{\partial c_2} = (1-c_1)\frac{\partial x_1}{\partial c_2} + (1-c_2)\frac{\partial x_2}{\partial c_2} - x_2 \qquad [6]$$

Equation [4] for changes in welfare, and eqn [6] for changes in plan costs, are the same except for the presence of x_2, the cost shifting effect of a change in c_2, a transfer ultimately paid by the consumer in any case. Using eqns [4] and [6] a rule for a welfare change, in terms of changes in plan-paid costs, can be stated.

Rule for Welfare Effects

The welfare effect of a change in coverage is equal to minus the change in plan costs net of the cost-shifting effect of the coverage change.

Proof. From eqns [4] and [6] the result is

$$\frac{\partial U(c_1,c_2)}{\partial c_2} = -\frac{\partial R(c_1,c_2)}{\partial c_2} - x_2 \qquad [7]$$

This rule for welfare effects constitutes, in Chetty's (2009) term, a 'sufficient statistic' for welfare evaluation of health insurance changes. The measure, change in plan costs less cost shifting, is equal to the welfare change, and thus yields an 'if and only if rule': Welfare goes up if and only if plan costs less transfers go down.

The rule brought out in this article can be used to interpret the existing logic of the offset literature which focuses on total costs, plan paid plus patient paid, and concludes that an improvement in coverage for good 2 is worthwhile if it 'pays for itself' in savings on good 1. Consider a reduction in c_2 that decreases use of covered good x_1 (an offset effect). Suppose the improvement in coverage for x_2 'pays for itself' in the sense that the reduction in the total cost of x_1 exceeds the increase in plan costs for x_2. This rule tells us that this condition is neither necessary nor sufficient for an increase in welfare. It is not necessary because the cost-shifting effect of the change in c_2 is disregarded for welfare. It is not sufficient because it is not total costs that measure the value of the offset, but plan-paid costs. Instead of looking for a coverage improvement to 'pay for itself,' the following simple rule, expressed in terms of demand elasticities for when an improvement in coverage improves welfare via an offset effect, is proposed.

A Simple Rule for When Offsets Increase Welfare

Welfare goes up with a decrease in c_2 (improvement in coverage) when the partial derivative in eqn [4] is negative, or alternatively

$$(1-c_1)\frac{\partial x_1}{\partial c_2} > -(1-c_2)\frac{\partial x_2}{\partial c_2} \qquad [8]$$

Putting this in elasticity form and dividing through by $-\varepsilon_{22}$ (a positive number), the criterion for a welfare improvement with a decrease in c_2 becomes

$$-\frac{\varepsilon_{12}}{\varepsilon_{22}} > \frac{(1-c_2)x_2}{(1-c_1)x_1} \qquad [9]$$

In eqn [9], ε_{12} is the cross and ε_{22} is the own-price elasticity with respect to c_2. The RHS of eqn [9] is positive and equal to the ratio of plan paid costs for service 2 to service 1. The following rule can now be stated: For a decrease in c_2 to improve welfare, the goods must be substitutes ($\varepsilon_{12} > 0$); and the ratio of the absolute values of the cross to the own-price elasticity must exceed the ratio of the plan paid costs for the two services.

The offset rule for welfare is simple to apply. Suppose it is known that the own-price elasticity of drugs is -1.0 and the cross-price elasticity for hospital services is $+0.2$. If the plan paid drug costs are less than 20% of the plan-paid hospital costs, an improvement in coverage for drugs improves welfare.

Attention to plan rather than total cost can change the tenor of the policy implications of offset effects, particularly for drug coverage where plan shares are relatively small. Turning to some results in significant recent offset papers illustrates the quantitative importance of the plan-cost perspective. Comparing the change in total costs for drugs and hospitals, Chandra *et al.* (2010, p. 208) found that a decrease in coverage for drugs reduced total drug costs by $23.06 per member per month, but increased total hospital costs by only $7.23 – the offset amounted to only a 1:3 ratio of hospital cost increases to drug cost savings, and in the authors' judgment was 'unlikely to be enough' to reverse the perceived value of the co-payment increase. However, taking the plan rather than total cost perspective it can be said that because drugs are covered at roughly 50% and hospital cost at 100%, the offset ratio doubles, to approximately 2 to 3. It should be noted here that the California change studied in Chandra *et al.* (2010) also involved increases to outpatient co-pays, which are ignored in this illustrative example. These increases also saved money, making the offset ratio 1:5. By ignoring this other benefit change in this discussion, it is, in effect, assumed that it is the drug coverage change that causes the offset.

Final Comments

In applied policy research, offset effects played an important role in the discussion about the design of optimal health insurance for mental health treatment, and more recently they do so in the case of coverage for drugs. Most public and private plans cover drugs, but the coverage is partial in the sense that a drug formulary typically excludes many drugs, and for those drugs that are covered, the percent paid by the plan is much less than for other health care services. Interestingly, the co-payment for generic drugs is often so high that it exceeds the acquisition cost to the health plan. The ideas in this article about valuing offset effects have the most current direct application to the question of coverage for drugs. If health insurance markets worked perfectly, competition would maximize welfare of the representative consumer, implying the efficiency issues discussed here would be taken care of in competitive equilibrium. Health insurance markets are fraught with sources of market failure, however, such as moral hazard, adverse selection, imperfect competition, externalities due to the participation of multiple insurers, as well as concerns about equity. In many cases there can be little assurance that

market forces alone will lead to optimal coverage, leaving a role for calculations of the type illustrated here.

The major limitation of this rule for offsets and model setup generally, stems from the assumption that quantity is determined by the equality of marginal benefit to the consumer/patient and patient co-payment. Although the standard demand model is widely applied in theoretical and empirical health care research, it is also seriously questioned as a basis for describing the outcome of patient–provider interactions. Effective physician agency on behalf of the patient would be consistent with this approach, but it is acknowledged that the marginal benefit–marginal cost equality is still a strong assumption. Relatedly, health economists doubt whether consumer demand should be interpreted as marginal benefit when assessing the efficiency of changing coverage. Perspectives from 'value-based insurance design' and behavioral economics both question the conventional welfare framework for assessing the efficiency cost of added coverage for a service.

Demand for and Welfare Implications of Health Insurance, Theory of

JA Nyman, University of Minnesota, Minneapolis, MN, USA

Introduction

Importance of the Theory

Why do consumers purchase health insurance? To purchase anything, the consumer must give up something, and in the case of health insurance, that 'something' is the premium payment. Although the nature of the premium payment is clear (to both consumers and economists), what is not clear is the nature of the benefits that consumers receive in return. This represents the central objective and the challenge of health insurance theory: to describe just what it is that consumers receive in return for the premium. If this is known, then why consumers purchase health insurance will be known.

This is an important question because it can affect consumer welfare in fundamental ways. From the perspective of the insurance firm, if insurers knew precisely what it is that people value in insurance, they would be able to design more competitive insurance contracts, contracts that provide more of what consumers want to purchase. From a public policy perspective, policy makers would be able to design more efficient and effective government health insurance programs, implement more equitable subsidies and taxes, and encourage more efficient behavior with regard to the types and amount of health care insured consumers purchase. From a larger social perspective, if it were known why consumers purchase health insurance, politicians would better know the value of health insurance relative to other goods and services, and thereby better understand the importance of health insurance programs compared to all the other programs that government could sponsor.

Complexities of Health Insurance

Although this might seem like a relatively straightforward exercise, it is not. Insurance contracts have a number of complexities that make them difficult to analyze. Here is a listing of the most important ones. It should be noted that many of these complexities were identified by Kenneth Arrow in his famous 1963 paper on the characteristics of the medical care portion of the economy that make the sector unusual.

First, there is the uncertainty with regard to illness itself: not everyone becomes ill during the contract period and many of the benefits that consumers derive from paying a premium occur only if they become ill. Payoffs that are contingent appear in many types of contracts so they are not unusual, but they always make things more complex because they require the consumer to think about what might happen in the future.

Second, because illnesses vary, there is uncertainty with regard to the cost of treating illness. Some illnesses require health care expenditures that are relatively affordable to the typical consumer, but other illnesses are catastrophically expensive. Not only do the costs of different illnesses vary, but also the resources available to individuals if they were to remain uninsured and had to pay for health care themselves. That is, some consumers who become ill are rich and some are poor. On top of that, the diseases and the procedures used to treat them may also reduce the budget if the consumer is no longer able to work and make income. The variation in economic circumstances of consumers interacts with the variation in the cost of the illness, and both conspire to make a large portion of health care expenditures unaffordable to a substantial segment of the population. This complexity must also be accounted for in the theory.

Third, uncertainty also occurs with regard to the effectiveness of the health care in treating the disease. Sometimes the health care cures the disease, and sometimes it does not. Indeed, sometimes the health care is represented only by the palliative care during the short period before death. Although the variability in the effectiveness of the health care is a consideration in the purchase of insurance, it is clear that modern health care is often effective and for that reason, can be very valuable to the consumer. Thus, the value of the health care covered by the insurance benefit is a consideration in determining why consumers purchase insurance. This is especially true in light of implication of the second complexity that sometimes the health care would not be affordable and thus accessible to the consumer without insurance.

Fourth, the contingent benefit of insurance is based on the consumer transitioning from a state of being healthy to a state of being ill. The change in health state clearly affects how one values medical care – what 'healthy' person would value chemotherapy or a leg amputation enough to 'consume' it? Sometimes, the change in health state can also affect how consumers value the other goods and services that can be purchased. For example, some illnesses can be in the form of a broken bone or a minor respiratory disease, where it is clear that one is feeling poorly on a temporary basis and the state of illness represents largely an inconvenience. Other illnesses, however, may have severe symptoms in terms of pain and ability to function normally, be chronic, or threaten the lives of the individuals suffering from them. Thus, when thinking about the value of all the benefits of an insurance contract, the consumer would likely need to consider how they would regard the benefits of insurance if they were filtered through the perspective of being in an ill state. In the ill state, consumers may appreciate the various aspects of life – both the medical care and the income to spend on entertainment, travel, and other consumer goods – differently than in a healthy state, and this would bear on how the benefits of insurance are perceived and evaluated. Theorists who desire to model why people purchase insurance would need to acknowledge this change in perspective in order to produce a complete theory.

Fifth, health insurance contracts are not perfect. Although we may think about illness as an exogenous event that we have no control over, in actuality, we have a great deal of control over whether we become ill. For example, whether we develop heart disease is associated with a number of discretionary

 doi:10.1016/B978-0-12-375678-7.00906-8

behavioral choices – whether we smoke, are overweight, exercise, eat cholesterol-laden foods, etc. Insurance contracts (so far) do not distinguish between illnesses that are brought on by the behavior of the insured and those that are caused by factors beyond the control of the individual. The problem this creates for insurance is that sometimes being insured might alter the extent to which a consumer acts to avoid disease. 'Moral hazard' is the term that those in the insurance business use to describe the changes that occur in behavior of the insured and '*ex ante* moral hazard' is the term used by economists to describe the type of behavioral change where the probability of becoming ill increases when an individual becomes insured.

Sixth, most health insurance contracts simply pay for the sick consumer's health care. As a result, the amount of the insurance benefit when ill is not fixed in advance of becoming ill (nor is the benefit even totally dependent on becoming ill). Insurers often pay for more health care than the ill consumer would pay for if they had remained uninsured. '*Ex post* moral hazard' is the term used to describe the type of behavioral change where once insured persons become ill, they purchase more health care and incur greater expenditures than they would if they were not insured and were paying for the care themselves.

And finally, the basic idea behind insurance is that many people who are not ill pay into a pool in order to benefit the few members of the pool who become ill during the period of insurance coverage. This means that one of the fundamental incentives for prospective purchasers of insurance is to try to join the pool 'after' one becomes ill, in order to avoid paying premiums during the years when one is not ill. This phenomenon is called 'adverse selection' and is represented by the tendency of those who purchase insurance to be sicker or more prone to becoming sick, and therefore more costly to insure, than the average person. If the insurer does not catch this bias and charge these people higher premiums, the firm would pay out benefits that are greater than the premiums it takes in. Again, health insurance contracts are not perfect.

Modern health insurance plans often provide other benefits – the ability to bargain down producer prices, the evaluation of new technologies for effectiveness, the screening of physicians and other providers for quality – that add to the complexity, but those that are listed above represent the major complexities associated with the *quid pro quo* of the traditional insurance contract. In the discussion that follows, we consider how improvements in our understanding of insurance have coincided with increases in the benefits that are recognized to derive from insurance. We begin, however, with the conventional theory that the demand for health insurance is simply related to the avoidance of the uncertainty associated with illness and the loss of income that paying for one's own health care would entail.

Conventional Insurance Theory

The Gain from Certainty

The conventional theory of demand for 'health insurance' was originally borrowed from the theory of the demand for 'insurance,' which was concerned primarily with a type of indemnity policy where the consumer possesses a certain asset for which they desired protection from loss. For example, a homeowner might want protection from fire. The consumer has the choice between remaining uninsured and accepting the chance that the asset and its value might be lost to fire, or paying a premium for an insurance contract that would pay the consumer a lump-sum payment equal to the value of the asset if the asset were lost. Assuming that there is no difference between the premium payment and the expected loss if uninsured – that is, assuming that the insurance premium is actuarially fair and nothing extra is included in the premium to cover the administrative costs of the insurer – the consumer is better-off with insurance.

The insurance decision for this type of loss was laid out in 1948 by Milton Friedman and L. J. Savage in what has come to be regarded as the seminal article in the health economics literature (Friedman and Savage, 1948). **Figure 1** shows the fundamental relationship that economists assume exists between utility, on the one hand, and either income or wealth, on the other. Utility increases with income or wealth, but at a decreasing rate. The shape of this curve, U, derives from that intuitively appealing principle that consumers would gain more utility from a given amount of additional income or wealth (that is, consumers would value or appreciate it more) if they were poor than if they were rich. For example, a consumer with \$20 000 in wealth gains more utility from an additional \$1000 than he would if he had started out with \$100 000 in wealth.

The gain from purchasing insurance can be demonstrated using **Figure 1**. A consumer starts out with assets (or income, but for simplicity, the discussion will use assets) of \$100 000 and is faced with a 50% chance of becoming ill and incurring a \$80 000 loss due to the need to purchase a medical procedure. The utility function, U, indicates the utility of \$100 000 is $U(\$100\,000)$ and the utility of \$20 000 is $U(\$20\,000)$. Without insurance, the expected value of the consumer's assets is \$60 000 because he starts out at \$100 000, but loses \$80 000 with a 50% probability, so the expected loss is \$40 000. Similarly, with regard to utility, without insurance, the consumer starts out at utility of $U(\$100\,000)$ but falls to $U(\$20\,000)$ with a 50% probability, so the expected utility is $EU(\$60\,000)$ as in **Figure 1**. Thus, point A represents the expected position of the uninsured consumer facing a loss of \$80 000 with a 50% chance.

Assume that the insurer charges the actuarially fair premium, one that reflects only the expected payout and none of the administrative costs or profits. The actuarially fair premium is \$40 000 because that is the amount that the insurer expects to payout for each person that is insured for this illness (that is, \$80 000 payout times the 0.5 chance of illness, for each person who is insured). If the consumer pays such a premium and purchases insurance, she will have \$60 000 regardless if healthy or ill. If the consumer stays healthy, she would start out with \$100 000 in assets, would have no health care expenditures and receive nothing in payout from the insurer, but would pay a \$40 000 premium, leaving \$60 000 in assets. If the consumer becomes ill, she would start out with \$100 000 in assets, would incur health care expenditures of \$80 000, would receive \$80 000 from the insurer, but must pay a \$40 000 premium, again leaving \$60 000 in assets. Thus,

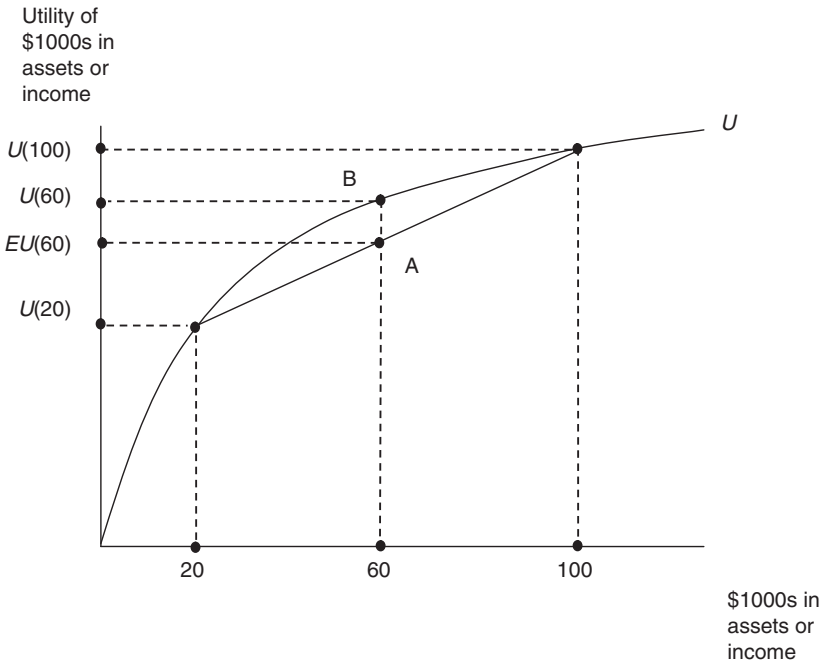

Figure 1 Gain from insurance under conventional theory.

regardless of whether the consumer stays healthy or becomes ill, if she purchases this insurance, she has $60 000 in assets. The utility of $60 000 with certainty is determined by the utility function as U($60 000), and so with insurance, the consumer would be at point B in Figure 1. The gain in utility from insurance is measured by the vertical distance between points B and A, or the difference between U($60 000) and EU($60 000) on the vertical axis. This difference in utility is the welfare gain from buying health insurance under the conventional theory, and represents the sole reason for purchasing it under this theory.

To this theory was added the complexity of loading fees (the additional amount that the insurer includes in the premium to cover administrative costs and profits), but the basic source of the gain remained the same. Friedman and Savage interpreted this gain as satisfying the consumer's preference for certainty, as opposed to uncertainty, and many have viewed the benefits of health insurance from this perspective. Based on this theory and the utility gain from the certainty that health insurance contracts provide, Arrow concluded in his 1963 article that the case for health insurance was 'overwhelming.' This is the theory that has been used over the years to explain why consumers purchase health insurance.

Limitations of the Theory

The theory, however, has a number of limitations. First, the theory would only apply to those medical procedures that are affordable. This is because there is no uncertainty if the loss cannot occur, and this would most likely be the case if the cost of the procedure is so high that the ill consumer cannot pay for care. It is possible that the consumer might be able to borrow the additional resources, but an uncollateralized loan for a risky procedure would be difficult to obtain and so this option is limited at best. Saving for the procedure is also possible, but saving when ill may be out of the question because of the ill consumer's diminished earning capacity and the limitations on time available. Thus, this theory does not recognize that many procedures and health care episodes may be too expensive to be financed privately, save for insurance. This is an important omission because, given that about half of all health care expenditures in the US are incurred by the top 5% of spenders (Stanton and Rutherford, 2006) and that those under 65 in the lowest quartile of the income distribution in the US have virtually no net worth and those in the second lowest quartile of the income distribution have net worths that average close to their annual income (Bernard *et al.*, 2009), procedures that are too expensive for consumers to afford to purchase privately make up a substantial proportion of health expenditures in the US.

Second, the 'loss' in this theory is the income or assets lost due to the spending on the medical care. In contrast to the simple destruction of an asset (e.g., a house burning down), the spending on medical care is not really a loss, but part of *quid pro quo* transaction where the consumer spends income or wealth to obtain medical care. The medical care that the consumer obtains in return for this 'loss' may be very valuable, but the value of the medical care does not appear in the model.

Third, the model assumes that the utility that the consumer gains from income or assets when ill is the same as the utility when healthy. For example, it assumes that $100 000 in assets is just as valuable when healthy and being spent on restaurant meals, gas for the car, etc., as it would be when ill and being spent on restaurant meals, gas for the car, and a $50 000 medical procedure that saves the consumer's life. In fact, this model implicitly assumes that the utility from income is

derived 'only' from the nonmedical care purchases that one can make with income, and that becoming ill does not alter at all the utility that is derived from these purchases. And as was noted, the utility from income that can be used to purchase medical care when ill simply does not enter the model.

Fourth, as mentioned, the motivation for purchasing insurance under this model was interpreted by Friedman and Savage to reflect the consumer's natural preference for certain ones over uncertain ones and that this preference for certain losses summarized the reason why consumers purchase health insurance. Whether consumers actually do have a preference for certain losses over uncertain ones has been tested by Kahneman and Tversky. In a series of experiments that led to the formulation of prospect theory (and to a Nobel prize in economics for Kahneman), these researchers found that consumers generally prefer uncertain losses to certain ones of the same expected magnitude, the opposite of what the conventional insurance theory asserted (Kahneman and Tversky, 1979). If this preference for uncertain losses is generally true of consumers, as the experiments appeared to show, then the demand for health insurance cannot be attributed to a preference for certain losses.

Fifth, the payoff in this theory is in the form of a lump-sum transfer of income to the insured. Although such a policy is possible and actually exists for some types of insurance, such as personal accident insurance (e.g., policies that pay $50 000 for the loss of sight in one eye), most health insurance policies pay off by paying for care (or a portion of it after some copayment by the insured). Moreover, spending (that is, the loss) with and without insurance is assumed to be the same in this simple model. As a result, this model does not allow for moral hazard.

Moral Hazard Welfare Loss

Of all the limitations of this risk avoidance model, the one that was seized on initially was the lack of recognition of moral hazard – but not all moral hazard, only *ex post* moral hazard. As mentioned earlier, economists distinguish between two types of moral hazards. *Ex ante* moral hazard occurs when the consumer takes less care to avoid losses if insured than if not insured. For example, because health expenditures are covered, a consumer might have an increased probability of illness if insured, compared with if uninsured. *Ex post* moral hazard was defined originally as the additional spending that occurs after one becomes ill, insured versus uninsured. Recently, some economists have suggested that *ex post* moral hazard is represented only by the portion of the change in this behavior that is due to a response to prices, but that was not the original view. This distinction has come about only recently, because for a long time it was thought that *ex post* moral hazard was 'only' a response to prices.

In a 1968 comment on Arrow's (1963) article, Pauly wrote what was to become 'one of the,' if not 'the,' most influential articles in the health economics literature. Pauly's article led to almost a 'preoccupation' among American health economists with the notion that the basic problem with the high health care costs in the US was the consumption of too much care (and, implicitly, not the high prices of health care). This perspective, in turn, led to important policy initiatives in the US over the next 30 or 40 years that focused on reducing the quantity of care: The introduction of copayments into insurance policies, the adoption of managed care, and the promotion of consumer-driven health care (where policies with large deductibles are paired with health savings accounts). Indeed, some economists argued during this period that high prices of medical care were beneficial because they choked off demand by making coinsurance rates more effective.

Pauly's argument recognized that health insurance policies paid off not by paying a lump-sum amount when the consumer became ill, as the Friedman and Savage model assumed, but by paying for any health care that the individual consumed. Thus, the impact of insurance on the consumer's behavior was essentially to reduce the price of health care, to which the consumer responded by demanding a greater quantity of care. **Figure 2** shows the observed or Marshallian demand for health care, D, by the individual consumer and the quantity of health care consumed, m_u, if uninsured and if 1 is the price of a unit of medical care, m. If the consumer becomes insured under a contract where the insurer pays for a percentage of care represented by $(1-c)$ with c representing the coinsurance rate, then the price of care that the consumer faces effectively drops to c and the consumer purchases m_i quantity of health care. So, *ex post* moral hazard is represented by the increase in consumption from m_u to m_i.

The problem with moral hazard according to Pauly's model is that the additional care is worth less than the cost of the resources used to produce it. If the health care market is competitive, then the market price of health care, 1, would also represent the marginal cost of the resources used to produce the care, that is, the value of the goods and services that the same resources could have been produced in their next most valuable use. The marginal cost curve represents the cost of producing each of the units of health care, given the assumptions of the model. The value of health care is measured by the willingness to pay for it, as shown by the height of the demand curve at each level of m. For example, according to the demand curve, the willingness to pay for the m_u unit of medical care is just equal to 1, the market price. If the price were to drop to c because of insurance, the additional health

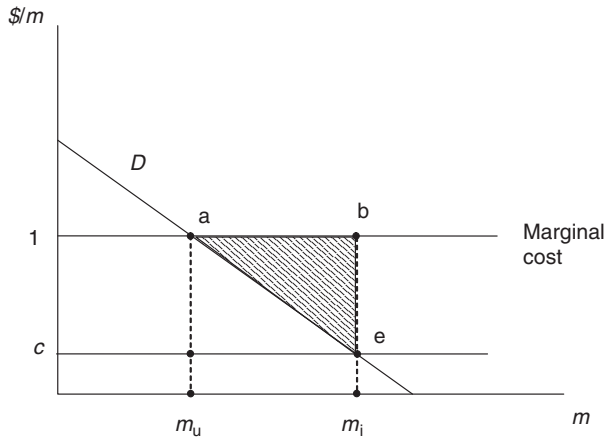

Figure 2 Welfare loss from moral hazard under the conventional theory.

care consumed, that is, the moral hazard, is $(m_i - m_u)$. The value of this additional care is represented by the area under the demand curve, area aem_im_u. The cost, however, is the area under the marginal cost curve, or abm_im_u. Costs exceed the value by the area *abe*. This area, then, represents the welfare loss associated with moral hazard.

Empirical and Professional Support

With the publication of Pauly's paper, the conventional theory of the demand for health insurance was now set. The demand for health insurance was represented by the gain from averting the risk of loss, but it was necessary to subtract from this gain the welfare loss from *ex post* moral hazard. Pauly thought that the loss was potentially so important that the net effect, 'could well be negative' (Pauly, 1968, p. 534), implying that insurance could make the consumer worse-off, especially if the government mandated its purchase. In 1973, Martin Feldstein empirically estimated the net gain from health insurance in the US based on conventional theory and concluded that "the overall analysis suggests that the current excess use of health insurance produces a very substantial welfare loss" (Feldstein, 1973, p. 275). Feldstein argued that raising the coinsurance rate to 67% across the board would improve welfare. This view persisted over the remainder of the century and into the next. In 1996, for example, Willard Manning and Susan Marquis found that low coinsurance rate health insurance policies also resulted in a net welfare loss based on conventional theory and concluded that a coinsurance rate of approximately 45%, also across the board and with no limit on out of pocket spending, would be optimal.

During the same period, a health insurance experiment – the most costly social experiment ever performed in the US – was also conducted by the RAND Corporation. The RAND Health Insurance Experiment randomly assigned some participants to receive free care and others to care with some form of cost sharing. As was expected, those assigned to free care consumed more medical care – both physicians services and hospital admissions – than those who had to pay for a portion of the cost of their care, but more importantly, aside from better correction of vision problems, there was no significant improvement in health for those who received more care (Newhouse, 1993). Thus, the influential findings of the RAND health insurance experiment fit the Pauly's model like a glove: Insurance generated additional care, but the additional care was not very valuable because it did not result in any important improvements in health.

Why Pauly's focus on *ex post* moral hazard caught on among American economists is not clear: after all, two other sources of inefficiency in health insurance contracts – *ex ante* moral hazard and adverse selection – were also broadly recognized at the time. *Ex ante* moral hazard would have generated a similar welfare loss from the reduction in purchase of efficient health preservation services and the increase in the purchase of inefficient health recovery services once ill (medical care), because the prices of the recovery services were made to be artificially low relative to the prices of the health preservation activities. The inefficiency associated with adverse selection (the nonpurchase of insurance by those who would have purchased insurance were it not for the high premiums caused by adverse selection) was also broadly recognized at the time, but this inefficiency did not rise to the level of a component of the basic theory. Although the confirmatory studies by influential economists were clearly a factor, perhaps even more important for its appeal was that it underscored the importance of competitive prices, which was consistent with the prejudices of economists. Moreover, its diagrammatic argument was accessible, elegant, and easily taught.

Alternative Theory

The Gain from an Income Transfer When Ill

Recently, an alternative theory has been suggested that incorporates all the factors that were limitations to the conventional theory (Nyman, 2003). The basic notion is that health insurance represents a *quid pro quo* contract where the consumer pays an actuarially fair premium to the insurer when healthy in order to receive a lump-sum income payment if the insured were to become ill during the period of time covered by the insurance contract. If the insured consumer does not become ill, the contract holder simply relinquishes the insurance premium. An actuarially fair health insurance contract is therefore purchased because the utility gained from the additional income if ill exceeds the utility lost from paying the premium if the consumer remains healthy.

This theory is fundamentally different from the Friedman and Savage theory because it does not incorporate a designated loss when ill as part of the insurance decision. That is, there is no loss of assets or income from illness recognized by the theory. As a result, there is no 'preference for certainty' in this model and no 'smoothing of income' across the states of the world, as some have interpreted the Friedman and Savage approach to imply. The only loss of income that occurs in the alternative model is the loss of the insurance premium if the insured person remains healthy. Because the theory does not incorporate a designated loss, the income payment when ill can be any amount and does not need to reflect the spending that would occur without insurance.

Advantages over Conventional Theory

This theory has a number of advantages over conventional theory. First, the theory is not limited to explaining the demand for insurance coverage for only that portion of medical care that the consumer could otherwise purchase if uninsured (the portion that would generate a loss of income and/or wealth due to such spending), but it also explains why consumers purchase insurance coverage for medical care spending that would exceed the consumer's resources. Indeed, the access that the insurance payoff provides to that medical care that would otherwise be unaffordable is one of the main reasons why insurance is purchased under this alternative theory.

Second, the value of insurance is directly linked to the value of the medical care that the consumer can purchase as a result of being insured and receiving an income payoff when ill. As was mentioned, some modern medical care is

ineffective, but much of it is very effective and can generate large health improvements, both in terms of limiting the negative effects of illness and expanding life expectancy. The health improvements derived from this medical care can be very valuable to consumers, and there is often no alternative (private) means for obtaining this care other than to purchase insurance. This value, entirely missing from the conventional model, is emphasized in the alternative model.

Third, this model recognizes that consumer preferences can be altered when the consumer becomes ill by specifying two utility functions for both consumer commodities and medical care: one when healthy and another when ill. This allows for the consumer to incorporate a different evaluation of consumer goods and services in the two states. For example, is spending on traveling or home improvements as valuable when ill as when healthy? But, more importantly, it allows for a different evaluation of medical care by the consumer in the two states. For example, is spending on a new heart valve or leg amputation as valuable when healthy as when ill? It recognizes that illness changes preferences so that a coronary bypass procedure or course in chemotherapy now becomes valuable, whereas it would reduce utility if purchased when healthy. Under this theory, insurance is the mechanism by which an increase in income occurs at precisely the same time as the onset of illness generates a change in preferences, making it possible to purchase the medical care services that would not be valued or purchased, given preferences when healthy.

Fourth, rather than trying to explain the purchase of insurance by claiming that consumers generally exhibit a preference for certain losses over uncertain losses of the same expected magnitude – a claim that has been thoroughly discredited and indeed proved to be diametrically opposed to the preferences of most consumers by the empirical studies underlying prospect theory – the alternative theory suggests that preferences for certainty are not part of the demand for health insurance at all. Uncertainty exists in life, clearly, but insurance cannot do anything about it other than to coordinate the uncertain occurrence of illness with an equally uncertain payment of income.

Fifth, the conventional theory focuses on a welfare loss from *ex post* moral hazard, all of which is deemed to be welfare decreasing because it is generated by a reduction in price and a subsequent movement along the consumer's demand curve with a payment of income. It is as if a hospital suddenly announced a sale on coronary bypass procedures and additional shoppers flocked to take advantage of the bargain, whether they were ill and needed a bypass operation or not. With the alternative theory, the price reduction is the vehicle by which income is transferred from those who purchase insurance and remain healthy to those who purchase insurance and become ill. As a result, the price reduction applies only to those who are ill enough to need an important health care intervention and the income transfer within the price reduction works to shift out the demand curve of those who are ill. It is as if a hospital suddenly announced a sale on coronary bypass operations and those additional patients who now flocked to the hospital are only those who suffered from coronary artery disease and could not afford to purchase the procedure at the existing market prices.

Welfare Implications of Moral Hazard

Actually, the moral hazard response to the price reduction under the alternative theory requires some additional explanation because it can be partly a response to the price decrease that is used to transfer income and partly due to the income transfer itself. Indeed, this is one of the important implications of the new theory: Some of the additional spending due to insurance (moral hazard) is efficient and due to the income transfer, and some is inefficient and due to using the price reduction to transfer income. It is the efficient moral hazard that represents one of the most important reasons for purchasing insurance. At the same time, inefficient moral hazard also exists, but it is not quite the same as described by Pauly (1968). A short explanation is required.

As described earlier, conventional theory suggests that the response to insurance can be described as a movement along the observed or Marshallian demand curve. In **Figure 2**, at the market price, 1, a certain amount of medical care, m_u, is demanded. If insurance was purchased, the price of medical care faced by the consumer is c, then m_i would be purchased. Thus, conventional theory uses the Marshallian demand curve to show the response to insurance. With insurance, however, the price does not simply drop due to exogenous market forces as would be consistent with the Marshallian demand, but instead, the price reduction must 'be purchased' by paying the premium for an insurance contract. Moreover, the greater the price reduction or lower the coinsurance rate specified in the contract, the greater the premium that must be paid. The payment of the premium reduces the amount of income remaining that can be used to purchase medical care after insurance is purchased, and thus reduces the amount of care that is purchased at the lower insurance price. (Medical care is a 'normal good' implying that less would be purchased if the consumer had less income.) For example, for a family of 4 making $40 000, an 80% reduction in the price that occurred as a result of market forces would generate a greater increase in the quantity of medical care purchased than would an 80% reduction in the price which the family had to pay for with a $20 000 health insurance premium. This implies that the insurance demand curve is steeper than the Marshallian demand curve used by Pauly, and that the actual moral hazard welfare loss is smaller than would be the case if evaluated by a movement along the Marshallian demand curve.

More importantly, however, the price reduction is the mechanism used in the insurance contract to transfer income out of the insurance pool to the consumer who has become ill. For example, without insurance, a consumer who contracts breast cancer would spend $20 000 of her own money on a mastectomy. If she purchased an insurance contract for $6000 that lowered her price to 0, she would purchase the $20 000 mastectomy, plus the $20 000 breast reconstruction and two extra days in the hospital to recover for $4000, all paid for by the insurer. The additional $24 000 in spending on the breast reconstruction and the two extra days in the hospital represents the moral hazard. Although the price has fallen to 0 to the consumer, the price of the care that the hospital and physicians provide has not changed, and $44 000 must come out of the insurance pool to pay for her care. Of that amount, $6000 represents the premium that she paid originally, but the

rest, $38 000, represents the premiums that others paid into the pool and that were used to pay the providers on her behalf. These payments represent a transfer of income to her. If the insurance contract was such that this income transfer were paid directly to the consumer upon becoming ill, it would cause the consumer to purchase more medical care than if uninsured, and thus generate a portion of the moral hazard.

Indeed, by comparing the total moral hazard under a standard insurance contract to the moral hazard under a contract that paid off with a lump-sum equal to the same income transfer, one can distinguish the efficient moral hazard from the inefficient moral hazard. If the insurer had paid off by writing a check to the consumer for $44 000 upon the diagnosis of breast cancer, this additional income may have caused the consumer to purchase the $20 000 breast reconstruction, but not the two extra days in the hospital for $4000. If this were the case, then the $20 000 breast reconstruction would represent efficient moral hazard because the consumer could have used the additional income to purchase anything of her choosing. So, if she chooses to purchase the medical care, one can assume that the additional income has shifted the preinsurance demand curve outward and that the willingness to pay now exceeds the cost of producing the care. The $4000 for the extra hospital days is inefficient and consistent with Pauly's original concept.

Conventional versus Alternative Theories of Moral Hazard Welfare Compared

The alternative theory can now be compared directly with the conventional theory of the moral hazard welfare loss. In Figure 3, the Marshallian demand curve D shows the response to an exogenous change in the price for the consumer who has become ill. At a medical care price of 1, the consumer, if uninsured, would consume m_u medical care. If the price had fallen to c exogenously, m_e would be purchased, but that would not represent the response to 'purchasing of a price of c' through an insurance contract. Purchasing a price of c through an insurance contract would have generated a smaller demand response because income in the amount equal to the premium payment is no longer available to use in purchasing medical care at the lower insurance price, c. The effect is to make the insurance demand steeper and to reduce spending from m_e to m_i. And as increasingly lower insurance prices (cs) are purchased, the difference between the Marshallian demand and the insurance demand would increase, because of the increasingly greater insurance premiums charged for lower and lower coinsurance rates. At the same time, the effect of the income transfer would shift the Marshallian demand curve to the right, D^i, exhibiting this shift directly for all prices above 1, but for prices below 1, both the price and income transfer effects together would be manifested as a simultaneous movement along an increasingly steeper demand curve and a shifting of that portion of the curve to the right.

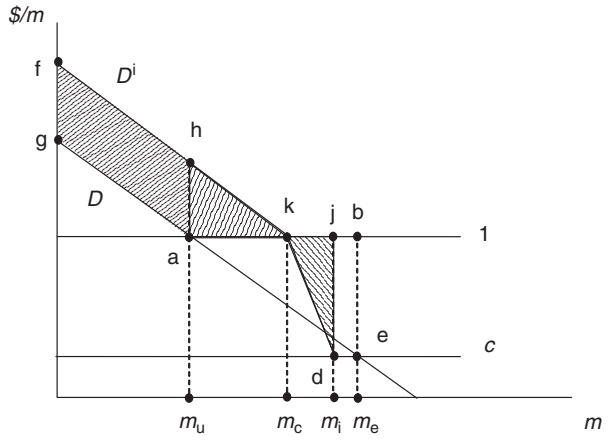

Figure 3 Net welfare gain under the alternative theory.

If a price of c were purchased with the insurance contract, the additional medical care that would be purchased because of using a price reduction to transfer income is represented in Figure 3 as $(m_i - m_c)$. The welfare loss from this purchase can be represented by triangle *kjd*. The shifting out of the demand curve caused by the income transfer to D^i would result in $(m_c - m_u)$ additional medical care purchased, relative to the amount that would have been purchased if uninsured. This additional medical care has a welfare value, that is, an increase in the consumer surplus equal to triangle *hka*. In addition, the transfer of income through insurance would increase the willingness to pay for all the care that was being purchased without insurance, resulting in an increase in the consumer surplus of area *fhag*. In contrast, under the conventional theory, there would only be a welfare loss defined by a movement along the Marshallian demand and equal to area *abe*.

Implications of the Alternative Theory

The implications of the alternative theory are far-reaching, and contrast dramatically to the implications of the conventional theory. Here are some of them.

First, not all moral hazard is welfare decreasing. Some moral hazard purchases are efficient and some are inefficient, and the challenge for policy is to distinguish one from the other in order to apply cost sharing only to the inefficient moral hazard. Thus, the theory is consistent with the concept of value-based insurance design which attempts to apply coinsurance rates only to those areas of insurance coverage that are to be discouraged, and not to others. Contrast this to the policies supported by conventional theory to apply high coinsurance rates to all types of medical care across the board, and with no limit on out-of-pocket spending, in order to reduce all moral hazard spending.

Second, health insurance is more valuable than has been deemed so under conventional theory because of the explicit recognition that insurance provides access to expensive health care that would otherwise be unaffordable and for which there would be no alternative way to access privately. That is, insurance is valuable precisely because of the additional care that it allows the ill consumer to purchase. Indeed, it has been argued that the RAND Health Insurance Experiment was biased by attrition and that the attrition accounts for the lack of a health effect from the reduction in health care use, especially hospitalizations, among the participants assigned to the cost-sharing arm. This means that, far from being welfare decreasing, insurance is welfare increasing, and

government programs designed to insure the uninsured represent beneficial public policy.

Third, an insurance policy that pays-off by paying for care represents a stand-in for a *contingent claims* insurance policy that would pay off by making a lump-sum income payment upon diagnosis. Although there may be a moral hazard welfare cost from the prevalent use of the standard policy, it is likely that the welfare cost of a contingent claims policy would be higher. For example, before a claim could be paid, the insurer would need to hire physicians or other health professional to review each claim and verify that the claimant actually had the claimed diagnosis. Moreover, to specify the various payment adjustments that would be required in the event of the various complications or adverse events that could occur with a diagnosis and its treatment, the insurer would need to hire a number of lawyers, actuaries, economists, accountants, and others to write the contracts and to keep them updated in light of scientific advances, price increases, and other changes that would necessitate adjustments in the payoff. If the moral hazard welfare costs in a standard insurance policy represent the transactions costs of transferring income to those who become ill and if the level of these costs in the standard policy is the lowest of any type of policy, then these costs can essentially be ignored as a necessary inefficiency.

Fourth, by focusing on the moral hazard welfare loss, conventional theory led economists to focus on solutions to the health care cost problem in the US that were related to reducing the quantity of medical care, rather than reducing the price of care: applying coinsurance rates and deductibles, moving to managed care and promoting consumer-driven health care insurance arrangements. These policies seemed to work. Using recent Organization for Economic Cooperation and Development statistics for the Group of 7 (G7) countries (Canada, France, Germany, Italy, Japan, the UK, and the US), it can be shown that Americans went to the doctor about half as often and spent half as many days in the hospital as citizens of the other G7 countries. Nevertheless, the US spent over twice as much per capita as the comparable average for the rest of the G7 countries. One interpretation of this is that by focusing on the moral hazard welfare loss, conventional theory misled economists to focus on the solutions that would reduce the quantity of health care consumed, when the more important source of the health care cost problem in the US was high prices that were generated by the monopoly power of providers.

Demand for Insurance That Nudges Demand

MV Pauly, University of Pennsylvania, Philadelphia, PA, USA

Introduction

The primary benefit from health insurance for risk averse people is to spread the risk of high expenses. But it can also affect the use of medical care. Although insurance coverage can then do harm to efficiency by distorting consumer/patient demand for medical services, it can also provide potential benefit by offsetting existing distortions. An important further consideration in some countries and in some settings, however, is whether such corrections will be offered by competitive insurers and accepted by buyers in voluntary insurance markets. Will market insurance coverage, that nudges people to do the right thing, be supplied and purchased?

The answer, to be discussed in this article, is the usual answer in welfare economics: 'It depends.' Depending both on the source of the distortion and the parameters of buyer preferences, corrective insurance may sometimes be strongly demanded, might or might not be expected to occur, or be unlikely to happen in unregulated insurance markets.

For example, the idea that individuals can be incentivized to change behaviors that are harmful to them is at the core of the normative appeal of behavioral economics (Della Vigna and Malmendier, 2006). Beginning with the observation that people with given incomes faced with a set of prices for different goods and services sometimes make mistakes, and sometimes do so in predictable ways, economists have developed normative analyses to show how incentives including prices can be changed to nudge, push, or drive people away from these consistently irrational acts into behaviors that will end up making them better off, at least in some way and along some dimensions (Thaler and Sunstein, 2008; Kahneman, 2011).

Both healthcare and health insurance have, not surprisingly, been prime candidates for nudging. Because information about illness and medical treatment is imperfect (for consumers, but also for providers of care and suppliers of insurance), there are many cases in which choices are made that turn out to be wrong later. More relevantly, there is also suspicion that consumers have less information than the maximum amount available, and so may make choices that do not maximize expected net benefit, either for them or for society. As a result, there is interest in changing how health insurance is designed and sold in order to improve matters (Chernew *et al.*, 2007; Fendrick and Chernew, 2009; Fendrick *et al.*, 2012). The most prominent (but not the only) example: if consumers do not have a full evidence-based understanding of the benefit from some treatment, and systematically use less or more than the amount that would maximize expected net benefit, might cost sharing for that treatment be changed in ways that help (Pauly and Blavin, 2008)?

In much of the analysis, the identity of the agent who is going to be doing this incentive changing is not specified; it is enough to show that 'we' could change things in such a way as to make 'us' better off. In some of the specific applications to such things as employee retirement benefits (Madrian and Shea, 2001), the implicit incentive-planner would plausibly seem to be the employer, though the proof that doing things that make workers better off will also make the stockholders of the firm better off is usually absent. In the largest share of this literature, it is government, broadly imagined as an entity interested in maximizing ex post economic welfare, that appears to be the intended customer for the normative advice (Bernheim and Rangel, 2009). What is probably least common is a serious investigation of the question whether or when voluntary markets in behavioral change might emerge and function efficiently.

This article investigates under what circumstances consumers might choose to change the health insurance incentives they face in order to bring about behavior which is likely to make them better off. (What exactly 'better off' means will be important.) Although attention will be paid to the risk reduction benefits of insurance, it is also worth noting that the main tradeoff in insurance – pay a higher fixed amount initially (the premium) in order to reduce the price at point of use later (the coinsurance) – is the same structure that has been studied for health clubs, great book clubs, and other examples of devices to bring about behavioral change.

In this model consumers can be perceptive about their failings; they are assumed to be able to understand that sometimes, for various reasons, they may not choose behavior which is ex post optimal for them, or that something needs to be done, either to information stock or user prices, to improve choices. Therefore, it is necessary to investigate whether it is possible that insurance that covers its costs and corrects such failings that will be demanded. It is assumed that supply is competitive so insurers will supply the kind of changes consumers might demand.

A main finding is the likelihood that consumers will voluntarily agree to be nudged depends critically on the reason why their behavior was nonoptimal in the first place, and even then, on the values of key variables in the problem. Sometimes there will be demand for nudging, and sometimes not.

Outlined here is a simple model of economically efficient cost sharing when consumers might underestimate the marginal benefit of some kinds of medical care; also indicated here is the voluntary insurance and medical care choices these consumers would make in such a situation, compared to what they would choose if they correctly estimated benefit. Then it is asked whether and when consumers would be willing to choose something different from this choice of both insurance and medical care, is there something else that they would prefer and which would make them better off? One fairly tautological model is provided where the outcome of voluntary efficiency-increasing nudging does occur with competitive insurers. That model is compared as a benchmark with other stories that raise serious issues of whether people will voluntarily demand the incentive-changing mechanisms that will make them better off, and whether insurers will supply them if

they are demanded. It is shown that under not implausible assumptions there are some cases in which voluntary demand will not materialize in the ideal way, and it is explained why. At the end the question addressed is whether institutional arrangements alternative to voluntary insurance markets, like public sector interventions, can do better, and show that government in a democratic setting might be subject to similar problems.

The Core Model

The model is one of competitive insurers choosing to offer policies with possibly different levels of cost sharing for different services. Two kinds of services, 'preventive' and 'treatment,' come to mind. The distinction is that a 'preventive' service affects the probability of future health or illness states, whereas a treatment service provides only short-term (if valuable) benefit when an illness strikes. Thus a preventive service both provides benefit in the form of improved future health and potentially lower demand for treatment if illness is avoided; the concept includes both what is usually labeled prevention but also the great majority of other health services in the first stage or early onset of some illness that affects what happens to health later.

In the absence of insurance, demand for either kind of service bought in a competitive market by fully informed consumers would be (presumably) first best optimal, at the point where marginal benefit equals marginal cost. For treatments of this condition, this just equates the (money) value of current period health benefits to price, assumed to be equal to marginal cost. For preventive services, both current period cost and future 'cost offsets' are part of the full marginal cost, whereas the value of expected future health (if care were costless) is the measure of marginal benefit. Alternatively, the value of marginal future health could be combined with cost offsets as a measure of benefit, to be equated to the current period price or cost of preventive care.

A simple version of the first order condition for optimal preventive care use would be:

$$P_S = \Delta\Pi\left(\frac{\Delta U_H}{\lambda} + C\right) \qquad [1]$$

where $\Delta\Pi$ is the change in probability of future illness due to consumption of one more unit of the preventive service, ΔU_{H} is the marginal utility of future health (comparing health in the illness state vs. health in the healthy state), λ is the marginal utility of money, and C is the cost of treating the future illness.

If there is no insurance coverage, consumption of both services will be at the optimal level. In particular, the consumer in deciding on consumption of the preventive service will take future reductions (cost offsets) for the cost of treatment into account, along with the value of health benefits. That is, the consumer sees and satisfies condition, eqn [1]. However, if there already exists coverage of the treatment, and there is a positive cost offset, there should be insurance coverage of the preventive service that reflects the part of any cost offset for treatment that is covered by insurance. This is a second-best argument. In the absence of such an adjustment, the consumer ignores the cost offset term, and underconsumes the preventive service.

In the limiting case in which the expected cost offset ($\Delta\Pi C$) exceeds the price of the preventive service, and the other service is fully covered, insurance coverage of the preventive service should be 100% in the absence of insurance administrative and claims processing costs, regardless of the degree of price responsiveness (Glaser and McGuire, 2012). If there is a positive marginal administrative cost to insurance coverage, that consideration would reduce the ideal extent of coverage. If there would be positive use of preventive care in the absence of coverage, then coverage should be higher the greater the price responsiveness of the use of coverage to cost sharing (Held and Pauly, 1990). If price responsiveness is low, coverage per se may increase the aggregate expected insured expenses, and the higher premium is offset by these higher benefits. However, if there are administrative costs, those additional costs, when applied to paying benefits where use would have occurred in any case, are wasteful.

The Setting and the Behavioral Model

This simple case is well known. But the more interesting questions arise in one of the most frequently discussed (and topical) applications of behavioral economics: the idea that cost sharing in health insurance might be used to guide people to choose more efficient levels of consumption of effective medical care than they might otherwise select, which is commonly called 'value-based' cost sharing in the health insurance literature (Chernew *et al.*, 2007). The alternative model in the discussion is usually one in which cost sharing is uniform across all settings associated with a given level of spending (e.g. 20% coinsurance or a $1000 deductible for all covered medical expenses); it is alleged that value-based cost sharing will produce a better outcome than this.

But this status quo is not the best alternative system. The theory of optimal insurance (Pauly, 1968; Zeckhauser, 1970) envisions varying coinsurance as well, but for different reasons and in different ways than prescribed by value-based cost sharing. Therefore, the question arises whether value-based cost sharing that dominates some or all of these alternatives in terms of ex post net benefits would be preferred by consumers.

The benchmark framework in mind is this: competitive insurers in unsubsidized and unregulated markets are free to set cost sharing levels (as proportional coinsurance) at different levels for different services. Consumers choose among insurance plans based on their premiums and their cost sharing. Each insurance plan's premium must cover the costs of the benefits it pays out plus administrative expenses, and may yield positive economic profits if the market is not competitive. The first question is whether a plan that selects the level of cost sharing prescribed by the value-based approach will be preferred by consumers to plans offering other levels of benefits and associated premia. (The second question, whether insurers will offer that plan, will be considered later in the article.)

It has been shown (Pauly and Blavin, 2008) that, in the absence of cost offsets, a necessary condition for value-based

cost sharing to improve outcomes in competitive insurance markets is that the patient's marginal benefit or demand curve differs from the curve that represents true marginal benefits. If patients always consider correctly the value of effective medical care, they will use highly (marginally) effective care even if cost sharing is high, but will use only less marginally effective and inefficient care if cost sharing is low. To control this moral hazard, coinsurance will be chosen to make the second-best optimal tradeoff between such overuse and risk protection. Moreover, under full information but with variation across types of care in patient response to cost sharing, uniform cost sharing will not be optimal; rather, other things equal, optimal cost sharing will vary directly with patient demand responsiveness. No further consideration of 'value' is needed to specify the ideal level of cost sharing.

Figure 1 provides an illustration of this model. D_I represents the true marginal (expected) health benefit curve for some kind of care; *MC* is its cost and price net of cost offsets. (This service is both uncertain and has a positive marginal net cost; cost offsets from its use are not sufficiently large that consuming more of it reduces total benefits cost.) Because of uncertainty, it is assumed that consumers get benefit from insurance coverage of this service. There is a (second best) optimal level of coinsurance, indicated in the diagram as c_I^*, which consumers will also prefer to any other level of coinsurance. At this point the marginal welfare cost from lowering coinsurance will equal the marginal benefit from further risk reduction. At that point, the quantity will be second best optimal. Optimal coinsurance (other things, including risk characteristics and risk aversion, held constant) will be lower for less price responsive types of care and higher for more price responsive types of care. In all cases, the marginal benefit will be less than the marginal cost. At this optimal pattern of coinsurance, the value or marginal benefit from each type of care will equal the level of coinsurance per unit. At a given level of coinsurance, when informed consumers are in equilibrium, no one type of care will have higher marginal value than any other, so there is no need to further vary coinsurance with value. However, at the optimal level of coinsurance the marginal value of less price responsive care will be lower than that for more price responsive care because the lower coinsurance that leads to a lower value provides an offsetting benefit in terms of better risk protection.

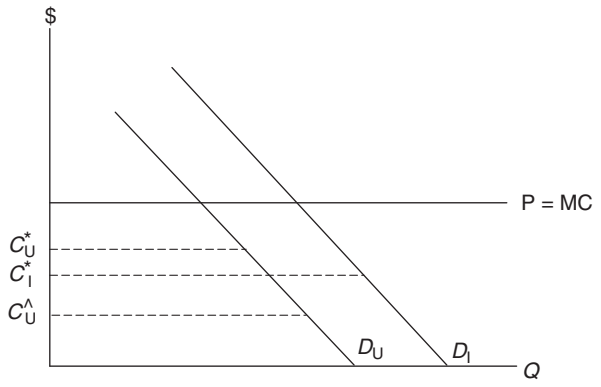

Figure 1 Optimal coinsurance and the demand for care.

Deviations from Optimality

Now suppose that the marginal benefit curves that patients are using are lower than the true curve. What then? Start with a simple comparison. Suppose that three plans are offered. One (informed plan) sets the coinsurance rate (as described above) at the optimal level given the consumer's risk aversion and given the marginal benefit curve that would be generated if patient demands were based on accurate estimates of the marginal benefit from different amounts of care. However, patients are assumed to underestimate the benefit from some important service, and so would consume less than the full optimal information amount if they were in the first plan. The inaccurate expected marginal benefit curve is indicated in Figure 1 as D_U. So an alternative value-based plan (Nudge Plan) is offered with lower cost sharing at $c_U^\wedge$. The purpose of the lower cost sharing is to offset the effect of benefit underestimation by increasing quantity demanded by using a lower user price. This is the optimal level of cost sharing, given that the marginal benefit curve is underestimated.

There is, however, a third alternative insurance plan, one that the consumer might prefer: Specify c_U^*, the coinsurance rate and premium that would be optimal given the actual (though underestimated) demand, and the lower rate of use and lower premium associated with that plan. The uninformed plan generally has a higher coinsurance rate (at c_U^*) than either $c_U^\wedge$ or c_I^*, with both a lower premium and lower expected medical costs than the Value-Based Nudge Plan. The reason why the coinsurance rate is generally higher than with the true marginal benefit curve is that, with lower demand at any level of coinsurance, there is less risk.

Figure 1 depicts each of the three plans under alternative assumptions that the marginal benefit curve is the informationally correct demand curve D_I or the actual (uninformed) demand curve D_U. Note that the welfare cost of moral hazard is smaller at all coinsurance levels along the D_U curve than it would be under the informed plan with the informed demand curve.

The Gain from 'Nudging'

This simple example shows that there can be gains from getting the consumer to choose the Nudge Plan. How does the size of the gain vary with the position of the uninformed demand curve? The answer depends in part on whether the informed plan or the uninformed plan is used as a benchmark. The case is simplest if welfare under the Nudge Plan is compared with what it would have been under the fully informed plan. Pauly and Blavin (2008) show that, over some of the range of possibly underestimated demand curves, welfare may actually be higher with underestimation and the Nudge Plan than with the informed plan. This is what they call the 'benefit of blissful ignorance.'

There is obviously a gain from permitting the marginal benefit curve to fall short of the true curve as long as it remains above that curve which hits the x-axis at the optimal level of use (ignoring income effects). That curve is D_U^* in Figure 2; should it prevail, coinsurance can be set at zero and yet use will be first best optimal (ignoring income effects). The

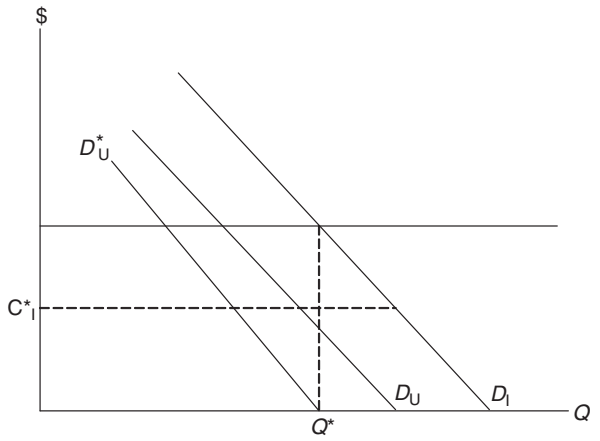

Figure 2 Lower bound on demand for care.

consumer can completely avoid the consequences of moral hazard, and have both full protection against risk and optimal use of medical care. To the left of D^*_U welfare begins to fall, but remains above that with the informed plan at c^*_I over some range.

Modeling Deviation

With this as background, a model can be made of the causes of deviations in the patient's marginal benefit curve from the true value and corrective strategies. Begin by thinking of what kind of medical service would be one for which consumers would demand insurance but underestimate true marginal value. Think of a service for which demand is stochastic today and which affects health tomorrow. Although some acute-care services yield immediate utility benefits (analgesics, suture of a bleeding wound), the bulk of medical services are of this 'two-period' character. Statins for people who have already had a heart attack, asthma medications, and cancer surgery are all things that a person might or might not need, depending on the onset of the chronic condition, but which then all generate disutility in one period in return for a benefit in the future. (There are some complexities associated with insurance coverage over multiple periods which will be ignored for the present.) The person decides on insurance coverage for such services at time t_0. It is assumed that there is such a service with a (gross) market price in period t of P_t and nonmarket costs (time, pain, bother) of C, all incurred at time t_1. If the person consumes the service, health is increased in period $t+1$ and future periods.

The first order condition for optimal choice (slightly re-written) is:

$$P_t + C_t + \sum_t \frac{\Delta C_{t+j}}{(1+r)^{t+j}} = \sum_t \frac{MH_{t+j}}{(1+r)^{t+j}} \qquad [2]$$

Here ΔC_{t+j} is the cost offset in the $J(j=1,2,\ldots,J)$ future periods the person will pay, MH_t is the value of the additional health at time t from the service measured in dollars, and r is the interest rate; the expression on the right gives the present discounted dollar value of additional health. It can be assumed that MH falls as the service is consumed at a higher rate. That is, the consumer compares the price with the discounted marginal benefits minus any nonmonetary cost from treatment.

There is only one way a consumer can estimate marginal benefit correctly, but there are (apparently) many incorrect ways to do it. Consider patient nonadherence to a physician's prescription to use some product or service, conditional on a diagnosis of some chronic condition. The things that can be, apparently, estimated or considered incorrectly are all in eqn [2]: the cost offset (because of insurance coverage), the value of the marginal health product or the service, the interest rate, and the nonmonetary cost of the service.

Insurance coverage distorting the consumer's value of the cost offset is one reason why patients may not use the care they should. Imperfect information is another likely reason offered, especially if patients have difficulty understanding the physician's explanation for some prescribed treatment. In addition, if people use nonexponential discounting, they may fail to consume services of high marginal (future) benefit, even if they correctly perceive that benefit, because they underestimate the value of that benefit. Quasi-hyperbolic discounting would be one way to model this imperfect discounting. Finally, the nonmonetary cost itself may be high, higher than is perceived by the physician who recommends the service and is then disappointed when patients are nonadherent to the recommendation. In this case it is the information for the potential 'nudger' that is incorrect, but it is a possible scenario for trying to persuade consumers to change.

The case for voluntary value-based cost sharing as a function of these four rationales for value-based cost sharing will now be explored.

The Best Case for Voluntary Value-Based Cost Sharing: Positive Insured Cost Offsets

The most obvious case why some level of coinsurance might be too high is if there are positive cost offsets (the current preventive service reduces future costs along with improved health) and, although those future services are covered by insurance, that is not taken into account in specifying the coinsurance for the preventive service. Then in calculating marginal benefit the consumer fails to take these reductions in cost (and in insurance payments to cover those costs) into account.

Most of the examples of the success of value-based cost sharing deal with this case. However, the conventional theory of optimal voluntary coinsurance in competitive markets is already supposed to have taken these effects into account because the cost of the preventive service is the net (of cost offsets, positive or negative). The idea is that the insurer will recognize these effects, and build them into the premium adjustment that matches any change in the level of coinsurance for the service. This happy state of affairs can be impeded if there is turnover among insureds – if the person potentially leaves the plan before the cost offsets occur. Other than this, however, the market solution to this case is well known; it is one in which the consumer does not require extra nudging beyond what would have been built into optimal insurance in the first place. The consumer notices that the plan

with 'nudging' coinsurance carries lower premiums and better benefits than any other, and chooses that plan.

A Good Case for Voluntary Value-Based Cost Sharing: The Consumer Looking to the Future Seeks to Control His Irrational Current Self

The strongest behaviorally motivated case for the value-based plan is to note that it is the plan that maximizes ex post utility, given the underestimated demand curve and the true marginal benefit curve. It is the former curve which describes behavior, but the latter which describes the actual outcome and its value. A split-personality or self-control model is a very common approach in the literature to this case, usually applied in cases where discounting is hyperbolic or inconsistent in some way. The approach of Della Vigna and Malmendier (2006) and Della Vigna (2009) that they used for health club annual memberships (as opposed to paying per use of the gym), modified to fit the health insurance case, will be followed.

The idea is the consumers realize that, although they should exercise, get their test, or take their medicine, because of lack of self-control they will not do so when they are facing the full price per unit, or even at the full information ideal level of cost sharing. They therefore prefer incentives that will be set at a level such that, given their expected attenuated future demand behavior, they do what they should. They therefore sheepishly prefer a plan with low enough cost sharing to get them to do what they ought to with any alternative, because it dominates all other alternatives in terms of ex post net benefit. In this case, the most common interpretation is that it is not that the consumer misperceives, it is that he or she misbehaves.

An alternative interpretation, based on the psychological work of Zauberman *et al.* (2009) is the consumer misperceives time. Exponential discounting of misperceived time can be equivalent to hyperbolic discounting of correctly perceived time. Either way, this case can be described as resulting from using a discount function that differs from the conventional exponential one – for example, by being hyperbolic.

Formally, imagine multiplying the discount rate $(1/(1+r))$ by a term B that reflects the underestimation of the value of future benefits (at time $t+1$ and later). This value is the one the consumers attach to future benefits at the time t when they might consume the costly and bothersome service. The usual model at this point imagines that the consumer considering precommitment at time t_0 with regard to behavior at time t_1 seeks to reproduce the behavior at time t_1 which would have occurred under exponential (nonmyopic) discounting (Rasmusen, 2008).

But in this case the paradoxical results on optimal underestimation means that the goal is not to get the consumer to fully correct the imperfect discounting. Doing that would lead to the D_{I} demand curve, although utility is higher if the demand curve is only at D^*_U. Put slightly differently, in deciding how to control one's 'bad' self in the two-selves model, one does not want to get that second self to do what the first self would have done under a fully correct perception of the discount rate. Instead, one wants to adjust cost sharing to produce a rate of use potentially greater than current (myopic) self-use and coverage but not as much as would be used by the nonmyopic self. In effect, the first self takes advantage of the impatience of the second self as a way of controlling moral hazard on services with preventive benefits. Far from wanting to correct a later shortsighted behavior, one would want it to remain shortsighted, just not as much.

There is an additional issue here of some potential importance. It may well be that the decision to precommit in period p_0 changes the person's demand curve in period p_1 when period p_1 arrives. That is, recognizing the arrangements for precommitment, the person may be less resistant to proper discounting; there may be feedback from the decision to precommit to behavior in some event to the behavior that would occur in that event. This might be especially likely to happen if Zauberman's model of discounting holds: observing the precommitment device changes how one thinks about time closer to its true value. If this happens – if the discounted marginal benefit curve in period p_1 is moved closer to the true curve (as perceived in period p_0, or period p_2 or later), then the structure of the precommitment device – the lower user price – will need to be changed to one that has a higher user price. But if the demand curve is shifted up enough, the expected utility under precommitment may actually end up lower than at the initial no-precommitment point. In this case no voluntary nudging will occur.

More generally, what is the ideal level of cost sharing in such self-control cases? It depends on the position of the uninformed marginal benefit curve relative to the true curve. At one extreme, if the reduction in demand is so great that the quantity demanded at a zero user price (full coverage) is less than or equal to the quantity at which true marginal benefit equals marginal cost, then optimal cost sharing is zero regardless of risk or risk aversion. (Negative prices are ruled out in favor of the corner solution.) If the quantity at a user price of zero is greater than the quantity at which marginal benefit equals marginal cost, then the optimal extent of coinsurance is calculated, as in Pauly and Blavin, (2008), by comparing the true marginal welfare cost with the marginal risk premium given the level of use and loss distribution that prevails under the underestimated demand curve, taking into account the person's risk aversion or 'risk premium.' It will be optimal to have some positive coinsurance for the person who lacks self-control as long as the distortion is not too large. (This question will be regarded when the alternative form of nudging is considered involving providing information on what the marginal benefit actually is.)

The consumers will voluntarily choose the cost sharing option that precommits them to lower payment per unit in return for payment of a lump sum payment (premium or membership). This provides two kinds of gain. To the extent that the use of the service is stochastic (Della Vigna (2009) describes even health club visits as stochastic), there is a risk premium gain to a risk averse person from paying some of the expected cost in advance. And then there is the gain in expected utility from precommitment.

How binding is the precommitment? Once the people are facing the possibility of paying for and using the preventive service, they attach less value to using it and, in view of low likely use, would prefer an insurance with higher cost sharing and lower premiums. There is no absolute barrier to changing

insurance coverage at any point in time; usually contracts for employment related coverage are for a year but individual insurance can be changed at any time. However, it is likely that no single specific coverage would motivate a change – our consumer in the throes of myopia would just prefer insurance with less coverage of preventive care in general. One could model the decision to renege as based on a comparison of the transactions costs of changing behavior versus the difference in expected utility between the precommitted coverage and the myopically optimal coverage. Of course, if the medical event occurred close to the time when the person is deciding to make an annual election, things could be different.

Better Information as the Solution

Another reason for benefit underestimation is imperfect information about benefit. One strategy is to provide information. But when would it be socially efficient to provide information? If marginal benefit is underestimated by a sufficiently large amount, more information may help; if not, more information may do harm, even if it is costless, as discussed earlier.

Imagine varying the D_{U} curve by changing information, and plot various levels of coinsurance.

As illustrated in Figure 3, if the nudger can control both information and the coinsurance rate, it would provide no corrective information but set coinsurance along the *BC* line. In contrast, if it can only control information but consumers choose coinsurance along *AC*, it would choose information to move the marginal benefit curve to D', where use at the consumer-chosen coinsurance rate C'_U is just at the optimal level.

But in the context of voluntary choice of insurance, it may be hard to be explicit about keeping people ignorant. Thus both characterization of settings in which leaving underestimation untouched is a good strategy and asking whether people will voluntarily and explicitly choose to leave things that way, is required.

Here is the source of a serious dilemma. The simplest explanation is to assume that the consumer focuses only on the final outcome (in terms of comparison of health improvement, premiums, and expected out of pocket costs), recognizes that this outcome is superior to that with the uninformed plan, and therefore prefers the nudge plan with a health outcome which (given its cost) is better ex post. The dilemma arises if the consumers reflect on the source of this improvement. Suppose they realize that it comes from the fact that the initial perceived marginal benefit curve was incorrect, and was less than the true curve. But if the consumers become aware of this fact and respond by increasing their demand curve, use and outcomes under the Nudge plan's coinsurance rate will not replicate what is anticipated under the informed plan. Instead, faced with a relatively low coinsurance rate, use will be higher. Health outcomes will be even better than under the informed plan, but (in the short run) the insurer will lose money, and, after seeing an increased premium to cover this higher use, the consumer will judge the higher premium and higher expected out of pocket cost to overshadow the health improvement. If the demand curve shifts all the way to the true demand curve, the ideal coinsurance rate will also rise to the level that is optimal.

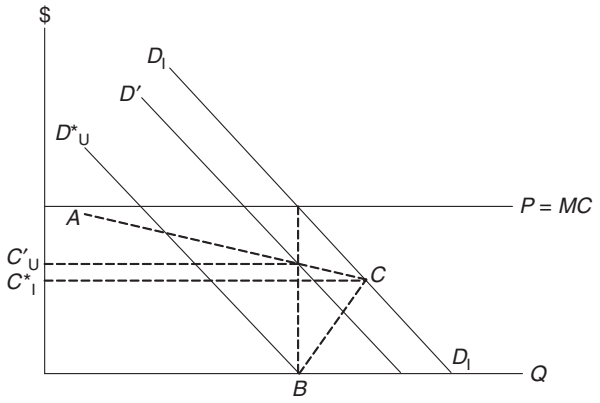

Figure 3 Tradeoff between demander information and coinsurance.

For information to work properly to achieve a better outcome, the consumer must purchase insurance and care based on the uninformed demand curve. But to be motivated to buy the plan, the consumers may need to know (and be convinced) that the health outcome they will achieve at the level of use they target under the plan's coinsurance rate will be much higher than they would expect. This is the heart of the dilemma: they will prefer the nudge plan only if they think their health outcome will be better than what they think it will be as embodied in their (uninformed) demand curve. Convincing them of this will arguably shift the actual demand curve.

Putting the pieces together, it is noted that the strategy of improving information only improves ex post welfare if the marginal benefit curve is below D^*_U. Even then, the uninformed demander will not be willing to pay the higher premium for better coverage as long as they remain ignorant. Providing information can shift the demand curve for care and coverage, so if information is relatively cheap and effective it may pay for a firm to charge a little more after paying to shift demand. Even here, however, the level of coverage will be on the *AC*-locus, not on the *BC*-locus. Merely offering the optimal level of coverage on any underestimated demand curve will not be persuasive. To get the consumers to prefer coverage on the *BC*-locus one would have to fully inform them, but then demand would shift to a level with higher coinsurance and higher moral hazard. Less information means less moral hazard but less correction in coverage. It does not seem possible to reach the first best outcome in a voluntary way.

The Cost of Bother

Both imperfect self-control and imperfect information are reasons why demand does not reflect marginal health benefit. But the informal literature on adherence also suggests another reason: The consumer forgets, or it is too much bother – there are subjective costs. In effect, there are additional costs on top of any cost sharing. It is these subjective costs that shift the marginal benefit curve downward.

But note that what prompts them to take their medicine is the lower user price, implying that decisions are made

rationally by comparing perceived benefits to 'short run' costs including time and bother. In the ignorant case it is the perceived benefit estimate that is wrong; in the 'bother' case there are some additional (uninsured) costs. If these costs are expected to be real (that is, if people know from past experience that they must work hard to remember, and do not just overestimate the actual effort in remembering), then people will expect to incur those costs if the user price is lowered enough to result in the desired behavior. Here again, but for a different reason, ex post welfare will be lower under the Value-Based Nudge Plan, and people may refuse to be subject to the push.

Perception of Nonmonetary Cost

Another reason why people may fail to follow provider advice about services which affect future health is because they experience or expect to experience nonmonetary costs associated with those services. Those costs may represent physical side effects (nausea, impotence, dizziness) or they may represent the effort needed to remember to take the medicines or treatment on the prescribed basis or even the bother of filling the prescription.

In the first best world these costs will be taken into account in determining the net marginal benefits, but in the setting in which physicians write prescriptions they may have a difficult time knowing what these costs are. If they prescribe based on, say, the average patient's net benefit from a drug, those who have above-average nonmonetary costs may rationally choose not to comply; there may be rational nonadherence. Lower the user price, and there will be more adherence as those who rationally failed to adhere when they were exposed to the full monetary cost of the treatment and their nonmonetary costs now find positive net benefit when the nonmonetary cost falls. But when confronted with a higher premium to pay for this change in future behavior, this group will correctly judge its net benefit to be negative.

Other Threats: Heterogeneity

What will the market look like if some consumers underestimate marginal benefits but others do not? If some consumers understand marginal benefits correctly but insurers cannot tell who is who, the well informed patients will find it advantageous to themselves to be pooled with other underestimating consumers who use less care at given coinsurance levels. The breakeven premiums will then reflect an average of the use of both classes of consumers, just as in conventional adverse selection models, which will make low coinsurance value-based policies even less attractive.

The Mixed Case

Now consider the most complex but probably the most realistic case: one in which patients underestimate the true marginal benefit curve (imperfect information) but also overdiscount those benefits (imperfect discounting). If the underestimation can be kept secret, the consumer might be willing to agree to a plan that lowers the user price enough to offset the imperfect discounting.

The key issue here as before is how far the demand curve is shifted to the left by these two influences. If it is still to the right of D_U^*, the two-self model will tolerate some reduction in cost sharing without having to turn to information to move the curve. The change will be the utility maximizing coverage based on a correctly discounted but underestimated marginal benefit curve.

Focus Group Evidence

A series of focus groups using subjects from the state of Michigan were asked about various aspects of alteration of insurance coverage to vary cost sharing with measures of clinical (net) value using a set of scenarios (Swinburn *et al.*, 2012). There was no scenario based on quantitative values for changes in use of care, health outcome, and total medical spending or premiums but there are some qualitative results of interest for the models that have been discussed.

One scenario proposed lowering copayments to zero for a medical condition (diabetes) thought to be characterized by underuse of recommended care and poor health outcomes. The scenario envisioned cost offsets in employment based insurance (patients with lower cost barriers are more likely to stick with the care they need, which would make them 'more likely to use fewer healthcare dollars'), but the total premium will initially increase though the employer 'expects to make it up with healthier employees' and will eventually have less costly health insurance.

Participants generally supported the intervention as described but with several caveats that are important for our analysis. First, they would support lowering copayments for diabetics 'only if the program saved money.' Although this response is somewhat vague, a reasonable interpretation is that they would not favor the program if premium costs they had to pay were increased even if health was improved for those workers with diabetes. There was also an equity consideration that offset efficiency gains: discounts should be available (a majority thought) only to those low income people who could not afford the prior cost sharing – even if lower cost sharing might change behavior of wealthier participants in a health-improving way.

The other interesting finding was also couched in terms of equity. It was felt to be unfair to provide lower cost sharing benefits to people with conditions under which they failed to follow physician advice. This was both rewarding irresponsible behavior and failing to reward people with conditions where adherence was high, or who had no chronic conditions. These observations could also be interpreted as referring to risk selection, benefitting high risk patients who behave incorrectly at the expense of those who manage their care properly or are low risk to begin with.

Overall, respondents felt that this new design should be used some of the time, but only in certain circumstances.

Another report (Midwest Business Group on Health and Buck Consultants, 2012) obtained similar results from another set of focus group participants. There was skepticism about the

ability of insurers to identify these cases, and a feeling that those who were compliant needed the help of lower cost sharing more than those who were less compliant.

Solutions

Solutions to these problems depend in large part on the cause. In the case of people with understanding of self-control problems, there should be a demand for nudging even without any intervention. Here providing accurate and persuasive information on the actual benefit ex post will be helpful not only to get the demand as right as it can be but also to motivate the demand for insurance.

For people who underestimate marginal benefit because of information imperfections, the strategy of providing information on actual benefit may backfire, as noted, because it will be associated with a greater rate of use in inefficient situations. There is a partial solution that may work in some cases. Suppose that the perceived marginal benefit curve is to the left of D'. Then it is possible that the utility under full information with cost sharing at the optimal level is higher than the utility with no action. In such a case providing information about the true curve and then doing the best that can be done may be preferred to the original state.

However, in this case the optimal and demander-chosen levels of coinsurance coincide; there is no need for value-based adjustments. In the more general case, it seems difficult to get the person to prefer the insurance with value-based cost sharing *a priori*.

Dentistry, Economics of

TN Wanchek and TJ Rephann, Charlottesville, VA, USA

Introduction

Dentistry is the field of medicine that is concerned about diseases of the teeth and other tissues and bone structures in the oral cavity. It is different to a degree from other medical services in its product attributes, market characteristics, and the level of government involvement. Although dental disease is not completely predictable, it is less random than other diseases and disorders, some of which can have potentially immediate catastrophic effects. In addition, preventative services make up a much larger portion of the care provided than for other health care services. When treatment of dental caries (tooth decay) is needed, patients are often presented with the option of restoration or removal. This type of choice may not exist for many other medical problems. These characteristics of dentistry allow consumers more flexibility in when and what they purchase. In addition, consumers are generally better informed about dental services. They can often observe and identify their disorder and have more contacts and familiarity with the limited number of dental diseases, diagnostic tools, and procedures than they would with conditions in other fields of medicine. Although poor dental health can affect one's general health in many ways over time and impede workforce performance and childhood development, dental diseases are not communicable unlike some diseases. Dentist services are generally provided by small, independently owned providers in a situation approximating pure or monopolistic competition in contrast to physicians who are more likely to be organized in larger consortia of providers such as hospitals and health groups with significant local market control. These features suggest that dental care may function more like a standard product market than other health care services where market failures are more pronounced.

Oral health has improved markedly in high-income countries over the last several decades. In contrast, many low-income countries have experienced deterioration in oral health in recent years. The improvements in high-income countries can be attributed to a variety of factors, including increasing incomes, expanded access to dental insurance, improved technology, dietary changes, and fluoridation. Many developing countries are seeing an increase in the prevalence of dental caries, largely due to an increase in consumption of sugars and inadequate exposure to fluorides.

In the US, dental service prices have increased at a much faster clip than other goods and services and even slightly faster than other medical services. However, expenditures on dental care are still a relatively small share (less than 5%) of total health care costs in the US. Unlike the large expenditures going toward medical care, the public sector in the US funds only approximately 6% of the costs. Most of the funds are for low-income children's programs (i.e., Medicaid and CHIP) and military and veterans care. Private insurance accounts for about half of spending with out-of-pocket funding the residual.

There are also notable differences in the physician and dental workforces. Dentists make up a relatively large percentage of the total health care provider labor force, with an estimated 181 725 active dentists in the US in 2010 compared to 784 199 active physicians who work on all other parts of the body combined. However, although approximately 80% of physicians are specialists and 20% are general practitioners, the reverse is true for dentists. Moreover, dentists are increasingly more likely to rely on auxiliaries to assist with dental procedures and to provide preventative care. New laws and legislation have been introduced to expand the range of services provided by auxiliaries even further. In contrast, other countries, such as New Zealand and the UK, rely more extensively on the use of mid-level oral health care providers.

Although problems in dentistry have featured less prominently in discussions about health care reform, the field is presented with its own set of challenges. Industrialized countries such as Japan and many members of the European Union offer public dental insurance. In the US and elsewhere, a relatively large percentage of the population is uninsured, resulting in serious inequities in access to care. In the US, disadvantaged individuals, minorities, and rural residents are much less likely to exhibit good oral health. In addition, dental labor markets may not work as efficiently as they could if they were less impeded by licensure/regulatory requirements that do little to enhance patient welfare.

The following sections examine these areas in further detail in order to provide a more comprehensive picture of the economics of dentistry in the present day. The first section looks at the chief focus of dentistry: improving oral health. It reviews determinants of oral health, the economic and general health consequences of poor oral health and trends in oral health outcomes. The second section examines dental demand and its determinants, including availability of insurance, time and out-of-pocket costs, public programs, oral health conditions, and other factors. The third section reviews important issues with respect to dental service supply including the supply and distribution of dentists. The fourth section considers the expanding role of other dental care providers in the US and elsewhere.

Oral Health

Determinants of Oral Health

There are many factors that ultimately determine an individual's oral health, including oral hygiene habits and behaviors, dietary choices, tobacco use, genetics, use of dental services, income, tastes and preferences, and age. One way to conceptualize individual choice about oral health outcomes is to use Grossman's well-known model of health capital in which individuals choose between spending time producing health and purchasing medical services. Health depreciates

with age, whereas education increases one's efficiency at producing health at all ages. In the dental context, people demand oral health. Oral health can be produced with various productive inputs. Individual behavior, such as brushing and flossing regularly and consuming less sugar, constitutes one type of input. Other inputs can be purchased such as checkup exams, cleanings, filling and caps for carious teeth, or extraction and replacement with bridges and dentures. People can also consume other goods, such as fluoridated water or fluoride supplements that improve oral health. How much of each input a person purchases in the market depends on a variety of factors including the price or opportunity cost of the services, the present quality of teeth, tastes and preferences for good teeth, age, etc. Applying Grossman's model to oral health, people demand less dental care as the cost of care and the time needed to produce oral health increases, suggesting people do make trade-offs between good teeth, consumption of other goods, and time.

People vary in their tastes and preferences for good oral health outcomes. Studies have found lower perceived need for care in rural areas and among individuals with a low socioeconomic status, which may be due to the social environment and expectations for good teeth. Family environment, particularly among children, is an important factor in health outcomes. In the US, whether a parent visited a dentist is strongly correlated with whether the child also had a dental visit. Similar results are observed in China. A survey of adolescents (11, 13, and 15 years old) from eight Chinese provincial capitals found that there is a strong relationship between oral health behaviors and the socioeconomic status of parents, school performance, and peer relationships. Looking at Medicaid programs, even when states increased children's Medicaid provider compensation to levels comparable to private insurance, utilization rates do not rise to the level of those with private insurance. The lower utilization rates suggest that there are significant nonfinancial barriers among low-income populations in seeking dental care, which could be interpreted as a lower preference for good oral health outcomes, increased costs of gaining access to dental services or a shortage of providers.

Age also plays a role in the demand for oral health care services. In the US, the elderly tend to have low utilization rates. In 1999, 53.5% of adults 65 and older reported that they had visited a dentist, the lowest rate of any adult age group. Although costs are a factor, even when services are available for free or at a reduced cost or when insurance is available, utilization only increases slightly. Low income and less-educated elders often have lower expectations of good oral health in their old age. As a result, they may be more accepting of pain as a normal part of aging rather than an indicator of the need for oral health care.

Consequences of Poor Oral Health

Economic consequences

Oral disease has negative economic consequences for both individuals and society. Oral disease increases consumers' direct spending on care and also creates indirect expenditures through lost worker productivity. These expenditures could be reduced with a greater investment in preventative care including better oral hygiene habits, decreased prevalence of families consuming unflouridated water, and greater use of dental sealants and fluoride varnish.

Adults also suffer reduced hours of work and earnings when burdened with oral disease. Much of the loss in hours of work appears to accrue to lower income individuals and is often a result of delaying treatment until symptoms are severe. Time lost from work tends to be correlated with previous time lost, low income, being nonwhite, and having poorer oral health. Interestingly, preventative visits account for the most episodes of lost time, but the fewest hours of lost work, suggesting that delaying treatment resulted in greater treatment need. Not only is there a loss in productivity due to the time needed to receive treatment, but poor oral health also appears to affect earnings more generally. The implementation of community water fluoridation during childhood increases earnings for women by 4%, but does not have an effect on men's earnings. These findings are consistent with a differing effect of physical appearance on earnings of women and men.

Among children, oral disease is correlated with greater absenteeism and poorer academic performance. For example, children with oral health pain are three times more likely to miss school due to pain and that missing school due to pain results in poorer school performance. However, the absence for routine oral care is not correlated with poor school performance.

Medical consequences

Traditionally, oral health was viewed in terms of esthetics or localized pain and was compartmentalized from overall health. Recent research, however, has found numerous links from oral health to overall health and well-being, including a correlation with general health, nutrition, digestion, speech, social mobility, employability, self-image and esteem, school absences, quality of life, and well-being. Both bacteria and inflammation resulting from oral disease appears to have a negative association with other chronic diseases such as cardiovascular disease, stroke, adverse pregnancy outcomes, respiratory infections, diabetes, and osteoporosis.

Oral Health Over Time

Over the past few decades, oral health has improved dramatically for the average individual in high-income countries. Adults have fewer dental caries, the prevalence of dental sealants has increased, and the elderly are less likely to have edentulism (i.e., the loss of some or all teeth) and periodontitis. Over the past few decades, the prevalence of cavities in US children has declined, as has the mean number of missing teeth and percentage of edentulous adults. Among the reasons for this general trend are increased utilization of dental care caused by expanded dental insurance coverage and higher incomes, improved quality of dental care, better oral hygiene practices, widespread adoption of fluoridation in public water supplies and fluoride in dental hygiene products, and greater prevalence of sugar substitutes.

Worldwide, trends in oral health are more mixed. International comparisons of oral health typically rely on the

Decayed, Missing and Filled (DMFT) Index. In general, high-income countries have high, but decreasing rates of dental caries. Lower income countries tend to have low levels of dental caries, but the prevalence of caries is increasing. In recent years, there have been an increase in the DMFT index for 12-year olds in the World Health Organization Regions of Africa, Eastern Mediterranean, and Southeast Asia, but a decrease in the Americas, Europe, and the Western Pacific (see Table 1). The result is that the difference in caries experienced by high- and low-income countries over the past two decades has narrowed. The consequence of low levels of oral health care can also be observed in the likelihood of caries being treated. In low-income countries, almost all caries remain untreated, in middle-income countries the proportion of the DMFT index that is filled is only 20%, and in high-income countries the rate is 50%. Within all countries sociobehavioral risk factors play a significant role in oral health outcomes. The increasing consumption of sugar, particularly in areas with inadequate fluoride, and high use of tobacco, is a major risk factor.

Table 1 Regional oral health trends among 12-year olds (DMFT Index)

	2004	*2011*
Africa	1.15	1.19
America	2.76	2.35
Eastern Mediterranean	1.58	1.63
Europe	2.57	1.95
Southeast Asia	1.12	1.87
Western Pacific	1.48	1.39
Global	1.61	1.67

In the US, utilization of dental services, defined as the percent of adults with a dental visit in the past year, increased dramatically from a little more than 30% in 1950 to more than 65% in 2009 (see Figure 1). Real per capita expenditures have more than doubled over the same time period from $116 to $312 per person. As a result of general improvement in oral health, demand for dental services has shifted toward preventative, diagnostic, and cosmetic care and away from restorative work.

Despite this general trend, there are still segments of the US population that have continued to suffer from generally poorer oral health, such as low-income, minority, and rural populations. Adults 20–64 years of age who are below or near the poverty level (less than 200% of the Federal Poverty Level) are more than twice as likely to have untreated tooth decay than the nonpoor (see Figure 2). Moreover, black and Mexican-American adults are twice as likely to have untreated tooth decay as whites. Similar disparities are found among children. The rate of untreated dental disease among low-income children is significantly higher than that of high-income children. Among 14-year-old white children, the use of dental sealants, a preventive service, is almost four times that among African-American children.

Rural US populations often have poorer oral health than their urban counterparts. Among the reasons for the disparity are lower rates of dental insurance and higher rates of poverty. There are also differences in culture and environment, which may affect the perceived need for dental care. Lower levels of water fluoridation due to reliance on wells and small water supplies may also play a role. Beyond these factors, rural populations also must contend with a lower per capita supply of dentists and longer distances to providers. In 2008, there were

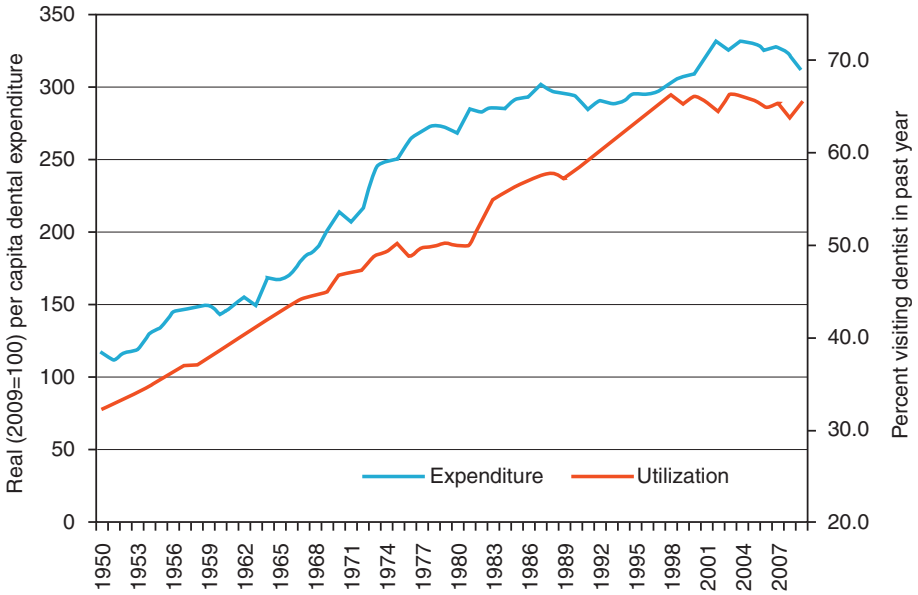

Figure 1 Dental utilization and per capita spending in the US, 1950–2009. Reproduced from U.S. Department of Commerce, Bureau of Economic Analysis (2011). Personal consumption expenditures for dental services, 1950–2009. 22 nonspecialist dentists per 100 000 population in rural areas in the US and 30 per 100 000 in urban areas. Additionally, a higher proportion of rural dentists were more than 55 years old.

Determinants of Dental Demand

Private Insurance and Income

Countries vary in their use of public or private dental insurance. By reducing the out-of-pocket cost of care, dental insurance can be an important component in the decision to seek dental care. Having private dental coverage significantly increased the proportion of individuals visiting a dentist. In the US, approximately 54% of the population has private dental insurance and 12% has public insurance, leaving 34% without coverage at all. Among those with private dental coverage, 56.9% had a dental visit, whereas only 32% with public coverage had a dental visit and 27% with no dental coverage had a dental visit in 2004. Among people with a dental visit, having insurance is associated with more visits per year and higher dental expenditures. However, some positive correlation between dental insurance and utilization would be expected due to adverse selection. Individuals who expect to need dental care are more likely to buy coverage. Thus, those with insurance would be expected to have higher rates of utilization.

The extent of dental insurance used in other industrialized countries varies. For example, in Norway dental care is provided by private practitioners without public or private insurance, whereas Sweden offers dental services to all adults either free of charge or with a large subsidy. In low-income countries, dental insurance is rare. Oral health services are often provided at urban hospitals where the focus is on pain relief and emergency care rather than prevention or restoration.

Income is also an important component of dental utilization. Of those who are poor in the US only 26.5% had at least one dental visit, whereas the rate was 57.9% among high-income individuals in 2004. However, higher income families are much more likely to have dental coverage. Nonetheless, even after controlling for dental coverage, lower income individuals without coverage are less likely to report a dental visit.

Out-of-Pocket Monetary Cost

Not only is having dental insurance important, but also the generosity of coverage matters. Unlike medical insurance, dental care routinely requires a substantial out-of-pocket payment. In the 10 largest US states, for example, 49.1% of dental expenditures are paid out of pocket, relative to 16.2% for all health care expenditure. Furthermore, utilization of dental services increases significantly as cost-sharing declines. Enrollees in free plans have 34% more visits and 46% higher dental expenses than enrollees in the 95% coinsurance plan. The mix of dental services may also be sensitive to the degree of cost sharing where prosthodontics, endodontics, and periodontics are more responsive to changes in coinsurance. In general, insurance has had a pronounced effect on the use of more expensive dental care, almost doubling the likelihood that a user will obtain bridge work and increasing the probability of a crown by 38%. Dental insurance, however, has had little or no effect on the use of X-rays and dental cleanings.

Evidence from the RAND Health Insurance Experiment, conducted between 1974 and 1982 in the US, found that dental services were significantly more responsive to cost sharing than other out-patient health services during the first

year, but not during subsequent years. The high response during the first year was due to a transitory surge, with individuals taking care of a backlog of problems when low-cost or free care became available. This response was significantly higher than that for other outpatient health services and was observed primarily among low-income groups.

Public Dental Insurance

Although private dental insurance is clearly linked to greater dental utilization, the same trend does not exist with public dental insurance in the US where dental insurance primarily targets low-income children. The most common form of public dental insurance is Medicaid, which typically covers children through age of 20 years, although some limited dental coverage is often available for adults. Medicare for seniors does not include dental coverage. Most US states have found that both enrollment and utilization are both low for Medicaid dental insurance. Nationally, among the children without dental insurance, approximately 3 million are likely eligible for public insurance but had not enrolled. Among those enrolled, often only 20–30% of children actually receive dental care in a given year.

There are several reasons for the low utilization rates. A major hindrance to utilization is that reimbursement rates for dentists serving Medicaid recipients is significantly below usual and customary dental fees in most states, reducing the number of dentists willing to accept Medicaid patients. Dentists also cite administrative difficulties (prior authorization and eligibility verification) and an excessive number of broken appointments as reasons for not accepting Medicaid patients. In fact, Medicaid utilization rates are typically not related to the absolute number of dentists in a county, but rather to the number of dentists accepting Medicaid patients. This suggests that simply increasing the number of providers may not be sufficient to increase use of dental services in underserved areas.

Some states have developed innovative Medicaid programs that have dramatically increased utilization rates. For example, in 2000, Michigan implemented a Medicaid program, Healthy Kids Dental, where in select counties a private insurance carrier, Delta Dental, administered the program and reimbursed dentists at the private rate. The results of the program were to increase utilization by 31.4% overall and 39% among continuously enrolled children. Furthermore, the program resulted in a substantial increase in dental participation and a decline in the distance between providers and the children receiving care.

Time Costs

Beyond the direct monetary costs of dental care, there are also indirect costs to seeking care such as the time spent traveling to care and waiting on service. The empirical evidence on the importance of these costs is inconclusive and measuring the effects is complicated by the fact that individuals often bundle their purchases of dental services with other goods and services, and that provider prices may vary in response to expected wait times. Furthermore, wages, which are the opportunity cost of visiting a provider during working hours, tend to be lower in rural areas. As a result, the cost of the extra travel time is at least partially offset by the lower opportunity cost of time.

Other Variables

Money is not the only determinant of the demand for dental services. Dental anxiety may curtail demand for some individuals. Educational achievement probably affects awareness of the benefits of dental care and may make it possible to lower the costs of obtaining dental care. As one would expect, an immediate need for care as measured by presence of tooth pain or gum bleeding has been found to be associated with a greater likelihood of seeking care. Less obviously, a very low state of dental health may actually lower an individual's need for care. Although poorer quality dentition on average might indicate greater need for care, lost teeth no longer need preventive care and costly restoration procedures over an individual's lifetime. This is one reason why studies investigating the effect of community water fluoridation on dental demand have been inconclusive. Although fluoridation is effective in reducing decay, it results in the retention of more teeth over a lifetime, which could increase the need for care during a person's life.

Determinants of Dental Service Supply

Roughly speaking, the supply of dental services can usefully be broken down into three parts: the supply of dental professionals, the hours those professionals choose to work, and the mix of services offered by dentists, hygienists, and auxiliaries. In the short run, supply of all trained dental professionals and the mix of services offered by each type of professional is relatively fixed. It takes time to gain the required education and begin practicing, and the service mix is largely determined by state licensing regulations. The third factor, hours worked, can respond relatively rapidly to changes in wages.

Dentist Profession

The chief dental care provider is a dentist. Typically, industrialized countries require a dental degree from a university to become a licensed dentist. In the US, entry into the profession requires a graduate degree consisting of four years of training leading to a Doctor of Dental Surgery degree or the equivalent Doctor of Dental Medicine degree. The first two years include basic medical and dental science and the second two years focus on clinical training. In many other countries, a dental degree is provided as a bachelor's degree program.

Graduates of accredited dentistry programs in most countries must also obtain a license to practice dentistry. In the US and Canada, graduates must pass a national licensure board exam and meet other state or province licensure requirements in order to practice. European countries, alternatively, permit free movement within the European Economic Area once a dentist is licensed to practice. However, other restrictions, such

as the ability to treat patients participating in Germany's sickness funds, limit the mobility of dentists.

Dental schools and many other institutions (generally, universities with medical schools, or large hospitals) offer advanced education programs of one to six years duration that train dentists to provide better quality clinical care or specialty care such as endodontics, periodontics, orthodontics, prosthodontics, and oral/maxillofacial surgery.

Supply of Dentists

Supply over time

Higher wages may induce fairly rapid changes in the supply of dentists' services as some dentists postpone retirement or work more hours. However, higher wages could also induce some dentists to work fewer hours, choosing to substitute leisure for work, a phenomenon referred to by economists as a backward-bending labor supply curve because increasing wages have the unexpected effect of reducing the amount of work people are willing to provide. Among dentists in the US, this choice to work less as wages rise may in fact be occurring at the margin. Dentists work, on average, far fewer hours than physicians. Therefore, higher wages could actually reduce the amount of services available. In the long run, expanding the number of licensed dentists will require an expansion of the number of spaces available in dental schools either through expansion of existing schools or the building of new ones.

It is interesting to note that, if dentists are indeed on the backward-bending portion of their supply curve, then increasing the supply of dentists has a larger effect on the supply of dental services than it does on the supply of dentists. Insofar as the added dental graduates drive dentist wages down, then, on average, already licensed dentists will expand their hours. In this way, each new graduate increases the supply of dental services by more than their own contribution of hours to the labor force.

In estimating the supply of dentists needed in the coming years, changes in productivity should also be taken into account. Since 1960, there have been significant fluctuations in productivity, ranging from an increase of 3.95% annually from 1960 to 1974, 0.13% annually from 1974 to 1991, and 1.05% growth annually from 1991 to 1998. The first increase was due to the use of high-speed drills and more auxiliary labor, whereas the 1991–98 increase was likely due to general economic expansion and the further increase in auxiliary employment.

The composition of the dentist workforce can also influence the supply of services. Studies have found differences in hours worked between male and female dentists, as well as differences by the age of the dentist. Older dentists, particularly males, worked fewer hours. Having children reduced the hours work among female dentists. Men and women are equally productive on a per hour basis, but women work part-time twice as often, at least up through age 45.

Internationally, the dentist-to-population ratio varies significantly. Low-income countries tend to have very low dentist to population ratios. In Africa, for example, the dentist-to-population ratio is 1:150 000 compared to 1:2000 in most industrialized countries. Furthermore, most dentists are located in big cities, resulting in even lower dentist-to-population ratios in rural areas.

However, simply increasing the number of dentists may not solve the problem. Between 1985 and 1998, the number of dentists in Syria increased from 2000 to 11 000, resulting in a ratio of 1:1500 dentists per population. The Care Index (F/DMFT∗100%) of the child population remained unchanged and adults only increased from 17% to 33%. Similarly, in the Philippines the dentist-to-population ratio is similar to high-income countries at 1:5000, but the Care Index of children remains very low. The likely explanation is that the majority of the population cannot afford restorative work even when dentists are available.

Licensure and regulation

Occupational licensure has been shown to be an important source of variation among US states in the supply of dentists, other dental professionals, and dental services. Each state sets its own licensure requirements for both new dentists and for those moving into the state. Licensed dentists who wish to move to a new state must obtain a license in that state. This process can be facilitated if states have reciprocity agreements in which state dental licensing agencies agree to recognize the validity of each other's license, or if they have licensure by credential in which states will grant licenses to practicing dentists who have met certain criteria, such as being in continuous practice for a specified period of time.

There are both benefits and costs to occupational licensure. On the one hand, licensure is intended to reduce uncertainty for consumers by ensuring a minimum level of competency or through greater standardization in care. On the other hand, licensing may increase cost and reduce supply by limiting entry into a market. It could also potentially reduce quality by screening out the most qualified individuals. Individuals with a high opportunity cost of time may opt not to enter a profession because of the high cost of obtaining a license.

Licensure generally does not have a significant direct effect on the quality of oral health outcomes, but can influence prices and the supply of dentists. For example, dental records from US Air Force enlistees reveals that stricter regulation has no effect on overall quality of outcomes. Restrictive licensing does, however, raise prices for consumers and earnings for dentists. A state that increased from low or medium to high restrictiveness could expect an 11% increase in the price of dental services. State-mandated restrictions on the number of branches of a dental practice and on the use of dental hygienists also results in higher prices.

Distribution of Dentists within US States

Where dentists settle within the US depends in large part on the size of the state's population and the state's per capita income, both of which are correlated with the per capita number of dental providers. Within the health care sector overall, there is virtually no relationship between the state of degree production and employment. Rather, the production of advanced degrees tends to be concentrated in large, densely

populated states, and providers disperse across the country after degree completion. Often, however, providers do return to their home state after degree completion.

A separate issue from the total number of dentists in a state is how they are distributed within the state. The distribution of providers within states and the decision to locate to rural and/or underserved areas has been studied more thoroughly in the context of physicians than dentists, although many of the findings can be applied to the dental profession. For medical students, having a rural upbringing and specialty preference for rural practice mattered. For medical schools, a commitment to rural curriculum and rotations were the most significant factors in encouraging graduates to locate in rural areas. Similar results were found when UCLA/Drew Medical Education Program students participated in medical rotations in South Los Angeles, an impoverished urban area. After 10 years, 53% of graduates were located in an impoverished or rural area, compared with 26% of other UCLA graduates, even after controlling for race and ethnicity.

Applying these results to dental education, a recent national demonstration project involving 15 schools established goals of increasing senior students' time providing care to underserved patients, educating students to treat underserved populations and expanding enrollment of underrepresented minorities. Results reveal that the quantity of time spent in community settings increased from 10 to 50 days, the participating schools developed courses in cultural competency and public health, and underrepresented minority enrollment increased. However, support from a government sponsored loan repayment program was the most significant predictor of plans to go into public service. Alternatively, increasing educational debt was the most significant barrier to public service plans.

Dental Auxiliaries and Other Providers of Oral Health Services

Types of Oral Health Providers

In addition to dentists, there are a variety of dental auxiliaries and other health professionals that provide oral health services. They include dental hygienists, dental assistants, dental therapists, and dental laboratory technicians. Regulations, training requirements, and the specific functions performed by each auxiliary type varies from country to country, and not every country licenses each type of auxiliary. Table 2 summarizes the training, licensure, or certification typically required, and the functions typically performed by dental auxiliaries found in the US. Dental hygienists focus on preventative care. Dental assistants provide more direct aid, working alongside the dentist. Most states have enacted provisions to permit dental assistants to conduct more tasks after obtaining additional certification.

Dental therapists are less widespread in the US. As of 2011, only Minnesota and some remote parts of Alaska permitted dental therapists. The safety and effectiveness of dental therapists tend to be high. In Alaska, dental therapists exercise good judgment, provide appropriate care, and have highly satisfied patients.

In contrast, dental therapist is a well-established profession in a number of countries. In New Zealand, where dental therapy began in 1921, dental therapists focus on children. The result is more than 60% of children from 2 to 4 years old utilize public oral health services, with an average cost of US $99 the per child. Currently, there are at least 54 countries that use dental therapists, most often staffing school-based programs.

Beyond these standard auxiliaries, individuals may receive oral health care from other providers. Primary care physicians, for example, can be involved early in oral health through a number of possible interventions including screening, counseling, referral to dentists, application of fluoride varnish, and the provision of supplemental fluoride. However, many pediatricians are not actively providing oral health services. More than 90% of pediatricians said that they should examine teeth for caries and educate families, but only 54% did so for more than one-half of their patients between the ages of zero and three. Only 4% of pediatricians regularly applied fluoride varnish. The most common barrier is lack of training.

Regulation of Dental Hygienists

The experience of the dental hygiene profession in the US illustrates the potentially negative effects of restrictive licensure practices for dental auxiliaries. In the US, state dental boards are typically responsible for regulating the dental hygiene profession, making dental hygiene the only licensed profession regulated by another profession. States vary significantly in both their entry requirements, including what is required to obtain a licensure by credentials, and in their

Table 2 Types of dental auxiliaries

Auxiliary	*Typical education/ training in US*	*US Licensure/ certification*	*Typical functions*
Dental hygienists	2–4 years	License	Preventive oral health services including oral prophylaxis and dental hygiene education services
Dental assistants	On-the-job or 1-year program	No (certification optional in most states)	Prepare equipment, update patients' records, work along side dentists during procedures, remove sutures, apply topical anesthetics or cavity-preventive agents, remove excess cement during filling processes
Dental therapist	4–6 years	License	Function of Dental Hygienists plus extractions and simple fillings
Dental laboratory technician	On-the-job or 2 year accredited program	No (certification optional in most states)	Creates dentures, bridges, crowns, and orthodontic appliances by following a dentist's written instructions

scope of practice restrictions, which range from allowing only basic teeth cleaning and polishing services to conducting more complex or potentially hazardous procedures such as administering anesthesia and conducting restorative functions. States also regulate the level of supervision required by dentists, ranging from direct supervision to complete autonomy.

The consequence of restrictive scope of practice regulations is to increase the demand for dentists, while underutilizing hygienists. The US Federal Trade Commission (FTC) estimated that the price effects of state-imposed restrictions on the number of dental auxiliaries that dentists are permitted to employ or the functions hygienists can perform resulted in a 7–11% increase in prices, which cost consumers approximately $700 million in 1982. In 2003, the FTC issued a complaint against the South Carolina Dental Board for prohibiting hygienists from providing teeth cleaning services to Medicaid children. The case was eventually settled. The restrictions dentists have placed on hygienists suggest that dentists view expanded dental hygiene services as a substitute for dental services. What the evidence suggests is that hygienists may also serve as a complement to dentists allowing dentists to specialize in more complex procedures.

The consequence of regulations restricting the use of hygienists and other mid-level providers is often to eliminate the lower cost, lower quality segment of the market. The elimination of the lower cost market segment is troubling when it serves to prevent lower income individuals from purchasing important services and simply forgo treatment that would improve health outcomes. Researchers have found a correlation between restrictive dental hygiene regulations and dental hygienist salaries, dental office visits, hygienist employment levels and, ultimately, access to oral health care.

Conclusion

Oral health has generally been improving in industrialized countries, along with increased utilization and per capita spending on dental care. However, the US experience illustrates that such improvements can occur while significant disparities persist. Tooth decay continues to be a major problem among its low-income, rural, and minority populations. The trend goes the opposite direction for low-income countries where the prevalence of dental caries is increasing from previously low levels because of the adoption of developed nation diets without the corresponding dental care infrastructure.

There are both economic and medical consequences of poor oral health, yet the solutions for improving oral health outcomes are far from clear. Insurance and income are both strong predictors of demand for dental services, but as the US illustrates low reimbursement rates and administrative difficulties can render public insurance for low-income individuals less effective at raising utilization rates. The availability of oral health services is likely to increase in the coming decades. If the international pattern follows that of developed countries, the supply of dentists is likely to increase with rising incomes and greater need in developing countries in the coming decades. Dental auxiliaries and other oral health providers may also play an increasingly important role in the provision of dental services as oral health systems modernize. Without adequately funded and managed public programs to target disadvantaged populations and prudent consumer-friendly regulations, much of this increase in dental service will bypass many of those most in need.

Glossary

Agency relationship The relationship between an agent and a principal. Classically in health care, the role of a physician or other health professional in determining the patient's (or other client's) best interest and acting in a fashion consistent with it. The patient or client is the principal and the professional is the agent. More generally, the agent is anyone acting on behalf of a principal, usually because of asymmetry of information. In health care, other examples include health managers acting as agents for their principals such as owners of firms or ministers, regulators as agents for politically accountable ministers, ministers as agents for the electorate. In health care, the situation can become even more complicated by virtue of the facts, first, that the professional thereby has an important role in determining the demand for a service as well as its supply and, second, that doctors are expected (in many systems) to act not only for the 'patient' but also for 'society' in the form, say, of other patients or of an organization with wider societal responsibilities (like a managed health care organization), or taxpayers, or all potential patients. There can be much ambiguity, as in seeking to understand the agency relationships in overseas aid giving and management, and as in establishing the extent to which formal contracts can enhance efficiency.

Aid effectiveness A measure of the effectiveness of aid by examining the contribution of Overseas Development Assistance to the extent to which countries have achieved a reduction in poverty or an increase in growth.

Conditionalities Many countries stipulate that aid is given on particular conditions being met, for example, a package of macroeconomic policies is undertaken.

Development Assistance for Health Overseas Development Assistance that is specifically earmarked for use only within the health sector.

Developmental aid Aid given solely for the purpose of alleviation of poverty or for achieving a higher growth rate compared, say, with aid for military improvements or for foreign policy reasons.

Donor coordination A means of avoiding fragmented aid giving, thereby avoiding needless project duplication. One of the easiest ways to coordinate funding streams is to fund particular ministries rather than single specific projects.

Earmarking International development assistance (aid) or taxes within a jurisdiction stipulated for a particular purpose.

Fungibility A term used to describe the substitutability of one entity for another. For example, money is fungible, in that a ten dollar bill is equivalent to ten one dollar bills. In aid policy, the phenomenon of external funding intended for one purpose but ultimately used by a recipient government for another is another example.

Background

In 1990, development assistance for health (DAH) flowing from the Organization of Economic Cooperation and Development (OECD) countries amounted to only US$4 billon accounted in the index year of 2009. This figure had increased to US$19 billion by 2010, although the year 2009 saw a decline in DAH perhaps due to the economic downturn in the developed countries. Figure 1 shows the dramatic increase since 2000. Although much of it can be due to the commitment to combat human immunodeficiency virus (HIV)/acquired immune deficiency syndrome (AIDS) epidemics, the overall increase is substantial, and there has been recognition of other health care issues as well, as shown in Figure 2. Naturally, questions have risen as to the effectiveness of development assistance for health. Of course, the pathways through which one can examine whether aid has contributed to improved health are extremely difficult to discern. This is one of the issues addressed below. A substantial number of intermediary issues have been examined in the literature. Among the important issues concerning the pathways are what has been recognized as fungibility, coordination, and fragmentation. After a brief description on flow of development assistance on health (DAH), the authors ascertain the current thinking on aid effectiveness.

Trends in Development Assistance on Health

Of the US$127 billion distributed in overseas development assistance (ODA) in 2009 from OECD-DAC, approximately 16% (19 billion) was directed toward health; the corresponding figure for the sub-Saharan Africa (SSA) is 44% (US$12 billion of US$26.7 billion ODA). Thus, health issues play a prominent role in the total development assistance where poverty issues loom large. The prominence of recognition of HIV/AIDS as a global problem resulted in a proportion of DAH going to HIV/AIDS, rising from being approximately 10% of the total amount DAH in 2000 to nearly 40% by 2007 (see Figure 2). Perhaps, due to this crisis there have been proliferations of other actors such as private foundation, global health partnership, and NGOs toward ensuring greater DAH. Once these mechanisms have been taken into account, estimation of total DAH can rise by 20–30%.

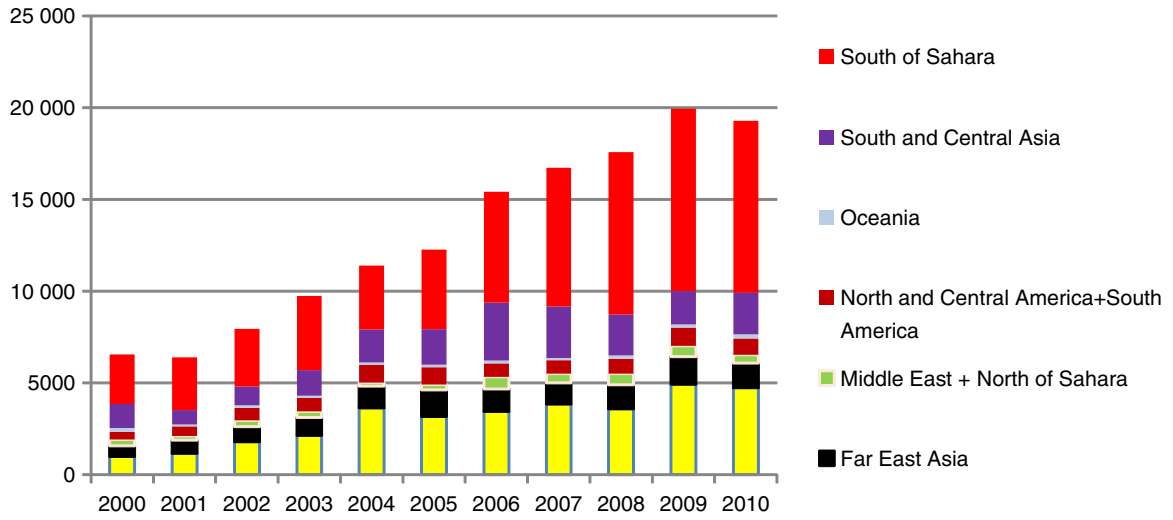

Figure 1 Total and regional patterns in DAH (in millions of 2009 US$). Reproduced with permission from OECD (2013). Available at: http://www.oecd.org/dac/stats/ (accessed 15.07.13).

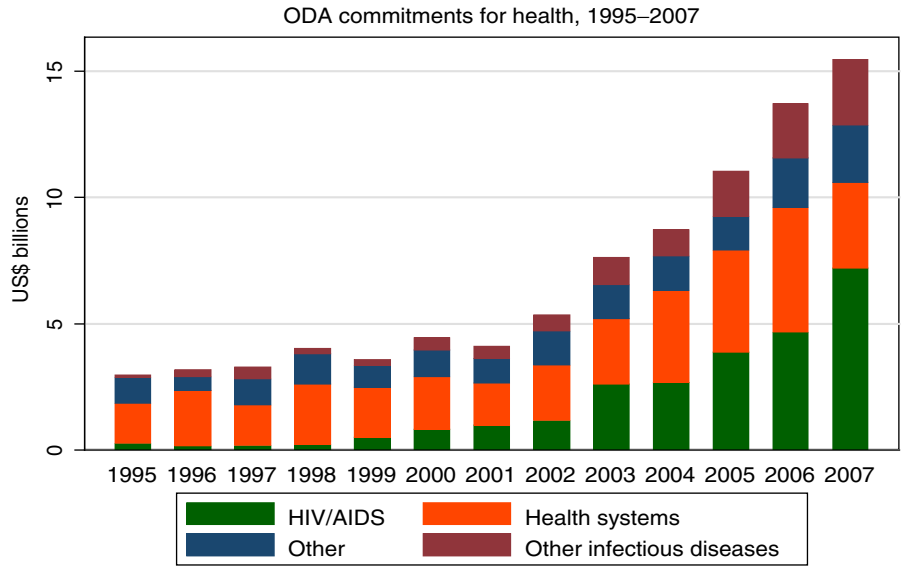

Figure 2 Trends in priorities for development assistance for health (2009 constant US$ billion commitment).

Given that for some countries DAH can amount to a large proportion of the public health budget, the modality of funding is an important issue. A useful literature that feeds into analysis of aid-effectiveness is the examination of the wide variety of funding modalities, which depend on the amount of earmarking for specific usage and the extent to which the myriad of actors rely on government systems for planning, disbursement, and monitoring of funds. The myriad of modalities include direct funding of projects, program aid, sector-wide approaches, and budget support, with projects having the most earmarking and budget support the least. A more recent form of aid giving has been through direct NGO funding. Discerning these channels from the existing data sets has been difficult. At least one study concludes that aid modalities independent of government may induce greater commitment of funding toward health improvement from the government. Although one can take account of a certain degree of endogeneity from the fact that the recipient country's governance structure influences the method through which aid is delivered, these results do not prove conclusive. Knack notes that the use of country infrastructure by the donors is related to (1) donor's share of aid provided to the recipient, (2) perception of corruption in the recipient country, and (3) the public support for aid in the donor country. The perception of corruption in aid has been tied to the issues regarding fungibility. Another concern has been that aid is provided through multiple transfer instances what one may label as aid events; and for a single country there are multiple donors as indicated already. There are two concerns underlying here: firstly that aid giving involves multiple episodes of transactions between the donors and the recipients; and secondly that there may

be too many aid givers. These two issues have been recognized as aid fragmentation, perhaps stemming from lack of coordination among donors.

As ODA can be specified to be used only for developmental use as opposed to military use, within the developmental budget, there is, of course, a mandate as to what can be funded, such as health and education. Various modes have been used to mandate that the health budget have to provide for both specific and general use. One mode of delivery is to offer through basket funding to the government's nonmilitary budget; this has little or no earmarking. A widely used method is called the sector-wide approach (popularly known as SWAP) which can be described as a coordination mechanism for donors working on the same sector. It is a form of budget support where funding is more targeted. Program-based approach has gained prominence; they are characterized by having a single comprehensive program and budget framework, donor coordination in budgeting procedures, management, procurement and reporting. In recent years, nearly exclusive to funding health problems in developing countries are the global health initiatives, which are vertical programs to tackle a single public health issue through a consortium of ODA and private funding.

Effectiveness of ODA is a much discussed recent topic in the economics literature, although initial literature dates back to Pack and Pack in 1983 when much of ODA may have been driven by geopolitical concerns; and there were essentially two donors. The geopolitical nature of aid giving induces Rajan and Subramanian, for example in their now well-known paper, to leave out Egypt.

Measuring Effectiveness of DAH

The unambiguous conclusion from the empirical literature on aid effectiveness as stated by Bourguignon and Sundberg is that it has 'yielded unclear and ambiguous results.' They also state that this should not be a surprise given the politics of aid with the heterogeneity of motives; and more importantly, the complex causality chain linking external aid to final outcomes. For ODA, one of the most important outcome measures of development has been growth rate. Ignoring the mechanism through which ODA may affect the growth rate, a set of oft-quoted studies using reduced form equations have estimated the impact on growth rate to get results that indicate that the relationship between aid and development outcomes is fragile and often ambiguous. The results are slightly more optimistic when some form of mechanism through which aid can affect growth rate has been taken into account. For example, Arndt and coauthors show a positive impact of ODA on growth through a structural model where life expectancy along with investment and education are intermediary factors through which aid affects growth.

The use of reduced form approaches have prevailed in showing the impact of DAH. DAH is, of course, intended for improving health in most cases. It is also part of the developmental aid as opposed to the military or the politically motivated assistance. Clements and coauthors have indicated that for the short run aid allocated to support budget and balance of payments commitments and infrastructure result in rising income. They speculate that aid promoting democracy, health, and education will have a long run impact on growth. Minoiu and Reddy have shown through a Gaussian Mixture Model that developmental aid contributes to growth, whereas the same cannot be said of nondevelopmental aid. Burnside and Dollar conclude that ODA equivalent to 1% of GDP in the recipient country reduces child mortality by 0.9%. Mishra and Newhouse have shown through a Generalized Method of Moments estimation for data from 1975 to 2004 that doubling per-capita health aid decreases infant mortality by 2% for the subsequent five-year period. Earlier, Peck and Peck had showed statistically insignificant results for infant mortality rate.

As mentioned, the mechanism through which aid can improve an outcome is too complex, and simply answering whether an outcome is achieved or not is not very helpful especially if the answer is that the outcome of interest does not seem to have a desirable relationship with ODA. One way to discern pathways through which ODA may or may not work is to ask questions as to whether elements of an economy that ODA funds make for sound policy-making. This may involve macroeconomic analyses or an impact evaluation of projects. It is not possible to evaluate all projects; it is certainly not possible to list all projects that may have used DAH wisely in this monograph. Given the nature of implementation of projects, it is also likely to be misled to list successful projects to be applied from places and times different from the original situation in which they were placed.

The general structure of aid giving is likely to have played a significant role in achieving the outcome which the authors finally arrive at. Many ODA was distributed through conditionality which may have resulted in binding policy makers around donor priorities to ensure policy compliance and implementation. The Paris Declaration on Aid Effectiveness adopted in March 2005, with 100 country signatories, recommended improving aid coordination, promoting donor alignment with country strategies, and cutting the 'compliance burden'. Examining the methods through which ODA have been delivered and the intermediary processes it may engender can help us to understand whether ODA would be effective or not. In doing so, it is not emphasized on private philanthropy which is already engaged in development project funding in a significant way, especially in aiming to improve health. Private philanthropy should not be considered as DAH as for some countries it is also domestic fund; and secondly the rules governing such funding are entirely different from that of ODA funding.

Factors Affecting the Effectiveness of DAH

Clearly a factor that would affect aid effectiveness is whether or not it goes to the right place; that is, do the poorest people of the world receive DAH. Secondly, given that some of the DAH is targeted toward particular activities, are these in some ways the right activities that should be funded? It is then turned to a more subtle point of aid architecture or process factors that might be affecting how well DAH is able to improve health: predictability, fragmentation, and

fungibility. Finally, some important elements that motivate the actions of the players involved in making aid more effective are noted.

Funding the poor

Given that the countries of SSA, the poorest region to which aid flows, have received a large share of foreign aid in terms of DAH, the aim of development assistance to generate human development perhaps is likely to have been met. Despite the published results of a cross-country analysis that found no correlation between countries' GDP per capita and the amount of DAH they received, although this is improving, in terms of per-capita DAH is indeed aimed toward poorer countries. Although in terms of total aid the amount of DAH or ODA is aimed at the country which has the largest number of poor – India, as it is a middle income country, it receives a very low-level of per-capita DAH. Distribution of DAH is fairly consistent with the motive of aiding the poor in the poorest country. Figure 3 shows the relationship between the cumulative proportion of poor (defined as living under US$1 a day) and the cumulative amount of DAH distributed for 56 countries, including India and China, but excluding countries with a population smaller than one million and those for which DAH made up for less than 1% of their total government budget. These countries were ranked by per-capita income, averaged over 1995–2006. For this sample of countries, the first 25 countries amounted to containing 26% of the total poor, whereas the amount of health ODA going to these countries amounted to 51.5% of the total amount of aid in our sample. Of these countries, 22 were in SSA. In some countries DAH does nearly make up for the entire public sector health budget and this may perhaps lead to aid dependency.

Funding Illnesses

As funding can be earmarked, it is important to know how it is earmarked. One way to measure the impact is to see how the burden of illness matches funding. A commonly used measure is disability-adjusted life years (DALYs) for burden. Nugent has shown that while US$0.78 per DALY is allocated toward combating noncommunicable diseases in 2007, US$23.9 per DALY was allocated to HIV/AIDS, Malaria, and tuberculosis. However, a bulk of the latter funding was targeted toward combating HIV/AIDS. Of the US$13.8 DAH that could be accounted for by Ravishankar and coauthors, US$4.9 was spent on HIV/AIDS, compared with US$0.6 billion spent on tuberculosis; the corresponding numbers for malaria and health system were US$0.7 billion and US$0.9 billion. More funding is allocated toward drugs than to human infrastructure.

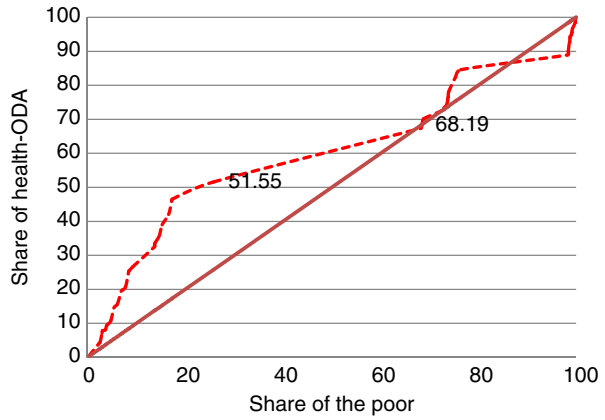

Figure 3 Cumulative distribution of health ODA in relation with the distribution of poor in 2006 (Martinez-Alvarez and Acharya, 2012).

Predictability

For donor countries, ODA is discretionary spending without the backing of any electoral constituency that needs to be placated through political seigniorage. Predictability in regard to ODA is defined by OECD as (1) long-term consistency and (2) disbursement of committed funds in a timely manner. A panel regression of data from 60 low-income countries from the time period of 1990–2005 found that annually there was a great deal of differences between disbursements and commitments, particularly in SSA and the time trend did not show an improvement. Some of this discrepancy can be attributed to a lack of stability in the recipient country. However, the larger reasons for the discrepancy may well be due to the unmet policy conditions by the recipients, donor administrative and political problems. A lack of consistency in funding availability hinders planning for the long term and may force adjustments and changes to original budget plans in the recipient country.

Fragmentation

An increased level of development funding has resulted in the proliferation in the number of donors as well the number of transactions that mobilize the funding processes. Frot and Santiso found Tanzania, a poor stable democracy, had 1601 aid projects in 2007, although the attraction of Tanzania may be due to its stronger institutions. Acharya and coauthors note that fragmentation causes direct transaction costs both to the total aid budget and the recipient country; further, it exacerbates skill shortage in the recipient country by diverting management attentiveness. Anderson shows through econometric techniques that fragmentation does impose administrative costs. Fragmentation may lead to duplication of projects and repetitive activities. Mueller and coauthors have observed that there is great many similar types of training for health workers in Malawi. As fragmentation can be due to the presence of increasing number of donors, Knack and Rahman have emphasized that bearing of responsibilities of outcome of developmental funding can be diluted. Individual country will be less able to claim credit for success; and the result may be that fear of free-ridership induces a lack of effort on the part of donor countries. Fragmentation may also limit economies of scale as project expansion may be limited by the donor's budget ceilings. Principally, the 2005 Paris declaration may have been aimed at fragmentation; 100 countries have recognized that improving aid coordination and promoting alignment with country strategies is a big step toward making ODA more effective.

Fungibility

Fungibility centers around the possibility that ODA becomes a substitute for developmental expenditure that recipient countries are willing to undertake rather than complement the government's developmental budget. It has also become synonymous with corruption. However, fungibility can be seen to be a rational response to sectoral earmarked funds. It also signals that the donor and recipients may have different priorities. One way that a finance ministry can see any type of ODA is to view it as extra revenue. Naturally, for a particular sector the recipient countries would increase the total expenditure in that sector; it may or may not maintain or increase its funding from its own revenue. However, among some policymakers there seems to be an expectation that any increase in DAH should not reduce any domestic expenditure. The response in the academic literature has been very different than policy makers. The academic literature sees fungibility as an extension of the literature on centralized allocation under a federalized system. Economists generally would be surprised by the fact that the local expenditure actually exceeds what would be predicted by the income effect of additional revenue allocated from the central government. Estimates of the extent of fungibility in the health sector for every dollar allocated through DAH on average to a country vary from a decrease in US$0.27–1.65 to a US$1.50 increase. These results depend on the methodologies used including how the dependent variable of total domestic expenditure is calculated. Some factors can be associated with increased fungibility; these include low-levels of GDP per capita of the recipient, fragmentation, and lack of predictability of DAH flow. From a fiscal point of view, the optimal response to lack of reliability of ODA flow is to smooth DAH by spreading it across different years, a practice advised by the IMF.

Motivations and Relations

The issue of fungibility highlights the fact that as economic agents donors and recipients are likely to have different motives. Donors may well be monolithic in their home political structures but by no means in their home country's attitude toward ODA; and the recipient make up for divergent types of governments ranging from those that are war torn to those that have experienced more or less stable democracy since independence. The donors are accountable to their government and domestic public opinion. The recipients stand in relation perhaps to fill the revenue gap for funds needed for developmental project.

As Knack and others have pointed out, the number of donors shapes donor incentives where development can be seen as a public good which is likely to result in donors eluding individual responsibility. The equivalence of Niskanen type of rational bureaucracy on the donor's part may well be toward spending of funds rather than achieving results where the links from funds to outcome may be tenuous. This has come to be known as 'money-moving syndrome.' The consistency between the donor government's motives and development also plays a role. One must also note that the governments of the recipient countries may have different developmental interest or may even have little interest beyond remaining in power. The relation between the donor and the recipient can be understood as something similar to the canonical principal–agent relationship. The donor is not able to judge or monitor the recipient's commitment to development the way that may have been agreed. The donor stands in relation as the principal who may wish for outcomes which can only be achieved by the recipient, the agent. Usual aid practices ignore this fact and unenforceable conditionalities have been usually implemented. Bourguignon and Sunderberg recommend that the aid recipient be free to choose development policies and to implement them and that aid should be "made dependent on observed or possibly foreseeable progress in development outcomes like poverty reduction, improved literacy rates, lower child mortality, etc., and on the observable general quality of policies."

Discussion

What can be highlighted here is that effectiveness of DAH measured in terms of outcome is inconclusive; but most likely DAH along with ODA has not resulted in very significant changes in health outcomes. The key factors affecting the impact of aid on the development that are emphasized here are allocation of resources, donor fragmentation, fungibility of funding, and issues related to making the recipient accountable. That the auhors are unable to gauge the performance of ODA or DAH clearly does not entail that assistance to poor countries should be stopped or even drastically curtailed. Further, political expediency is not likely to move toward such a situation. Thus, making aid effective is a priority for many countries.

Where the link between outcomes and DAH would always be statistically questionable, for ODA relation to be based on performance one would need to examine factors such as governance, country practices, and the outcome results that are observables or can be monitored. An examination of small-scale programs will be valuable toward determining a set of best practices. For successful scaling up of best practices, as has been noted by Medlin and coauthors, the important factors are country ownership, strong leadership and management, and realistic financing.

Diagnostic Imaging, Economic Issues in

BW Bresnahan and LP Garrison Jr., University of Washington, Seattle, WA, USA

Introduction

Diagnostic imaging uses noninvasive devices to visualize internal human anatomy and physiology. In higher-income, developed economies of the world there is enormous variation in the use and rate of growth of use of diagnostic imaging technology like computed tomography (CT). Even in high use jurisdictions like the US there is a large variation. Compared to other Organization for Economic Co-operation and Development (OECD) countries, the most recent per-capita use rates in the US for CT and magnetic resonance imaging (MRI) are more than twice the median OECD rate. There are also substantial geographic variations among the Medicare regions – with the highest per-capita rate of noninvasive imaging in the Atlanta region being 150% greater than Seattle, the lowest use region (Parker *et al.*, 2010). Rapid growth and extreme and variable utilization rates suggest that there may be a lot of inappropriate diagnostic imaging use in the US, and this is especially of concern given that it has relatively poor population-level health indicators among the OECD countries. Inappropriate use has health and economic consequences, which from an economic perspective can be framed as questions of static efficiency and dynamic efficiency. The former is about obtaining good value of money in current spending, and the latter is about eliciting the optimal rate of innovation given the substantial global fixed costs of research and development (R&D). And they are related in that current spending provides the funds needed to support R&D for the long term.

Some characteristics of diagnostic imaging as a medical product – such as strong economies of scale for high fixed cost equipment, informational asymmetry between providers and patients, and the potential for moral hazard – create obvious challenges to promoting its efficient use. For the majority of imaging applications, the marginal cost is relatively low, leading patients and their doctors to seek the information even if the marginal health benefit is low. However, marginal cost pricing would neither cover the fixed costs of the equipment nor provide sufficient funds for long-term dynamic efficiency. However, fee-for-service (FFS) average cost pricing may induce providers to increase volumes to cover the fixed cost, providing incentives for greater use of imaging rather than lesser use – whether the use is appropriate or not. Between 2000 and 2010, physician fees for diagnostic imaging in US Medicare population grew by more than 80%, targeting attention on diagnostic imaging (Medicare Payment Advisory Commission (MedPAC), 2012). Different countries have tried very different approaches to controlling use and costs – discussed elsewhere – the focus here will be on structural economic incentives in the US marketplace and related evidence – such as cost-effectiveness studies, appropriate use strategies, health spending trends, and the impact of payer policies. Finally, designing reimbursement policies that will support appropriate utilization and stimulate levels of innovation consistent with dynamic efficiency is discussed.

The Role of Diagnostic Imaging in Healthcare Delivery

Diagnostic imaging is clearly about reducing uncertainty when diagnosing health conditions. Over the past 120 years, the major 'modalities' of diagnostic imaging (**Table 1**) have become essential components of medical care. Early innovation in imaging was linked to the advent of radiographic imaging (X-ray) in Germany in the 1890s and the introduction thanks to French scientists Pierre Curie and Paul Langevin of ultrasound in the 1940s and 1950s. The so-called 'advanced imaging technologies' were created in the 1970s by Hounsfield in the UK and Cormack in the US with CT imaging or computed axial tomography, again in the 1990s by Bloch and Purcell in the US with MR or MRI, and during the late-1990s by Townsend and Nutt in the US with the nuclear medicine innovation of positron emission tomography (PET) and combined PET/CT imaging.

Imaging can be used in many ways in healthcare delivery. Imaging can inform healthcare decision-making to assist inpatient planning and management, or can be used with interventional procedures (which are not discussed here). Imaging can be used only once or multiple times during the process of making decisions about using specific medications, procedures, surgeries, or other treatments. The resulting information helps the managing physician to refine the diagnosis to support better overall clinical decision-making. This information can increase the likelihood that the patient will ultimately receive the appropriate stream of treatments in order to reduce morbidity and mortality. But the diagnostic test information can also increase the physician's and patient's confidence in the chosen course of clinical action. This can add valuable comfort and peace of mind for the patient. This benefit has been called the 'intrinsic value' or the 'value of knowing,' and can undoubtedly be important to patients and their providers.

Imaging testing relies on a complex mix of specialized labor and capital, information technology (IT) applications, and processes of communication in ordering and reporting. The high-cost equipment producing high-quality images may provide clinical utility through accurate information for treating providers if the scans are ordered, performed, and interpreted appropriately. From an economic perspective, appropriate use would generally be defined as use for which the long-term marginal social benefit exceeds the long-term marginal social cost. Clinically, the goal has been to use a 'correct test, correct indication, and correct timing for the correct patient.' Although it seems likely the majority of use would be found to be appropriate, identifying, and measuring

Table 1 Description of select modalities

Analog radiography, also referred to as conventional plain film X-ray, uses radiation beams that pass through the body and are absorbed in different amounts depending on the density or composition of the anatomic material subjected to the radiograph. Dense bones appear as white on X-rays, whereas organs, fat, or muscles appear as darker in the image.
Digital X-ray machines capture a computerized image rather than using traditional photographic film capture of images. Digital X-ray technology has become the standard for institutions updating their equipment, due to lower radiation emission and faster scanning capabilities.
Mammography machines are specialized low-dose X-ray machines designed specifically for imaging breast conditions. Mammograms are used during the detection and diagnosis of breast disease. Digital mammography, also referred to as full-field digital mammography, uses computerized technology to create the image, evaluate the image, and store the image, rather than printing mammograms on photographic film.
Sonography or ultrasound uses equipment with a transducer probe which emits high-frequency sound waves through the body, reflecting information signals that provide details related to anatomical abnormalities or health status related to pregnancy, thyroid conditions, organ damage, or other internal conditions.
CT imaging combines X-ray equipment with computers. The X-ray is enclosed in a rotating cylinder that sends signals to high-powered computers to produce cross-sectional images of organs or tissue in the body. CT scans generate multiple diagnostic pictures depicting 'slices' of specific portions of the body. CT scans, like conventional X-ray, have radiation exposure risk for patients, so inappropriate utilization is a concern.
Magnetic resonance imaging (MRI) uses magnets encapsulated in a cylinder, rotating around the patient to send strong magnetic fields and radio waves through the body to depict conditions and to detect abnormalities. MRI equipment does not emit radiation and thus does not have the same risk as CT or radiography. However, owing to the use of magnets, MRI use includes restrictions for patients with internal metallic items or specific devices. MRI is best able to depict blood vessels and soft tissues, but does not depict bone structure.
Hybrid imaging: Positron emission tomography (PET) equipment uses a gamma camera along with radioactive pharmaceuticals (tracers) to detect disease and molecular activity. PET imaging is most often aligned with CT (PET/CT) images to coordinate anatomical positioning and computers generate 3-dimensional images of the anatomy, organs, and tumor presence, with its size, spread, and severity in the body. This nuclear medicine modality is able to indicate with high-quality images how tissues and organs are functioning, including molecular function and activity associated with oncologic tumors.

the amount and consequences of inappropriate use is difficult but important. Nonetheless, as will be described below, many of the market and policy responses observed in the US in the past decade represent efforts to control or limit inappropriate use.

Overview of the Market for Diagnostic Imaging

The market for diagnostic imaging is about the demand for and supply of information. All of the various modalities provide the managing physician – i.e., the patient's agent – with additional information to reduce diagnostic uncertainty and therefore to enhance the probability of successful treatment. It is, thus, a derived demand from the patient's point of view, but it is also an imperfect good, subject to some testing and diagnostic inaccuracy. Also, imaging can be subject to considerable moral hazard if neither the patient nor physician face substantial direct monetary consequences. From the supply side, equipment with high fixed and high operating costs are involved, and also complementary services are provided by the radiologist or other interpreting physicians. Throughput in imaging interpretation can be very high (e.g., 7–8 scans read per hour), and the short-run and long-run marginal cost can be fairly low (e.g., the average US payer reimbursement amounts can be on the order of less than US$100 for an X-ray, US$200–300 for a CT scan, and US$400–500 for an MRI). None of these alone would be sufficient to warrant the purchase of catastrophic insurance protection by patients. Still, this equipment represents major investments for most health systems or providers, and many national health systems control their acquisition and deployment. However, in the US, a healthcare system where many insured patients have first-dollar insurance and tax-subsidies for insurance purchase at the margin, it is easy to understand the potential for moral hazard, when the out-of-pocket cost for patients (i.e., often approximately 20% of reimbursed amounts) is far below marginal social cost.

Supply of Equipment: Cost, Location, and Regulation

Imaging manufacturing has a relatively high fixed cost of entry, but the marketplace includes a mix of diversified large global firms, medium-sized innovative cross-industry firms, and smaller niche firms specializing in specific equipment with more focused applications for different conditions. The global market for advanced imaging equipment is substantial – on the order of US$5 billion per year. Manufacturers have an incentive to produce equipment at a quality level that their customers (hospitals, outpatient centers, and physician offices) find sustainable: i.e., given the reimbursement level, the customers can recover their investment and be in a position to upgrade equipment to be competitive in their local provider market. Given that advanced imaging modalities, such as CT or MRI machines, may have a useful life of 5–10 years, individual customers do not purchase new equipment each year, but manufacturers offer improved software upgrades. The larger manufacturers also provide lease/purchase arrangements, financing mechanisms, imaging software, bundled contracting for multiple purchases, and service contracts, effectively reducing the transparency of specific imaging equipment purchase arrangements, and presumably allowing some price discrimination among buyers.

Imaging providers are located in three main locations: hospital facilities, physician offices or clinics, and independent diagnostic testing facilities (IDTFs). Emergency departments are most often connected to hospitals and usually have dedicated imaging equipment available, but may share resources

with the hospital-based inpatient providers. The principal manufacturers are located in Germany (Siemens), the UK (Philips), and the US (General Electric).

Imaging devices are costly and require major investments on the part of health systems. Less advanced imaging equipment, such as ultrasound or analog X-ray machines can range from US$25 000 to more than US$100 000, with the most advanced digital radiography equipment costing several hundred thousand dollars. CT equipment costs may be closer to US$1 000 000, whereas new MRIs and PET/CT scanners can cost US$2 000 000 or more. Service contracts with vendors usually add approximately 8–10% of the purchase price. Countries with national health systems must make major, central financing decisions about purchasing and allocating imaging equipment. In the US, imaging equipment purchases are made by private and public institutions with limited federal guidance or restrictions. The US system is more decentralized, with for-profit and nonprofit hospitals acquiring equipment independently, along with health maintenance organizations (HMOs) and outpatient facilities, such as IDTF. Other more centralized systems use a more publicly reported, transparent planning approach to imaging equipment acquisition.

The regulatory hurdles for new diagnostic imaging devices differ substantially from those of pharmaceuticals and are generally less burdensome. In the US, the Food and Drug Administration oversees safety and efficacy standards for both medical devices and drugs. Devices are categorized as either class I, II, or III, which align with specific premarket authorization notification requirements, or the 510(k) process, as well as with demonstrating that good manufacturing practice compliance standards are met. The class III devices are generally considered higher risk and thus have higher evidentiary standards for manufacturers to meet – more similar to innovative drugs. For lower-risk devices, such as 'next generation' diagnostic imaging equipment that is similar to older models and has relatively marginal modifications, diagnostic equipment suppliers can add innovative features or updates with a limited regulatory evidence requirement: clinical trials are not required.

Demand for Imaging: Moral Hazard and Asymmetric Information among Providers and Patients

At the point of care, managing physicians and their insured patients often have a strong incentive to get more information regardless of social marginal cost. The traditional principal-agent relationship applies to imaging, with the patient being the principal consumer and the physician agents providing technical expertise (e.g., radiologist and ordering provider). The size of the market and the complexity of selecting which test is appropriate and choosing how to interpret images have led to further technical subspecialization among imaging professionals, for example, cardiologists also read scans. Patients often have little knowledge of how imaging works technically and/or which modality, such as CT, MRI, or ultrasound, would be most appropriate for a particular condition. This provides an opportunity for radiologists to gain rents for providing their technical expertise for test appropriateness and test interpretation. Physician preference may increase further imaging in cases where initial testing is not definitive, as indicated in a radiology report or through a sequential testing strategy by ordering providers – though payers place constraints on this, as described below.

Patient demand can also lead to higher rates of medical imaging. Patients are becoming more informed and more active in making their healthcare decisions. Although patients rely on their providers as agents with technical expertise, they are more frequently engaging their providers with information obtained from their networks, the internet, or other sources. Given the influence of third-party insurance payments, because patients do not incur the full cost of imaging services, they may not have a strong copayment disincentive to not be tested. Shifting more financial responsibility to patients in the form of higher copayments for higher-cost imaging, such as for MRI, is being used in some US health systems.

Some observers see physician-induced demand as a factor in this market, particularly when providers have some ownership of the equipment that they are referring patients for imaging. This is, however, a more general phenomenon that links the increased use of healthcare services to physicians having a financial incentive to provide care, whether in the form of more office visits, conducting testing, or performing invasive procedures. In the US, this is generally called self-referral and has been a focus of attention by researchers and the government. **Figure 1** shows the change in specialty practice revenue estimated to come from diagnostic imaging, comparing 2000 with 2006. Imaging by cardiologists and vascular surgeons had the largest increase. Expenditures for imaging associated with self-referral are discussed further below.

Finally, the highly litigious US medical practice has been cited as a contributing factor to providers requesting more imaging, other things equal. Health systems, hospitals, outpatient clinics, and emergency departments may perform more imaging than is clinically or economically appropriate due to concerns of lawsuits and fears of misdiagnosing or under diagnosing a condition without imaging. Although it is difficult to prove that not conducting an imaging test is a wrongful act, providers and systems are at some risk and may choose to image more patients to protect against legal consequences. Tort reform has been suggested by medical professionals as needed to reduce defensive imaging. Smith-Bindman *et al.* (2011) assessed diagnostic imaging tests of the head in an emergency department setting in 10 US states with varying medical malpractice laws. They found that states with more reforms restricting monetary payments from lawsuits against providers or reforms limiting legal fees had a reduced usage of neurologic imaging.

Fee-for-Service Payment and Incentives

Market incentive structures are a key issue when assessing the behavior of providers and the use of diagnostic imaging. In the US, providers are largely reimbursed under the FFS system, creating a limited incentive to reduce the number of imaging tests being conducted, or to put strong mechanisms in place to increase the proportion of appropriate imaging

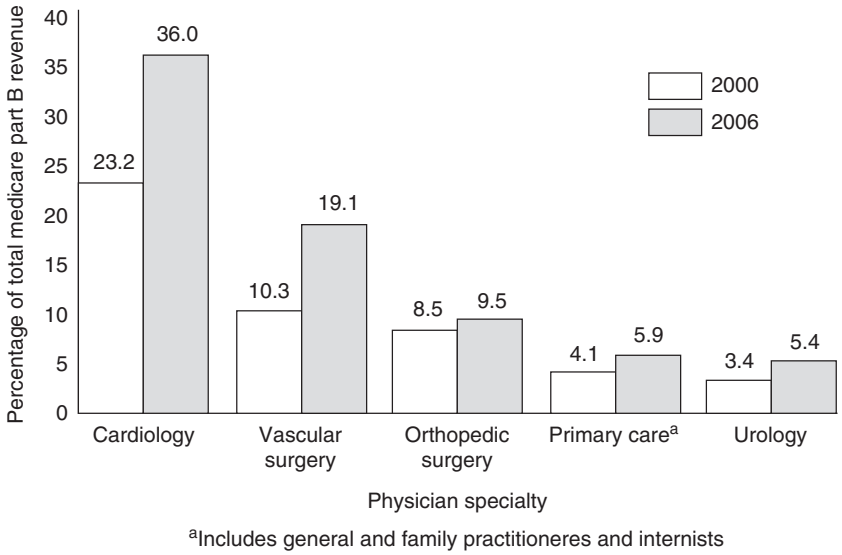

Figure 1 Share of total Medicare part B revenues derived from in-office Imaging services by physician specialty, 2000 and 2006. Reproduced from United States Government Accountability Office (US GAO) (2008a). Rapid spending growth and shift to physician offices indicate need for CMS to consider additional management practices. *Report to Congressional Requestors, Medicare Part B Imaging Services*. Washington, DC: US GAO. GAO-08-452.

performed and to reduce more inappropriate scans. In general, the FFS model applies most directly to outpatient imaging, where a technical (facility) fee is charged, along with a professional fee charged that is linked to work-related relative value units, which serves as a proxy for intensity of provider services used and physician time allocated for a particular service. In addition, for imaging in outpatient, emergency department, and inpatient settings, insured patients most often will be responsible for a copayment associated with imaging services, whereas self-pay patients (uninsured) will be expected to pay the full associated charges with limited ability to negotiate reduced payments. The US system used for current Medicare and non-Medicare reimbursement for diagnostic imaging services is essentially a side product of a system designed primarily to reimburse physician services: the Resource-Based Relative Value Scale. Payment, assigned thorough 9600 Current Procedural Terminology codes, is divided into three parts – physician work, practice expenses, and professional liability – and is adjusted geographically. Approximately 600 of the codes apply to diagnostic imaging, although a small portion of these comprise the majority of use and cost to payers.

Medical charges for imaging services are also not closely tied to actual value delivered, rather tend to be based on expected average cost. Reimbursement amounts for Centers for Medicare and Medicaid Services (CMS's) are often determined through the use of resource use surveys completed by provider facilities, which provide estimates for the amount of time and intensity of resources used to provide a particular service, whether using an older piece of imaging equipment or a newer model. Rates for specific modalities and anatomical regions are modified regularly by CMS as well as by other payers, and can increase or decrease from year to year. It is not immediately obvious whether reimbursement for a particular imaging test or imaging modality would be profitable for a particular facility because it would likely vary by patient subgroup.

Incentives for inpatient imaging in the US may discourage imaging because hospitalizations are reimbursed using assigned diagnosis-related groups (DRGs) based on hospital discharge diagnoses and other factors. The DRG system reimburses hospital providers using a standard 'lump sum' payment per DRG for the hospital stay, with variation based on complication-related modifier codes. In general, in-hospital providers or individual practitioners requesting imaging tests may not have a strong incentive to reduce inpatient imaging for their own patients. The hospital administration, of course, has an incentive to control costs, but subject to professional norms and legal risks: they may seek to promote the appropriate use of imaging.

Modifying payment models is a centerpiece of US health reform and health system experiments. As an alternative to FFS in the US, many HMOs use salary-based models for compensating providers, which is likely to reduce direct financial incentives associated with ordering and conducting imaging studies at these institutions. Rather than paying non-HMO physicians on a salary basis, the US is experimenting with episode-based payments or bundled payments for outpatients, requiring coordination among multiple physicians or groups of providers. These models are expected to be a standard of reimbursement in the near future, at least for specific procedures and patient types. Simple examples of bundling imaging payments are payer policies that combine reimbursement for performing multiple imaging procedures at a lower total amount for imaging procedures that are often conducted together (e.g., 75% of time used simultaneously), rather than reimbursing for each imaging test separately. However, these strategies still do not reimburse based on value delivered: they are cost-based approaches based on utilization metrics (Figure 2).

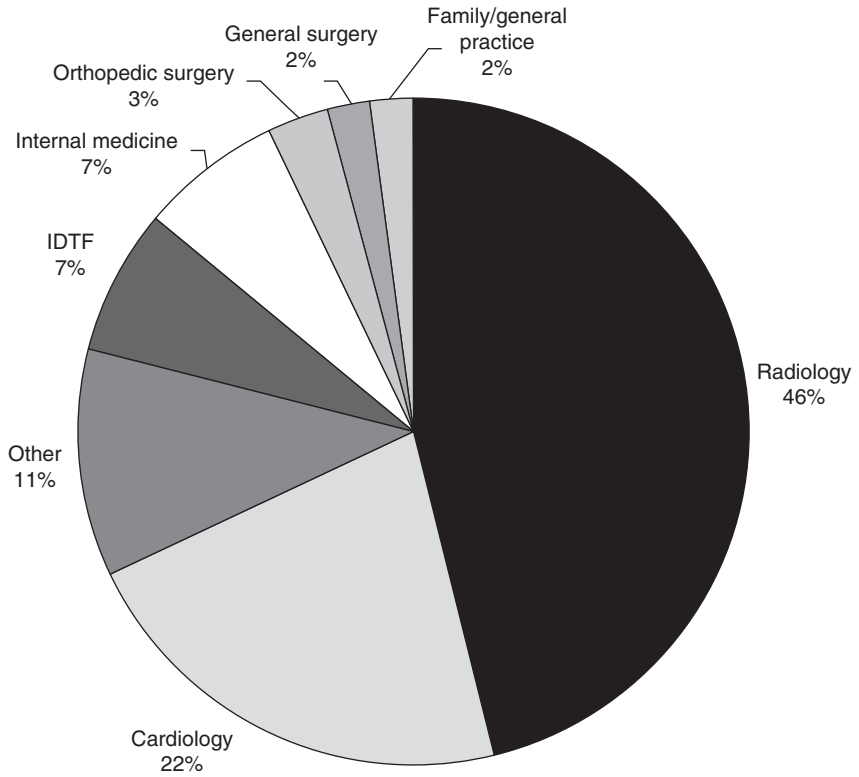

Figure 2 Radiologists received nearly half of physician fee-schedule payments for imaging services, 2009. Reproduced from Medicare Payment Advisory Commission (MedPAC) (2012). A databook: Health care spending and the Medicare program.

Economic and Comparative Evaluations of Imaging Appropriateness

This section begins with a discussion of issues to consider in thinking about an economic framework for analyzing imaging appropriateness. Then, two general groups of evaluations are discussed, in turn: (1) economic evaluations, including cost-effectiveness analyses, and (2) comparative effectiveness research (CER).

An Economic Framework for Evaluating Imaging Appropriateness

The assessment of imaging appropriateness faces several challenges common to devices in general. Drummond *et al.* (2009) assessed differences and similarities for medical devices compared to pharmaceuticals. They identified six primary differences: (1) many devices are diagnostic and do not provide final outcomes, (2) randomized controlled trial (RCT) data are more limited for devices compared to pharmaceuticals, partly due to rapid innovation, (3) device efficacy is in part determined by the device user, (4) there may be more extensive health system impacts for devices, such as training or infrastructure needs, (5) generally less comparative evidence is available for devices, and (6) dynamic pricing flexibility may be greater in device markets due to continuous new product introductions.

Most of these differences also apply to diagnostic imaging specifically. The intermediate nature of diagnostic imaging as informing the referring physician decision-making produces even more challenges for evaluation. Diagnostic scans occur in the middle of the value stream of healthcare delivery, which implies that measuring direct impact on patient outcomes depends on the choice of subsequent interventions. Imaging is more distal to patient outcomes compared to pharmaceutical or surgical interventions. Partly owing to less restrictive regulatory requirements, imaging manufacturers are able to bring new models of scanners to the market with relative frequence, most often without evidence from RCTs. Clinical trials in imaging are often smaller in size and have restrictions in generalizability due to new innovations being introduced during the study. Patients are not likely to enroll in RCTs where they may not be assigned to an arm with the diagnostic test, or the newest test available. All of these challenges contribute to lower levels of evidence for diagnostic imaging modalities.

Fryback and Thornbury (1991) provided an oft-cited hierarchical model for assessing levels of 'efficacy' in relation to diagnostic tests, with higher levels associated more closely with outcomes and economic metrics. The initial assessment for a test should focus technical efficacy (image quality) in Level 1. Once a test has shown good technical performance, Level 2 assesses diagnostic accuracy, sensitivity, and specificity associated in specific patient groups and the interpretation of their scans. Level 3 evaluates the impact on diagnostic thinking or modifications to the diagnostic plan of the referring provider. If diagnostic testing introduces a change in treatment planning, Level 4 assesses the impact on the patient management plan by the ordering provider. Level 5 efficacy measures

the impact on patient outcome, including survival, morbidity, and quality-of-life-metrics. If costs and resource constraints are considered, Level 6 would assess societal efficacy of resources used by evaluating costs and benefits or cost-effectiveness from a societal perspective.

A central feature of imaging is the strong capital and labor interaction that influences whether a test is effective for its intended use. The equipment should produce an accurate image and the radiologist should be able to provide a correct interpretation. However, more advanced and complex imaging tests may have associated imaging artifacts or incidental findings that require a determination on whether it is appropriate to conduct follow-up testing, related to Fryback and Thornbury's Level 3, where diagnostic testing findings can lead to more diagnostic testing. Likewise, lesser trained or lesser experienced radiologists, cardiologists, or other specialists conducting imaging may not interpret scans correctly, or may not be able to provide meaningful summaries of imaging findings, thus providing limited guidance to referring physicians. More advanced imaging equipment and more complicated medical scans will require greater levels of skilled providers to produce the imaging result and interpretation, thus potentially more controls on appropriate use. Newer molecular imaging studies or advanced cardiovascular studies require attenuation correction for image quality and reference points to allow more precision in specific anatomical positioning, and skilled technologists, radiologists, IT personnel, and physics teams are needed to complete accreditation requirements and monitor equipment.

To evaluate the clinical impact and resource use implications of imaging, a model is usually needed to simulate the use of the testing strategy, as well as downstream impacts from either false positives or false negatives. For example, false positives may lead to unnecessary biopsies being conducted for verification. Likewise, imaging may occur for exploring indeterminate results or incidental findings. False negatives from imaging may also have serious health consequences: patients may not receive needed treatments which could lead to disease progression with adverse clinical and/or economic impacts. Therefore, understanding the likelihood of sensitive and specific results from a diagnostic testing strategy and the follow-up implications is essential in estimating the comprehensive impact of diagnostic test use.

The identification of and follow up of incidental findings observed on imaging studies, meaning those not related to the primary condition of interest for obtaining the diagnostic imaging test, can lead to high resource use and high anxiety on behalf of patients. Establishing the costs and health consequences of incidental findings is a critical issue for imaging practice. These variable outcomes not only add complexity to conducting economic evaluations, but also are affected by health system and provider practice variations. Concern about legal liability may influence providers to follow up these findings more aggressively.

Economic Evaluations Including Cost-Effectiveness Analysis

Economic evaluations of diagnostic imaging address a range of different issues and involve a variety of assessment approaches. These analyses study: (1) diagnostic test utilization patterns, referral patterns and imaging, (2) impacts on use after introduction of decision support systems, (3) trends for specific conditions, and (4) the cost-effectiveness of particular diagnostic strategies in defined subpopulations. The data sources include observational studies, retrospective reviews, prospective studies, and secondary database analyses. As noted, imaging studies may result in findings that require further testing to more conclusively determine if patients have a condition or not. Clinical studies may not capture these comprehensive sets of events that occur due to diagnostic imaging, and retrospective analyses are suboptimal due to a limited availability of health status data or clinical information. For a variety of reasons, medical record data and resource use data are often not connected electronically.

Cost-effectiveness analysis (CEA) and cost-utility analysis (CUA) are important tools to assess the potential appropriateness of imaging interventions. Their growth has paralleled the growth in imaging spending and payer requirements to demonstrate value for expenditures. Cost-utility studies generally estimate cost per quality-adjusted life-years (QALYs) gained (a combined time and quality-of-time metric). In 2008, Otero and colleagues evaluated 20 years of cost-effectiveness studies for radiology (1985–2005), providing an assessment of 111 published CUAs. During this period, there was an increase from a few CUAs each year to approximately 10 per year. Nearly 80% of the CUAs they identified pertained to diagnostic radiology. They summarized studies by modality and disease/condition. Ultrasound and angiography were the most frequently studied imaging tests, followed by MRI and CT. The five most frequently assessed disease areas were peripheral vascular disease, cerebrovascular disease, ischemic heart disease, musculoskeletal and rheumatologic disease, and lung cancer. Importantly, approximately 80% of studies used secondary data from the literature to estimate quality of life 'utility scores' for the QALY estimation rather than primary data collection. This highlights the need for more comprehensive prospective studies to assess the economic impact of imaging on patient outcomes.

Most economic evaluations of diagnostic imaging have estimated the marginal effects of imaging interventions on particular types of patients by comparison with alternative testing strategies. The incremental costs and consequences associated with using health resources for one condition or type of medical test can be compared with those costs and outcomes from using other tests, and potentially compared among conditions. To date, the number of well-designed imaging evaluation studies is still very limited. The clinical scientific imaging literature has predominantly focused on diagnostic accuracy characteristics and comparisons. Recently, more incremental cost-effectiveness studies of imaging are being conducted and published. But these studies face considerable challenges in sorting out the heterogeneity associated with estimating cross-population or cross-indication effects associated with implementing diagnostic testing guidelines.

Economic assessments can be conducted at a health system level as well as for a typical patient with a health condition. Consider a policy that tries to encourage adherence to findings from a diagnostic test that indicates a low likelihood that a

surgery would improve a patient's morbidity or mortality status. This could result in fewer surgeries of that type being performed, thereby reducing the aggregate number of surgeries expected to have suboptimal outcomes and lower cost. Likewise, a diagnostic test that leads to additional testing, treatments, or procedures may result in other patients not receiving specific procedures or care, particularly in systems with a fixed health budget. Therefore, a comprehensive assessment of the economic impact on the health system of using a diagnostic test should include these direct and indirect effects. Practically speaking, however, few, if any, economic assessments of diagnostic imaging interventions have taken a comprehensive societal perspective.

Establishing a Comparative Framework for Appropriateness

In recent years, there have been calls for more CER in imaging. CER incorporates multiple stakeholder perspectives (e.g., patients, providers, payers, and systems) and attempts to identify those medical products or programs that provide substantial benefits to patients and those that do not. In addition, effectiveness data for patient subgroups are often lacking. In 2009, an Institute of Medicine report provided recommendations on the top 100 national priorities in the US for comparative effectiveness research, citing advanced imaging (CT, MRI, PET, and PET/CT) in oncology as a top-tier priority for additional comparative studies. A total of nine topic areas relevant to imaging approaches were included in the top 100 priorities. Most of these nine areas included recommendations to compare multiple imaging modalities used in specific indications.

Gazelle *et al.* (2011) suggested a framework – aligned with the Fryback–Thornbury hierarchy – for thinking about CER in diagnostic imaging. They suggest that designing practical evidence requirements for imaging technologies should consider the size of the population at risk for a condition, the likely clinical impact of imaging, and the overall cost impact of diagnostic testing, including the cost of the test, subsequent costs of treatments and testing, and the impact on payers' budgets. In a market-oriented system such as the US, differences in access to healthcare can affect health outcomes among ethnic, racial, or income groups. The CER initiatives and national priorities identified racial and ethnic disparities as a primary area of US healthcare requiring more comparative evaluations.

Imaging Utilization Management Strategies and Appropriateness Tools

The goal of improving the appropriateness of diagnostic imaging has been addressed in multiple ways by the various stakeholders, including payers, providers, professional societies, and policy makers. Six tools aim to limit overuse and promote efficiency are briefly described in this section: (1) professional appropriateness criteria, (2) radiology benefits management (RBM), (3) clinical decision support (CDS), (4) coverage with evidence development (CED) by CMS, (5) Congressionally mandated, across-the-board reductions in payment amounts, and (6) quality improvement (QI) metrics.

First, imaging appropriateness criteria have been developed by the American College of Radiology. Duszak and Berlin (2012) provide an overview of their rationale and a historical perspective of utilization management. Owing to the overall scarcity of comparative imaging evidence and long-term outcomes studies, these types of criteria often rely on expert opinion, supported by the medical literature when available: they are most often not based on large randomized studies or strict evidence-based clinical guidelines. However, they serve as a guide to using imaging more appropriately, which can reduce testing that does not provide high marginal clinical benefit but does impose cost on the system.

Second, RBM gained momentum in the 1990s as a mechanism to control use and costs, similar to prior authorization requirements for prescribing expensive biotechnology medications. Insurance companies hire RBM brokers to manage their imaging-related benefits, such as in requiring preauthorization for MRI scans or other expensive tests. Although providers argue these systems are restrictive and remove patient-provider preferences from decision-making, assessments have shown a reduction in imaging expenditures related to a 'gatekeeper effect.'

Third, CDS systems are generally less restrictive than RBMs and are more real-time use oriented at the point of ordering, but require a computerized ordering system. Providers enter patient-level clinical and demographic information, including diagnosis codes, and then request an imaging test. The tools provide an appropriateness score based on an embedded algorithm. Individual imaging managers or health systems can decide how restrictive to make the algorithm and whether to allow all orders to be processed or to disallow imaging tests based on specific appropriateness ranges.

The introduction of RBMs and CDS systems to control imaging requisitions highlights a key point related to imaging use: radiologists do not typically order scans. They traditionally have not served as effective self-regulating providers who perform only appropriate imaging tests based on requisitions; hence, ordering-point controls have arisen.

Fourth, CMS has attempted to control or better understand imaging use though CED. In 2005, a CED approach was used to require enrollment in a registry as a mechanism to restrict coverage and reimbursement for PET and PET/CT scans in oncology indications while more evidence was gathered about this new modality. CED can effectively slow the diffusion of new products and the CED cohort can be linked to utilization claims to evaluate how innovations impact overall utilization.

Fifth, in a broad, national-level effort to control costs, the US Congress passed the Deficit Reduction Act (DRA) of 2005, which included mechanisms to slow the growth of medical spending on Medicare and Medicaid. The law imposed reductions in reimbursement rates for imaging services, as well as allowing states to modify conditions associated with Medicaid programs. At the state level, in particular, access to care for lower-income individuals and families was affected due to provisions allowing states to modify eligibility or documentation requirements, with a goal of saving billions of dollars in the Medicaid program.

Finally, QI metrics are being used by providers, payers, and health technology assessment organizations to directly and indirectly incentivize appropriate care. For example, emergency department throughput reporting is required by CMS, direct cost comparisons for academic medical centers have been added to the University Hospital Consortium, and reimbursement restrictions are being implemented for cardiovascular patients having hospital readmissions within 30 days of discharge. Imaging in inpatients impacts overall efficiency of workflow and net reimbursement for providers, leading hospitals to evaluate imaging use and direct costs relative to other hospitals.

Trends in US Imaging Spending: Growth and Controls

In terms of the growth in imaging spending, the period since 2000 can be divided into two intervals: the period before the DRA of 2005 and the period since then. In the first period, imaging growth outpaced all other medical expenditures, leading to the initiatives described above. In the period 2006–11, imaging growth slowed, and in later years even declined in evaluations of specific payers. Nonetheless, attention to physician ordering patterns and geographic variability continues to be a target for standardization as well as efficiency and appropriateness assessment.

A 2008 report by the US Government Accountability Office (US GAO, 2008a) evaluated use and expenditures for different imaging modalities, including MRI, CT, nuclear medicine, ultrasound, X-ray, and other procedures between 2000 and 2006. They analyzed trends in the number of tests per Medicare beneficiary and the estimated payments for technical and professional fees for imaging per beneficiary. Overall, there was a steady increase in imaging use and payments to physicians in per beneficiary spending. The report also highlighted substantial state-level variability in imaging outpatient expenditures per beneficiary, ranging from less than US$100 per beneficiary to greater than US$400, with Florida and Nevada having the highest levels of per beneficiary spending. The GAO assessment noted a shift in the proportion of physician services paid through physician offices and IDTFs, rather than through institutional outpatient settings of hospitals.

Overall Medicare Part B spending on imaging during this period increased from under US$7 billion to more than US$14 billion, including imaging in hospitals, provider offices, and IDTFs (Figure 3). The overall size of the imaging spending pie doubled, although the allocation of spending shifted more heavily toward nonhospital imaging (Figure 3). These expenditure trends were influenced by higher rates of increases in advanced imaging, such as for CT, MRI, and nuclear medicine (Figure 4).

Levin *et al.* (2011) assessed Medicare trends in noninvasive diagnostic imaging from 1998 to 2008 and reported steady increases in overall imaging utilization rates during this period. Their assessment of advanced imaging showed that CT rates per 1000 Medicare beneficiaries continued to increase, but MRI and nuclear medicine testing started to level off from 2005 to 2008. A MedPAC assessment of essentially the same time period indicated that the number of head CT increased from 112 per 1000 Medicare beneficiaries in 2000 to 205 per 1000 in 2010. In the same period, all other CTs increased from 258 per 1000 to 548 per 1000 beneficiaries. Overall MRI rates essentially doubled from 2000 to 2010, with MRI of the brain increasing from 45 per 1000 beneficiaries to 79 per 1000, and all other MRIs increased from 64 per 1000 to 141 per 1000

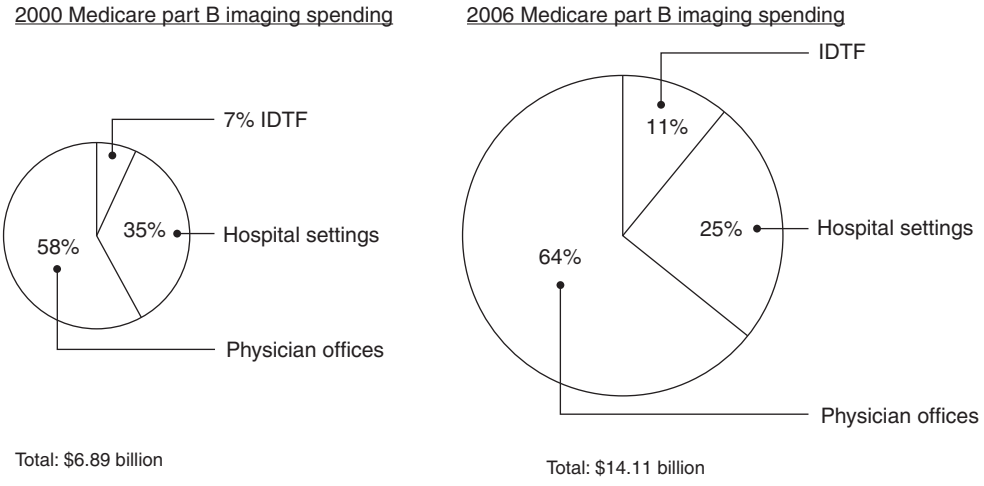

Figure 3 Medicare part B spending on imaging by setting, 2000 and 2006. Hospital settings include inpatient and outpatient departments and emergency rooms. The IDTF category also includes imaging services provided in other outpatient facilities such as mammography screening centers and independent physiological laboratories that are paid under the physician fee schedule. Expenditures include fees for physician interpretation of imaging services in hospital settings, and fees for interpretation and provision of services in physician offices and IDTFs. When the imaging examination is performed in an institutional setting, such as a hospital or skilled nursing facility, the physician can bill Medicare only for interpreting the examination, while payment for performing the examination is covered under a different Medicare payment system. Reproduced from United States Government Accountability Office (US GAO) (2008a). Rapid spending growth and shift to physician offices indicate need for CMS to consider additional management practices. *Report to Congressional Requestors, Medicare Part B Imaging Services.* Washington, DC: US GAO. GAO-08-452.

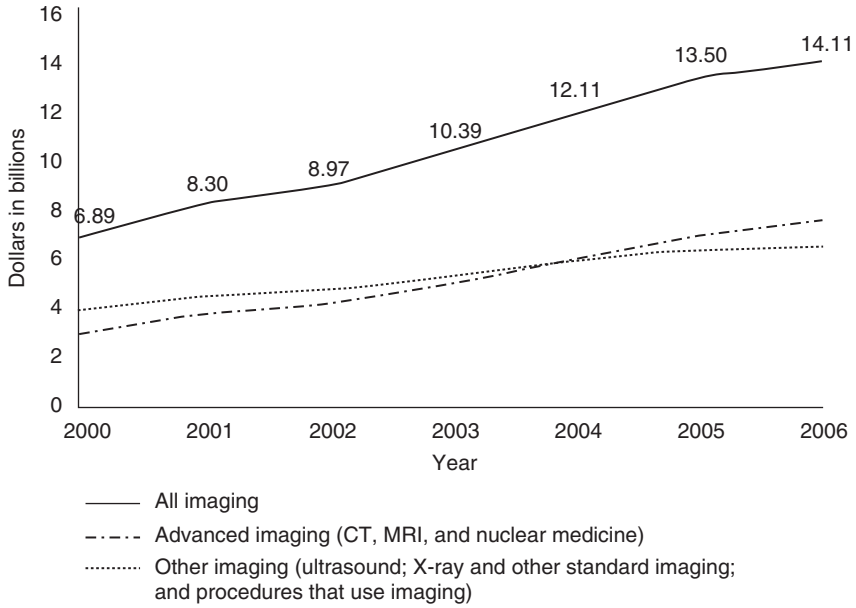

Figure 4 Total Medicare expenditures for imaging services paid under the physician fee schedule, 2000–06. Reproduced from United States Government Accountability Office (US GAO) (2008a). Rapid spending growth and shift to physician offices indicate need for CMS to consider additional management practices. *Report to Congressional Requestors, Medicare Part B Imaging Services*. Washington, DC: US GAO. GAO-08-452.

beneficiaries (Medicare Payment Advisory Commission (MedPAC), 2012).

A recent 2012 GAO report evaluated the role of self-referral of imaging services to assess Medicare trends in imaging utilization. As noted earlier, self-referral implies that an ordering provider has an ownership interest in a facility they direct patients to have imaging testing. The report presents the number of CTs and MRIs between 2004 and 2010 for self-referred imaging and nonself-referred imaging. Between 2006 and 2010, nonself-referred MR imaging was associated with a decline in office-based or IDTFs. Self-referred MRIs continued to increase during this same period. For CT services, nonself-referred imaging increased at a slowing rate between 2004 and 2009, and declined from 2009 to 2010. Self-referred CTs, however, although lower in magnitude, gradually continued increasing throughout the period 2004–10.

Levin *et al.* (2010) found a decreased effect on outpatient imaging rates in a multistate pre-RBM and post-RBM analysis of a large private insurer introducing this control mechanism. Rates of CTs, MRIs, and PET scans were reduced subsequent to the introduction of increased management of ordering by approximately 10–20% measured as the number of imaging studies per 1000 members. Blackmore *et al.* (2012) summarized the impact of several imaging utilization programs tested in statewide initiatives, hospitals, and individual health plans. An observed reduction in growth rates for CT scans in Massachusetts General Hospital (MGH) of approximately 10% was greater than the impact on MRI growth, which was negligible. In Minnesota, the Institute for Clinical Systems Improvement (ICSI) coordinated a CDS initiative with five large provider groups, and reported a restriction in imaging growth to nearly zero. In MGH and ICSI, these tools were also used as an education tool for providers consistently ordering less appropriate scans, with an intention of changing behavior. A Virginia Mason CDS tool implemented in Seattle, WA was able to reduce overall imaging rates in target conditions.

A 2008 GAO report estimated the impact of the DRA on imaging expenditures in the Medicare population (US GAO, 2008b). The outpatient prospective payment system cap resulted in fee reductions for approximately 25% of overall imaging tests, with a greater relative reduction for advanced imaging tests. Following DRA outpatient reimbursement rate reductions, overall imaging expenditures per beneficiary decreased by approximately 10% between 2006 and 2007, although the number of total imaging tests per FFS Medicare beneficiary continued to increase.

The overall financial impact of QI initiatives focused on efficiency metrics have likely put downward pressure on costs and potentially have reduced inappropriate imaging, although no comprehensive published studies are available. Several policies have been recently introduced, so there is limited data on the effects of QI programs on expenditures. As the impacts of broader US health reform and QI are studied in the coming years, the impact of cost-focused QI programs will be better understood.

Recently, Lee and Levy (2012) analyzed multiple samples of insured populations and found that annual rates of CT and MRI growth, although increasing fairly rapidly from 2000 to 2006, started to decline after 2006. In some instances, CT utilization per 1000 beneficiaries showed absolute declines in use in 2008 and 2009. Their evaluation of a combined set of 47 health plans indicated a doubling of CT and MRI rates per 1000 plan members between 2002 and 2009, but MRI growth was close to zero from 2006 to 2009. They describe that findings were contemporaneous with general policy trends of increased prior authorization, CDS, RBM, and general

economic challenges. Nevertheless, more attention toward appropriateness and utilization strategies – including more attention to CT radiation dose exposure–seemed to contribute to slowing the growth of imaging.

It would, of course, be very difficult to estimate accurately the resulting health impacts on society or to separate the role of each of these influences. It is also difficult to claim causal effects due to any specific payer or government policy related to imaging, but taken as a whole, the attention placed on reducing imaging expenditures since 2005 was associated with at least a leveling off of growth rates and a bending of the cost curve for imaging. However, the US still uses the highest amount of advanced imaging of nearly all countries, spends more on healthcare in general, and does not have adequate structural incentives to encourage substantial reductions in diagnostic imaging. Although imaging is not the highest category of US medical expenditures, more alignment with appropriateness at the point of imaging ordering should improve the static efficiency of use.

Innovation and Dynamic Efficiency

Given the complexities of providing diagnostic imaging in the US healthcare system, it is unclear how much use is inappropriate (i.e., inefficient in a static sense), and it also unclear how much underuse there is for those with access problems. Furthermore, no national estimates are available of the social cost of either overuse or underuse.

In such a second-best world, it is also unclear how close the system is to achieving dynamic efficiency, i.e., eliciting the optimal amount of innovation from a longer-term perspective. Given the lack of hard evidence and estimates, reasoning about incentives may be the best option. In this vein, it has been argued that the lack of value-based reimbursement in radiology is likely to inhibit innovation (Garrison *et al.*, 2011). In theory, fixed payments per scans of different types lead manufacturers to provide a quality level of imaging that is only financially sustainable within that payment limit. Furthermore, it is not clear whether the amount the reimbursement system pays for imaging results is being divided between the capital equipment owners and scan readers (usually the radiologist) in a manner that supports optimal capital innovation. The science behind imaging is a global public good, and the equipment is sold worldwide, including the sale of lower quality or refurbished equipment in developing country settings. Such differential pricing can provide greater support for research and development and counter the incentives in the US that might hinder the rate of innovation.

Conclusion

Advanced imaging modalities have revolutionized medical practice by improving clinical diagnostic ability to meet the goal of having reliable, condition-specific test results to support better decision making. The potential benefits associated with an improved ability to accurately diagnose medical conditions using advanced imaging should be weighed against the resource costs for payers and society in order to assess the appropriateness and efficiency of its use. However, specific features of diagnostic imaging provide unique challenges for economic evaluations. Also, policy attention to imaging use has increased in an effort to target the most rapidly increasing components of medical imaging. Rates of spending growth have slowed since 2007 due presumably to several payer and policy initiatives, but overall imaging spending remains high. Nonetheless, there is clearly a dearth of economic research on either the actual cost-effectiveness of specific imaging applications or on the impact of current reimbursement rules and other market incentives on health system performance. At best, most cost-effectiveness analyses show only the potential value of appropriate imaging in specific applications. Continuing high and variable utilization rates suggest significant overuse in the US. Across-the-board cuts and other utilization controls have curbed spending growth, but the extent of inefficiency – both static and dynamic – remains unclear.

Disability-Adjusted Life Years

JA Salomon, Harvard School of Public Health, Boston, MA, USA

Introduction

The disability-adjusted life year (DALY) is a summary measure of population health that accounts for both mortality and nonfatal health consequences. DALYs were first developed for the primary purpose of quantifying the global burden of disease (GBD). In this context, the DALY was designed as the unit of analysis for measuring the relative magnitude of losses of healthy life associated with different causes of disease and injury. In addition to measurement of the burden of disease, another intended use for DALYs was as a metric for health benefits in the denominator of cost-effectiveness ratios. This article introduces the conceptual and computational basis for DALYs and discusses key issues relating to value choices underlying DALYs, with a brief discussion of how DALYs relate to quality-adjusted life-years (QALYs).

Basic Concepts

A DALY is equivalent to one lost year of healthy life. DALYs accumulate when individuals die prematurely or when they live with the health consequences of diseases, injuries, or risk factors. For a particular cause of disease or injury, DALYs are computed as the sum of (1) 'years of life lost' (YLLs), which capture premature mortality and (2) health losses in 'years lived with disability' (YLDs), which capture lost healthy life due to living in states worse than perfect health. The following sections elaborate on these two components.

Years of Life Lost

YLLs are measures of health losses due to premature mortality. Calculation of YLLs requires some quantification of how long people 'should' live, that is, a normative target lifespan by which the length of life lost due to each death at a certain age may be evaluated. For example, the normative target might imply that a person who is aged 60 years should expect to live another 10 years, that is, until the age of 70 years. In that case, 100 deaths among people at the age of 60 years translates to $100 \times 10 = 1000$ YLLs. There are various possible ways to define a normative target lifespan, as described by Christopher Murray in his 1996 essay entitled 'Rethinking DALYs.' Some norms imply a target lifespan that is constant across ages at death, whereas others imply a target lifespan that shifts depending on the age that has been attained. The latter are typically based on life tables that give expectations of life at different ages. In the GBD study, a global standard life table has been used based on an egalitarian argument for valuing a death at a particular age as the same loss irrespective of where the person lived. Another choice that is made is whether the same life table is used for males and females. In the GBD for the year 1990 and revisions through 2008, two different life tables were used, with the standard for females based on a life expectancy at birth that was 2.5 years greater than the life expectancy at birth in the standard for males. The argument for the different standards was based on a plausible biological difference in longevity. In the revision of the GBD for the year 2010 (hereafter 'GBD 2010'), a new standard was used, based on a synthetic life table constructed from the lowest currently observed mortality rates at each age. The other change in the GBD 2010 was that a single standard life table was defined for both males and females.

Years Lived with Disability

YLDs may be understood conceptually as partial losses of healthy years due to living in health states that are worse than optimal health, weighted for the severity of the states. For example, 10 years lived in a health state that constitutes a 50% reduction in health, i.e., a state that resides halfway between death and perfect health, would imply a total of $10 \times 0.5 = 5$ YLDs. Construction of YLDs requires a defined measurement construct for health losses, a way to quantify these losses, and an approach to attribute losses to years of life lived with a particular condition.

Cases and sequelae

The GBD maps losses of health due to disease and injury through the concepts of cases and sequelae. For cases of a given disease or injury in the population, the experience of health until remission or death will include an array of different health states. For the sake of parsimony, burden of disease calculations require that this multitude of health states be approximated by a small number of discrete entities characterized under the umbrella term of sequela. The sequela is the unit of analysis for epidemiological estimates and YLD calculations. In the GBD, health states are defined by levels of functioning within a set of health domains, for example, mobility, pain, vision, or cognition. These health states are not defined in reference to general well-being or 'quality of life' (both broader constructs). Nor do the health states refer to aspects of participation in society, although different levels of functioning in domains of health may clearly affect – and be affected by – these other aspects.

Incidence and prevalence

YLDs may be computed based on either an incidence or a prevalence perspective. In an incidence perspective, the YLDs associated with a particular sequela are computed in terms of the number of incident cases of the sequela, times the average duration of time spent in the sequela, times a disability weight reflecting the magnitude of health loss experienced for each unit of time lived with the sequela. (Disability weights are discussed further in the next section.) For example, if there were 100 new cases of blindness in a population, and each case of blindness had an average duration of 20 years and an average disability weight of 0.25, then the YLDs due to blindness computed from

 doi:10.1016/B978-0-12-375678-7.00511-3

an incidence perspective would be $100 \times 20 \times 0.25 = 500$. From a prevalence perspective, the calculation is simply the prevalence of a sequela at a defined point in time (e.g., the midpoint in the year of interest), multiplied by the disability weight. For example, if in a population there were 1000 people living with asthma this year, and asthma had a disability weight of 0.10, then the YLDs due to asthma computed from a prevalence perspective would be $1000 \times 0.10 = 100$.

Disability weights

Disability weights provide the bridge between information on mortality and information on nonfatal outcomes in DALYs. These weights represent cardinal measures of health decrements on a scale ranging from 0 (signifying conditions that are equivalent to ideal health) to 1 (signifying conditions that are equivalent to being dead). Thus, for example, if a year lived with deafness has a disability weight of 0.25, this implies that 4 years lived in deafness would be an equivalent health loss to dying 1 year 'too early' in reference to some defined target for longevity (i.e., $4 \times 0.25 = 1$).

Disability weights are needed for every sequela that is included in the study. For most sequelae, a single disability weight is applied to time spent in that sequela under the simplifying assumption of an approximately constant, homogeneous health experience for those living with the sequela over its specified, average duration (taking an incidence perspective). Within this framework it is important to recognize that an individual may have more than one disabling sequela at the same time. The disability weight refers to the average health loss for individuals with a particular condition in the absence of other comorbidities. Without adjustment for comorbidities, the implicit assumption is that multiple sequelae in the same person combine additively, which may not accurately describe the real effects of comorbidity on functional health. Some researchers have suggested various alternative approaches to account for the presence of multiple sequelae, other than assuming additivity.

Assignment of disability weights to the range of sequelae in the first iteration of the GBD 1990, undertaken during the early 1990s, was based on first defining six different disability classes, and then mapping from each sequela into the class or classes that applied to incident cases of that sequela. The six disability classes were defined in reference to limitations in activities of daily living such as eating and personal hygiene; instrumental activities of daily living such as meal preparation; and four other domains (procreation, occupation, education, and recreation). Weights were assigned to the different classes by a panel of public health experts using a rating scale approach. Once the weights attached to each of the six classes were determined (by averaging the values from the expert panel), the disability weight for a particular sequela was estimated by (1) specifying a distribution of incident cases across the different classes – reflecting either the proportion of time an average incident case would spend in different disability classes, or the proportion of incident cases that would be characterized by different severity levels and (2) computing the average weight across this distribution.

For the revision of the GBD 1990 that was completed in 1996, a new approach to estimating disability weights was devised based on two variants of the person trade-off (PTO) method. The revision of the approach was inspired by some specific criticisms of the original approach: (1) that the disability classes were appropriate only for adults (because, e.g., children were naturally dependent on adults for some of the referenced activities); (2) that no formal, replicable protocol was available to guide those aspiring to undertake a national burden of disease exercise; (3) that the class with the lowest level of disability was valued at 0.096, which produced a scale that was too blunt to capture very mild conditions; and (4) that the valuation task itself did not allow the expert panelists to reflect on the policy implications of their values.

New disability weights in the 1996 exercise were elicited from a panel of health professionals following an explicit protocol. In the protocol, a series of 22 indicator conditions were evaluated through an intensive group exercise involving two variants of the PTO and incorporating a deliberative process to encourage reflection on the values that emerged during the exercise. The first type of PTO question asked participants to trade off life extension in a population of healthy individuals versus life extension in a population of individuals having a particular condition. The second type of PTO question asked participants to trade off life extension for healthy individuals versus health improvements in individuals with the reference condition. Participants were required to resolve inconsistencies in the numerical weights implied by the two alternative framings of the PTO. The final consistent values implied by the reconciled PTO responses, averaged across participants, defined the disability weights for the 22 indicator conditions, which were then clustered into seven different classes of severity. As each class contained several of the indicator conditions, these indicators thereby supplied an intuitive and easy-to-convey operational definition of the severity of each class (see **Box 1**).

To generate disability weights for the remainder of the disabling sequelae in the study, participants were asked to estimate distributions across the seven classes for each sequela. In this second stage, the indicator conditions in each class were used as 'pegs' on the scale from perfect health to conditions equivalent to being dead to guide estimation of the distribution across the seven classes of disability. As described above for the first iteration of GBD 1990, the distributions across classes were intended to reflect either the proportion of time a typical case for a given sequela would spend in each class or the percentage of cases that would be categorized in each of the different classes. Distributions across disability classes were estimated separately for treated and untreated cases where relevant, and weights could also vary by age group. The box below presents a few examples of disability weights for common causes.

Various critiques have challenged aspects of the 1996 disability weight measurement exercise. For instance, several critics have questioned the use of healthcare professionals as respondents and suggested that there might be cross-cultural variation in disability weights that should be evaluated. In 1999, Trude Arnesen and Erik Nord argued that there was a serious ethical problem with the first variant of the PTO question used and a logical problem with the requirement that there should be numerical consistency between responses to the two different variants, given that these addressed two different issues. These critiques notwithstanding, the disability weights used for updates of the GBD undertaken through

Box 1 Disability weights in the Global Burden of Disease study, 1996 revision

Based on a deliberative protocol built around the PTO method, disability weights for 22 indicator conditions were estimated, and the conditions were then grouped into seven different classes reflecting a spectrum of severity levels:

- Class 1, with weights ranging from 0.00 to 0.02, included vitiligo on face; and weight-for-height 2 SDs or more below the reference median
- Class 2, with weights ranging from 0.02 to 0.12, included watery diarrhea, severe sore throat, and severe anemia
- Class 3, with weights ranging from 0.12 to 0.24, included radius fracture in a stiff cast; infertility; erectile dysfunction; rheumatoid arthritis; and agina
- Class 4, with weights ranging from 0.24 to 0.36, included below-the-knee amputation; and deafness
- Class 5, with weights ranging from 0.36 to 0.50, included rectovaginal fistula; mild mental retardation; and Down syndrome
- Class 6, with weights ranging from 0.50 to 0.70, included unipolar major depression; blindness; and paraplegia
- Class 7, with weights ranging from 0.70 to 1.00, included active psychosis; dementia; severe migraine; and quadriplegia

Weights for all the full range of sequelae in the study were estimated by defining the distribution of incident cases across these seven classes, using the indicator conditions in each class as illustrative benchmarks. Examples of the resulting weights include:

- Episodes of otitis media: 0.02
- Cases of asthma: 0.10 (untreated); 0.06 (treated)
- Episodes of malaria: 0.21 (ages 0–4 years); 0.17 (ages 15 years and older)
- Rheumatoid arthritis cases: 0.23 (untreated); 0.17 (treated)
- Episodes of meningitis: 0.62
- Terminal cancer: 0.81

(eds.) *The global burden of disease: A comprehensive assessment of mortality and disability from diseases, injuries, and risk factors in 1990 and projected to 2020*, pp 1–98. Boston: Harvard School of Public Health.

2008 were still largely based on the GBD disability weights as measured in the 1996 exercise. For certain conditions, where weights were not available from the original GBD Study, provisional weights were used from the Dutch Disability Weights study or from the Australian Burden of Disease study. The Dutch Disability Weights study used a similar protocol to the GBD 1996 revision, with the addition of health state distributions for sequelae described in terms of a variant of the EQ-5D classification system.

More recently, prompted by a more general research agenda on developing internationally comparable summary measures of population health at the World Health Organization, the use of the PTO as the basis for disability weights in DALYs has been reconsidered. The most recent thinking on DALYs reflects an effort to more precisely delineate the concept embodied in the nonfatal component of the measure, which has led to the explicit definition of disability weights as measures of overall levels of health associated with health states rather than as measures of the utility associated with these states or the contribution of health to overall welfare. Although some have argued that the burden of disease must be quantified in terms of overall welfare loss because health and well-being are not separable, others have challenged this view, and this debate goes on. In the GBD 2010, a large empirical exercise to measure disability weights has been conducted using household surveys in five countries and an open-access internet survey. This study uses a much simpler method for eliciting weights, based on simple paired comparisons of sequelae described with brief labels. A number of the new weights are lower than the previous ones, including weights on sensory impairments, infertility, and intellectual disability. Other weights are higher in the new study, including weights for some states relating to epilepsy, illicit drug use disorders, and low-back pain. Another significant finding in the new study is that responses to comparisons of health states are remarkably consistent across the diverse sampled populations, which contradicts the prevailing hypothesis that assessments of disability must vary widely across cultures.

Other Value Choices Relevant to Both Years of Life Lost and Years Lived with Disability

Discounting

Many of the arguments around discounting invoked in the context of QALY measures have also been rehearsed in the discussion of DALYs as population health measures. Until recently, the use of an annual discount rate of 3% has been the default standard in the construction of the DALY, as in the recommended base case analysis for cost-effectiveness studies; in both cases it is typically advised that alternatives should be considered in sensitivity analyses. For the GBD 2010, a simpler variant of DALYs has been adopted for the base case, with no discounting.

Age Weights

In addition to discounting, some have argued for assigning unequal weights to life years lived at different ages, and the standard DALY prior to the GBD 2010 included weights that give the highest values to years lived in young adulthood. A range of arguments have been considered in relation to age weighting, with reference to empirical findings on weights that people attach to years over the life course and to important ethical considerations. The developers of the DALY measure previously argued for unequal age weighting based on the social roles played at different ages, but age weights remain controversial. For the GBD 2010, the base case DALYs are not differentially weighted by age.

Applications

DALYs have been used for both quantifying the burden of disease and as the unit of effectiveness in the denominator of cost-effectiveness ratios for economic evaluation of health interventions and programs. The major debut of the DALY in the World Bank's *World Development Report 1993* introduced applications of the measure toward both ends. Various revisions of the GBD have continued to use DALYs as the main unit of account for assessing the relative magnitude of health

losses associated with various diseases, injuries, and risk factors, with the latest revision (GBD 2010) introducing some changes in the specific value choices reflected in the construction of DALYs for base-case analyses, as described above. For use in cost-effectiveness analyses, guidelines from the World Health Organization on conducting 'generalized cost-effectiveness analyses' – with a particular focus on health policies in developing countries – have included an explicit recommendation to use DALYs as the measure of benefit in these analyses.

DALYs and QALYs

DALYs are closely related in concept to QALYs. Both are metrics that take healthy time as the unit of account. Both attach weights to the continuum of health outcomes residing between optimal health and death. An important distinction is in the intended uses of the two metrics. As noted above, DALYs are used both as summary health measures for purposes of descriptive epidemiology, i.e., as units for measuring burden of disease, and as measures of the health benefits of interventions, for example, in cost-effectiveness analyses. QALYs are used primarily for the latter purpose, but there have been assessments of a related measure called 'quality-adjusted life expectancy' as a measure of the overall average level of health in a population. The construction of summary measures of population health has much in common with the construction of measures of the benefits from health interventions, so the distinction is unimportant when considering many of the features of the measures.

Christopher Murray and Arnab Acharya, in their 1997 essay on DALYs, characterized the relationship between DALYs and QALYs as follows: "DALYs can be considered as a variant of QALYs which have been standardized for comparative use." There are certain key distinctions worth noting.

As DALYs are negative measures that reflect health losses, the scale used to quantify nonfatal health outcomes in DALYs is inverted compared with the scale used in QALYs; that is, numbers near 0 represent relatively good health levels (or small losses) in DALYs, whereas numbers near 1 represent relatively poor health levels (or large losses). The inverted scale means that interventions that improve health result in DALYs averted, whereas QALYs are gained.

Disability weights in DALYs, which are the health state valuations analogous to the 'quality' adjustments in QALYs, are intended to reflect the degree to which health is reduced by the presence of different conditions, whereas at least one interpretation of the weights in QALYs is based on the individual utility derived from different states. The current interpretation of weights in DALYs reflects some evolution over time, as discussed above. Another distinction relating to disability weights is that in the GBD disability weights are assigned to health states that are attached explicitly to the sequelae of specific diseases and injuries, whereas in many applications of QALYs health states are described in terms of concrete symptoms and functional losses, without reference to specific conditions.

The standard formulation of DALYs used in revisions through 2008 has weighted healthy life lived at different ages according to a variable function that peaks at young adult ages, whereas QALYs do not typically incorporate unequal age weights. As noted above, the GBD 2010 revision has moved to using DALYs without age weights.

For measuring the burden of disease, YLLs due to premature mortality at different ages are computed with reference to a standard life table. For purposes of cost-effectiveness, this distinction is largely inconsequential, because the standard life expectancy largely nets out when benefits of interventions are computed as the change in DALYs. As a simplified example, imagine an intervention that defers one death from the age of 50 years to the age of 70 years, and suppose that the normative target lifespan used as the yardstick for DALYs is 80 years (irrespective of one's current age). Then the number of DALYs averted through intervention is a change from $80-50=30$ to $80-70=10$, for a net of 20 DALYs averted, which is the same as the number of QALYs gained through the intervention. (Note that in the actual standard life table that is used, as in most life tables, the target lifespan, equal to the number of years of remaining life expectancy at age x plus x, rises slightly with advancing adult ages rather than remaining constant as per the simple example here. This will produce a slight discrepancy between DALYs averted and QALYs gained, but this difference is usually negligible.)

Dominance and the Measurement of Inequality

D Madden, University College, Dublin, Ireland

Glossary

Bootstrap A technique for obtaining the sampling distribution of a statistic via resampling with replacement from the original sample.

Cardinalization A situation where a transformation is applied to ordered, categorical data whereby the transformed data can be regarded as cardinal.

Decomposability In the context of a measure of inequality, this is the property whereby if a population can be exclusively and exhaustively separated into a finite number of groups, then overall inequality of the population will exactly equal the sum of within group and between group inequality.

Dominance Dominance, as it is used in this article, refers to a situation whereby health in one population is regarded as superior to health in another population for a wide range of evaluation functions.

Entropy measures of inequality A family of measures of inequality deriving from the degree of order or disorder in a system. Complete equality corresponds to maximum disorder, so the gap between the actual order and maximum disorder is an index of inequality. One of the measures has the property of decomposability.

Gini coefficient A commonly used summary measure of inequality which ranges from zero to one. A value of zero indicates complete equality, whereas a value of one indicates that all health is concentrated in one person.

Jackknife A technique for obtaining the sampling distribution of a statistic via resampling from the original sample but with observations successively deleted.

Kolmogorov–Smirnov test A nonparametric test for the equality of continuous, one-dimensional probability distributions.

Likert scale In a situation where responses to questions come in the form of ordered categories with numbers assigned to them such as '1, 2, 3...' but where no cardinal interpretation can be assigned to the numbers, the Likert scale is obtained by summing the values of the responses. Thus, for example, given 10 questions, where the subject responds with '2' in each case, the Likert score would be 20.

Lorenz curve The Lorenz curve graphs the cumulative proportion of the population (in increasing order of health) on the horizontal axis against the cumulative proportion of total health on the vertical axis. If health is distributed exactly equal, then the Lorenz curve is a 45° line.

Mean/median-preserving spread The situation whereby the degree of variance or spread in a population is increased, whereas the mean/median remains unchanged.

Scale independence The property whereby a summary statistic, such as an inequality measure, is independent of the underlying scale of whatever is being measured. For example, an inequality measure is scale independent if inequality in weight is independent of whether weight is measured in pounds or kilograms.

Stochastic dominance Given an outcome such as health or income, stochastic dominance refers to a situation whereby the probability distribution of the outcome in population A is always ranked higher than the population in population B for all evaluation functions where more is better than less. Higher order definitions of stochastic dominance refer to situations where restrictions such as concavity are imposed upon the evaluation function.

Introduction

This article covers a number of measurement issues which arise in Health Economics. The first of these arises when economists wish to make comparisons between populations on the basis of some measure of health, h, where h_i refers to the value of the health measure for individual i. Such comparisons may be between different populations at the same point in time, or between the same population at different points in time, or indeed a combination of the two. In some cases it may be desirable to compare some measure of central tendency, such as the mean, μ_h.

In some cases however, there may also be of concern about how this health measure is distributed throughout the population. This may arise, for example, because the underlying individual utility function is increasing and concave in the health measure, h_i (presuming for the sake of exposition that a higher value of the health measure increases utility) or it may arise because the ethical views of society are such that society has a degree of 'inequality aversion' with respect to the distribution of this health measure. In the latter instance the inequality aversion of society will be reflected in the way in which individual utility functions are aggregated into some measure of social welfare. In both cases social welfare (defined as some aggregate of individual welfare) will be sensitive to both the level and distribution of h.

In either case, comparison of the health measure will be influenced by the precise utility and/or social welfare function employed, because this will determine the relative importance attached to the average value of the health measure and its distribution. This can be problematic, because the ranking of any two populations may well be sensitive to the choice of specific utility/welfare function. This is where the issue of dominance becomes relevant. Intuitively, a dominance result is obtained if it can be demonstrated that the distribution of health in one population, P will always be ranked better

 doi:10.1016/B978-0-12-375678-7.00725-2

(in terms of conferring higher welfare) that the distribution of health in population Q, for all welfare functions which obey certain broadly agreed upon properties. Dominance results are powerful in that they permit fairly unambiguous comparisons to be made between populations, where the term 'fairly unambiguous' is used in the sense that the ranking between the populations would hold for a wide range of welfare functions. Below, more formal, specific, definitions of dominance are given but for the moment the aforementioned explanation will suffice.

Where dominance is not found, then analysts must rely upon comparisons of some measure of central tendency, usually the mean or the median. If distribution is also an issue they must rely upon the specific utility/welfare function or, if the focus is solely upon distribution then specific inequality measures must be used, in either case running the risk that the ranking of populations may be sensitive to the choice of function/measure. In the case of health however, there may be a further complication. Some health measures are cardinal (e.g., life expectancy) and thus lend themselves to comparison via the mean and also via well-known inequality measures such as the Gini coefficient or coefficient of variation. In many cases however, the health measure is not cardinal but instead is ordinal and categorical, for example, self-assessed health (SAH). In such cases, analysts have essentially two choices: They can either transform their data from ordinal to cardinal, and then proceed using the cardinal approach referred to earlier. Alternatively, they can employ measures which are specifically designed to deal with ordinal data, bearing in mind, however, that there are relatively fewer such measures to choose from than in the case of cardinal data. The case of data which is measured in intervals lies somewhere in-between. Analysts have the choice to convert interval data into cardinal data by assuming that all observations within an interval take the range of, say, the median of that range. Of course, this may be an overly strong assumption to make and ignores any within interval variation, though it may be acceptable if the intervals are comparatively narrow. An alternative would be to convert interval data into cardinal data using the interval regression approach described later.

In this article, the application of dominance methods and the measurement of inequality in health economics, for the case of both cardinal and ordinal data, are reviewed. First, the case where the health measure is cardinal is considered. In the discussion which follows, it can be noted that what could be termed 'pure' health inequality, i.e., inequality in health without reference to an individual's socioeconomic resources will be discussed. This distinguishes this review from the extensive literature on inequality in health outcomes with respect to income or other measures of resources. The article concludes with a brief discussion on statistical inference.

Dominance and Health Inequality with Cardinal Data

In analyzing issues of dominance and inequality in the case where health is measured cardinally, the results and methods employed in the case of income inequality are available for use. It is probably easiest to deal with the case of inequality first. In what follows it is assumed that comparisons between two populations are made with respect to a measure of health h_i where it is assumed that higher values represent better health.

The primary dominance concept in the analysis of inequality is Lorenz dominance. This involves comparison of the Lorenz curve for h_i for the two populations. The Lorenz curve orders individuals in increasing order of h_i and then plots, against the cumulative proportion of the population so ordered, the cumulative proportion of total health going to each proportion of the population. The graph corresponding to the 45° line represents complete equality – everyone has the same health. The closer the graph is to the 45° line, the more equal are the distributions. Thus if one distribution lies above (nearer to the 45° line) for all values of p then that distribution is said to Lorenz dominate and would be ranked as more equal by all inequality measures obeying certain basic properties. These properties are anonymity (permutations of health among the population do not matter for overall inequality), population (the measure of inequality is independent of the size of the population), relativity (absolute levels of health do not matter for inequality measures), and transfer (inequality must fall if there is a transfer of a unit of health from a more to a less healthy person).

Where Lorenz dominance is found, the issue of inequality is essentially resolved. However, it is frequently the case that dominance is not found, in which instance specific inequality measures must be used. There is a wide range of such measures. Among the most frequently used are the Gini coefficient, the coefficient of variation, and the entropy family of measures. The Gini coefficient is closely related to the Lorenz curve and can be calculated as the ratio of the area between the Lorenz curve and 45° line of perfect equality to the area of the triangle below the 45° line. A more formal expression for the Gini coefficient is

$$G = \frac{1}{2N^2\mu_h}\sum_{j=1}^{N}\sum_{k=1}^{N}|h_j - h_k|,$$

i.e., the sum of all the differences between all pairs of health normalized by dividing by the squared population, where N is the total population and μ_h is the mean of the population health.

The coefficient of variation can be obtained from the expression

$$C = \frac{1}{\mu_h}\sqrt{\sum_{i=1}^{n}(h_i - \mu_h)^2},$$

i.e., the standard deviation of health divided by mean health.

The entropy family of inequality indices are given by

$$GE(a) = \frac{1}{a(a-1)}\left[\frac{1}{N}\sum_{i=1}^{N}\left(\frac{h_i}{\mu_h}\right)^a - 1\right]$$

where notation is as before and the parameter a reflects the weight attached to inequality at different parts of the distribution. More negative values of a reflect a higher weight on the lower part of the distribution, whereas higher positive values reflect a greater weight on the upper part of the distribution.

A further additional property which may be desirable in an inequality measure is that of decomposability. Suppose the

population can be clearly partitioned into groups, for example, by region, then the overall inequality index can be decomposed into inequalities within regions and inequalities between the regions. The only commonly used inequality index which can be exactly decomposed (in the sense that the sum of the within group inequalities and between group inequalities exactly add up to overall inequality with no residual) is the Theil index (one of the entropy family above, with $a=1$).

Lorenz dominance is concerned with comparing health in two populations purely on the basis of inequality, without any reference to the average level of health. From a social welfare perspective, greater inequality of health may be a trade off for a higher average level. To take an extreme example, suppose in population Q, there is complete equality of health, whereas in population P, there is a high degree of inequality, yet the least healthy person in P has higher health than the average level in Q. Many would regard P as having superior health to Q even though Q Lorenz dominates P.

In these instances, stochastic dominance results can be applied. The degree of stochastic dominance will depend upon whether the data are cardinal or ordinal and also on the nature of the underlying utility function. For example, with first-order stochastic dominance, suppose that the cumulative distributions of health in populations P and Q are given by $F_p(h)$ and $F_Q(h)$, respectively. Then distribution P dominates distribution Q if for any value of h, $F_Q(h) \geq F_P(h)$, i.e., for any value of health, h, the fraction of population with health lower than h is less in P than in Q. Alternatively, suppose there is a monotone nondecreasing function of h, $u(h)$, then P dominates Q if $\int u(h)dF_P \geq \int u(h)dF_Q$ for all values of h. In this case, $u(h)$ can be regarded as a utility function which is monotonically increasing in health.

Thus if it is simply assumed that individual utility is increasing in health, then dominance for population P over population Q holds if the cumulative distribution of health for population P first-order stochastically dominates that for population Q.

Assuming that individual utility functions are not only increasing, but are also concave in the measure of health, then provided the health measure is cardinal, dominance may also be observed if the cumulative distribution of population P second-order stochastically dominates that of population Q. Thus, $\int u(h)dF_P \geq \int u(h)dF_Q$ and now $u(h)$ is monotone increasing and concave. In terms of the comparison of cumulative distribution functions, what is now important is the area under the distribution functions. Thus P will second-order stochastically dominate Q if $D_Q(h) = \int F_Q(h)dh \geq \int F_P(h)dh = D_P(h)$. Note that comparison of the areas under the distribution function implies that h, the argument of the distribution function, can be summed in a meaningful way. This implies that second- and higher order stochastic dominance is only meaningful if h is cardinal and cannot be applied if h is ordinal. It is also worth noting that in this case second-order stochastic dominance is equivalent to what is known as Generalized Lorenz dominance, where the Generalized Lorenz curve is simply the original Lorenz curve scaled up by the average level of health.

There is one further branch of dominance theory which is of relevance for comparison of some specific health measures between populations. In some cases, it would be of concern if the value of a specific health measure lies above (or below) a critical threshold, although at the same time, it may not be of concern should the value of the health measure be below (above) that threshold. This has clear parallels with the study of poverty and dominance results from the poverty literature can be applied in these cases. One obvious area within health economics where such techniques could be applied is obesity, with its focus on individuals whose body mass index (BMI) lies above a critical threshold. This approach is particularly useful when there may not be complete agreement over where the critical threshold should be drawn. A further example of an application of this technique in health economics is with regard to mental stress (Madden, 2009). Here mental stress is measured via a Likert scale derived from answers to the General Health Questionnaire (GHQ) and once again the threshold value of the scale which indicates mental stress is open to question. Stochastic dominance techniques are used here to show that regardless of where the threshold is drawn, there was a fall in mental stress in Ireland over the 1994–2000 period.

The analysis of mental stress in Ireland referred to earlier essentially interpreted the Likert scale derived from the GHQ as a cardinal measure of mental health. Strictly speaking this is not true as the underlying data used to construct the scale are of an ordinal categorical nature. Much health data, including the frequently encountered SAH measures, are of this nature and the application of dominance techniques and the calculation of inequality in these instances raise particular questions, to which we now turn.

Dominance and Inequality with Ordinal Data

Whereas there are some health measures which are cardinal, they tend to concentrate only on specific dimensions of health, for example, BMI. More general cardinal health measures are comparatively difficult to come across. Measures such as the SF-36 or Euroqol are available only for a limited range of countries. Probably the most frequently employed measure of general health is SAH. Individuals answer a question of the form: In general, how good would you say your health is? The possible answers are: very bad, bad, fair, good, and very good (the exact wording can differ from survey to survey but it is generally of the aforementioned type). Whereas this measure appears to be a good indicator of overall health it is not cardinal, and with only five categories, it is not suited to the application of the standard inequality indices referred to earlier.

The breakthrough in analyzing inequality with such data came from Allinson and Foster (2004). They showed how standard measures of the spread of a distribution which use the mean as a reference point, such as the Gini, are inappropriate when dealing with categorical data. This is because the inequality ordering will not be independent of the (arbitrarily chosen) scale applied to the different categories. In this instance a more appropriate reference point is the median category and the cumulative proportions of the population in each category is the foundation of their analysis of inequality with categorical data. This is because, whereas changes in the

scale used will affect the width of the steps of the cumulative distribution, the height of the cumulative distribution is invariant to the choice of scale, thus providing the crucial property of scale independence.

Allison and Foster (2004) thus develop a partial ordering based on a median-preserving spread of the distribution (analogous to the partial ordering based on a mean preserving spread provided by say a Lorenz comparison). Thus, suppose a measure of SAH with n different categories which can be clearly ordered $1, \ldots, n$. Let m denote the median category and let P and Q denote two cumulative distributions of SAH with P_i and Q_i indicating the *cumulative* proportion of the population in category i, in each distribution, where $i = 1, \ldots, n$. For the case where both P and Q have identical median states m then P has less inequality than Q if for all categories $j < m$, $P_j \leq Q_j$ and for all $j \geq m$, $P_j \geq Q_j$. What this is effectively saying is that distribution Q could be obtained from distribution P via a sequence of median-preserving spreads.

Allison and Foster also deal with dominance when the focus is on the level of the health measure. In this case distribution P will dominate distribution Q if the cumulative frequency at each point on the ordinal scale (as we go from lower to higher) is always higher in Q than in P. This is equivalent to the first-order stochastic dominance condition referred to earlier. For a recent example of an application of this approach to a comparison of SAH between different social classes, see Dias (2009). As pointed out earlier, it is important to note that when data are ordinal then second-order stochastic dominance is not defined, because it requires that the health measure h can be summed in a meaningful way.

Of course, the Allison–Foster measure shares with Lorenz dominance the property that it only provides a partial ordering and there may be instances when the aforementioned conditions do not hold and it is not possible to rank different distributions of categorical data. Abul Naga and Yalcin (2008) address this issue and build upon the Allison–Foster approach in presenting a parametric family of inequality indices for qualitative data. Like its cardinal data counterparts such as the Gini coefficient or coefficient of variation, it will always provide a ranking, but it lacks the generality of the dominance approach. Subsequent to the Abul Naga–Yalcin paper, Lazar and Silber (2011) have provided an alternative index for ordinal data building upon work in the area of ordinal segregation. The Abul Naga–Yalcin work has also been extended to provide an index which can be used to make comparisons when the two distributions in question do not have the same median category.

The aforementioned contributions show that real progress has been made toward measuring inequality in the case of ordinal data. However, at this stage, in the literature there is still only a limited number of indices specifically designed for ordinal data, so, unlike the case with cardinal data, the analyst has less opportunity to check the sensitivity of results to alternative indices. In this instance, there is another approach which can be taken. It is possible to transform ordinal data to cardinal data, and then apply the cardinal indices referred to earlier.

Much of the literature in this area developed in the context of measuring health inequality related to socioeconomic resources and a very useful summary is available in van Doorslaer and Jones (2003). Their favored approach is to use interval regression to obtain a mapping from the empirical distribution function of what is regarded as a valid index of health (such as the McMaster Health Utility Index (HUI)) to SAH. By mapping from the cumulative frequencies of SAH categories into an index of health such as the McMaster HUI it is possible to obtain upper and lower limits of the intervals for the SAH categories. These can then be used in an interval regression to obtain a predicted value of the index for all individuals. Comparisons which they carry out for measures of SAH in Canada suggest that this approach to cardinalization outperforms other approaches and it also appears to be the case that the values of the health index obtained are not very sensitive to the cutoff points chosen. Hence it may be regarded as acceptable to use cutoff points from the Canadian HUI to calculate a cardinal index of health for other countries.

A key question then is, how do the results obtained from such an approach compare with those from an index specifically designed to deal with ordinal data? Madden (2010) carried out such an exercise, calculating ordinal inequality indices using the Abul Naga–Yalcin approach and also cardinal indices using generalized entropy measures and applying them to Irish data for the years 2003–06. In terms of the ranking of the different years there was very little correlation between the ordinal and cardinal indices. This is a specific result obtained with a specific dataset but it underlines that the choice between the application of an ordinal index versus transforming data into cardinal format and then using a cardinal index may not be trivial.

Statistical Inference

Sections 'Dominance and Health Inequality with Cardinal Data' and 'Dominance and Inequality with Ordinal Data' outlined approaches for the testing of dominance and measuring inequality, using both cardinal and ordinal data. Should dominance be found then of course, it is necessary to check if such a finding is statistically significant. Similarly, it may be used for the calculation of the standard errors associated with any particular index of inequality calculated.

Dealing first with dominance in the case of cardinal data, in the case of inequality alone this issue boils down to checking for statistically significant differences between the ordinates of the Lorenz curves. Suppose that L_i is the ith Lorenz ordinate ($i = 1, 2, ..k$), where the kth ordinate is equal to one. Then, as shown in Beach and Davidson (1983), given estimated Lorenz ordinates from two populations P and Q with sample sizes N_P and N_Q respectively, there are $k-1$ pairwise tests of sample Lorenz ordinates:

$$T_i = \frac{\hat{L}_i^P - \hat{L}_i^Q}{\sqrt{\frac{\hat{V}_i^P}{N_P} + \frac{\hat{V}_i^Q}{N_Q}}}, \quad i = 1, 2, ..k-1 \tag{1}$$

In large samples, T_i is asymptotically normally distributed. Bishop et al. (1991) suggest the following criteria when testing for Lorenz dominance: If there is at least one positive significant difference and no negative significant differences between Lorenz ordinates then dominance holds. Two distributions are

ranked as equivalent if there are no significant differences, whereas the curves cross if the difference in at least one set of ordinates is positive and significant although at least one other set is negative and significant.

In the case of first- and second-order stochastic dominance for cardinal data, Kolmogorov–Smirnov tests can be applied. Such tests can also be applied to ordinal data for first-order stochastic dominance.

If Lorenz dominance is not found then individual inequality indices must be calculated and the appropriate standard error obtained. Obtaining analytic expressions for standard errors in the case of many inequality indices is far from easy as the expressions may be highly nonlinear and whereas asymptotic results may exist, robust, small-sample results are more difficult to obtain. Given this problem, the bootstrap approach may be preferable, as evidence suggests that bootstrap tests perform reasonably well in these situations (see Biewen, 2002).

In the case of the ordinal inequality index developed by Abul Naga and Yalcin to date there has been no progress in terms of statistical inference for this index. However, the Lazar–Silber paper provides jackknifed standard errors and it is also worth observing that in the related literature of the measurement of polarization for ordinal data expressions for the calculation of confidence intervals for such measures have been produced.

Conclusion

This article has summarized some of the main results with respect to dominance and inequality in the case of health data. It was seen that a crucial distinction must be made between cardinal and ordinal health measures. In general the literature for cardinal health measures is more developed, in terms of dominance, indices, and statistical inference. There have also been developments in the analysis of dominance in more than one dimension. The area of multidimensional dominance raises important issues for the measurement of population health which are currently being vigorously debated in the poverty literature. One of the principal issues to be resolved is whether aggregation of different dimensions of health should take place before dominance or inequality analysis is applied (e.g., if single-dimensioned dominance/inequality analysis were to be applied to an aggregate cardinal health measure such as the SF-36), or whether alternatively an explicitly multidimensional approach is adopted whereby analysis is applied to separate dimensions of health and aggregation which takes place at the level of the inequality index itself.

For the case of ordinal health measures, which are arguably more widely employed, dominance results are generally less applicable, there are fewer inequality indices and statistical inference is less well developed. In this area, future developments are perhaps most likely to involve further contributions along the lines of Lazar and Silber (2011) with the development of a wider menu of inequality indices. It is also to be expected that further progress will be made in the area of statistical inference.

Dynamic Models: Econometric Considerations of Time

D Gilleskie, University of North Carolina, Chapel Hill, NC, USA

Introduction

Empirical health economists are likely to encounter questions regarding health and health behaviors that involve dynamics. What does one mean by dynamics? Put simply, a dynamic model of economic behavior captures the element of 'time.' In contrast, a static model leaves out time. More specifically, intertemporal dependence is made explicit in dynamic models. This article discusses some of the econometric methods used to estimate dynamic empirical models.

To motivate these methods, the article begins with three examples of individual behaviors studied by health economists that exhibit meaningful relationships across time. Building on these examples, the article presents the econometric methods that have been used by health economists to measure dynamic relationships or behaviors that are connected over time. Much of this work attempts to recover causal effects of variables on outcomes (as opposed to mere statistical correlations) in a dynamic empirical setting. The article concludes with a description of solution and estimation of optimization problems that recover the underlying 'primitive' (or structural) parameters that characterize how economists model dynamic decision making.

Examples of Dynamics in Health and Health-Related Behaviors

As demonstrated in each example in this section, behaviors that are dynamic involve an event, outcome, or action in the past that affects current decisions regarding that behavior or, related, an event, outcome, or action today that impacts future decision making. A distinction needs to be made as to whether the observed event, outcome, or action is endogenous or exogenous. The adjective endogenous implies that the agent (individual or firm) had a role in choosing or influencing the event, outcome, or action; exogenous implies that characteristics of the agent do not affect the event, outcome, or action. Most importantly, endogeneity suggests that unobservable characteristics of the agent likely affect adjacent (in time) behaviors. Another important characteristic of the examples that follow is that the observations of interest are specific to an individual (i) over time (t). We will assume that the econometrician has access to data with repeated observations on the same individuals. We need many observations in the 'individual' dimension, but may have only a small number of observations in the 'time' dimension.

Example 1: Health Production

It is difficult to think about dynamic models in health economics without thinking of Michael Grossman's seminal work on health capital and the demand for health (1972). Grossman was the first economist to formally model the optimal health and medical care consumption of individuals. He recognizes, and emphasizes, that health is inherently dynamic. Indeed, time is such an integral part of health-related decision making that Grossman framed it as an optimization problem being solved over a lifetime.

In this example, the evolution of an individual's health is a dynamic process. Grossman describes our health as a stock, or a capital good. One might compare it to the concept of human capital, or the stock of education that an individual acquires over her lifetime. In fact, similar to education or any capital good (e.g., computer equipment) that a firm uses in production, the stock of health requires maintenance, and depreciates, over time. And, like other capital goods, health can be characterized by its stock and its flow. The stock is an instantaneous measure of current health. The flow is the services or benefits that are generated from a stock of health.

But health cannot be purchased. An individual cannot go to the store to buy more health when her health stock falls below a particular level. Rather, an individual produces health – with the operative words being 'individual' and 'produce.' The first word signifies that each individual is responsible for their own health stock. This responsibility does not imply that accidents can always be avoided. It is quite true that unfortunate events that reduce our health stock happen, and happen with no fault of our own. Yet, our own behaviors can and do influence our health stock.

That influence is exactly where the second word 'produce' comes in. An individual chooses inputs to sustain or augment a health stock. She may also choose inputs that reduce or weaken her health stock. An obvious example of a positive input (i.e., one in which the marginal product is positive) is medical care. If one's health deteriorates, she may consume medical care to repair it. Other examples, of both positive and negative inputs, include food, cigarette, and alcohol consumption. In addition to market goods that affect health, nonmarket goods may impact health. For example, exercise, sleep, and stress are health inputs.

Given this understanding of health capital economists model it as a dynamic productive process with depreciation. That is, let H_{it} define an individual's health stock at time t. Let I_{it} denote a selected amount of health input at time t. Then, according to the description of the evolution of the health stock, a simple mathematical definition of the dynamic process might be

$$H_{i,t+1} = (1 - \delta_t)H_{it} + f(I_{it}) \quad [1]$$

where δ_t measures the depreciation rate of health capital in each period t to $t+1$ and $f(\cdot)$ is a function that converts the period t health input into health next period. Given this definition or model, it should be immediately obvious that the health production process involves time. Health in one period

 doi:10.1016/B978-0-12-375678-7.00721-5

evolves into health in the subsequent period with the help of chosen behavioral inputs during the transition period. Unfortunately, social scientists do not observe an individual's rate of health depreciation nor do they know with certainty the effectiveness of any one health input for a particular individual. Yet, these are exactly the empirical questions health economists seek to answer when studying health and health behaviors.

Example 2: Addictive Good Consumption

Cigarette consumption was described in Example 1 as a (negative) health input. To measure the effect of cigarette consumption on health outcomes, an econometrician must first understand decisions to smoke. (Smoking is an example of an action that is endogenous. Unobservable individual characteristics that affect smoking might also affect the health outcome of interest, which will bias estimates of the smoking effect.) A simple approach to modeling demand for any good is to consider the demand to be static. That is, today's demand for a good depends only on measures of specific variables today: an individual's income today, her current age, the price of the good today, and even the prices of goods that are substitutes for or complements to the good being considered, etc. However, health economists place cigarettes in a different class of goods, namely addictive goods (Chaloupka and Warner, 2000). Other examples of addictive goods might be alcohol, fast food, illicit drugs, etc.

What characterizes an addictive good? The basic premise is that past consumption of the good alters the enjoyment an individual receives from current consumption. That is, the demand for the good today depends not only on measures of specific variables today, but also on measures of specific variables in the past. Herein lies the role of time, or dynamics.

Economists have labeled three ways that past consumption of an addictive good might alter the enjoyment of the good today. The first characteristic of an addictive good is tolerance: The amount of the good consumed in the past directly affects 'happiness' today or, in the economist's terminology, contemporaneous 'utility.' Using fast food consumption as an example of a negative addiction, someone who has consumed a lot of greasy French fries in the past is unhappier (all else equal) than someone who has not developed this addiction. However, a beneficial addiction might be to exercise. Tolerance suggests that someone who has engaged in exercise routinely in the past may experience greater happiness today, all else equal.

The second characteristic of an addictive good is withdrawal: Consumption of the good provides positive utility. Put differently, an individual foregoes this utility if they choose not to smoke. Thus, a smoker, who anticipates the reduction in utility today associated with their past use, can look forward to the boost in utility they receive from continuing to smoke today. If they quit, their utility is lower.

The third characteristic is reinforcement: The marginal utility of consumption of the good today is greater when the person has a history of consumption of the good. This characteristic suggests that consumption of the good in two consecutive time periods is complementary. Adjacent complementarity also implies that reducing consumption of the addictive good (or quitting) is harder the more one has consumed in the recent past.

Each of these characteristics suggests that the demand for an addictive good depends on past behavior related to that good. That is, demand is dynamic. Note, however, that this dependence on past behavior also suggests that behavior today will impact optimal future behavior. That is, an individual deciding whether or not to smoke today (and the amount to smoke) takes into consideration their past smoking behavior, but also understands that their decision today will affect their optimization problem regarding the same behavior tomorrow. Hence, today's decision, which is based on maximizing lifetime utility from this period forward, depends not only on past behavior, but also on expected optimal behavior in the future conditional on today's choice.

Health economists theorize that the demand for an addictive good (under particular assumptions about the optimization problem of the individual) is described by the function:

$$C_{it} = c(C_{i,t-1},\, P_{it},\, C^{*}_{i,t+1},\, X_{it}) \qquad [2]$$

where C_{it} is current consumption of cigarettes, $C_{i,t-1}$ is lagged consumption, and $C^{*}_{i,t+1}$ is expected future consumption. The contemporaneous price of cigarettes is denoted as P_{it} and exogenous individual characteristics are denoted as X_{it}. Given this demand relationship for addictive goods, one can easily see how time plays a role. In particular, consumption of the addictive good in different time periods affects current consumption of the good.

Example 3: Health Insurance Selection

The optimal health insurance decision, or the demand for health insurance by an individual, is another example of a health-related behavior that involves elements of time. More specifically, an individual decides today, without perfect knowledge of her future need for medical care, whether or not to purchase a health insurance plan, which reduces the financial responsibility for medical care consumed in the near future. That is, health insurance is chosen before realization of the health state, and hence, medical care expenses. Put differently, at the point of insurance decision making, medical expenses are uncertain (Arrow, 1963).

A basic, stripped down model of optimal health insurance purchase involves choosing a plan to maximize expected utility. The uncertainty of health, and therefore medical care consumption, requires an individual to forecast – at the time of the insurance decision – the distribution of future medical care expenditure. The decision of an individual to purchase health insurance depends not only on the individual's expected medical care expenditure (i.e., some average measure), but also on the tails of that distribution. How likely am I to experience a disastrous health event that requires high medical care expenditure?

Suppose the set of health insurance alternatives differ by the level of cost-sharing or reimbursement (which ranges from 0% to 100%) and the premium (i.e., the price of the plan). That is, if an individual chooses a 30/70% plan, the insurance

company pays 70% of medical care costs during that insurance year, whereas the individual is responsible for the remaining 30% of total expenses. The premium, or price of insurance, increases with the level of coverage. Assuming utility is a function of wealth, the individual decides on the optimal level of insurance coverage that will maximize her expected utility under uncertain health or medical expense. Specifically, an individual selects insurance as if she were solving the following optimization problem:

$$\text{Max} \int U(w_{it} - D_{it} - \alpha p_{it} + \alpha D_{it})\, \mathrm{d}F(D_{it}) \qquad [3]$$

where w_{it} is the individual's wealth in period t, D_{it} is the unknown medical care expense at t with known distribution, $F(\cdot)$, and p_{it} is the insurance premium per percentage of payout, α, which measures the level of insurance coverage. In this simplified model, the individual maximizes expected utility by choosing the optimal level of coverage α (which is between 0 and 1 inclusive). Mathematically, the solution involves integrating over the medical care expense distribution, $F(\cdot)$, because costs of medical care are not known with certainty. Therefore, the optimal level of coverage depends on initial wealth, the price of insurance, the individual's level of risk aversion (captured here by the shape of the utility function $U(\cdot)$), and finally, the distribution of medical care expenses.

Here, the role of time is a bit more subtle. This example abstracts from the very realistic assumption that previous experience with particular health insurance plans or past medical care utilization may influence the current value of each health insurance alternative; in that case, the role of time mimics previous examples. However, the simple model above highlights a role of time that is different from the previous examples: Optimal decision making requires the individual to forecast future medical care expenses based on current information. Below we discuss how to solve and estimate this dynamic behavior.

The examples presented above relate to individual health behavior. Yet, there are many examples of dynamics on the supply side of health economics. Consider, for example, technology adoption or the decision of a firm to enter or exit the market. How do a firm's actions today affect the likely actions today or tomorrow of its competitors? The health literature examines these dynamic behaviors in hospital entry and exit, medical equipment adoption, and learning by firms or physicians about drug or procedure effectiveness, just to name a few areas.

Econometric Methods to Capture Dynamics

The first two examples describe the production function for health and the demand function for an addictive good. Equations [1] and [2] depict the relationships between the explained variables (i.e., health and consumption of addictive goods) and the explanatory variables. Economic theory guides the inclusion of particular explanatory, or right-hand side, variables. Then, the economist or econometrician can think about estimating an empirical model that captures the dynamic relationship.

Consider the following steps taken by the econometrician.

Step 1: Specify the Econometric Model

Given a theoretical relationship between variables of interest, the first step is to specify an appropriate econometric model. An econometrician might specify the evolution of health capital, depicted theoretically as the health production function in eqn [1], as follows:

$$H_{i,t+1} = \alpha_1 H_{it} + \alpha_2 I_{it} + u_{it} \qquad [4]$$

where α_1 and α_2 are coefficients to be estimated. They reflect the measured effect of the variation in the explanatory variables on variation in the dependent variable. In particular, α_1 measures the depreciation of the health stock between periods t and $t+1$ and α_2 measures the investment in the health stock obtained by consuming an additional unit of the input I_{it}. The u_{it} term measures the unobserved or unexplained variation in health among individuals. It captures the fact that the relationship between $H_{i,t+1}$ and H_{it} and I_{it} is not perfect or, rather, that H_{it} and I_{it} do not fully explain $H_{i,t+1}$. Error terms are always added to statistical models that describe behavior of individuals because we are social beings, and our behavior is often not as completely predictable as it might be for many natural or physical behaviors. To avoid introducing too much additional notation, the notation u_{it} is used to capture unobserved heterogeneity, generally, in all the equations that follow. The reader should understand that the amount of error and, hence, the variable that captures that error, depends on the behaviors being explained as well as the power of the observable explanatory variables.

The health production relationship can be made more realistic (and more complicated) by including additional explanatory variables that make sense theoretically. For example, Grossman himself suggests that education influences the marginal product (or effectiveness) of a health input. Let X_{it} define demographic characteristics of the individual. The econometrician might test the hypothesis that education matters by estimating the following regression:

$$H_{i,t+1} = \alpha_1 H_{it} + \alpha_2 I_{it} + \alpha_3 X_{it} + \alpha_4 I_{it} X_{it} + u_{it} \qquad [5]$$

It should be noted that the relationship in eqns [4] and [5] holds for all time periods. Thus, the model can be rewritten as

$$H_{it} = \alpha_1 H_{i,t-1} + \alpha_2 I_{i,t-1} + \alpha_3 X_{i,t-1} + \alpha_4 I_{i,t-1} X_{i,t-1} + u_{i,t-1} \qquad [6]$$

Turn now to the example of addictive good consumption. The econometrician might specify the equation that depicts the demand function described in eqn [2] as

$$C_{it} = \gamma_0 + \gamma_1 C_{i,t-1} + \gamma_2 P_{it} + \gamma_3 C^*_{i,t+1} + \gamma_4 X_{it} + u_{it} \qquad [7]$$

where the variables have been previously defined, and the marginal effects of these variables are depicted by parameters, γ, to be estimated.

Step 2: Determine the Measurable Variables to be Used in Estimation

Having specified the model, the econometrician has to determine whether data exist to estimate the model as it has been

specified. For example, how should health stock be measured? What variable exists in a data set that best captures a person's stock of health? What inputs affect health? Do measures of those inputs exist? Which inputs need to be modeled because they are chosen by the individual? For now, consider only one health input: medical care. Later, the case where multiple inputs may better explain the evolution of health will be considered.

Estimation of the empirical model in the addictive good example requires that the econometrician observe an individual's consumption and the price of cigarettes over time. In some cases where longitudinal information on individual-level consumption has not been available, econometricians have used their knowledge of the dynamic nature of addictive good consumption and the availability of cigarette prices over time to replace past and expected future consumption with the relevant price information at the time of consumption. Hence, eqn [7] becomes

$$C_{it} = \varphi_0 + \varphi_1 P_{i,t-1} + \varphi_2 P_{it} + \varphi_3 P_{i,t+1} + \varphi_4 X_{it} + u_{it} \qquad [8]$$

One can still see that 'time' plays an integral role in predicting current consumption. Specifically, prices of cigarettes yesterday, today, and tomorrow may affect cigarette consumption today.

Step 3: Evaluate the Role of Unobservables Associated with the Dynamics of the Model

Given a dependent variable (e.g., H_{it} and C_{it} in the two previous examples) and a set of observable explanatory variables, one might initially consider the use any one of the statistical estimators described in previous articles. An ordinary least squares (OLS) regression seems like an obvious candidate. However, the dynamic feature of the equations begs the question: Do unobserved individual differences (heterogeneity) that explain the observed lagged outcome ($H_{i,t-1}$), action ($I_{i,t-1}$), or event ($P_{i,t-1}$) in the past also influence the current outcome (H_{it}) or action (C_{it}) that is being explored? If so, then the error terms that explain the dependent variable and the right-hand side variable are serially correlated. It may also be the case that these unobservables are heteroskedastic (i.e., the amount of variation in the error differs by observable characteristics), but the focus in this article is on the intertemporal dependence in behaviors, outcomes, and events over time.

First, consider the desire to estimate the effect of an outcome in $t-1$ ($H_{i,t-1}$) on the same outcome in time t (H_{it}). How might the same unobservable affect both the variables H_{it} and $H_{i,t-1}$? One example must be that of unobserved health. Recall that one of the data questions above was about the measurement of health. It is hard to think of, let alone find in an available data set on individuals, a variable that fully captures one's health stock. Thus, unobserved measures of health (that are correlated with the observable measure) are captured by the error term, and these unobserved measures of health are likely correlated over time. This endogeneity produces either upward or downward bias in the OLS estimate of the endogenous variable's effect.

However, an unbiased estimate of depreciation (α_1) can be obtained only by using specific econometric techniques to account for the correlation in the unobservables. Other examples of this correlation in measures of health over time are unobserved family health history, unobserved rates of time preference that capture how forward-looking an individual may be, and unobserved health inputs. One might encounter the same problem when trying to estimate the effect of an action in $t-1$ ($C_{i,t-1}$) on the same action in time t (C_{it}). Unobservables that affect cigarette consumption today are likely correlated with consumption yesterday.

Now consider a desire to estimate the effect of an action in the past ($I_{i,t-1}$) on an outcome today (H_{it}). Might $I_{i,t-1}$ be correlated with H_{it} through unobservables that affect both? Unobserved health, for example, may be correlated with both medical care decisions and observed health outcomes. That is, lagged observed health $H_{i,t-1}$, and thus also lagged unobserved health, may affect both one's input decisions last period, $I_{i,t-1}$, and current realizations of health, H_{it}. If current unobservables 'move with' those past unobservables (i.e., are correlated), then estimated coefficients that measure the effect of these lagged observable variables are contaminated with endogeneity bias (if the econometrician does not address the correlation).

To illustrate more fully, decompose the period t error term (u_{it}) into three components. We want the first component to capture permanent unobserved differences in individuals. We label this permanent heterogeneity μ_i. These unobserved individual differences do not vary over time, but may affect observed actions or outcomes in each period. Examples of this type of heterogeneity include risk aversion, genetic characteristics, rates of time preference, or other aspects of the production process or decision-making process that remain fixed over the life cycle. The second component captures time-varying unobserved characteristics of individuals that might be correlated with the explanatory and to-be-explained variables. We label this time-varying heterogeneity v_{it}. Examples include unobserved health shocks, stress, or behaviors that may differ each period. The third component, ε_{it}, is an identically and independently distributed (iid) unobserved error term that is uncorrelated over time and uncorrelated with each of the explanatory variables of the equation. This last component does not cause any problems econometrically. The first and second must be dealt with appropriately. More formally, the general error term can be decomposed into three components:

$$u_{it} = \mu_i + v_{it} + \varepsilon_{it} \quad \text{for all } t \qquad [9]$$

As the examples suggest, the unobservables that impact estimation of variable effects may be either permanent (μ_i) or time varying (v_{it}). There are different econometric techniques that can be used to address these unobservables, depending on the type of variation/correlation.

Step 4: Determine the Appropriate Estimation Method

Economists recognize that dynamic relationships often lead to correlation in variables, or their unobserved determinants, over time. Consider, now, four different methods for addressing the econometric problems associated with unobservables that are correlated over time.

Instrumental variables

In the case of cigarette consumption (eqn [7]), economists recognize that unobservables that determine smoking behavior in the last period may affect smoking behavior in this period, which will bias the measured effects of lagged smoking on current smoking if not addressed econometrically. One solution is to find another variable that varies across individuals that explains lagged smoking behavior but, conditional on the observed lagged smoking behavior, does not independently impact current smoking behavior. Economic theory suggests that smoking decisions in each period depend on the price of cigarettes in each period. Hence, without measures of lagged smoking behavior, $C_{i,t-1}$, one can replace the behavior with its determinants, namely the price of cigarettes in the lagged period, $P_{i,t-1}$. Equation [8] above depicts the new equation using this approach.

For this variable to be a valid 'instrument' for lagged smoking behavior, the econometrician has to answer several questions. First, does this variable vary over individuals? Individual-level variation in prices is difficult to find, but price series that differ by county or state exist. And prices often vary over time. So, cigarette prices by state of residence and time of consumption usually provides enough variation to identify the effect of prices on individual behavior. Second, might $P_{i,t-1}$ be correlated with C_t through unobservables that affect both? If the 'price' of cigarettes is measured by any public policy variable such as cigarette taxes or smoking bans in public places, a public finance economist would probably answer this question with a 'yes'. The political process naturally reflects the preferences of the people, and hence these measures of the costs of smoking are correlated with demand behavior. For the purposes of this article, consider variation in the prices of cigarettes (across states and across time) to be exogenously determined. Thus, there is no need here to worry about unobserved correlation between $P_{i,t-1}$ and C_{it}.

Before stating a third question that must be answered to determine the validity of an instrument, reflect on the specification of eqn [8], which suggests that lagged prices, current prices, and future prices each affect current consumption of cigarettes in some way. It is often the case that adjacent measures of price are correlated. Such multicollinearity among variables makes estimation (and interpretation) of this model difficult. And this difficulty suggests the third question: Although the assumptions about exogeneity of cigarette prices might be valid, do individuals know prices with perfect foresight (as eqn [8] implicitly assumes). If not, then future prices, $P_{i,t+1}$, cannot be included in the equation. Rather, expectations of future prices could be included. But how do people form expectations of future prices today? They may use all information available to form an expectation equal to the true expected value of prices (i.e., rational expectations). Or they may have adaptive expectations and predict future prices using current and lagged observed prices of the good, which are already included in the equation. Regardless of one's assumption about the formation of price expectations, the role of lagged price is now twofold: it captures the effect of lagged price on both lagged smoking behavior and the distribution of future cigarette prices. Yet, theoretically, the econometric work was begun with the goal of measuring the habitual or addictive effect of lagged consumption on current consumption, measured by the coefficient on lagged price. Empirically, the revised specification (eqn [8] without the $P_{i,t+1}$ variable) no longer supports that interpretation.

Assuming that the answers to these questions support the use of an exogenous 'event' (i.e., the price of a good), as an appropriate instrument for a lagged endogenous variable, then the econometrician can proceed with estimation. Either replace the endogenous variable with the exogenous one and estimate the current smoking behavior as a function of current and lagged cigarette prices, or estimate the endogenous action (i.e., lagged smoking) as a function of lagged prices, and use the estimated predicted value of lagged smoking in place of the observed lagged smoking variable. This method requires that lagged prices have no independent explanatory power in the current smoking equation conditional on the predicted lagged smoking behavior.

One should note two things about this instrumental variables method. The former approach (i.e., replacement of $C_{i,t-1}$ with $P_{i,t-1}$) eliminates the need for panel data on individual smoking behavior. Of course, longitudinal data on cigarette prices (or taxes, or smoking bans) that vary by state of residence are needed. The second approach, which involves estimation of the lagged smoking behavior, obviously requires longitudinal data on smoking behavior. Note also that there is no need to model the permanent and/or time-varying unobserved differences among individuals with either of these approaches because the correlation is 'dealt with' by replacement of the offending variable with one that is not correlated with the error term.

Fixed effects

An alternative econometric approach is to model explicitly the permanent and time-varying unobserved differences among people that lead to correlation in variables over time. In this case, panel data on individual behaviors or outcomes is required.

First consider the case where the source of correlation across time periods is permanent unobserved individual differences that affect behavior or outcomes in all periods. That is, in the health production example, eqn [5] can be expressed as

$$H_{i,t+1} = \alpha_1 H_{it} + \alpha_2 I_{it} + \alpha_3 X_{it} + \mu_i + \varepsilon_{it} \qquad [10]$$

and in the addictive good consumption example, eqn [7] can be expressed as

$$C_{it} = \gamma_0 + \gamma_1 C_{i,t-1} + \gamma_2 P_{it} + \gamma_3 X_{it} + \mu_i + \varepsilon_{it} \qquad [11]$$

In each example above, μ_i is the permanent unobserved individual heterogeneity and ε_{it} is the serially uncorrelated iid unobserved (error) component. Conditional on μ_i, H_{it}, and I_{it} are uncorrelated with ε_{it} (and $C_{i,t-1}$ is uncorrelated with ε_{it}). Two fixed-effects methods – the within-groups estimator and the first-differencing estimator – eliminate the fixed individual unobserved effect (μ_i) by transforming the estimated equation. The former involves subtracting the mean of each variable over all years from each individual observation in each cross-section. As the mean of the fixed effect is μ_i itself, the permanent heterogeneity is eliminated. Similarly, the latter approach involves first differences ($H_{i,t+1} - H_{it}$ or $C_{it} - C_{i,t-1}$), which eliminates the permanent component.

The latter first-differencing method is used most frequently among health economists. There are tradeoffs in the econometric properties of each of these estimators.

One advantage of the fixed-effects method is that it not only addresses the serial correlation (caused by permanent heterogeneity) that creates the endogeneity bias associated with having the lag of the dependent variable as an explanatory variable, but it also addresses the correlation associated with endogenous behaviors that affect outcomes (i.e., the input behavior, I_{it}, in eqn [10]).

However, the fixed-effects methods have some disadvantages. The approach relies on changes in explanatory variables over time to identify effects of interest, eliminating time-invariant variables (e.g., gender, race) as explanations for observed behaviors. It is less efficient due to a loss in degrees of freedom in estimation. It ignores correlation generated from time-varying unobserved differences across individuals.

Random effects

The econometrician can employ another estimation tool to model the unobserved heterogeneity. Rather than treat the permanent heterogeneity as individual specific, they can treat it as random, with some distribution, and attempt to estimate the effect of explanatory variables on a behavior or outcome of interest while integrating over the distribution of the correlated unobserved heterogeneity. Sometimes the econometrician estimating with random effects will specify (or assume) the distribution of the unobserved heterogeneity. At other times, the distribution of the heterogeneity will be estimated.

An econometric approach that requires no (or few) distributional assumptions on the unobservables is called the discrete factor random-effects (DFRE) estimator. The random-effect specification introduces an unobservable, μ, that takes on the estimated discrete values $\mu_1,\ldots,\mu_k$ (rather than individual specific values indicated by an i subscript in the fixed-effect specification), with estimated probabilities $\varphi_1,\ldots,\varphi_k$, and $\Sigma_k\ \varphi_k=1$. In this case, consumption behavior in periods $t=2,\ldots,T$ are estimated with the dynamic equation:

$$C_{it}=\gamma_0+\gamma_1 C_{i,t-1}+\gamma_2 P_{it}+\gamma_3 X_{it}+\mu+\varepsilon_{it} \qquad [12]$$

and estimation involves integration of the likelihood function over the estimated discrete distribution of μ.

The DFRE procedure also allows for the introduction and estimation of time-varying unobserved heterogeneity (i.e., the v_{it} term in eqn [9]). One simply needs to also estimate the mass points and probabilities of the mass points associated with this type of heterogeneity.

Another advantage of the DFRE approach is the ease with which an econometrician can jointly estimate two (or more) behaviors of interest. Referring to the health production function example, a source of correlation could be between the lagged health outcome and current health outcome, but it could also be between the input behavior and the health outcome. Modeling the latter correlation explicitly requires jointly estimating the input behavior (i.e., medical care consumption, cigarette consumption, etc.) with the health production function. The linear DFRE version of the multiple equation case would also require the estimation of factor loadings on the unobserved heterogeneity components in each equation to capture different effects of the heterogeneity on different outcomes. There is a nonlinear approach where the joint probabilities of each of the two types of heterogeneity are modeled and estimated.

Note that in the jointly estimated set of equations, as in the health production function example where both the input behavior and the subsequent health outcome are modeled jointly, identification requires that there exists a variable that impacts input behavior but, conditional on the input, does not also affect health outcomes. Theory suggests such variables. For example, if medical care is the only input to health production, prices of medical care (captured perhaps by health insurance cost-sharing characteristics, distance to the physicians office or hospital, supply of doctors, etc.) affect demand for medical care, but do not independently affect health transitions conditional on medical care consumption.

However, it cannot be denied that health is a function of more than medical care inputs. As stated earlier, health depends on different types of medical care inputs (e.g., preventive care, curative care) and nonmedical care inputs (e.g., cigarette consumption, alcohol consumption, physical exercise, nutrition, sleep, stress, etc.). If any of the omitted inputs are complements to or substitutes for the included (i.e., observed) input, then they are necessarily jointly chosen with the included input and hence a function of the same explanatory variables. One can also prove that the income effect associated with a fixed budget set, irregardless of a cross-price relationship between inputs, suggests that the model is not identified as specified (Mityakov and Mroz, 2012). Hence, strong assumptions are necessary for estimation of unbiased effects of health inputs on health outcomes.

Additionally, it is necessarily the case that consumption in every period is correlated with the discrete factor, or permanent heterogeneity term, μ. But, consumption for the first period of observation in the data cannot be explained by the dynamic equation [12] because the econometrician does not observe smoking behavior before period one. Hence, an initial condition (i.e., smoking in the first observed period) can be specified in its reduced form and must be jointly estimated with the dynamic equation to obtain the correct distribution of the unobserved permanent heterogeneity. It is also necessary that the econometrician be able to identify this initial condition. That is, there must be a variable that explains the initially observed behavior (or outcome) that does not also explain subsequent behaviors (or outcomes) conditional on the lagged behavior (or initial condition in this case).

Generalized method of moments

Finding appropriate instruments (or identification variables) for estimation of these dynamic models is a big hurdle for econometricians. To address this difficulty, the methods have exploited the dynamic variation in behaviors, outcomes, and events over time in search of an instrument. As another example, the first-differenced generalized method of moments (GMM) estimator uses the twice-lagged dependent variable as the instrumental variable. Additional lags can also be used.

Identification in this context is similar to that in the DFRE approach. Both are identified through the variation in complete histories of the exogenous variables in the equations

being jointly estimated. Think of it this way: If cigarette consumption in period t depends on cigarette consumption in period $t-1$ (and period t prices of cigarettes), and one wants to model cigarette consumption using a dynamic equation every period, then the entire history of cigarette prices explains current smoking behavior. At the individual level (or state level) there is likely to be additional variation in this history of cigarette prices relative to the variation in the last period's cigarette price.

When multiple behaviors need to be modeled (i.e., the health outcome and the endogenous health input), GMM estimation can combine the set of moment conditions specified for the equations in levels with additional moment conditions specified for the equations in first differences. In this case, twice-lagged variables serve as instruments because they are uncorrelated with the differenced time t and $t-1$ error terms.

Up to now, it has been assumed that these time-varying unobservables are drawn every period, from the same distribution, where, by assumption, these errors are not persistent. That is, a draw in one period does not depend on the draw in the previous period. However, it may be the case that this time-varying heterogeneity is not completely subsumed (or reflected) by the observed period t behavior or outcome. Rather, the disturbance term may be autoregressive (i.e., $v_{i,t+1}=\lambda v_{it}+e_{it}$). With the differenced GMM estimator, the coefficient λ can be estimated. An econometrician could also use copula functions to explicitly model the serial correlation in nonpermanent, time-varying error terms.

Solution and Estimation of Dynamic Theoretical Models

This article has discussed econometric methods that attempt to recover the causal effect of variables of interest on outcomes of interest in a dynamic setting. Often, however, one may want to measure (or estimate) the value of a parameter of interest for which we do not have a corresponding observable variable. Consider the third example of dynamics in health-related decision making presented above: the optimal health insurance selection. A health economist may desire to understand what determines observed insurance choices. Theory suggests that a person's risk aversion (or aversion to the financial loss associated with reduced health and subsequent medical care consumption) plays a role in determining how much health insurance is optimal for him. Economists capture risk aversion with the shape of the utility function. A linear function, for example, reflects no risk aversion: given the risk of poor health (or medical care expenditure) an individual would be indifferent between having health insurance coverage and financing the full cost of care out of pocket. A concave utility function reflects risk aversion (or risk avoidance). But how can an econometrician use observed data to recover this unobserved risk preference?

This question requires that the econometrician parameterize and solve the individual's optimization problem (eqn [3]) and use data on observed health insurance choices, medical care utilization (or expenses), individual characteristics, and prices of insurance to estimate the parameters of the model. Rather than measuring correlations or causal effects in linearized demand functions (Example 2) or stand-alone production functions (Example 1), solution and estimation of the parameterized optimization problem (Example 3) recovers the preferences, constraints, technologies, and expectations of forward-looking individuals. Not only are the recovered parameters easily interpreted as common constructs used by economists, the estimated model can also be used to evaluate interesting health policy alternatives when variation in such policy parameters are not available in the observed data.

Looking specifically at the optimal insurance selection example, an econometrician solves an expected utility maximization problem. The shape of the nonlinear utility function, which depends on 'disposable wealth' (because, by assumption, the individual gets happiness from consumption which costs money), and the shape of the distribution of financial risk that an individual faces (i.e., medical care expenses), are critical components of the optimal solution. To understand optimal behavior, the econometrician must accurately capture both aversion to risk and the risk distribution. Of much importance is accurately capturing the tail of the expenditure distribution, for it is the rare or unlikely, large financial loss events that reduce happiness (or utility) the most. To complicate things further, these constructs may depend on individual unobservables that are likely correlated over time.

There is not enough space in this article to detail the methods used to solve and estimate such dynamic discrete choice problems in health economics. The methods that recover structural or primitive parameters, like those that recover reduced-form parameters, also require identification. The econometrician must be very specific about the observed behavior that helps to estimate the parameters of interest. Nobel prize winning economist Jim Heckman describes the problem of identification that econometricians want to avoid as occurring when 'many different theoretical models and hence many different causal interpretations may be consistent with the same data' (Heckman, 2000). Thus, no matter which estimation procedure is adopted, the econometrician must be clear about what assumptions are being made to justify identification, because the assumptions will inevitably affect interpretation of the estimated parameters. And after all, it is these measured parameters that form the basis of the answers to our originally posed questions.

Summary

This article introduces the concept of dynamics in an economist's model of behavior. The three examples depict economic relationships between variables over time using a demand function, a production function, and full solution of an individual's optimization problem. The reader is introduced to the main econometric problems associated with estimating models with dynamics. The article briefly discusses some econometric methods used to address the intertemporal dependence exhibited by dynamic empirical relationships. The article concludes by explaining the importance of theory in supporting both the justification for causal empirical interpretations as well as the understanding of dynamic health-related relationships over time.

Economic Evaluation of Public Health Interventions: Methodological Challenges

HLA Weatherly, RA Cookson, and MF Drummond, University of York, York, UK

Glossary

Budget constraint The limit to expenditure imposed by a cash-limited budget.

Efficiency A resource allocation is efficient if it is not possible to reallocate resources so as to increase one person's utility (or health, or output) without decreasing another person's utility (or health or output). In health economics the entity maximized is generally assumed to be utility, health, or welfare.

Extra-welfarism or Nonwelfarism A normative framework of economics which holds the evaluation of a policy or resource allocation should be based on a larger set of information than solely the utilities attained by members of society.

Matching (in biostatistics) Selecting a control population that is matched on some characteristics that may influence the outcome of interest independently of the disorder in question. Also a process through which pairs of individuals are brought together in order to trade, share, or otherwise engage in some mutual activity.

Partial equilibrium analysis Classic demand and supply analysis in which each market is treated in isolation from all others, compared with general equilibrium analysis.

Quality-adjusted life-year The quality-adjusted life-year (QALY) is a generic measure of health-related quality of life that takes into account both the quantity and the quality of life generated by interventions.

Value-based pricing A method of pricing pharmaceuticals that links their prices to the estimated value of the health benefits they generate.

Welfarism A tenet of welfare economics which holds that the evaluation of a policy or resource allocation should be based solely on the utilities attained by members of society.

Willingness to pay The maximum sum an individual (or a government) is willing to pay to acquire some good or service, or the maximum sum an individual (or government) is willing to pay to avoid a prospective loss. It is usually elicited from controlled experiments in which subjects reveal their willingness to pay.

Introduction

There has long been an aspiration to invest in promoting health, preventing ill health, and reducing health inequality. This aspiration can be realized through a wide variety of public health interventions, including not only screening, vaccination, and other preventive activities undertaken by healthcare professionals but also a broad range of fiscal and social programs and regulations beyond the healthcare sector with impacts on the health of the population.

Economic evaluation is increasingly used to inform decisions about which public health interventions to fund from scarce resources. However, there remains a dearth of evidence on the effectiveness and cost–effectiveness of public health interventions and the evidence that is available tends to be relatively weak – at least compared with evidence for healthcare interventions – with important methodological challenges remaining. In the UK, for example, the Wanless Report of 2004 noted the lack of evaluations undertaken in the public health field and the lack of methods development, expertise and funding available to generate the evidence.

Health economic guidelines for assessing the cost–effectiveness of healthcare technologies – such as new drugs, devices and medical procedures – have existed in many jurisdictions across the developed world for well over a decade. By contrast, methods for the economic evaluation of public health interventions are less well-established. Healthcare technology assessment guidelines use an economic evaluation framework to provide a clear and transparent approach for assessing the relative costs and benefits of alternative options with the aim of achieving an efficient allocation of resources. Typically, in relation to healthcare technology assessment, this framework focuses on the decision-making objective of maximizing health gain subject to an exogenously fixed healthcare budget constraint.

The economic evaluation of many public health interventions raises additional methodological challenges. As with the evaluation of standard 'clinical' healthcare technologies, it is important to determine effect estimates for use within economic evaluations of public health interventions. However, public health interventions tend to be directed at populations or communities rather than specific individuals, and can be less suited to evaluation through randomized controlled designs: the gold standard of study design for obtaining unbiased estimates of effect. In addition, public health interventions tend to generate a broad range of nonhealth benefits and opportunity costs, which may extend beyond the healthcare sector, with implications for other sectors subject to different objectives and budget constraints. Lastly, although standard health economic evaluation methods focus on maximizing health gain, a particular feature of many public health interventions is a concern to reduce health inequalities and so decision makers may be interested in information about the distribution of health levels, gains and opportunity costs within the general population as well as the average health gain for recipients of the intervention. It is, therefore, not clear how far standard methodological guidelines for healthcare technology assessment are appropriate in public health, and some public health scholars have argued

that over-zealous application of standard health technology assessment (HTA) evaluation processes and criteria in public health can lead to systematically misleading conclusions.

This article briefly reviews standard methods for the economic evaluation of healthcare interventions before identifying key methodological challenges for the economic evaluation of public health interventions. To illustrate the methodological issues, it contrasts National Institute for Health and Clinical Excellence (NICE) (http://www.nice.org.uk/) methods guides for economic evaluation of healthcare technologies and public health interventions, respectively, linking this to the methodological challenges of undertaking economic evaluation of public health interventions. Finally, it explores ways forward, noting some recent methods developments in the field.

Methods for the Economic Evaluation of Healthcare Interventions

Economic evaluation offers a clear analytical framework for assisting decision making. In the presence of limited resources and a fixed healthcare budget, economic evaluation offers a transparent approach, underpinned by explicit social value judgments, for choosing how to allocate society's scarce healthcare resources. To do this, decision-making objectives and comparator interventions are identified and the opportunity cost of selecting a particular intervention is assessed by considering whether its' value exceeds the value that would have been achieved if the next best alternative intervention were selected, given available resources. Costs and consequences of relevant alternative activities are compared, with the most efficient use of resources being the option that provides the best outcome.

There are two main philosophical approaches underpinning economic evaluation: the 'welfarist' approach and the 'non-welfarist' approach. Each has implications for the economic evaluation methods of choice. The key outcome in the welfarist approach is the satisfaction of individual preferences, typically measured using willingness to pay (WTP) reflecting the maximum amount an individual would pay for a particular intervention. In contrast, the nonwelfarist approach focuses on some other measure of outcome reflecting the decision-maker's objective, such as the quality-adjusted life-year (QALY) which can be used as a summary measure of total population health benefit. In practice, the nonwelfarist approach and the use of cost–effectiveness analysis (CEA) based on QALYs predominates in the healthcare sector, whereas the welfarist approach and the use of cost–benefit analysis (CBA) based on WTP estimates predominates in other areas of social policy such as transport, occupational safety, the environment, employment, housing, and so on. However, each approach can be applied in different ways and both CEA and CBA could in principle be conducted using different outcome measures.

One of the most comprehensive and commonly referred to set of guidelines for health economic evaluation methods is the NICE health technology 'reference case' from the UK. These guidelines are periodically revised – they were first issued in 2004, updated in 2008, and a third edition is currently being prepared that may incorporate substantial revisions related to a new system of 'value-based pricing' due to be introduced from 2014. The 2008 version, which sets out a thoroughly 'non-welfarist' approach to undertaking economic evaluations of healthcare interventions, is described in Box 1. Under this approach, the aim is to maximize health given a fixed budget constraint, whereby funding the new intervention involves displacing one or more existing interventions. A new intervention is considered cost–effective if the extra cost incurred to gain an extra one QALY, relative to the next best intervention, is less than approximately £20 000 to £30 000. This is the cost–effectiveness threshold value and represents the opportunity cost or health forgone by the displaced activity.

Methods Challenges for the Economic Evaluation of Public Health Interventions

Unlike clinical healthcare interventions, public health interventions tend to be directed at populations or communities

Box 1 Summary of the HTA and the public health reference cases (National Institute for Health and Clinical Excellence, 2008, 2009)

Element of assessment	*NICE HTA reference case*	*NICE public health reference case*
Defining decision problem	The scope developed by NICE	The scope developed by NICE
Comparator	Therapies routinely used in NHS	Therapies routinely used in Public sector
Perspective on costs	NHS and PSS	Public sector, including the NHS and PSS
Perspective on effects	All health effects on individuals	All health effects on individuals
Type of economic evaluation	CEA	Primary analysis CEA Secondary analysis CCA, CBA
Synthesis of evidence on outcomes	Based on a systematic review	Based on a systematic review
Measure of health effects	QALYs	QALYs
Source of data for measurement of HRQoL	Reported directly by patients and/or carers	Reported directly by patients and/or carers
Source of preference data for valuation of changes in HRQoL	Representative sample of the public	Representative sample of the public
Discount rate	Annual rate 3.5%, costs and health effects	Annual rate 3.5%, costs and health effects
Equity position	Additional QALY same weight regardless of other characteristics of individuals receiving health benefit	Additional QALY same weight regardless of other characteristics of individuals receiving health benefit

rather than specific individuals. One implication of this for evaluation is that public health interventions often have relatively small and hard-to-detect effects at the level of the individual, which can nevertheless sum to large effects at population level. Public health interventions also tend to generate a broader range of costs and nonhealth benefits, including costs falling on private consumption and public sector budgets beyond the healthcare sector. Finally, whereas standard economic evaluation methods focus on efficiency with the aim of maximizing health gain, typically the aim of public health interventions extends further to include a concern for reducing unfair health inequalities. Indeed, some public health professionals would go so far as to say that the primary goal of public health interventions is to generate a more equitable distribution of health in society. Based on these considerations, adjustments to standard health economic evaluation methods may be required to assess public health interventions. The formulation of social objectives, the range of outcomes and opportunity costs to be quantified, and the methods for evaluating those outcomes and opportunity costs may all need to be reconsidered, to align the methods with the broader scope and goals of public health interventions.

A number of reviews have explored the challenges of economic evaluation in public health. Four key methods challenges can be identified in applying standard health economic evaluation methods to public health interventions. These include (1) attributing outcomes to interventions; (2) measuring and valuing outcomes; (3) incorporating equity considerations; and (4) identifying inter-sectoral costs and consequences, as developed further below.

Attributing Outcomes to Interventions

Before undertaking CEA, it is essential to determine the effectiveness of relevant comparator interventions. Most healthcare interventions are directed at identified groups of individuals, and the randomized controlled trial (RCT) design is typically used as the 'gold standard' study design for primary data collection. Most published guidelines in the healthcare field, including the current NICE reference case, indicate a preference for using RCT evidence to identify and measure the effectiveness of relevant comparators. Some individually focused, face-to-face public health interventions may be suitable for evaluation using an RCT. However, this might not be feasible for more community-based public health interventions, and other forms of experimental data, such as cluster randomized trials, may not be available for obtaining effect estimates. Because there are likely to be fewer controlled trials of public health programs, it will often be necessary to use other approaches for obtaining an unbiased estimate of the intervention effect. Natural experiments and the use of nonexperimental data can be used to fill some gaps in the public health evidence base. However, evidence of this kind is vulnerable to selection bias. Where study participants are not randomized to the interventions, the effects estimated for different interventions may be biased because of confounding between assignment to the intervention and the study participant characteristics. This implies that effectiveness estimates may, in part, be caused by differences in population characteristics instead of the intervention of interest. More use may be made of statistical techniques that have been developed to analyze nonexperimental data, including a range of econometric methods and simulation modeling methods. Methods are available to improve the validity of the comparator groups through study design, such as matching patients across interventions and in the analysis of results by statistically adjusting for case mix, assuming sufficient data is available to do so.

Given the dearth of RCT evidence for many public health interventions, systematic reviews of evidence which exclude all non-RCT design evidence may not yield parameter estimates that could be used in economic evaluations. Instead, a common outcome would be that there was insufficient research evidence available for assessing effectiveness. Other methods such as narrative review summaries are not particularly helpful for analysts requiring empirical estimates. Instead, broader evidence synthesis techniques are required, which enable the analyst to include all relevant evidence within an economic evaluation, including robust nonexperimental evidence from natural experiments as well as RCTs. Modeling is also required to extend the analysis to an appropriate time horizon. This may be of particular importance for public health interventions which impact health over the longer term. Modeling is also required to indicate how uncertainty in the available evidence translates to the probability that a particular decision is the correct one.

Measuring and Valuing Outcomes

Typically the main aim of a new healthcare technology is to improve health. By contrast, public health interventions tend to generate a broad range of health and nonhealth benefits, which may extend beyond the healthcare sector. Many health economic guidelines, including the NICE reference case for HTA, recommend that health outcomes are measured in QALYs. For public health interventions, however, a range of nonhealth outcomes may also be relevant – including fairly tangible crime, education and employment outcomes as well as harder-to-measure outcomes such as public reassurance, the empowerment of citizens to make informed choices, and community cohesion. Some of these outcomes may be possible to incorporate within a QALY-type framework, others not. Therefore, the use of other outcome measurement and valuation methods may be appropriate – for example, subjective well-being scores, or multidimensional indices of well-being in which health is only one component, or WTP-based methods including the possibility of using some form of 'adjusted' WTP after purging the influence of income, incomplete information, misperceptions of risk, protected characteristics under equalities legislation and/or other determinants of 'raw' WTP that social decision makers may consider inappropriate reasons for public resource allocation decisions.

Intersectoral Costs and Consequences

Public health interventions may have impacts that extend beyond the healthcare sector. Costs and benefits associated with public health interventions can fall on different sectors of the public sector. For example, a public health intervention to reduce substance abuse may reduce criminal justice costs.

Interventions that are implemented in other sectors of the economy may also have public health implications. For example, improvements in housing could reduce illness and injuries, with consequent reductions in healthcare utilization and expenditure. In addition, individuals may incur out-of-pocket costs associated with accessing and using interventions. There may be ripple effects associated with an intervention that could extend across other sectors of the economy, including the private and voluntary sectors. An obvious way of addressing this challenge would be to monetize benefits. However, this still raises practical questions about how different health and nonhealth outcomes are to be valued and how to address the issue of fixed budget constraints faced by healthcare and other public sector decision makers, rather than assuming that all costs and outcomes are costlessly exchangeable between different policy sectors. It also raises deeper theoretical questions about whether and how it is possible to integrate 'welfarist' and 'nonwelfarist' approaches.

If a healthcare and personal social services (PSS) perspective is chosen, as for the NICE HTA reference case, resource use and costs falling on the healthcare and PSS sector are evaluated but impacts falling on other sectors are not. Where the healthcare sector budget is fixed, a new intervention can only be funded if other activity is displaced within the sector. There is an opportunity cost incurred in investing in the new intervention, i.e., the health forgone among the group of patients whose intervention is displaced and therefore no longer available. Under the NICE HTA reference case, this health opportunity cost is approximated by the cost–effectiveness threshold value. Using this approach, for approximately every £20 000 of expenditure the opportunity cost is one QALY lost through displacing existing interventions. However, the relevant opportunity costs and threshold values are likely to differ across sectors – with different sectors having different threshold values for both health and nonhealth opportunity costs.

The NICE HTA reference case recommends that analysts undertake CEA on the basis of benefits measured in QALYs and costs covering National Health Service (NHS) and PSSs resource use. To identify possible inter-sectoral impacts of public health interventions, the costs and benefits falling on other sectors could be considered for each comparator intervention. The cost–consequence analysis (CCA) approach, whereby a range of sector-relevant costs and consequences are measured and reported separately, could be informative. In addition, it might be appropriate to account for these impacts using real or hypothetical budgetary transfers across sectors whereby sectors that gain net benefits can 'compensate' sectors that lose net benefits – although the feasibility of this approach requires further investigation. For example, if a generic but sector-specific measure of outcome such as the QALY were identified for each sector, this could be used in reference to the relevant cost–effectiveness threshold value for the sector to compute net benefits for each sector.

Incorporating Health Equity Considerations

The final key methods challenge identified for the economic evaluation of public health interventions is a concern to reflect the health equity implications of public health interventions The importance of achieving health equity is recognized in many published guidelines for economic evaluation. However, in practice, health equity considerations are rarely quantified. In terms of health outcomes, it is typically assumed that the value of a QALY is the same whoever receives it. The analysis will also contain some judgment about which types of resource use to cost, and this can be influenced by equity considerations – for example, considerations of non-discrimination may influence judgments about how far to count productivity costs, which can be much higher for highly paid workers compared with those on low pay and economically inactive groups such as children and pensioners. However, current analyses do not examine health inequality issues – in particular the distribution of QALY levels or gains between population subgroups, for example, by socioeconomic status, ethnicity and gender – which are of particular interest in public health.

To reflect health inequality considerations, data on equity-relevant subgroups need to be identified, collected, and analyzed. Assuming the decision maker has the twin objectives of both reducing health inequality and improving health, if the cost-effective intervention is the option that also minimizes health inequality then the decision is clear. However, if one intervention achieves greater health outcome and the comparator intervention achieves greater health equality then under standard cost-effectiveness decision rules it is not clear which intervention to choose. Some methods have been proposed for dealing with this trade-off issue, as reviewed in the section on methods developments below.

Recent Guidance for the Economic Evaluation of Public Health Interventions

Before reviewing recent methods developments in the field, it is useful to refer to NICE guidance that has been developed to facilitate a consistent and transparent approach to undertaking good quality economic evaluations of public health interventions in the UK. The NICE guide to methods for the development of public health guidance is periodically updated: it was first issued in 2006, and has been updated in 2009 and 2012. Described below is the 2009 version, which is the most directly comparable to the 2008 NICE 'reference case' for technology appraisal. The main relevant changes in the 2012 edition are a reduced discount rate for costs and benefits and an even stronger emphasis on conducting CCA and CBA as well as CEA using QALYs, following a recent shift of public health budgets in England to local government and away from the healthcare sector. As detailed in **Box 1**, the NICE public health reference case (right-hand column) differs in a few characteristics compared to the NICE HTA reference case (left-hand column). These differences illustrate that elements of assessment have been adapted to reflect the characteristics of public health interventions.

The NICE public health reference case reflects the fact that public health interventions may involve resources, costs, and outcomes beyond the healthcare sector. It recommends that "important health effects and resource costs are all included"

and "effects and outcomes not related to health are included (if they are important for the public sector)." Therefore, NICE recommends that analysts include this information in addition to the information recommended for the NICE HTA reference case. As comparison of the two approaches shows, for the NICE HTA reference case the perspective on cost is fairly restrictive, including only NHS and PSSs costs. Also, the prescribed measure of health benefit is the QALY. Each QALY gained is assumed to have the same weight regardless of the other characteristics of the individuals receiving the health benefit (e.g., their age, socioeconomic status, or severity of their health condition). The NICE methods for developing public health guidance differ in that the perspective on costs is extended to encompass all costs falling on the public sector, recognizing the broader, cross-sector nature of most public health interventions. To facilitate comparability between NICE decisions, the QALY remains the primary measure of health outcome in the 'reference case.' However, for the public health reference case it can be supplemented by CCA and CBA approaches in order to take account of the broader aims and scope of public health interventions. This allows explicit consideration of multiple, nonhealth related and/or outcomes that are difficult to quantify. It also means that the impact of the interventions on the distribution in health gains can be evaluated to inform public health policy.

Methods Developments in the Economic Evaluation of Public Health Interventions

Given increasing interest in the economic evaluation of public health interventions and current public health economic evaluation guidance, it is useful to review some of the ongoing methods requirements and developments in the area that might be used in future evaluations.

Attributing Outcomes to Interventions

In terms of primary data collection to assess the relative effectiveness of public health interventions, it is often feasible to undertake individual or cluster randomized RCTs and where possible this is recommended for measuring outcomes, although it is likely to be possible only over the short term. Where this is not feasible, nonrandomized trials may be undertaken and use of methods to restrict entry to the interventions based on those with particular characteristics or selecting controls that match the cases in terms of the confounding factor(s) may prove useful. As it is likely that outcomes of interest will extend beyond the length of trial follow-up, it is useful if outcomes measured match those available in longer term observational studies. Analytical techniques may be used to analyze nonexperimental data including econometrics. Economics has a long tradition of analyzing nonexperimental data for deriving effects attributable to a range of public health interventions. These include various matching techniques such as propensity scores, difference in differences techniques, time series analyses of natural experiments, and, where appropriate, more sophisticated econometric modeling and structural modeling. In addition, Bayesian methods may be useful in synthesizing data (modeling) including in examining the data where participants in studies do not match typical NHS patients, where intermediate outcomes are used, where relevant comparators have not been used, where long-term costs and benefits extend beyond the trial period and in quantifying the decision uncertainty and variability around the estimates. Further research might be undertaken to develop the methods for synthesizing all relevant data, experimental and nonexperimental and aggregate and individual-level data, for use in economic evaluations of public health interventions.

Measuring and Valuing Outcomes

Given that the aims and scope of public health interventions tend to be broader than for standard healthcare interventions, the measures of outcome chosen need to reflect this. As discussed above, the NICE reference case recommends CEA using QALYs as the primary form of analysis, with patients and/or carers as the source of data for measurement of health-related quality of life (HRQoL) and with values based on a representative sample of the views of the public. CCA and CBA are recommended as a secondary analysis to include other measures of outcome appropriate to decision making given the interventions evaluated.

Ongoing research includes development of sector-specific generic outcomes based on the QALY approach, for example, a social care QALY, development of a nonsector specific multidimensional measure such as a well-being index and a nonsector specific unidimensional measure such as happiness. The choice of outcome measure reflects the normative foundation underpinning the analysis and can also reflect the impact of the intervention on a particular sector or across multiple sectors of the economy.

Inter-Sectoral Costs and Consequences

Where the costs and consequences of public health interventions extend beyond the healthcare sector, the NICE HTA reference case methods would need to be extended to demonstrate this impact. The NICE public health reference case accounts for broader outcomes in the sense that the use of the cost–consequence or cost–benefit approach enables the analyst to describe other outcomes beyond the QALY and the healthcare sector. In terms of costs, besides NHS and PSSs costs, other public sector costs may be considered. Use of the cost–consequence approach could, however, mean that decision rules are not explicit as there are no standard decision rules using this approach and it is not clear the value decision makers would attach to different impacts in order to come to a decision about the cost–effectiveness of an intervention. The use of CBA may require a shift in the normative position to a more 'welfarist' perspective, though it may also be possible to monetize at least some nonhealth outcomes using methods other than estimating 'raw' WTP for those outcomes – for example, using 'adjusted' WTP estimates, sector-specific threshold values, and relative valuations of those outcomes in terms of other outcomes that are more readily monetized.

Research is ongoing to assess the practicalities of evaluating possible budgetary transfers across different sectors of the

economy. In particular, an inter-sectoral compensation test approach to analyze the net benefit of costs, which fall on different sectors of the economy is being explored, and a stochastic mathematical programming approach is being developed to explore how to allocate resources in the context of different budgets and different budgetary policies across sectors.

Finally, research is also being undertaken to assess the use of a general equilibrium approach to simultaneously consider the impact of interventions across all sectors of the economy. The large majority of health economic evaluations undertaken to date take a partial equilibrium approach to analysis by assuming all other costs (and benefits) remain the same apart from those being evaluated. This is appropriate for evaluating the impact of most healthcare interventions. However, some health issues such as antimicrobial resistance and potentially pandemic diseases (e.g., seasonal flu, severe acute respiratory disease (SARS)) might have a macroeconomic impact that alters broader resource use and costs in the economy as a whole.

Incorporating Equity Considerations

The NICE public health reference case makes no explicit mention of equity considerations. However, the use of CCA, and assessment of subgroups in sensitivity analysis, assuming sufficient individual-level data on equity-related subgroups, may enable the analyst to include health equity issues. However, as a starting point, relevant health equity characteristics need to be identified and could include a whole range of possibilities such as socioeconomic status, degree of voluntariness or personal responsibility for health risk, and the value of treating current ill health versus preventing future health risk. If, following evaluation, the most cost–effective option is likely to be judged inequitable, either on the grounds of health inequality impact or procedural justice, it would be possible to assess the opportunity cost of not selecting that option, in terms of aggregate health gain forgone or additional resources used. Another approach that has been suggested is quantitative health impact assessment, allowing for health opportunity costs as well as health gains. Here, once a health inequality or a set of health inequalities have been determined, the distribution of net health impacts of the intervention is assessed by different equity-relevant groups. Building on this approach, it may be possible to assess the magnitude of any reduction in health inequality following adoption of the intervention and to clarify trade-offs with the objective of maximizing population health improvement.

The NICE reference cases state that an additional QALY is given the same weight regardless of other characteristics of individuals receiving health benefit. There has been some research into public and stakeholder views on equity weighting in a public health context and considerable additional research to overcome technical and practical issues is required to examine how much sacrifice in total population health is merited in order to pursue particular equity goals.

Summary

Economic evaluation provides a clear analytical framework for combining evidence and explicit social value judgments to inform decisions about how far investments of scarce resources in public health interventions are worthwhile. Given tight budgets and ballooning healthcare costs worldwide, policymakers are increasingly interested in ways of shifting the balance of effort toward preventative activity that has the potential to both improve health and reduce healthcare cost. So policymakers are likely to have an ongoing interest in assessing how far investments in public health interventions represent good value for money. Methods for the economic evaluation of healthcare interventions need to be adapted and refined in relation to the four methods challenges identified, in order to help analysts undertake good quality, relevant economic evaluations of public health interventions. Methods development in the field is still at an early stage and further research is required to improve the usefulness of methods and to pilot new methods with the aim of providing more useful information to support decisions about the investment of scarce resources into public health interventions.

Economic Evaluation, Uncertainty in

E Fenwick, University of Glasgow, Glasgow, Scotland, UK

Sources of Uncertainty

Uncertainty exists wherever the truth is unknown either due to imperfect information or imperfect measurement. Within economic evaluations of healthcare, there are a number of sources of uncertainty. Methodological uncertainty relates to the analytic methods used to undertake an economic evaluation. Sources of methodological uncertainty include whether discounting should be employed and, if so, at what rate or rates, and whose preferences should be used to value health outcomes (those of the patient, public, or professional). Structural uncertainty relates to the structure and assumptions employed within an analysis. For example, the assumptions underlying the extrapolation of outcomes from a trial or the choice of the number of health states in a Markov model. This type of uncertainty is particularly relevant to (although not limited to) model-based analyses. It is often overlooked within analyses, largely due to the complexities of incorporating changes to structure and assumptions, despite the potential for considerable impact on results. Stochastic (or first order) uncertainty reflects differences in how interventions are experienced and impact within a population. For example, the different length and/or severity of adverse events experienced by different patients with the same prognosis receiving the same intervention. Stochastic uncertainty reflects random variation between people within the population and is represented by the sample variance (in trial-based studies) or the dispersion in the output from first order Monte Carlo simulation (in model-based studies). Uncertainty within the population is not the main focus for economic evaluation which is concerned, instead, with uncertainty at the population level. As such, stochastic uncertainty will not be covered in this article. Note that stochastic uncertainty is fundamentally different to heterogeneity which reflects the variation between people that can be explained by their specific identifiable characteristics. These characteristics might include, for example, age, gender, ethnicity, geographical location. Heterogeneity is best handled through the use of subgroups within the analysis, with results either presented independently for each subgroup or, if required, included in a weighted analysis for an aggregate group. Finally, parameter uncertainty reflects the uncertainty associated with specific parameters employed within an analysis. For example, the uncertainty surrounding the effectiveness of an intervention or the utility value associated with a particular health state.

Incorporating Uncertainty within Analyses

The existence of these various uncertainties within an economic evaluation inevitably leads to uncertainty in the estimation of the costs, effects, and cost-effectiveness associated with the health intervention and ultimately to uncertainty in the decision about whether or not to fund the intervention. Undertaking an analysis of these uncertainties allows an assessment of the impact that they have on the results; illustrating the robustness of the results to changes in the inputs used in the analysis and assessing confidence in decisions. An analysis of uncertainty can also contribute to an assessment of the value of undertaking further research through a formal value of information analysis. According to the recent joint International Society for Pharmacoeconomics and Outcomes Research and Society for Medical Decision Making Modeling Good Research Practices Task Force Working Group Guidelines, "(t)he systematic examination and responsible reporting of uncertainty are hallmarks of good modeling practice. All analyses should include an assessment of uncertainty and its impact on the decision being addressed" (Briggs *et al.*, 2012). This assessment of uncertainty usually takes the form of sensitivity analysis (SA), where assumptions or parameter values used in the economic evaluation are systematically varied to observe the impact on the results. Within deterministic SA (DSA), this systematic variation is performed manually to ascertain the impact associated with specific combinations of assumptions and/or parameters (see Section Deterministic Sensitivity Analysis). In contrast, probabilistic SA (PSA) involves repeatedly varying all of the uncertain parameters simultaneously, in order to get an overall assessment of the impact of the uncertainty. Of the sources of uncertainty described in Section Sources of Uncertainty, only parameter uncertainty can be assessed using either DSA or PSA. Methodological and structural uncertainties should not be assessed within a PSA. In addition, in certain circumstances scenario analyses are employed (e.g., when investigating heterogeneity). Here, alternative assumptions or parameter values associated with specific subgroups are substituted into the economic evaluation to examine the impact on the results.

Deterministic Sensitivity Analysis

DSA involves manually varying the parameter values or assumptions employed within the economic evaluation to test the sensitivity of the results to these values. There are a number of methods available to undertake DSA. One-way, two-way, and multiway SA involve substituting different values for one, two, or more parameter(s), method(s), or assumption(s) at a time and examining the impact on the results. The results of DSA can be displayed either graphically or through the use of tables, or conversely the results can be summarized in the text. This is fairly straightforward for one-way, two-way, and even three-way SA (which can employ contour plots) but becomes more of a challenge with multiway SA when more than three parameters are changed simultaneously. Analysis of extremes involves changing all parameters and/or assumptions to their most extreme values (which can be either best or worst case values) simultaneously and assessing the impact on the results. The results can be reported in the text. All these methods of DSA require that the range of values that the

 doi:10.1016/B978-0-12-375678-7.01419-X

parameter(s) or assumption(s) can take is specified before the analysis. These ranges should be informed by and incorporate the available evidence base. In contrast, the final method of DSA, threshold analysis requires no such information. Here, the levels of one or more parameters, assumptions or methods are varied to identify the point at which there is a significant impact on the results, for example, the intervention becomes cheaper, more effective, or cost-effective. Again, the results can be displayed graphically, in tables or in the text. It is then left up to the user of the results to interpret and determine whether the values identified constitute reasonable levels for the parameter, assumptions, or methods.

Probabilistic Sensitivity Analysis

PSA involves repeatedly varying all of the uncertain parameters employed within an economic evaluation simultaneously, to get an overall assessment of the impact of the uncertainty. As such, PSA requires the specification of probability distributions for each parameter to fully reflect the parameter uncertainty. Each of these probability distributions represents both the range of values that the parameter can assume and the likelihood that the parameter takes any specific value within the range.

Assigning probability distributions to parameters

Within a PSA there are three main methods for assigning probability distributions to parameters:

1. Using patient-level data
2. Using secondary data from the literature
3. Assessing and incorporating expert opinion

Where sample data are available (e.g., from a clinical study) it can either be incorporated directly into the analysis through the use of bootstrapping (see Section Propagating uncertainty – bootstrapping) or the moments of the data can be used to fit a probability distribution.

Where historical data are available from previously published studies, this should be used to specify the probability distribution for the parameter. Here the premise is to match what is known about the parameter in terms of its logical constraints, behavior etc. with the characteristics of the distribution. As such, particular distributions are the most appropriate for specific parameters. For example, beta distributions should be used to specific uncertainty in probabilities, log-normal distributions should be used for relative risks or hazard ratios and gamma or log-normal distributions should be used for right-skewed parameters such as costs.

Where there are no primary or historical data available from which to specify the probability distribution for a particular parameter, then expert opinion can be used. However, care must be taken when eliciting opinions from experts, to ensure that it is the uncertainty in the parameter that is captured rather than various estimates of the mean. For example, the Delphi method is commonly used when eliciting expert opinion, however, this approach generally produces a single point estimate through consensus and therefore does not capture uncertainty. It is important that parameters are not excluded from the analysis of uncertainty because they have little information with which to estimate the parameter – these are precisely the parameters that need to be included, and with a wide distribution to represent the uncertainty.

Propagating uncertainty – Monte Carlo simulation

Once probability distributions are assigned to the parameters, the uncertainty is propagated through the use of (second order) Monte Carlo simulation. Here, a value is selected for each parameter from its probability distribution and the associated cost and effects are estimated based on these specific parameter values. These selections are most commonly made randomly from each probability distribution. Although recently, latin hypercube or orthogonal sampling (where selections are sampled from a specific section of the probability distribution) have been suggested to improve efficiency in sampling. The process is repeated thousands of times and a distribution of expected costs and effects is generated. These distributions reflect uncertainty at the population level, with each iteration representing a possible realization of the uncertainty that exists in the analysis, as characterized by the probability distributions.

Propagating uncertainty – bootstrapping

Within a trial-based study, an estimate of the population-level uncertainty can be obtained through bootstrapping the sample data. Here, samples are repeatedly taken at random from the original sample. These samples are each the same size as the original sample and are drawn with replacement. As with a (second order) Monte Carlo simulation, the bootstrap provides a distribution of the expected costs and effects associated with the intervention.

Presenting Uncertainty

Tornado Plots

Tornado plots can be used to illustrate the impact on the results (i.e., costs, effects, or cost-effectiveness) associated with a series of one-way SA involving different parameters (Figure 1). Here, the uncertainty in the results associated with the uncertainty in each parameter is illustrated in a series of stacked bars (one per parameter). The length of each bar illustrates the extent of the uncertainty in the results associated with the uncertainty in that particular parameter. The parameters (bars)

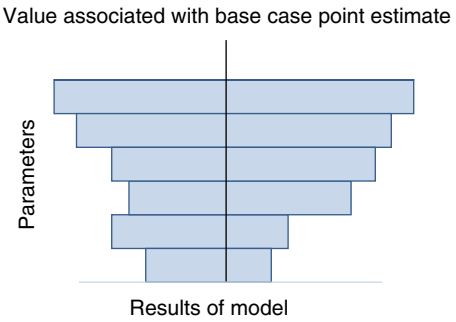

Figure 1 Tornado diagram illustrating the impact on the results of uncertainity in each parameter.

are stacked in order of length from smallest to longest (i.e., the parameters for which uncertainty in the parameter has the smallest impact on uncertainty in the results are at the bottom) forming a funnel or tornado shape. All of the bars are aligned around the result (cost, effect or cost-effectiveness) corresponding to the base case value for the parameter, hence the bars are not necessarily symmetrical and the funnel/tornado is not necessarily smooth.

Cost-Effectiveness Planes

Uncertainty in the costs and effects associated with an intervention, generated either from a probabilistic SA or from bootstrapping trial data, can be graphically represented on a cost-effectiveness plane. Where the decision involves only two interventions, the incremental costs associated with the intervention of interest are plotted against the incremental effects for each iteration from the simulation, as a series of incremental cost-effect pairs, on an incremental cost-effectiveness plane. Incremental costs are conventionally plotted on the *y*-axis with incremental effects on the *x*-axis. As such, the slope between any specific cost-effect pair in the plane and the origin represents the incremental cost-effectiveness ratio (ICER) associated with that cost-effect pair (i.e., the incremental cost/incremental effect). The plane is split into four quadrants by the origin (which represents the comparator). The NE and SE quadrants involve positive incremental effects associated with the intervention of interest, whereas the NE and NW quadrants involve positive incremental cost. Figure 2 illustrates the joint distribution of incremental costs and effects as a cloud of points on the incremental cost-effectiveness plane.

The location of the incremental cost-effect pairs in relation to the *y*-axis indicates whether there is uncertainty regarding the existence, or not, of cost-savings. For example, if all of the incremental cost-effect pairs are located above the origin (in the NE and/or NW quadrants) then the intervention is definitely more expensive. The spread of the incremental cost-effect pairs in relation to the *y*-axis indicates the extent of the uncertainty regarding the magnitude of incremental costs. For example, in Figure 2, the incremental cost-effect pairs are plotted closely together in terms of incremental cost indicating that there is little uncertainty surrounding the magnitude of the incremental cost. The same holds for the location and spread of the incremental cost-effect pairs in relation to the *x*-axis and the existence and extent of uncertainty in the incremental effects. For example, in Figure 2, the location and spread of the incremental cost-effect pairs indicate that there is no uncertainty regarding the existence of an effect benefit associated with the intervention of interest (in comparison to the alternative) but that there is considerable uncertainty regarding the size of the effect benefit.

The incremental cost-effectiveness plane provides a good visual representation of the existence and extent of the uncertainty surrounding the incremental costs and effects individually. In addition, the location of the joint distribution of incremental costs and effects (the cloud of incremental cost-effect pairs) within the four quadrants of the incremental cost-effectiveness plane can provide some information about the cost-effectiveness of the intervention. If the cloud is located completely in the SE quadrant (or the NW quadrant) then there is no uncertainty in the cost-effectiveness; the intervention dominates (is dominated by) the alternative. Where the cloud of incremental cost-effect pairs falls into the NE or SW quadrants or straddles more than one quadrant, the incremental cost-effectiveness plane does not provide a useful summary or assessment of the uncertainty in the cost-effectiveness. In addition, a distinction must be made between uncertainty in the cost-effectiveness of the intervention and uncertainty in the

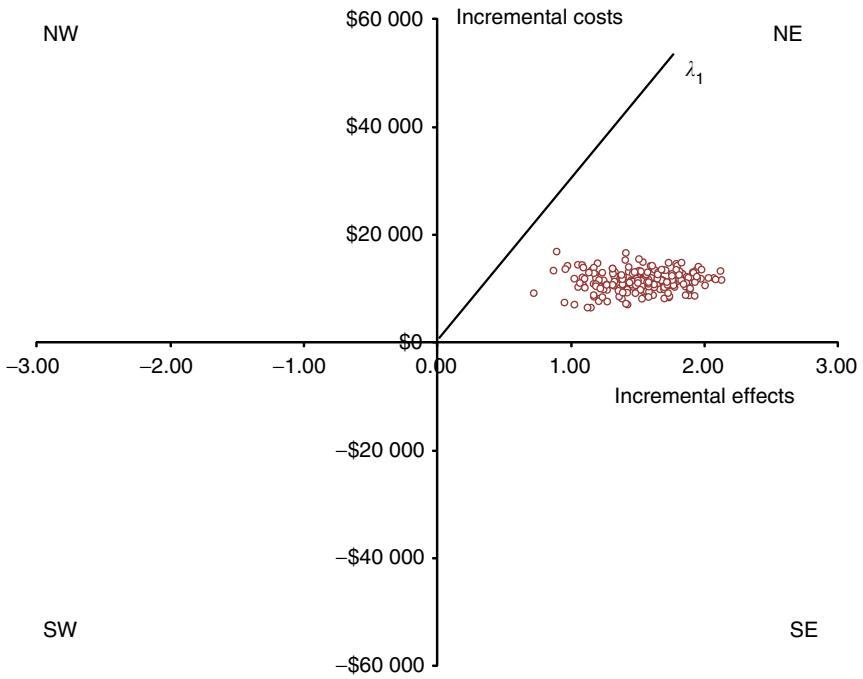

Figure 2 Incremental cost-effectiveness plans.

decision to adopt the intervention based on the current information about costs, effects and cost-effectiveness (decision uncertainty). Decision makers using the results of economic evaluations to guide decisions about whether to adopt new interventions are interested in the latter. An assessment of the decision uncertainty requires the comparison of the joint distribution of the incremental costs and effects with a predetermined, external threshold level representing the willingness to pay for the effects (λ) to determine the proportion of the joint distribution that falls below the threshold. The assessment of the decision uncertainty is not too daunting when the cloud of incremental cost and effect pairs falls into just one or even two quadrants, or when the cost-effectiveness threshold is known with certainty. Returning to Figure 2, at a willingness to pay threshold of λ_1 there is no uncertainty associated with the adoption of the intervention despite the considerable uncertainty in the cost-effectiveness of the intervention. This is because the entire joint distribution of incremental costs and effects falls below (to the South and East of) the cost-effectiveness threshold (λ_1). Where the cloud of incremental cost-effect pairs falls into the SE or NW quadrants there is also no decision uncertainty; the intervention is definitely cost-effective (SE) or definitely not cost-effective (NW). When the joint distribution of costs and effects covers three or all of the quadrants, or the cost-effectiveness threshold is unknown then the assessment of the decision uncertainty will involve considerable computation, and the incremental cost-effectiveness plane will not provide a useful summary of the decision uncertainty.

Where the decision involves more than two interventions, the costs and effects for each intervention are plotted (for each iteration from the simulation) as a series of cost-effect pairs, on a cost-effectiveness plane (see Figure 3). Here, the spread of the cost-effect pairs for an intervention in the y-axis (x-axis) provides information on the extent of the uncertainty in the costs (effects). In addition, the location of the cost-effect pairs for an intervention in comparison to the cost-effect pairs for other interventions provides some information about the existence of uncertainty in the incremental costs and incremental effects. For example, in Figure 3, it is possible to determine that intervention B is definitely more expensive than intervention A (incremental cost is positive), but it is not possible to determine that it is more effective than intervention A. In contrast, intervention C is both more costly and more effective than both A and B. For decisions involving more than two interventions, the cost-effectiveness plane can not provide an assessment of the uncertainty in the cost-effectiveness or an assessment of the decision uncertainty. For these assessments, knowledge is required regarding the relationship between each of the cost-effect pairs for each intervention (i.e., which cost-effect pair for intervention A relates to which cost-effect pair for intervention B and which cost-effect pair for intervention C). This information is not easily presented or computed in the cost-effectiveness plane.

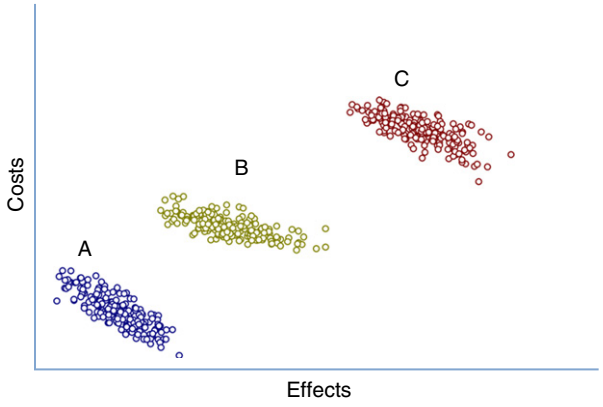

Figure 3 Cost-effectiveness plane.

Cost-Effectiveness Acceptability Curves

Cost-effectiveness acceptability curves (CEAC) provide a graphical representation of the decision uncertainty associated with an intervention. They present the probability that the decision to adopt an intervention is correct (i.e., that the intervention is cost-effective compared with the alternatives given the current evidence) for a range of values of the cost-effectiveness threshold (λ). This probability is essentially a Bayesian definition of probability (i.e., the probability that the hypothesis is true given the data), although some commentators have given the CEAC a Frequentist interpretation.

Where the decision involves only two interventions, the decision uncertainty is derived from the joint distribution of incremental costs and effects, as the proportion of the incremental cost-effect pairs that are cost-effective. In an incremental cost-effectiveness plane, this can be identified as the proportion of cost-effect pairs that fall below a specific cost-effectiveness threshold (as described above). The CEAC is then constructed by quantifying and plotting the decision uncertainty for a range of values of the cost-effectiveness threshold (λ). As noted in Section Cost-Effectiveness Planes, incremental cost-effect pairs that fall in the SE (or NW) quadrant are always (never) cost-effective, as such these incremental cost-effect pairs are always (never) counted in the numerator of the proportion. Incremental cost-effect pairs that fall in the NE and SW quadrants are either considered cost-effective or not depending on the cost-effectiveness threshold (λ). When the cost-effectiveness threshold (λ) is zero (i.e., the decision maker places no value on effects), only incremental cost-effect pairs in the SE and SW quadrants will be considered cost-effective (i.e., those with negative incremental costs). When the cost-effectiveness threshold (λ) is infinite (i.e., the decision maker only values effects and places no value on costs), only incremental cost-effect pairs in the NE and SE quadrants will be considered cost-effective (i.e., those with positive incremental effects). Between these two levels, as the cost-effectiveness threshold (λ) increases (i.e., the decision maker increasingly values effects), incremental cost-effect pairs in the NE (SW) quadrant are added to (removed from) the numerator. This reflects the fact that incremental cost-effect pairs in the NE quadrant (i.e., positive cost, positive effect) increasingly provide effects at a cost lower than the decision maker would be prepared to pay, whereas those in the SW quadrant involve a loss of effects without the level of savings that the decision maker would require. As a result, the CEAC does not represent a cumulative distribution function; its

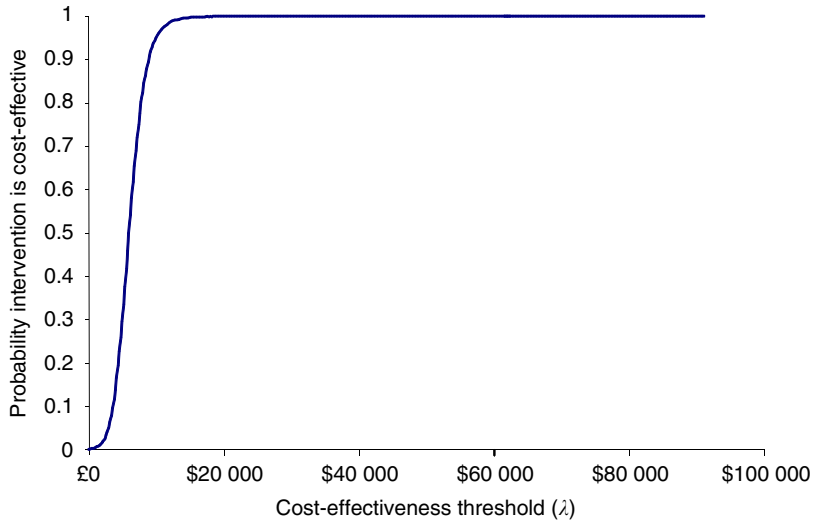

Figure 4 Cost-effectiveness acceptability curve.

shape and location will depend solely on the location of the incremental cost-effect pairs within the incremental cost-effectiveness plane. Figure 4, presents a CEAC for a decision involving two interventions. By convention, for decisions involving only two interventions, the CEAC is only shown for the new intervention of interest, however, the CEAC for the alternative could also be presented. Given that the interventions are mutually exclusive and collectively exhaustive (i.e., for each incremental cost-effect pair the new intervention is either cost-effective or the alternative is cost-effective) then the CEAC for the alternative has the opposite shape and location, with the curves crossing at a probability of .5.

Where the decision involves more than two interventions, CEACs can be constructed for each intervention by determining the decision uncertainty associated with each intervention compared to all of the alternatives simultaneously (i.e., the probability that the intervention is cost-effective compared with all of the alternatives given the current evidence). Again, as the interventions are mutually exclusive and collectively exhaustive (i.e., for each cost-effect pair intervention only one of the interventions A, B, or C is cost-effective) then the CEAC for every intervention will vertically sum to one. It is inappropriate to present a series of CEACs that compare each intervention in turn to a common comparator, as this provides no indication of the uncertainty surrounding the decision between the interventions. Figure 5 presents a series of CEACs associated with a decision involving more than two interventions.

It is very important to stress that the CEAC simply indicates the decision uncertainty associated with an intervention for a range of values of λ. Thus, in the context of expected value decision making (where the decision is made on the basis of the expected costs, effects, and cost-effectiveness) the CEAC does not provide any information to aid the decision about whether to adopt the intervention or not. Therefore statements concerning the CEAC should be restricted to statements regarding the uncertainty surrounding the decision to select a particular intervention, or the uncertainty that the intervention is cost-effective, compared with the alternatives given the current evidence. Information from the CEAC should not be used to make statements about whether or not to adopt an intervention.

The cost-effectiveness acceptability frontier (CEAF) has been suggested to supplement the CEAC in the context of expected value decision making. The CEAF provides a graphical representation of the decision uncertainty associated with the intervention that would be chosen on the basis of expected value decision making. As such, the CEAF provides no additional information about the decision uncertainty, it simply replicates the CEAC for the intervention that would be selected by the decision maker at each value of the cost-effectiveness threshold (λ). As such, discontinuities occur in the CEAF at values of the cost-effectiveness threshold (λ) at which the decision alters (see Figure 5).

Intervals and Distributions for Net Benefits

Net benefits (NB) have been suggested as an alternative method to present the results of economic evaluations. In this framework, the issues associated with ICERs are overcome by incorporating the cost-effectiveness threshold (λ) within the calculation to provide a measure of either the net health benefit or the net monetary benefit. Here, following a probabilistic SA or bootstrap of trial data, the cost and effect pairs for every iteration are replaced by an estimate of NB; generating a distribution of net benefit. Where the decision involves two alternatives, the incremental net benefit (INB) can be used. The uncertainty can be either be summarized and presented as a confidence interval for (I)NB or presented in full as a distribution of (I)NB. Given that the net benefit measure incorporates the cost-effectiveness threshold, where the threshold is unknown the results must be provided for a range of values of the threshold. Figure 6 presents the confidence interval for the INB for a range of values of the cost-effectiveness threshold as an INB curve. This curve provides information

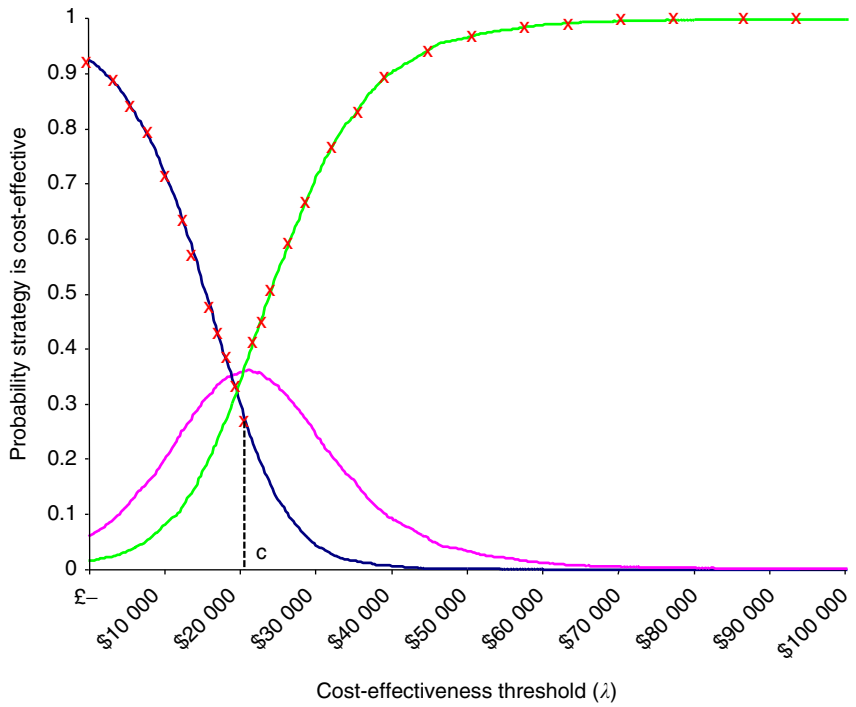

Figure 5 Cost-effectiveness acceptability curves and cost-effectiveness acceptability frontier. *Note*: c represents the value of the ICER where the decision switches; the shape of the CEAF is identified by **X**.

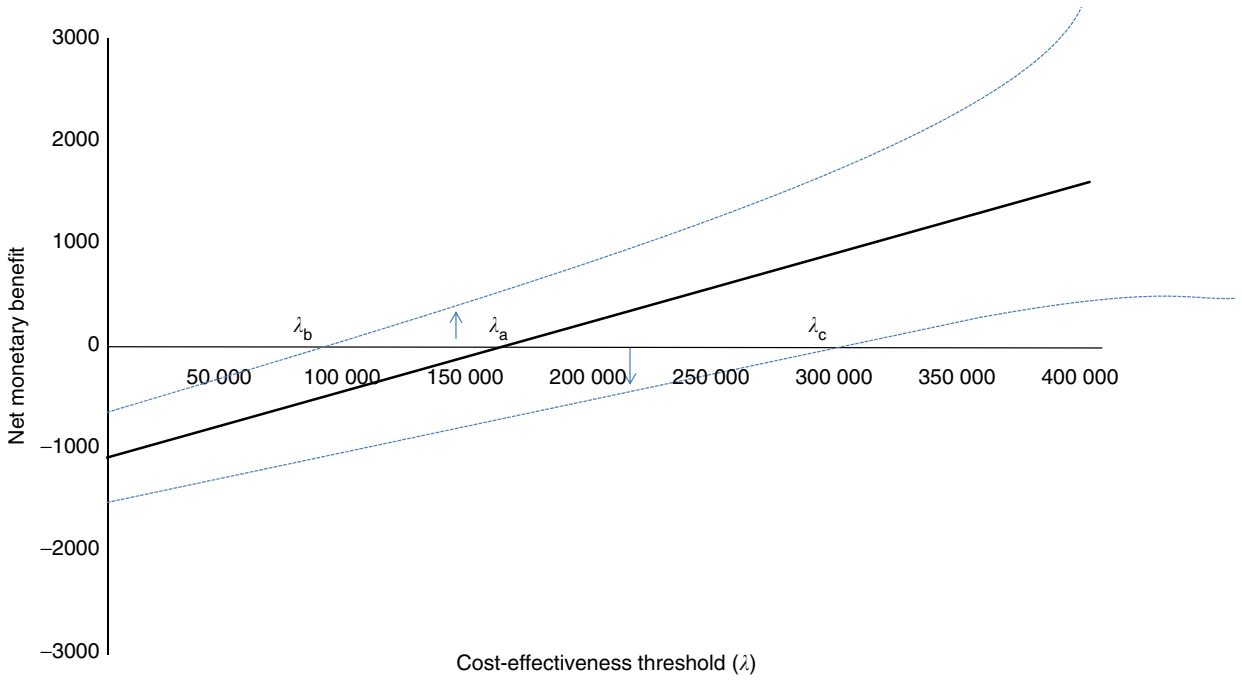

Figure 6 INB curve.

about the extent of the uncertainty in INB as well as identifying which intervention to adopt (on the basis of expected value decision making) for every value of the cost-effectiveness threshold (λ). For example, in Figure 6 for values of the threshold above λ_a the intervention should be adopted (as the INB > 0), below λ_a the alternative should be adopted. With regard to the decision uncertainty associated with the intervention, at values for the threshold below λ_b there is no

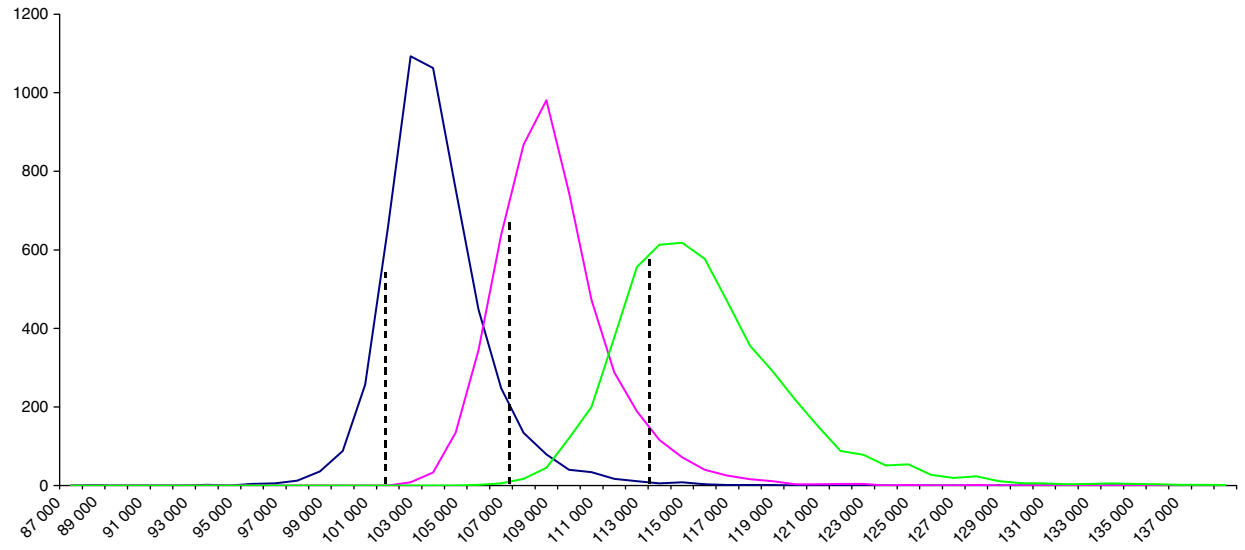

Figure 7 Distributions of net monetary benefit.

decision uncertainty; the intervention is not cost-effective. At values for the threshold above λ_c there is no decision uncertainty; the intervention is cost-effective. For values of the threshold between λ_b and λ_c assessment of the decision uncertainty associated with the intervention requires an evaluation of the proportion of the distribution of INB that falls above zero (i.e., the vertical distance from the *x*-axis to the 95% line). The decision uncertainty associated with the comparator is given by the proportion of the distribution of INB that falls below zero (i.e the vertical distance from the 5% line to the *x*-axis). Figure 7 presents distributions of NB for a particular value of the cost-effectiveness threshold (λ). As noted earlier, where the threshold is unknown the distributions would have to be provided for a range of values of the threshold. Figure 7 provides information about the extent of the uncertainty in the NB associated with each intervention as well as identifying which intervention to adopt (on the basis of expected value decision making) for a specific value of the cost-effectiveness threshold (λ). An assessment of the decision uncertainty associated with an intervention would require an evaluation of the proportion of the distribution of NB that overlaps with the NB distributions associated with the other interventions. Where the decision involves more than two interventions, this evaluation is not straightforward. Therefore it is only in the situation that the NB distributions are distinct (i.e., do not overlap) and there is no decision uncertainty, that the figure provides any information about the decision uncertainty associated with the interventions.

Linking Analysis of Uncertainty to Decision Making

The presence of decision uncertainty means that there is inevitably some possibility that decisions made on the basis of the available (uncertain) information will be incorrect and introduces the possibility of error into decision making. Where the decision maker has the authority to delay or review decisions (based on either additional evidence that becomes available, or that they request) an analysis of uncertainty is important because it links to the value of additional research.

Education and Health

D Cutler, Harvard University and NBER, Cambridge, MA, USA
A Lleras-Muney, UCLA, Los Angeles, CA, USA

In their seminal 1965 study, Kitagawa and Hauser documented that mortality in the US fell with education. Since then a very large number of studies have confirmed that the well-educated enjoy longer lives: for example, in 1980, individuals with some college education at the age of 25 years could expect to live another 54.4 years, whereas life expectancy at the age of 25 years for those without any college education was only 51.6 years.

Not only are the differences in health by education large, but also, by most measures, these differences have been growing in recent years. For instance, in 2000, those with some college education lived 7 years longer than those without any college education – thus the gap increased by 4 years since 1980. Education not only predicts mortality in the US but also is an important predictor of health in most countries, regardless of their level of development. Furthermore, the life expectancy gaps are growing around the world. Education gradients in mortality since 1980 are also known to have increased in Estonia, Sweden, Finland and Norway, Russia, Denmark, England/Wales, and Italy – although caution must be exercised as the number and composition of individuals within education categories has also changed substantially over time. The more educated are also noticeably healthier while they are alive, as they report being in better health, having fewer health conditions and limitations. Children of educated parents are also in better health in both developed and developing countries.

This review synthesizes what is known about the relationship between education and health in both developed and developing countries. Although previous work has thought of the effect of education separately for richer and poorer countries, there are insights to be gained by integrating the two. For example, education is associated with lower mortality in most developed countries, and this relationship is similar regardless of the generosity of the social protections and health insurance systems that are in place. This suggests that access to care is not the main reason for the association in the first place. This approach is illustrated by comparing the effects of education on various health and health behaviors around the world to generate hypotheses about why education is so often (but not always) predictive of health.

The review then goes on to examine theories for the relation between education and health and then review the empirical evidence on this relationship paying particular attention to causal evidence and evidence on mechanisms linking education to higher health.

Stylized Facts about Education and Health

To examine the link between education and health across countries, data from three sources are combined. Data for most developing countries come from the Demographic and Health Surveys (DHS) for years between 2004 and 2009. Data for the US come from the Behavioral Risk Factor Surveillance System (BRFFS) for 2005. Data for Europe come from the Eurobarometer Surveys (2005 and 2009). Data for a total of 61 countries are known. Each country was matched to its per capita level of gross domestic product (GDP) in the current US dollars reported by the World Bank. To create a consistent sample, the attention is restricted to women aged 15–49 years (the DHS does not collect data on men or older women). More details on the data construction are in the Data Appendix.

Education is measured as years of school in the DHS and the BRFFS, but the Eurobarometer only asks about the age at which a person finished schooling. It is assumed that years of schooling in the Eurobarometer data are 5 years less than the age at which schooling was finished. As some people take significant time off before finishing schooling, the authors truncate schooling at 25 years. Although not ideal, this is the only standardized data source with a large number of countries.

For all of these countries, the measures of height (in centimeters) and weight (in kilograms) are known, which are used to construct body mass index (BMI = weight/height squared), an indicator for being underweight ($BMI \leq 18.5$) and an indicator for being obese ($BMI \geq 30$). The data from the DHS come from actual measures, whereas the data for the US and Europe are self-reported. For all of the countries, it is also known whether the person is currently a smoker. For a few developing countries and all developed countries, it is known whether the person drinks alcohol. Finally, only for developing countries, measures of hemoglobin levels (HbA1c) are known, which is a key indicator of diabetes and a measure of whether the person had a sexually transmitted disease in the past year.

To document basic patterns in the relationship between education and health, the following ordinary least squares (OLS) regression for each country in the sample is estimated:

$$H_{ic} = \beta_0 + \beta_{lc} * Education_{ic} + X_i\alpha + \varepsilon_i \quad [1]$$

where H_i is a health or health behavior indicator of individual i in country c, *Education* is measured in years, and X_i contains basic demographics: age, age squared, marital status, ethnicity, race, and religion dummies. For each country and outcome, the regression coefficient β_{lc} is obtained, which is plotted by the level of GDP (in logs). All of the surveys have complex sampling design schemes, and the weights provided by the survey are used to compute means and weight regressions.

It is difficult to interpret the coefficient of education in these regressions as causal because education and health could be both determined by unobservable factors. Also the coefficient on education might reflect the effect of health on schooling rather than the reverse. These issues are discussed in the Section Evidence on the Causal Effect of Education. For the time being, the correlations that are observed are

 doi:10.1016/B978-0-12-375678-7.00309-6

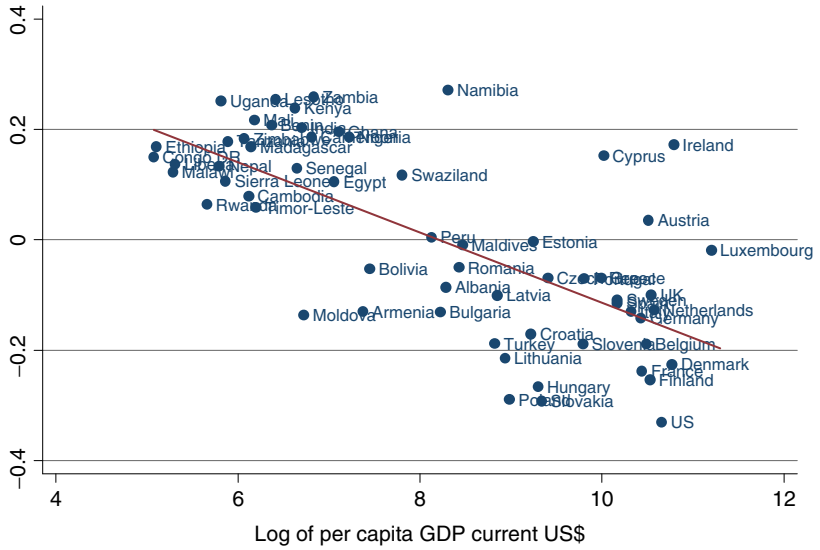

Figure 1 Coefficient of education on BMI by GDP.

described and the reasons for the patterns across countries are hypothesized.

The effect of education is estimated for each country in a linear model that includes years of education. It is not clear whether years of schooling are comparable across countries because the quality of education differs widely by country and thus the actual education of individuals might differ even when years of school are comparable. Ideally, one would use test scores or other measures of achievement (such as literacy and numeracy), but these are not available here or in most surveys. Also, one might prefer to look at nonlinear models, where the effect of education is allowed to vary depending on the level of education. Previous research has generally found that linear models are good approximations, although this refers to high-income countries. Nevertheless, the estimates are of interest because they mirror the standard estimates that are produced when looking at specific countries and times. The results presented here are restricted to women because the DHS surveys collect information systematically on them but not necessarily for men. Previous research documents that correlations between education and health are similar for men and women, although in general, correlations are stronger for men, but this varies depending on the outcome.

Figure 1 shows the education gradient in BMI as it relates to average income – each dot in the graph corresponds to the coefficient of education on BMI obtained from a separate regression for each country. BMI is generally taken as an indicator of short-term nutrition. The figure suggests a clear pattern by income: in poorer countries, those with more education have higher BMIs, whereas the opposite is true in richer countries. The crossover point is income of approximately US$3000 per capita, roughly the income of Bolivia and Peru. However, the relationship between health and BMI is not monotonic: higher weight (given height) is associated with lower mortality at low levels of weight, but after some threshold, increased weight is associated with larger mortality. To disentangle these effects, the next set of estimates reports the effect of education on the likelihood of being underweight and on the likelihood of being obese: both of these are indicators of poor health.

Figure 2 shows the patterns for being underweight. Overall, education is associated with a decrease in undernutrition: most coefficients are either negative and statistically significant or essentially zero (although there are a few exceptions). The effect of education is largest for the poorest countries and then becomes zero (or positive) as GDP rises. This is essentially due to the fact that there is very little undernutrition in countries that have reached middle levels of income, and there is no effect of education on malnutrition when the prevalence rates are low. This is more evident in Figure 3, which plots education coefficients against levels of malnutrition (the share of the population that is underweight).

Figure 4 shows the patterns for obesity. These patterns are very similar to the patterns for BMI: In poorer countries, the effect of education on obesity is positive and significant, whereas it becomes negative and significant for richer countries. This pattern has been noted before and it is more marked for women than men (The graphs presented here only show patterns for women).

Thus, it is observed that around the world the more educated avoid malnutrition, but not always obesity. It is possible that when levels of nutrition are low, obesity is associated with increased survival because people are better able to fight infectious disease, and chronic problems are not large killers. But once infectious diseases fall and chronic conditions become more important, the pattern reverses (conditional on knowledge that obesity is bad). It is also possible that girth is a status symbol or symbol of wealth in societies that are poor; but the same in rich societies where knowledge of the health consequences is widespread, the opposite becomes true, as rich individuals will devote their resources to staying thin and fit. But the data strongly suggest that the effect of education depends on the level of development and the position of the countries in the 'nutrition transition' in particular: as countries

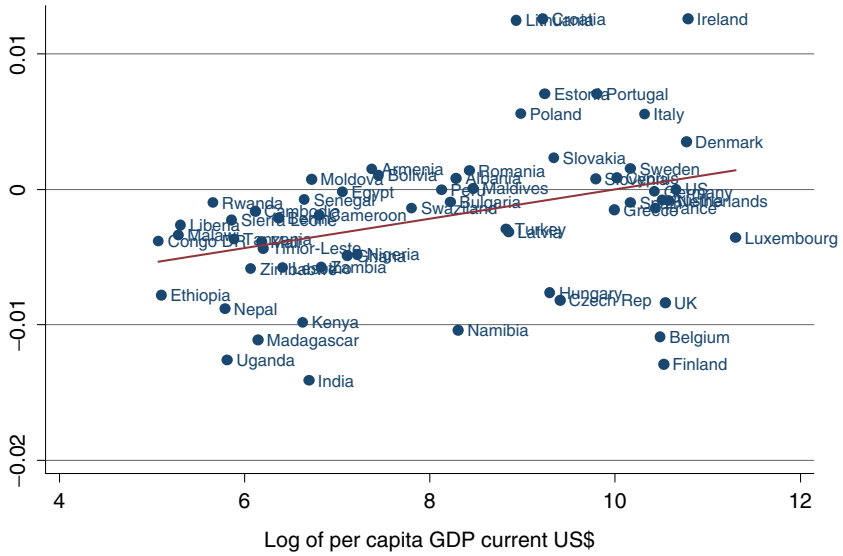

Figure 2 Coefficient of education on underweight by GDP.

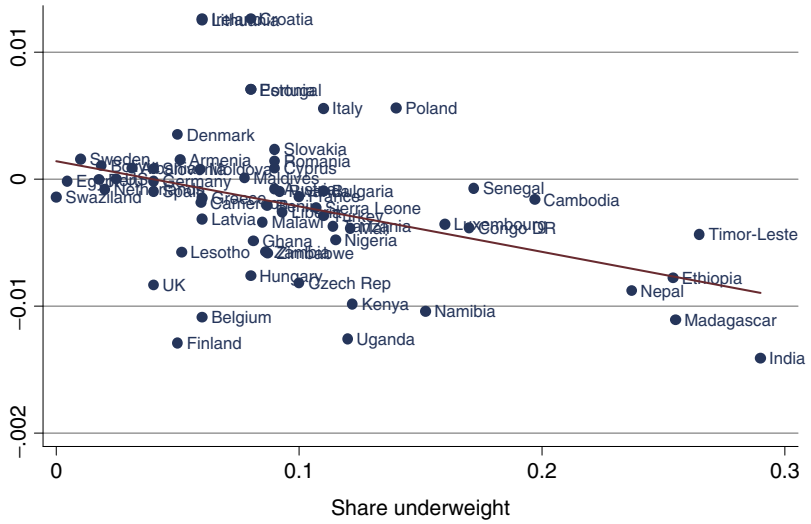

Figure 3 Coefficient of education on underweight by underweight level.

develop, the types of food available (high-fat, high-sugar, and high-density processed foods in particular) and their costs change substantially.

Figure 5 shows the patterns for hemoglobin levels by income – although only for women in developing countries. Again, it is found that the effect of education is protective at low levels of income, and then decreases with GDP; this is again a function of the fact that on average hemoglobin levels rise with GDP. So in poorer countries, the more educated avoid malnutrition. But Figure 6 shows that they do not always avoid disease; among very low-income countries, there are more countries where education is associated with a higher incidence of sexually transmitted infections (STIs) than countries where education is protective. But there is a trend by income again: education is more likely to be protective for higher levels of GDP. Recent work that looks at sexual behavior responses by education level in Africa also reports that the 'effect of education' varies depending on the stages of the human immunodeficiency virus (HIV) epidemic.

Figure 7 shows the patterns for the effect of education on smoking, the leading cause of preventable deaths worldwide. In general, the effect of education on smoking is negative, but for the poorest countries the coefficients tend to be very small. Also, for many middle-income countries, there is a positive effect of education. It is unlikely that this reflects differential knowledge of the harms of smoking among the better educated. The danger of cigarette smoking is well known around the world even in the poorest countries: for example, in Bangladesh, 93% of smokers report that smoking causes lung cancer (International Tobacco Control Policy Evaluation Project). Rather, it may reflect the social acceptability of smoking as income increases or the onset of public policies to reduce smoking at very high incomes. It is also possiblethat in some countries the effects of knowledge are counteracted by the

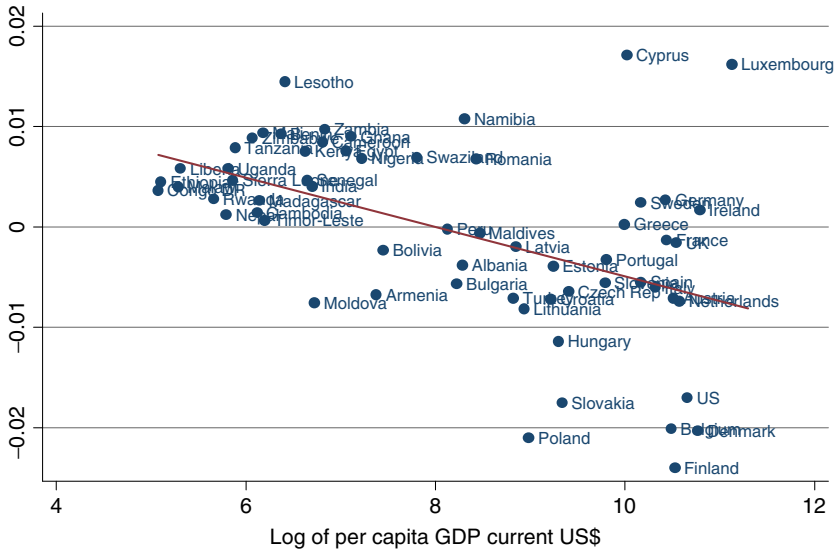

Figure 4 Coefficient of education on obesity by GDP.

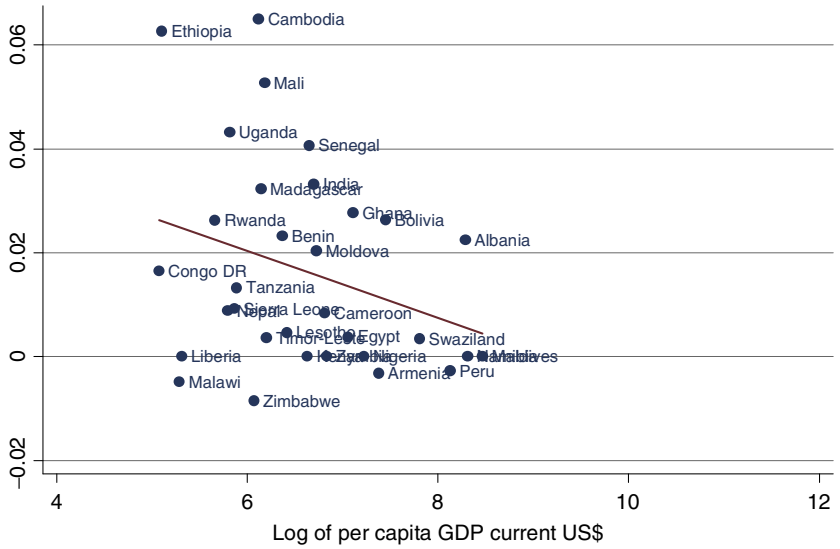

Figure 5 Coefficient of education on hemoglobin by GDP.

effects of higher incomes, because smoking is a normal good. Again these patterns suggest that the effect of education on smoking depends on the level of development defined both in terms of income and knowledge and will, therefore, vary over time and space. Table 1 presents some evidence of this 'smoking transition' for the US. In 1949, high school dropouts were less likely to smoke than high school graduates or individuals with higher education – the opposite of what is observed today. In 1949, dropouts were also more likely to think smoking was harmful. But between 1950 and 1970, the more educated became more likely to think that smoking was harmful as knowledge of the harms of smoking emerged; and by 1969 they were also less likely to smoke.

Figure 8 shows the patterns for drinking. Data on drinking for many developing countries are not known, so somewhat higher income countries are examined. Alcohol appears to be a normal good. Education increases the odds of drinking alcohol in almost all the countries that are examined. Modest alcohol consumption might not be detrimental to health, so it is not necessarily clear that these coefficients have the 'wrong' sign. Ideally, it would be better to determine whether education lowers heavy drinking, which does fall with education levels in the US and the UK, but the data are not consistently available across countries.

The previous figures suggest important patterns by education and could be taken as reflecting causal relationships from education to health. However, it can also be documented that education is partly determined by health by looking at height. Height is generally thought of as an excellent indicator of early childhood environment, as much of the variation in adult heights is determined by the age of 3 years. Thus, the coefficients of education on height from eqn [1] most likely

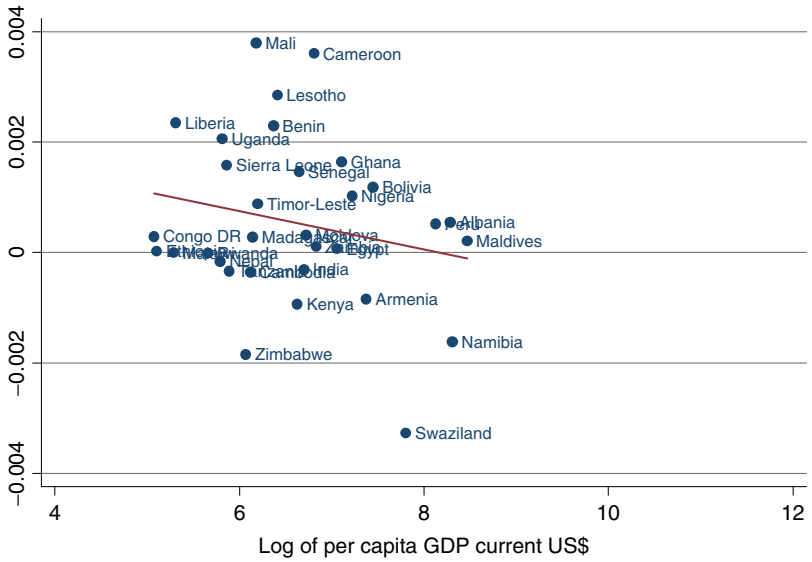

Figure 6 Coefficient of education on STIs by GDP.

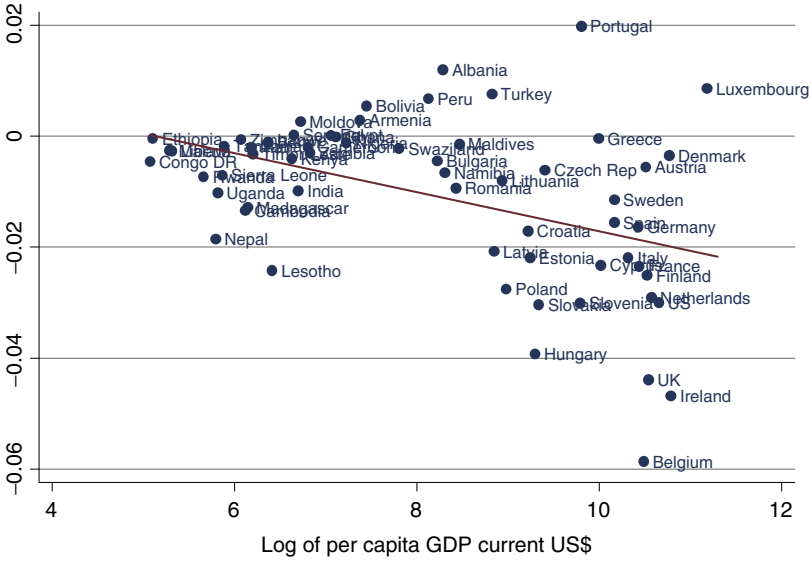

Figure 7 Coefficient of education on smoking by income.

reflect the effect of health on the quantity and quality of education individuals obtain, rather than the effect of education on final height. Before looking at this, two caveats are in order. First, there is a critical growth period in adolescence where the remaining differences in final adult height are determined. Thus, it is possible that some of the relationship between height and education is due to an effect of schooling on height. Second, height itself may be a function of parental education, which may independently affect child education. Nevertheless, most researchers treat the relationship between height and education as mostly reflecting the impact of exogenous health on education.

Figure 9 shows the results for height. For almost all the countries examined, more educated women are taller and the relationship is generally statistically significant. And although the effect falls a bit with GDP, education is still very strongly associated with height, even in very rich countries (with a couple of interesting exceptions among the richest countries).

Summary

All said, the international data on health and education show several stylized facts. The clearest relationship is between income and the education gradient in nutritional intake. Poorer countries are characterized by a mix of undernutrition and overnutrition. Many people are undernourished or anemic in poorer countries, and these outcomes are strongly negatively related to education. Less educated individuals are more likely to be underweight and anemic; better educated people are

Table 1 The evolution of knowledge and smoking gradients in education in the US 1949–69

Year of survey:	*1949*	*1954*	*1957*	*1969*
Panel A: Effect of education on knowledge				
Dependent variable:	"Do you think cigarette smoking is harmful or not?"	What is your opinion – do you think cigarette smoking is one of the causes of lung cancer, or not?		
Less than high school	0.057*	−0.054*	−0.065**	−0.041
Some college	0.012	0.032	0.116**	0.045
College +	0.021	0.067	0.172**	0.111**
Panel B: Effect of education on smoking				
Dependent variable:		Current Smoker?		
Less than high school	−0.056*	−0.016	0.024	0.054*
Some college	0.019	−0.026	−0.008	0.011
College +	−0.045	−0.061	−0.003	−00.076*

All regressions are adjusted for age, sex, and race. Individuals with a high-school degree only are the reference group.
Note: *, significant at the 10%; **, at the 5%.

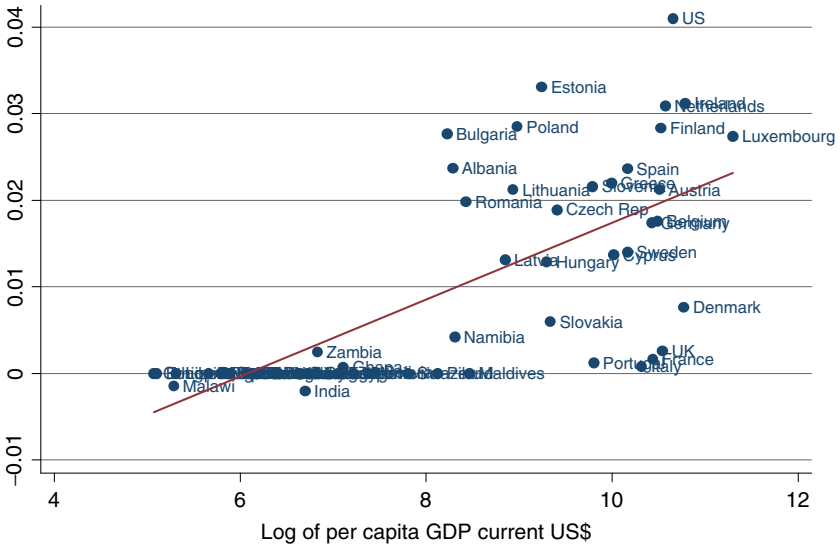

Figure 8 Coefficient of education on drinking by income.

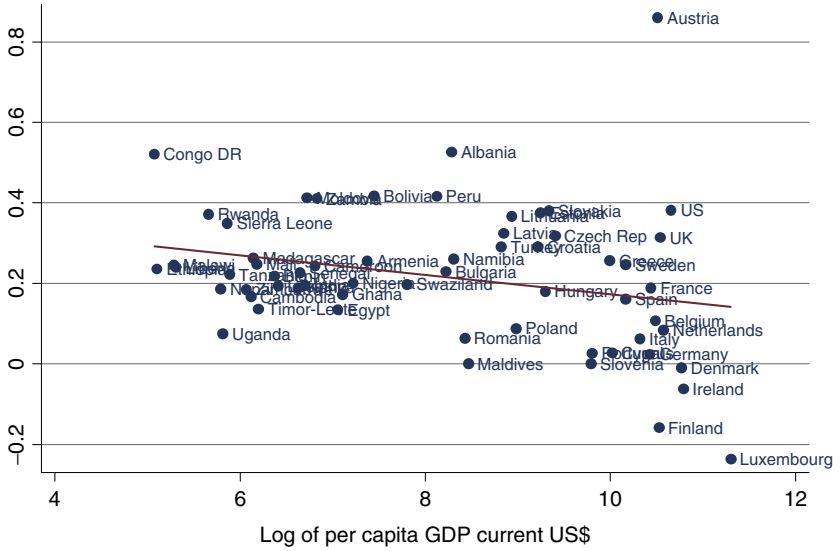

Figure 9 Coefficient of education on height by income.

more likely to be overweight or obese. In richer countries, where undernutrition is not very prevalent, there is no education gradient in undernutrition. In contrast, in these countries the prevalence of obesity is large and there is a large positive education gradient in obesity. This suggests that education is protective for the outcomes that are known to be bad for health.

The link between education and height is also clear. In all countries – even the richest – better educated people are taller than less educated people. The magnitude of the relationship is large throughout the world.

The link between education and other measures of health is much less clear. The correlation between education and smoking is nonlinear in income; the relationship between education and height or STIs is unrelated to income. These patterns demand a different explanation than a simple rich–poor dichotomy. They also suggest that the effect of education on health varies depending on the level of development, and holding GDP constant, on the specific health problems the country faces.

Understanding the Relationship between Education and Health

Education and health may be related for three reasons: poor health in early life may lead to less educational attainment; lower educational attainment may adversely affect subsequent health; or some third factor such as differences in discount rates may affect education and health-seeking behavior. Each of these pathways are briefly discussed.

The next section starts by describing the most important commonly unobserved determinants of both education and health. The first is parental resources: parents with more resources (broadly construed to include wealth, social networks, knowledge, etc.) will devote part of them to improving the survival of their children (by investing in their health) and also to improving their future outcomes, which, in turn, means they will invest perhaps more on their children's education. Second, there are some important individual characteristics that theoretically are expected to increase both education and health. *Ceteris paribus*, more patient individuals are more likely to invest more in both education and health. Also, smarter individuals might be more likely to obtain more schooling and also have better health.

Effect of Early-Life Health on Education

As the previous results indicate, there is a very strong correlation between early life indicators of health (such as height) and educational attainment – and this is true across all countries of the world. These correlations have been documented many times before, particularly in developing countries. As education is largely determined at young ages, this suggests that at least part of the correlation between education and health among adults is due to the fact that unhealthy children obtain few years of schooling and become unhealthy adults.

Recent studies show that the relationship observed – shorter (and sicker) children obtain less education – is a causal one. Two types of studies investigate the causal effect of health shocks on human capital accumulation: some take advantage of the so-called 'natural experiments,' whereas others use randomized controlled trials to investigate the question.

Most studies that investigate this causal chain find support for it: there are several examples of how disease and nutrition affect human capital formation. For instance, individuals affected *in utero* by the 1918 influenza pandemic obtained fewer years of schooling than those not affected. Individuals born during the Great Famine in China had lower educational achievement than those not born during the Great Famine. Malaria eradication in the US, various Latin American countries, and Sri Lanka resulted in greater education, although malaria eradication in India did not. Deworming campaigns had substantial effects on schooling in early-twentieth century American South and in Kenya today.

A related literature explores the consequences of birth weight on adult outcomes and finds similar results suggesting that those born with lower birthweights have lower levels of education, income, and health as adults. Although these studies do not directly look at nutrition, but rather at extreme events that influence birth weight, in many cases nutrition and disease are the most likely intervening mechanisms.

Direct evidence on the effect of nutrition and disease on education is available from several randomized experiments. Nutritional supplements, iron supplementation, and iodine supplementation trials *in utero* or during early childhood have resulted in higher educational attainment and increased cognitive ability.

Whether early life health affects education through morbidity at younger ages or expectation of life extension at older ages is unknown. Indeed, there is scant evidence on the extent to which expectations of longer life affects schooling but some evidence suggest that this channel also matters: when maternal mortality fell in Sri Lanka, girls' education increased (but not that of boys). But it is not clear as to what extent the education–life expectancy relationship is accounted by this channel.

Overall, the evidence is consistent in showing that nutrition and disease shocks early in life are quite detrimental for human capital formation. Interestingly, the reduction in educational attainment associated with early-life health insults is not the only theoretical possibility. Sickness increases the cost of going to school in terms of effort and might also lower the returns to school if it lowers life expectancy. Thus, parents of sick children might optimally choose lower levels of schooling for those children. However, illness also increases the cost of work and might increase the returns to school (in terms of avoiding more physically demanding jobs). Thus, it could be that the return to schooling increases as people become less healthy. However, there is no empirical evidence of this alternative, although perhaps it explains why education and height are negatively related in two very rich countries: Finland and Luxembourg (**Figure 9**). This discussion also underscores the fact that the observed relationship between height and education reflects not only the physical effects of disease in childhood but also the behavioral responses of

parents which might attenuate or exacerbate the effects of the health shock itself.

Given that health is an important determinant of schooling and the fact that education and health could simply be determined by common factors such as parental resources, it is extremely challenging to document whether in addition to these well-documented relationships, education itself affects health – this question is considered next.

The Effect of Education on Health: Theory

Theoretical foundations for a causal effect of education on health were first provided by the seminal work of Grossman (1972), based on the human capital model of Becker (1964). One key insight of Grossman's model of health capital is that individuals derive utility from health directly (they do not like being sick) and indirectly by affecting labor market outcomes (sick individuals work less and earn less). The other essential feature of the model is the recognition that there is a 'health production function' – that there are known factors that individuals (or institutions) can manipulate in order to affect health in predictable ways. These two features give rise to a behavioral model in which individuals demand medical care, food, and other goods and services because they are aware these factors will improve their health and ultimately increase their utility. (See Strauss and Thomas (2008) for an excellent exposition of the theoretical production of health over the life course and its determinants.)

In this type of model, education can affect health in a variety of ways. Most obviously, education affects the type of jobs that individuals get and the income they earn. A year of education raises income by at least 7%, and this is true in both developed and developing countries. Higher incomes increase the demand for better health, but they affect health in other ways as well. Richer people can afford gyms and healthier foods; they can also afford more cigarettes. Furthermore, when an individual's wage increases, it raises the opportunity cost of time: because many health inputs require time (such as exercise or doctor visits or cooking), in the short run, wage increases might reduce health. Thus, the income associated with higher education may or may not improve health.

Higher educated individuals are also more likely to take jobs that provide health insurance and other benefits such as retirement accounts. Although one expects these benefits to have a positive effect on health, it is theoretically possible that they do not. For example, individuals with insurance could be less likely to care for themselves because they face lower financial costs in the event of a disease. However, because the uncompensated costs of disease are large (morbidity and premature mortality), it is not expected that these indirect effects would dominate the access associated with better insurance.

Finally, more educated people work in different industries and occupations than less educated people. To the extent that job characteristics affect health, sorting into jobs may affect health as well. At the dawn of the industrial era, this relationship was undoubtedly positive. Early in the twentieth century, the more educated were more likely to work in white collar occupations, which were substantially safer than working in agriculture or manufacturing (fewer accidents, exposure to chemicals, physical strain, etc.). Today, most individuals work in the service sector and the better educated may have jobs that are worse for their health – for example, they spend more time sitting in front of computers, which could turn out to be bad: sitting (independently of exercise) has been recently shown to detrimental to health.

Thus, the effect of education on health, through its effect on the labor market, is ambiguous. Moreover, a positive association between education and disease can arise through the conscious choices of individuals: individuals may well know that exercise is needed to remain in good physical shape, but they may optimally trade off some of their health for increased incomes when wages are high. At the extreme, when individuals have no other resources than their bodies to earn a living, they will optimally 'use up' their bodies to earn a living: trading off higher lifetime earnings for shorter, sicker lives. The theory of compensating differentials predicts just that: individuals can be 'paid off' to accept risky occupations.

The second mechanism explored by Grossman is that education can affect the production function of health directly, acting as a 'technology' parameter. This is the so-called 'productive efficiency' mechanism, in contrast to the 'allocative efficiency' mechanism which has already been described (the more educated optimally chose different levels of health inputs because they face different prices and budget constraints). In its simplest formulation, productive efficiency posits that the better educated will have better health outcomes, even conditional on access to the same health inputs at the same prices. Better use of information is the classic example. More educated individuals might be better at following doctor's instructions (because they may have better self control for instance) or they might be more likely to believe the information produced by the scientific establishment and follow its recommendations perhaps (because they took science courses in school or know scientists directly).

Car safety knowledge provides another interesting case. Both more and less educated people strongly agree that one should wear a seatbelt while driving a car. But when the survey question is asked a different way, the pattern changes: the less educated are much more likely to agree with the statement that seatbelts are just as likely to harm as help you in an accident. It may be that better educated people have a deeper understanding of the risks of not wearing a seatbelt and the probabilities that go into a calculation of optimal seatbelt use. Another example concerns how successful individuals are at using certain health technologies such as devices to help quit smoking. Conditional on making an attempt to quit smoking, the better educated are more likely to be successful quitters.

There is a third theoretical reason why education could be related to health: education could change the 'taste' for a longer, healthier life. For example, education may lower individuals' discount rates, making them more 'patient.' There are two reasons for this. First, attending school per se is an exercise in delaying gratification, and school may teach patience; this may carry over into other aspects of life. Second, to the extent that individuals can 'choose' or learn what to like (in other words if discount rates can be chosen), then those with more education have a greater incentive to choose patience, because they face steeper income profiles over their lifetimes. The same argument might hold for risk aversion.

Finally, education affects the peers that individuals spend time with, and different peer sets may encourage different health behaviors. This is particularly important in the context of health, given that many health behaviors have an important social component. For example, individuals generally drink together and often smoke together. More generally, peers are thought to be essential in determining risky behaviors. Also, peers and social networks are an important source of information, and of financial, physical, and emotional support and hence can affect whether individuals get sick and how well individuals fare when they do. If on average more educated individuals have more educated peers, they will have access to a greater set of resources. If more educated individuals are more likely to be better informed (because they learned so in school or because they remain better informed later), then peers will help individuals reinforce their knowledge, in a 'multiplier' setting.

Note, however, that peers can influence behavior in a positive or negative manner. A peer group that focuses on sedentary lifestyles and lack long-term investment may encourage that same behavior among all members of the peer group, but one that focuses on exercise and fitness would promote the opposite.

Beyond the Grossman model, there are other theories that predict associations between education and health. The most prominent is that education predicts rank in society, and those with higher rank are in better health than those with lower rank. In small hierarchical groups such as apes and (perhaps) humans, those at the top will have access to more resources and greater control over their lives in general, whereas those at the bottom will have both fewer resources and control. As a consequence, those at the bottom will suffer more 'stress' and this, in turn, lowers immune responses and increases the likelihood of short-term illness and long-term chronic disease.

This theory has been shown to be accurate among mammals and other species (Sapolsky, 2004) and has been tested experimentally with animals to rule out genetic factors as the main explanation (e.g., the top of one hierarchy will suffer in health if they are transferred into a different group where they have a lower place in the hierarchy). Although it is not entirely clear whether and how this theory applies to humans in large modern societies – where reference groups are multiple and they are chosen endogenously – it provides another rationale by which education may affect health. It is to be noted that this theory has an interesting prediction: if all that matters is relative rank in society, a society with higher average levels of education may have no better outcomes than a society with lower average levels of education.

Education may also affect health because the things that kids do while in school are different than what they do outside of school. Although this is a trivial observation, this so-called 'incarceration effect' is extremely important to consider. For example, children in school may have less exposure to criminal activity or poor role models.

Finally, there are other possibilities. The more educated could inadvertently be better or worse off because of biological processes that are not well understood. For example, more educated women have higher mortality rates of cancers of the reproductive system. It has been hypothesized that this 'wrong' gradient emerges because more educated women have fewer children, and having children turns out to be protective from certain cancers. Overall, education appears to lower mortality even after all health behaviors are accounted for, which suggests that some of these nonbehavioral mechanisms might be important – although it is not obvious that all important health behaviors can be observed.

Certainly it is very likely that many of these mechanisms are at play at any one time and place and in combination they will yield complex patterns. The complex relationship between education and HIV in Africa is an interesting case in point – de Walque reports that "education predicts protective behaviors like condom use, use of counseling and testing, discussion among spouses, and knowledge, but it also predicts a higher level of infidelity and a lower level of abstinence." In this example it would appear as if the educated not only seek out information at higher rates, know more, and use their information and resources to purchase protection but also have some higher risky behaviors, perhaps because of their higher incomes or lower risk (they can 'afford' it).

Evidence on the Causal Effect of Education

A large number of early studies found supporting evidence for the Grossman model using largely descriptive tools. The usual prediction tested was that education and health were positively correlated. Clearly they are; the literature struggled with instruments for education to determine causality. However, these studies were not entirely convincing about whether education had a causal effect on health, because descriptive methods and imperfect instruments are not well suited to establishing causality.

A second generation of studies attempted to provide clearer evidence of a causal link between education and health again using 'natural experiments.' Many of these studies make use of compulsory schooling as a source of plausibly exogenous variation of education to investigate whether more school improves adult health. The intuition for this approach is simple: some individuals are forced to attend school longer because of compulsory school legislation, and researchers can examine whether the health of those who are forced to obtain more schooling improves compared with the health of those who are not required to stay in school. Studies in the US, Denmark, Sweden, the UK, and Germany using changes in compulsory schooling find that indeed these laws ultimately improved the health of the affected populations. However, recent work finds no effect of the same compulsory schooling laws on health in England and Sweden, and a study focusing on France also finds no effect of education on mortality.

The literature that has estimated the effect of education on health behaviors using natural experiments is also mixed. For example, some find that schooling lowers smoking rates but other studies find no evidence that schooling affects smoking behavior.

It is difficult to interpret this conflicting evidence. All of the papers that find positive effects of education on health use natural experiments to construct instrumental variables (IV) estimates of the impact of education. They tend to find effects that are larger than OLS. Although this has generally been interpreted as reflecting heterogeneity of treatment effects

(those that are affected by the legislation have larger returns), the alternative interpretation is that the 'natural experiment' did not in fact work well as an experiment, and there is still substantial bias in the education estimate. For example, the results for using compulsory schooling reforms in the US are not robust to the inclusion of state-specific trends. However, there is very little variation left once these controls are added, so it is not clear whether the effects are truly overestimated or whether the variation in the laws is not sufficient to estimate an effect of education. This discussion underscores the limitations of IV studies in general. From a methodological point of view, the regression discontinuity studies make the fewest assumptions, and they find no effects of education on health.

Also interesting to note is that available studies report impacts along different margins, not only because of the obvious reason that they study different times and places but also because the 'experiments' themselves are different. In the UK, the changes in compulsory schooling were strictly followed and an entire cohort of individuals was forced to obtain almost 1 more year of schooling as a result. In contrast, in the US, the laws that are typically studied increased educational attainment by 0.05 of a year – that is only 1 in 20 individuals obtained one more year of schooling. There are two important differences here. First, the affected population in the US is a small sample among those that were potentially affected – it is indeed possible that returns are different for this subset. Second, in the US, only a few individuals in a given cohort and place were affected, but entire cohorts were affected in the UK. If, for example, education matters because it affects a person's rank in society, then in the US, those who stayed in school had their rank increased relative to the counterfactual of no compulsory schooling law. This would not necessarily have been the case in the UK: an entire cohort increased their education by approximately 1 year, so an individual's rank within their cohort was unaffected by the policy.

It is also theoretically possible that the effect of education varies over time and place, and that the results from the previous studies correctly document this variation. Indeed, the international evidence suggests that the returns to education do vary across countries. It is notable that the two studies that find no effects of education in the UK and France, study cohorts during and shortly after World War II (WWII), a time when the income returns to education were falling and generally low.

The fact that the effect of education on labor market earnings itself is causal also suggests a positive effect of schooling: if schooling is rewarded in the labor market because it raises productivity, how does it do so? Whatever general human capital is learnt in school and rewarded in the labor market might also be useful in the production of health, because it is useful in the production of goods. If education makes workers better by making them better decision makers or better able to deal with complexity or uncertainty, then these abilities can be used in other domains, in particular for health.

One central conclusion of this discussion is that investigating the specific mechanisms by which education affects health would improve the understanding of education–health link substantially. The following paragraphs discuss what is known about this next, after describing the latest attempts to infer causality in the literature.

In addition to natural experiments described at the beginning of this section, there are a variety of experimental interventions that have been carried out, mostly in developing countries, that can be used to infer the effect of education on health. In Kenya, random distribution of school uniforms – a significant cost associated with school – among upper primary-level students increased levels of schooling for both genders by a substantial amount (the dropout rate fell by 18%). Seven years later, treated girls had significantly lower rate of marriage and pregnancy, but the treatment had no effect on sexually transmitted diseases. However, random provision of HIV information to the curriculum of some students had no effect on sexually transmitted diseases, but the rate of unwed teenage pregnancies fell.

Many countries have implemented conditional cash transfers programs to help the poor. Conditional cash transfers are transfer programs where the receipt of income is conditional on certain behaviors, generally related to health or schooling. Unconditional cash transfers do not have any strings attached. Studies find that the conditional cash transfer programs have resulted in lower levels of sexual activity, teen pregnancy, and marriage rates among young girls in the short term, in addition to increasing schooling in Africa.

Although curriculum information on HIV in Africa had little effect on schooling, other information campaigns have worked. For example, a small intervention in the Dominican Republic informed 14-year-old boys about the labor market returns to school. The intervention successfully increased schooling by 0.2 years, and significantly decreased work in the formal labor market. As a consequence of this, treated boys delayed debut of heavy drinking and were less likely to smoke than untreated boys.

These studies suggest that education affects specific health behaviors, but not all behaviors. However, even here, it is not clear that one can infer that education is the ultimate cause of the changes in the observed health behavior. The gold standard for establishing causality would call for randomly assigning individuals to various levels of education. Clearly, this approach is unethical and unfeasible. Instead, these studies look at an 'intent-to-treat' intervention, where individuals are randomly 'incentivized' to obtain different levels of education. With this design, it is possible to estimate the effect of education on health, if (1) the intervention successfully raises education levels and (2) the random incentives that are provided to increase schooling affect health only through education (the exclusion restriction assumption).

In this light, consider whether randomized interventions that potentially raise schooling can be used to estimate the causal effect of schooling. Typically, interventions are designed so that reasonably sized effects on education can be detected with the chosen sample. But even if this requirement is met and the intervention increases education levels, the intervention must induce students to attend school but not directly or indirectly impact any other determinant of health. It is difficult to design an intervention that meets this assumption. Providing scholarships to those that are credit constrained is equivalent to increasing income in the short run, which directly or indirectly is likely to affect health. Providing uniforms

is not quite like providing income, but it increases incomes indirectly by substituting for household spending. The more constrained individuals are in their consumption, and the higher the effect of the intervention on schooling is, the more likely it is that the income effects of the intervention are large. Finally, informing misinformed students of the returns to school affects the present discounted value of earnings of all participants, regardless of whether they are induced to attend school or not. Because health (and its determinants) is likely to depend on permanent rather than temporary (current) income, this intervention also fails the exclusion restriction assumption.

Another important limitation of randomized interventions is that in the short run schooling is not expected to affect health because the young are generally in excellent health and because health is a stock – instead it is expected that the health effects emerge slowly and cumulate. But it is difficult and expensive to follow individuals for many years; the interventions above follow individuals for several years but on average the participants are still quite young at the last follow-up (e.g., in the Dominican Republic study, the intervention takes place when boys are 14 years old and they are 18 years old when they are last interviewed). The interventions then look at health behaviors, but it is not clear how these effects will eventually translate into, for example, mortality.

There are only two studies of randomized education interventions that follow individuals over a long period of time. One looks at the participants Perry Preschool School program (PPP) 37 years later and the other looks at the participants of the Carolina Abecederian (ABC) Project at the age of 21 years. Both of these interventions occurred early in childhood, and they have been shown to have had persistent effects on wages and other outcomes. The results from these two studies are again in conflict: the treated students in the ABC program had significantly better health than the controls, but that was not true in the PPP program, although in both cases the treated appear to have better health behaviors. These results are to be taken with caution as in both cases the number of observations consists of only approximately 100 individuals.

Thus, simple randomized trials cannot conclusively answer the question of whether education affects health. But it is possible to make progress on this question by investigating mechanisms through which interventions affect education or designing more complex randomized interventions. The authors discuss the evidence on mechanisms next and conclude with a series of observations on what questions could be explored in future research.

Evidence on the Mechanisms Linking Education and Health

To be convincing, studies of the effect of education on health will need to understand the pathways that link the two. Because there are a large number of potential mechanisms, this is a difficult task. In addition, the evidence on mechanisms is somewhat weaker than the evidence on causality, because often assumptions about what constitutes a mechanism have to be made.

Some studies have attempted to look at why education matters for health. Consider the evidence on the effect of education on sexual behaviors and fertility. An important reason why education improves outcomes for girls is that it delays marriage and fertility, because the common practice is for girls to marry soon after finishing school. This, in turn, means girls will have fewer years of 'exposure' to get pregnant, and thus fewer children over their lifetime. Also girls in school have children later, which is beneficial because reproduction during the early teenage years is riskier for the health of the mother and the infant compared with reproduction in prime adult years.

The results from the randomized trial in the Dominican Republic also seem to be driven in part by the incarceration effect: most boys who are not in school start working or are idle – the set of people whom they interact with when they are not in school is different from their peers in school, and 'treated boys' (those given the message about the value of education) report that their peers are significantly less likely to drink and smoke. Note further that early exposure to a different set of peers could have important long-term consequences, as smoking and drinking are addictive behaviors that affect youth's physical and mental development.

Consider now the natural experiments that use compulsory schooling as an instrument for education. In the US in the 1910s, children who were not in school were either idle or working. The main occupation for children of ages 10–15 years at the time was agriculture. Agricultural work is substantially more hazardous to health than school work. Thus, it is possible that the health effects of forcing children to stay in school during this period are driven by the difference in health hazards across environments. However, by the 1940s the types of jobs adolescents engaged in when they were not in school were substantially different, and perhaps not as hazardous. This may explain why the returns to post-WWII compulsory education in the UK were smaller.

However, the evidence suggests that the effect of education is not limited to this incarceration effect alone. Uniform provision in Kenya delayed marriage well beyond the increase in years of schooling generated by the intervention, so at least in this case, incarceration alone cannot explain the observed effects.

Another possibility is that education matters (sometimes) for health because schools directly provide information on how to improve health, and it is the health information itself, rather than being in school that affects behaviors. More educated individuals are indeed better informed about health risks in developed countries. And when information first becomes available, it seems to first become known to the more educated, who, in turn, seem to be the first to respond. Educated mothers stopped smoking at higher rates after the 1964 Surgeon General Report first widely publicized the harms of smoking, and their babies' health increased more as a result. Smoking rates started declining for the best educated in the 1950s, before the Surgeon General's report, as the dangers of smoking were increasingly discovered. Similarly in Uganda in 1990, there was no relationship between education and HIV, but one emerged by 2000 after a decade of information campaigns on prevention. In the UK, when information was first (incorrectly) reported about possible autism risks

associated with the mumps, measles, and rubella (MMR) vaccines, vaccination rates fell more in areas with more educated individuals. In fact, in some studies it appears as if all of the effect of education is explained by information, for example, studies find that most of the effect of maternal education on child height can be explained by differences in information.

But information cannot be the whole explanation; differences are observed in health behaviors by education even when there are no differences in information by education. For example, in the experiment in the Dominican Republic that informed children on the returns to school, there were no differences in the extent to which smoking and drinking were perceived as harmful by the treated and the control boys, and yet the treated boys stayed in school longer, smoked less, and drank less. Similarly, in developed countries today, knowledge of the harms of smoking is nearly universal, and although there are some small differences by education in knowledge, these differences are very small compared with the differences in smoking rates by education. Curriculum interventions alone had little impact on behavior in the Kenyan intervention. Finally, observational studies suggest that a small portion of the effect of education on behaviors is due to differences in knowledge. It appears that when knowledge first becomes available on how to improve health, it substantially increases education disparities. But in the long run, information diffuses and other factors are more important in explaining the associations between education and health.

In this sense, information may be like other innovations in health. For example, more educated individuals are more likely to use recently approved drugs than the less educated, and this appears to be driven by those with chronic conditions who use drugs repeatedly, suggesting that learning is an important component of the education effect. Similarly, in developing countries, more educated individuals are generally more likely to adopt new innovations. Whether the initial advantage of the educated fades away or gets stronger with time, might, in turn, depend on the type of health technology. For example, some medication regimes are difficult to adhere to, and the educated might have a permanent advantage at using them – this is the case for diabetes type 1. Other innovations instead are 'deskilling,' such as the birth control pill, in which case eventually the less educated catch up. The results from malaria interventions provide some interesting evidence on this point: when access to malaria treatment improves, the gap in access between the educated and the uneducated falls. However the educated still behave quite differently from the uneducated in their treatment-seeking behaviors: they appear to be more likely to know the likelihood that they have malaria and they are more likely to visit a health-care center and less likely to use other treatments when their symptoms are worse. This is not true among illiterate individuals.

The evidence from randomized interventions suggests that some mechanisms are important, whereas others are not – but certainly as this paper discussion suggests the extent to which any findings are generalizable is not clear. Some of the effects of schooling might operate through the incarceration effect as already discussed. Another important mechanism is income, as the Malawi conditional cash transfer intervention suggests. Finally peers are also important. In the Dominican Republic intervention discount rates, risk aversion and health information were not affected by the intervention, even when schooling increased. However, treated boys had lower incomes and reported that their peers drank and smoked less – these two channels most likely explain the observed decreases in smoking and drinking among the treated.

Interestingly, this evidence is consistent with the exploratory and descriptive studies. Rough calculations from these suggest that observed factors can account for approximately 70% of the effect of education (in a statistical sense), through resources (30%), family and friends (10%), and information (10%) and cognition (20%). However, risk aversion, discounting, stress, and other personality traits did not appear to mediate the relationship between education and behaviors – although the noise in these measures gives one some pause.

Summary

On balance, the literature reviewed highlights a wealth of interactions between education and health. Education appears to be causally related to health in many settings, but not always, and the reverse is true as well.

Equally important, this review highlights some unanswered issues. The most important issue is to understand in more detail when and how education translates into health. To what extent is education associated with specific knowledge, with cognitive ability in general, or with different social settings, either during school or after? Some evidence on this may come from looking at the quality of education individuals receive. Most of the literature has looked at the impact of additional years of schooling. Yet many of the theories say that the quality of the years should matter as well. This has not been explored in any great detail.

Simple experimental designs that randomly encourage individuals to obtain schooling can be useful in providing further evidence of causality on health and health behaviors, but they cannot conclusively answer the question of whether education alone is responsible for the observed effects because in general it is difficult to satisfy the exclusion restriction that is needed to reach such conclusions. However, more sophisticated designs could be implemented to help identify mechanisms and causality both. For example, one could design an experiment with three treated groups, where individuals are given unconditional cash transfers (cash-only group), conditional cash transfers if they attend school (attendance group), and conditional cash transfers for both going to school and obtaining good grades (performance group). Under the assumption that all treatments induce changes in education, income, and grades, the separate effects of education, income, and health can be learned. By comparing the controls with the cash-only group one can estimate the effects of income on health and health behaviors. By comparing the outcomes of the cash-only group and the attendance group one can obtain an estimate of the effects of attendance. Finally, by comparing the performance group and the attendance group one can learn about the effects of education content.

Furthermore, it is vitally important to understand the translation from intention into action. In developed countries,

everyone knows the behaviors that are good for health and (as suspected) many would like to improve their health. Yet people systematically fail at this task, that is, they struggle to change their behaviors. How are these failures understood, and what types of interventions would reduce them? In a way, this is asking for a benchmark by which to compare education. Improving health by inducing more education is costly; many people do not enjoy schooling, and forcing additional years of schooling comes at a price. If the impact of education on health can be replicated using other methods, this would be very attractive.

In sum, the burgeoning literature on education and health is just the beginning. A review written a decade from now will ideally have many more specific conclusions to draw.

Data Appendix

DHS Surveys

The authors selected 31 countries with either a DHS-IV or a DHS-V survey that includes data on a woman's anthropometry (height and weight), education level, and her drinking or smoking habits. All surveys contain nationally representative samples of ever-married women between the ages of 15 and 49 years.

Height is the respondent's height in centimeters. BMI is computed as weight (in kilos) divided by height (in meters) squared. Underweight is equal to 1 if the person's BMI $\leq$ 18.5; obese is equal to 1 if the person's BMI $\geq$ 30. Anemia is coded 1 if the person is anemic at all, irrespective of the level of anemia (slight, moderate, and severe). Hemoglobin is the individual's hemoglobin level in g/dl adjusted for altitude. Anemia and hemoglobin were considered unknown if hemoglobin levels were less than 5 or greater than 50. If the adjusted hemoglobin level was not available, the unadjusted level was used. Smoke is coded 1 if the individual has currently smoked, 0 if not. STI is equal to 1 if the individual had a STI in the past 12 months. Drink is a binary variable if the individual has ever or recently consumed alcohol (this varies by country).

Regressions control for age, age2, education, married, religion dummies, and ethnicity dummies. Age and education are measured in years. Religion and ethnicity dummies are country specific. Marital status is 1 if the woman is married or living with a partner as if married, and 0 otherwise. All means and regression coefficients were computed taking survey design into account, unless strata or sample weights were not provided by the survey.

Eurobarometer Data

Our European data are drawn from two waves of the Standard Eurobarometer. Women's anthropometry (height, weight, BMI, and probability of being underweight or obese) are drawn from Eurobarometer 64.3, which was collected in November–December 2005. All other outcome variables of interest (alcohol consumption, smoking, physical activity and sport, and fruit consumption) are drawn from Eurobarometer 72.3, which was collected in October 2009. Both surveys contain nationally representative samples of women between the ages of 15 and 49 years in 29 European countries.

Height is the respondent's height in centimeters. BMI is computed as weight (in kilograms) divided by height (in meters) squared. Underweight is equal to 1 if the respondent's BMI $<$ 18.5; obese is equal to 1 if the respondent's BMI $\geq$ 30. Currently, smokes is equal to 1 if the respondent currently smokes, and is 0 otherwise; consumed alcohol in past year is equal to 1 if the respondent has consumed any alcoholic beverages in the past 12 months.

Regressions control for age, age2, education level, and marital status. Age is measured in years. Marital status is 1 if the woman is married or living with a partner, and 0 otherwise. Education level is the age at which the respondent left school, in years. All means and regression coefficients were computed using the poststratification weights provided with the surveys.

Behavioral and Risk Factors Survey for the United States

For the US, the authors use the 2005 wave of the Behavioral and Risk Factor survey, which contains height, weight, drinking, and smoking. Only women of ages 15–49 years are included.

Height is the respondent's height in centimeters. BMI is computed as weight (in kilograms) divided by height (in meters) squared. Underweight is equal to 1 if the respondent's BMI $<$ 18.5; obese is equal to 1 if the respondent's BMI $\geq$ 30. Currently, smokes is equal to 1 if the respondent currently smokes, and is 0 otherwise. A person is said to drink if they drank any alcohol in the past 30 days.

Regressions control for age, age2, education level, and marital status. Age is measured in years. Marital status is 1 if the woman is married or living with a partner, and 0 otherwise. Education level is measured in years of school. Race and ethnicity dummies are included. All means and regression coefficients were computed using the poststratification weights provided with the surveys.

GDP Data

The GDP per capita data come from the World Bank, using the GDP per capita (current US$) indicator. When the data set comes from a survey taken over multiple years, the GDP per capita figure is the mean during that period.

Acknowledgment

The authors are grateful to Pascaline Dupas and John Strauss for comments, to John Min and Tisa Sherry for excellent research support, and to the National Institutes on Aging for research funding.

Education and Health in Developing Economies

TS Vogl, Princeton University, Princeton, NJ, USA, and The National Bureau of Economic Research, Cambridge, MA, USA

Glossary

Fetal origins hypothesis A theory that posits an effect of *in utero* conditions on later life health and socioeconomic outcomes.

Human capital The stock of productive knowledge and skills embedded in an individual, most commonly measured as educational attainment.

Intergenerational link Effect running between generations within a family, for instance from parents to their children.

Intragenerational link Effect operating within an individual, either instantaneously or over time.

Longitudinal data Data following individuals over multiple time periods.

Natural experiment An observational study design in which individuals (or groups of individuals) are assigned to a treatment by a mechanism that mimics randomization but is outside the researcher's control.

Randomized controlled trial An experimental design in which researchers randomly assign individuals (or groups of individuals) to receive a treatment.

Introduction

In the course of development, few processes are as intertwined with economic growth as human capital accumulation. Schooling makes workers more productive, speeds the development of new technologies, and better equips parents to raise skilled children, all of which promote economic growth. Growth, in turn, incentivizes investment in human capital. Causal links point in every direction, traversing phases of the lifecycle as well as generations.

However, the entangled role of human capital is not limited to aggregate income growth. Education exhibits complex dynamic relationships with several components of wellbeing, including health. For example, education affects health in adulthood; life expectancy affects educational investment in childhood; and the health and education of parents – particularly mothers – affect both outcomes in their children. Just as with income, these relationships are likely to be especially important in developing countries, where levels of both schooling and health are low but have risen rapidly over the past half-century.

This article gives an overview of the current knowledge on the relationships linking health and education in developing countries. To emphasize the dynamic aspects of these relationships, the article will trace them out first within a generation, between childhood and adulthood, and then across generations, from parents to children. It will focus on reduced-form evidence of these effects rather than efforts to precisely pin down mechanisms, for two reasons. First, the existing literature focuses on reduced-form evidence. Mechanisms have received some attention, but the evidence comes mainly from rich nations; even that evidence remains sparse.

Second, the reduced-form evidence on dynamic links casts in stark relief the potential joint role of education and health in accounting for the intergenerational persistence of disadvantage. That is to say, the children of unhealthy and uneducated parents grow up to be unhealthy and uneducated parents themselves. Others have proposed similar arguments about the intergenerational dynamics of the relationship between health and socioeconomic status, more broadly construed. But the links between education and health, which typically lie at the crux of these arguments, can by themselves account for the dynamics. Given the current extent of inequalities in income, human capital, and health in developing countries, the links between education and health may prove important in shaping long-term trends in the levels and distributions of both variables.

Associations between health and education are not new, but with such tangled causal pathways, these associations sometimes prove to be uninformative. The recent literature in economics has made its main contribution in causal inference. Analyses of natural experiments and prospective trials have shed new light on long-standing hypotheses. They have also improved our ability to interpret careful associational studies, which are in many cases more generalizable than experimental studies but less internally valid. These advances have been key to identifying both the direction and the timing of effects in the causal system linking education and health. With this better understanding of what matters and when, policymakers will be better equipped to identify opportunities for well-targeted policies.

Mapping the Relationship between Education and Health

With its numerous pathways, the causal system linking education and health may seem convoluted. However, one can represent it in a simple but informative diagram. Figure 1 traces out the links between education and health, first over the lifecycle and then across generations. Each arrow represents a causal link that has empirical support in the literature. The blue lines signify intragenerational links – in other words, causal links that operate within a single person – whereas the red lines correspond to links that work across generations within a family.

 doi:10.1016/B978-0-12-375678-7.00109-7

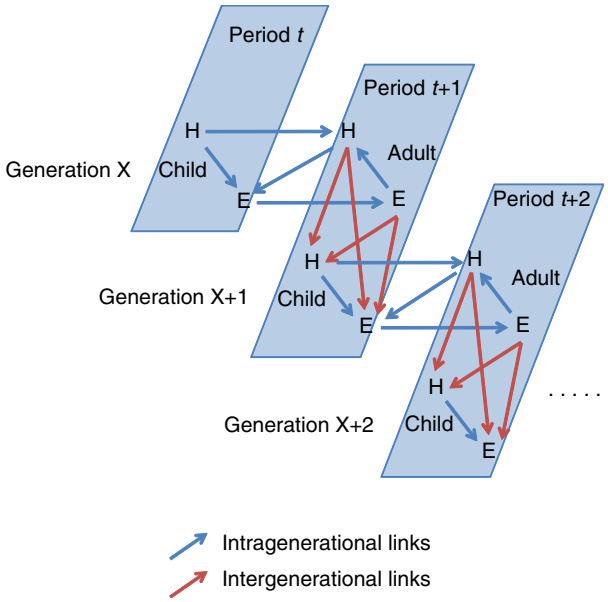

Figure 1 Causal links between health and education.

The system lays out a roadmap for the rest of the article. In childhood, good health improves educational outcomes. Additionally, the expectation of good adult health increases schooling investments in childhood. Both health and education persist from childhood to adulthood, at which point education boosts health. But adults are also parents, so their circumstance in middle age spills over onto the next generation. Healthier mothers have healthier and more educated children. Conversely, parental education promotes both the health and the education of the next generation. At this stage, the causal system repeats in the next generation. In the remainder of the article, the focus will be on the subset of the arrows in Figure 1 that connect health and education.

Intragenerational Links

Effects of Childhood Health on Educational Outcomes

Educational outcomes in childhood

The author begins with childhood, where abundant evidence suggests that health affects school enrollment and academic achievement. Health enables children to travel to school, concentrate, and think clearly, all of which may improve educational outcomes. Until recently, the evidence has primarily taken the form of cross-sectional associations between children's health and their educational outcomes. Many have critiqued these studies for inadequately addressing issues of causality and omitted variables.

Starting in the mid-1990s, a few analyses have made some headway on these issues by focusing on within-family variation. One early study in this literature analyzes data from Ghana and finds, in models with family fixed effects, that shorter siblings start school later than their taller brothers and sisters. A more recent article analyzes twin pairs and sibling sets in Chile, showing that twins or siblings born at higher birth weight perform better on exams. Within-family comparisons of this type eliminate concerns about family-level omitted variables, although they leave some concern about how parents allocate scarce resources among children with observably different health.

Analyses of natural experiments in disease eradication, micronutrient supplementation, and health care provision have also made progress on causal identification. One innovative study investigates the eradication of hookworm from the US South in the early twentieth century, finding that areas with higher initial hookworm burdens, and thus likely experienced larger declines in worm prevalence, saw larger increases in school enrollment. Another uses contemporary data from Tanzania, focusing on a maternal iodine supplementation program in Tanzania. Drawing on policy variation across time and space, as well as on sibling differences in program exposure, the study finds that *in utero* exposure to the program increased school participation. In addition to these effects on school participation and enrollment, early-life health boosts test scores. Using data from Chile (and Norway), a recent study takes advantage of the fact that infants born just below the threshold for very low birth weight (VLBW) receive much more care than those born just above. The study documents discontinuities around the VLBW threshold in both infant mortality rates and subsequent test scores, such that infants born below the threshold do better.

In addition to these innovative ways to glean causal effects from observational data, the past decade has seen a series of randomized controlled trials testing the effect of child health on schooling outcomes. Perhaps the best known is a deworming experiment in Busia district, Kenya. Intestinal worms cause anemia and other ailments, which may make children too weak or lethargic to study. After researchers experimentally varied access to deworming medications across 75 primary schools in the district, pupils in treatment schools exhibited significantly lower rates of worm infection, anemia, and school absence, although not test scores. Experimental data on other programs, including one that distributed iron supplements and deworming medication to Indian children and one that distributed protein supplements to Kenyan children, provide corroborating evidence.

Educational outcomes in adulthood

The fact that education is relatively fixed by adulthood facilitates the study of its relationship with health. Coupled with retrospective measures of child health, data on adult educational attainment can shed light on the effect of health on education in childhood. For example, just as height and schooling outcomes are associated in children, so too are they related in adults. Adult height positively predicts educational attainment in nationally representative data from Mexico, as well as in data on urban populations in Barbados, Mexico, Cuba, Uruguay, Chile, and Brazil.

In adulthood, too, the results of natural experiments and randomized controlled trials suggest that the associations partly represent an effect of health on education. One noteworthy finding comes from long-term follow-up of the deworming experiment in Kenya. When observed in young adulthood, individuals in the treatment group had stayed enrolled in school longer and performed better on a battery of tests than their counterparts in the control group. However,

long-term follow-up of hookworm eradication in the South US gives different results. If one compares birth cohorts born too early to be exposed to eradication to those born later, across areas with differing baseline worm infection prevalence, the results imply significantly positive effects on literacy but not years of schooling.

Several articles have used a similar strategy to estimate the long-term effects of malaria eradication on human capital, with mixed but on net positive results. One study draws on data from the South US, Brazil, Colombia, and Mexico. Here again, significant effects emerge for literacy but not years of schooling, which the author interprets as evidence that eradication made children more productive as students and as child laborers. Separate analyses have applied the same research design to men and women in India, as well as women in Paraguay and Sri Lanka. Although the Indian data show no evidence of positive effects on either literacy or years of schooling, the Paraguayan and Sri Lankan data show the opposite, with large gains in both outcomes.

Effect of Life Expectancy on Investment in Education

Unlike the effect of child health on education, which is rooted in the technology of skill formation, the effect of life expectancy on human capital investment is, at its core, about optimizing choices by households and individuals. According to the standard reasoning, if an individual expects a longer time horizon to reap the returns to human capital, then that individual will invest more. Analyses of macroeconomic data offer limited support for this hypothesis. Although adult mortality is negatively associated with secondary school enrollment, the relationship is not robust to the inclusion of covariates. However, given the paucity of high-quality data on adult mortality in most countries and the difficulty of assessing causality from cross-country associations, the macroeconomic patterns are suggestive.

Indeed, two microeconomic analyses have yielded convincing evidence that reductions in adult mortality risk increase human capital investment. One novel study uses a period of rapid decline in maternal mortality in Sri Lanka as a natural experiment in adult mortality. Parts of the country with higher baseline maternal mortality rates (and therefore larger subsequent declines in maternal mortality) saw larger increases in female educational attainment. A second study, analyzing the human immunodeficiency virus (HIV)/acquired immune deficiency syndrome (AIDS) epidemic in Africa, shows that the subnational regions that were hardest hit by the epidemic have also experienced the largest declines in education.

Effect of Education on Health in Adulthood

A long-standing literature reports positive associations between education and health in adults in wealthy countries, although the mechanisms linking the two variables are not fully known. To the extent that the association reflects an effect of education on health, important mediators of this effect may include income, working conditions, health-related knowledge, cognitive ability, patience, attitudes toward risk, and cultural capital (especially in interactions with health providers). Similar associations are evident in data from developing countries, although studies are rarer.

Both natural experiments and prospective trials suggest that although education can affect health, such effects may depend on characteristics of the population and the material being taught in school. Several studies use compulsory schooling laws in the US and Europe as instruments for education, with mixed but mildly positive results; some indicate positive effects on health and longevity, whereas others indicate no effect. Unfortunately, no similar studies exist on developing countries.

However, longitudinal follow-up of the recent spate of education-related randomized controlled trials in developing countries has begun to yield useful results on health behavior in young adulthood. One such study analyzes a program in the Dominican Republic that gave teenage boys information about the return to schooling. The information led the boys to stay in school longer, to delay the onset of heavy drinking, and to reduce smoking at the age of 18 years. Across the Atlantic in Africa, another study estimates the effects of a program that sought to provide adolescent girls with both vocational training and information about risky health behaviors. HIV-related knowledge and condom use both increased. However, less promising results have emerged from a Kenyan study on the medium-run impacts of a school subsidy program. Although the program increased schooling for both boys and girls, follow-up data show at best weak impacts on sexual behavior and sexually transmitted disease infection. Together, these studies suggest that keeping boys 'off the streets' and equipping girls with health information may be key to any effect of education on health in young adulthood.

Intergenerational Links

Effect of Parental Education on Child Health

In the context of poor countries, by far the most widely studied education-health association is that between maternal education and child health. Following a canonical study of child mortality in Nigeria in 1979, a large literature has emerged on this topic. The literature bares widespread correlations between maternal education and child health, measured by illness, anthropometry, or death.

Several studies question the extent to which the correlation reflects a causal effect running from maternal education to child health, as opposed to omitted variables. The relationship is not always robust to the inclusion of socioeconomic and community-level covariates, or to the inclusion of a fixed effect for the mother's sibship or for a multifamily household. However, one could interpret many of the socioeconomic and community-level covariates in the literature as mediators rather than confounders, and the inclusion of fixed effects exacerbates problems related to measurement error. The results of the revisionist literature are therefore inconclusive.

Analyses of natural experiments support a causal interpretation. The most compelling evidence comes from the US, where local college openings improve birth weight and gestational age. But some results are also available for

developing countries. Among Indonesian women, for example, exposure to a school construction program in childhood reduced mortality rates among their children.

Effect of Parental Health on Child Education

Parental health also affects children's schooling outcomes. Two mechanisms stand out in the literature. The first is indirect: Healthier mothers have healthier children, who in turn become better-educated adults. For instance, *in utero* exposure to the 1918 influenza epidemic decreased educational attainment for the cohort born in 1919 in the US, Brazil, and Taiwan. This effect supports the 'fetal origins hypothesis,' which posits that *in utero* conditions are crucial for the later health and skill development of her child.

The literature also highlights a second mechanism through which parental health affects child education: parental death. Good evidence comes from the HIV/AIDS epidemic, which has orphaned more than 15 million children, some 90% of them in Africa. Across Africa, orphans have lower school enrollment rates than the biological children of their caretakers. Furthermore, in South Africa and Kenya, the timing of parental death is associated with the timing of school dropout. The same is true in Indonesia, where parental deaths typically have little to do to HIV/AIDS. One can thus view the African results as representing a more general effect of losing a parent. Nevertheless, given the scope of the continent's orphan crisis, the results are most relevant there.

Open Questions

The existing literature fills in many of the links sketched in Figure 1, but open questions remain. For one, the distinction between aggregate and individual educational attainment has received little consideration but is almost certainly relevant for health systems in developing countries. How important is a country's education system in producing health professionals to support its health system? Additionally, the potential for the backwards intergenerational transmission of health information – from children to parents – remains underexplored. Such information transmission could prove useful in combating the rise of smoking and obesity in poor countries. Concerning intergenerational dynamics in the other direction, from parents to children, the literature would benefit from more focus on how parental behavior reinforces or compensates for exogenous changes in the health environment or educational opportunity. This last line of inquiry would put behavior back in the center of economic research on health and education.

Education and Health: Disentangling Causal Relationships from Associations

P Chatterji, University at Albany and NBER, Albany, NY, USA

Glossary

Endogeneity An economic variable is said to be endogenous if it is a function of other parameters or variables in a model.

Fixed effects models A statistical way of controlling for omitted variable bias when using panel data. The method is so-called on account of the fact that it holds constant ('fixes') the average differences between the determinants of a variable by using dummy variables.

Omitted variable bias In econometrics, the difference between the value of an estimated parameter and its true value due to failure to control for a relevant explanatory (confounding) variable or variables.

Production function A technical relationship between inputs and the maximum outputs or outcomes of any procedure or process. Also sometimes referred to as the 'technology matrix'. Thus a production function may relate the maximum number of patients that can be treated in a hospital over a period of time to a variety of input flows like doctor- and nurse-hours, and beds.

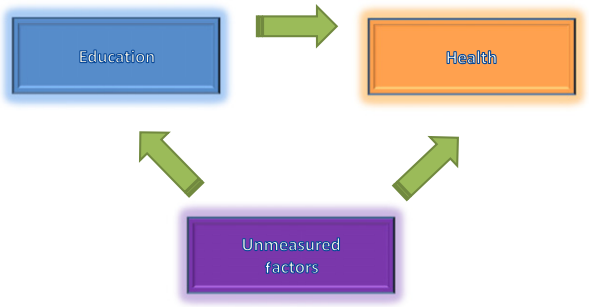
Utility Variously defined in the history of economics. Two dominant interpretations are hedonistic utility, which equates utility with pleasure, desire-fulfilment, or satisfaction; and preference-based utility, which defines utility as a real-valued function that represents a person's preference ordering.

Utility function A technical relationship that relates utility to the rate of consumption of various goods and services, or in some sophisticated cases, to the characteristics of consumer goods and services. Such determinants as health and educational attainment are postulated to yield utility directly as well as indirectly through an enhanced enjoyment of goods and services.

Introduction

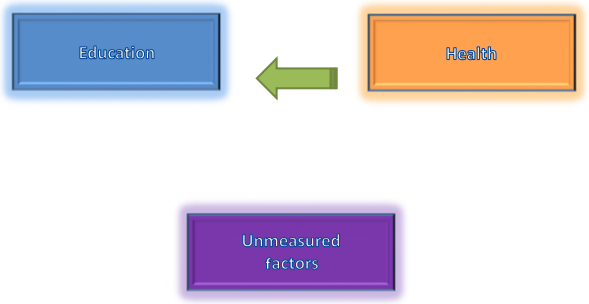
Most people would not be surprised to learn that education is positively associated with health. This seems intuitive, and consistent with what is observed in society. However, many would be surprised by the strength and pervasiveness of the link between education and health across different contexts and different indicators of health. More educated people live longer than those who are less educated, and the importance of education as a determinant of mortality is only growing over time. Chronic diseases, such as asthma and diabetes, are more prevalent among lower educated groups compared to higher educated groups. Even among those with chronic disease, education is positively associated with timely disease diagnosis, effective self-management, and better disease outcomes. Education is positively correlated with healthy behaviors such as exercise and use of preventive care and it is negatively associated with virtually all the risky health behaviors such as poor eating habits, lack of exercise, problem drinking, illegal drug use, and smoking. Maternal education plays a similar role as a determinant of children's health. Maternal education is positively associated with a broad range of children's health and developmental outcomes, ranging from children's preventive health care to mental health outcomes.

Some people argue that is it not education per se, but rather factors correlated with education, such as income, that lead to better health. It may be observed that educated people, for example, exercise more than the less educated. But this may be the case not because of education but rather because educated people earn higher incomes and can afford, say, gym memberships. To some extent, this is true – factors correlated with education, especially income and ability, do account for some portion of the association between education and health. But, in general, the strong and pervasive association between health and education persists and remains policy-significant in magnitude even when researchers take into account a broad range of other factors that are correlated with both education and health, such as income, family background, and demographic characteristics. Does this mean that education truly improves health, or are there factors that cannot be measured well that underlie this relationship? If education does indeed cause better health, what makes education so crucial to health? These questions have intrigued economists for the past four decades.

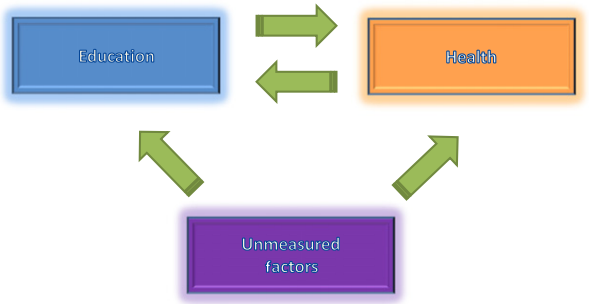


The existence of a robust, positive association between education and health does not necessarily mean that more education causes better health. The reverse causal pathway is also plausible. Better health early in life may lead individuals to complete more schooling, because longer life expectancy increases the benefits of educational investments, and/or because better health improves school attendance and helps students to learn better. There is a growing body of evidence suggesting that early health – even health in utero – can have profound implications for future, adult health, and well-being. Thus, an observed association between education and health among adults may result not from education casually affecting health but rather from early health affecting both health and education in adulthood.

 doi:10.1016/B978-0-12-375678-7.00813-0



Also possible is a noncausal explanation for the correlation between education and health. The correlation may come from unmeasured variables that are associated with both health and education, such as ability, genetics, or family socioeconomic status (SES). Some have suggested that individuals with strong preference for present versus future outcomes – that is, individuals with high discount rates – will not make long-term investments in health or education. If this trait is hard to measure in data, it may appear that education is positively associated with health, but in reality individuals' time preference, which is unmeasured, determines both health and education. In this case, a strong, positive association between education and health may exist, but it does not reflect a causal relationship. It is also possible that more schooling causes individuals to be more future-oriented. In this case, education may affect health causally through its effect on the rate of time preference.



In recent literature, economists employ innovative econometric methods to determine whether the association between education and health is causal. Although most studies are based on data from the US and the UK, increasingly data from around the world are being used to examine this relationship. The economics literature on education and health is very large, and it is expanding rapidly. This short review does not cover all health economics literature in this area. Instead, the focus is on empirical research on education and health in developed countries published in the past 10 years in economics journals. The goal is to highlight some provocative papers, synthesize results, and draw conclusions from recent studies that have attempted to distinguish causal relationships from associations between health and education.

The Grossman Model

Most empirical literature on education and health is motivated by the Grossman Model (Grossman, 1972a,b; 2000). The Grossman Model is a model of the demand for the commodity 'good health,' which is treated as a durable good, or a type of capital. Health has both direct consumption value as well as investment value in this model. Health has consumption value because individuals derive utility from being in good health. Health has investment value because it determines the total amount of time that is available to work in the market and nonmarket sectors. Briefly, in the Grossman Model, individuals maximize a utility function which includes health and other commodities with respect to investments in health, given budget and time constraints. Optimal gross investment in health determines the optimal amount of health, because the depreciation rate (e.g., wear and tear on health capital) and initial health are given.

Grossman analyzes the effect of education on health in his pure investment model. In this version of the model, the consumption value of health is not considered. Education is viewed as the technology of the health production function. More education makes individuals better producers of health. In other words, an increase in education would allow an individual to obtain more health from a given set of inputs, decreasing the marginal cost of an investment in health. The decrease in the marginal cost of investment increases the returns on health capital, and the optimal level of health is higher than before. Thus, according to the Grossman Model, more education leads people to choose higher levels of health because education increases individuals' productive efficiency in producing health (Grossman, 1972a,b; 2000).

The mechanism through which education increases productive efficiency is hard to pinpoint. One can argue, in fact, that it is more likely that education causes better health by improving individuals' allocative efficiency in producing health (Grossman, 2008, 1972a). For example, more education may cause individuals to understand better how to combine inputs to produce health; thus, individuals may make more efficient choices about how much to exercise, what to eat, how to adhere to medical treatments, and what health behaviors to avoid. The distinction between the productive and allocative efficiency arguments can be important from an empirical perspective. If education increases health primarily through improvements in allocative efficiency, if one is estimating a health production function, then there should not be an association between education and health if all inputs are included in the model as well (Grossman, 2008). This is not the case if education improves productive efficiency, because more education leads to individuals directly obtaining more health from a given set of inputs.

Grossman (1972a) emphasizes that one's stock of health is an endogenous choice variable. Current health depends on initial health, depreciation of the health stock in all previous periods, and gross investment (and thus inputs used to produce investments) in all previous periods (Grossman, 1972a). Therefore, when researchers estimate the effect of early health on subsequent education outcomes, it is important to include controls for factors that may affect education directly and also may affect early health through prior health investments, such as family background. However, it is possible that the controls included do not completely account for prior health investments, and that these factors remain in the error term of the equation. Thus, endogeneity resulting from omitted variable bias is a concern to researchers when estimating the effects of early health on later education outcomes.

When estimating effects of education on health, omitted variables bias is still a possibility, because unmeasured factors such as ability may exist that are correlated with both education and health. But in this case structural endogeneity is potentially a problem as well because in a full model of education and health, education and health may be determined simultaneously. Moreover, when estimating the effects of education on health, a reverse causal pathway, with current health affecting current education, is plausible. Thus, when estimating the effects of education on health, health is considered to be endogenous in a structural as well as in a statistical sense.

Econometric Methods Used to Test for Causal Effects

In recent literature, two main empirical approaches have been used to distinguish causal relationships between education and health from associations. The first approach is to rely on a natural experiment. Some examples of natural experiments that have been used to identify effects of early health on later outcomes are famines (Chen and Zhou, 2007), periods of religious fasting (Almond and Mazumder, 2011), outbreaks of illness (Bleakley, 2010; Almond, 2006), rainfall (Maccini and Yang, 2009), nuclear accidents (Almond *et al.*, 2009), and crop infestation (Banerjee *et al.*, 2010). These events are treated as exogenous shocks to early health. One drawback of examining the effects of these events is that the results sometimes may not be readily generalizable to other settings.

In studies of the effects of education on health, researchers have taken advantage of the natural experiments induced by variation in educational policies across time and place. Some examples of natural experiments that have been used to identify effects of education on health are variation in policies that affect school entry (Braakmann, 2011), access to secondary education (Arendt, 2005), and variation in county-level access to college (Currie and Moretti, 2003). Frequently, researchers have drawn on these natural experiments to implement instrumental variables (IV) methods (Eide and Showalter, 2011). The primary advantage of using IV methods in this context is that this approach addresses both the statistical and structural endogeneity. A drawback of this approach, however, is the possible low predictive power of the instruments and its associated problems (Staiger and Stock, 1997). Also, IV findings cannot be generalized to individuals whose educational decisions are not 'at the margin' or, in other words, individuals whose educational decisions are not influenced by the policy that is being used as an instrument.

The second approach used to test for causal relationships in this literature are sibling/twin fixed effects models. This method involves estimating the correlation between within-twin (or within-sibling) differences in birth outcomes and within-twin (or within-sibling) differences in later educational outcomes. This approach essentially 'differences out' family-specific fixed characteristics that may confound an observed association between early health and later education outcomes. Sibling/twin fixed effects models address a specific form of statistical endogeneity – confounding by unmeasured, fixed family-specific characteristics.

There are some advantages in using twins rather than siblings to implement these models. In studies on the educational consequences of birth weight, within-sibling birth weight can vary because of differences in intrauterine growth retardation (IUGR) and/or differences in gestational length, whereas between twins, variation must come from a single source, IUGR (Oreopoulos *et al.*, 2008; Almond *et al.*, 2005). Also, sibling fixed effects models do not address time-varying family characteristics. Maternal health behaviors may vary by birth order, or SES could change between births. These changes may be unmeasured (Oreopoulos *et al.*, 2008; Royer, 2009) and confound an observed relationship between early health and later education outcomes. This issue does not arise in the case of twins, who are born at the same time. Also, unobserved individual heterogeneity, such as genetic differences, may exist within siblings and within fraternal twins (Almond *et al.*, 2005).

In these ways, sibling fixed effects models implemented using data on twins, particularly monozygotic twins, are subject to fewer biases. However, an important advantage of using siblings instead of twins is that the results are more easily generalized to the population. Moreover, even analyses based on within-twin differences can suffer from problems related to measurement error, unstable estimates (Royer, 2009), and selection problems caused by mortality at birth within-twin pairs (Black *et al.*, 2007; Royer, 2009).

Effect of Health on Education

Health at Birth

Malnutrition and poor health in utero or early in childhood is a predictor of later health outcomes, including infant mortality, height, cognitive function, chronic disease, and disability (Barker *et al.*, 1989; Banerjee *et al.*, 2010; Case and Paxson, 2009; Van Ewijk, 2011; Delaney *et al.*, 2011; Chay and Greenstone, 2003). Economic conditions measured at birth have been found to be related to adult mortality (Van Den Berg *et al.*, 2006). These findings, which demonstrate the importance of the early health environment for later health, imply that poor health environment early in life may affect economic outcomes as well. In estimating long-term effects of health at birth, the challenge is in determining whether poor early health is the cause of later problems, or whether it is instead a correlate of such problems (Oreopoulos *et al.*, 2008; Black *et al.*, 2007). There is a burgeoning health economics literature in this area, focusing on education as an outcome, with many innovative identification strategies being used. Numerous studies focus on estimating the long-term effects of birth weight, a single aspect of early health. However, increasingly other measures of early health are being considered. In fact, in many studies, researchers estimate reduced-form models in which the health environment early in life is linked directly to later educational outcomes. In these papers, the mechanism through which early health detracts from later education is not always well-understood.

In a landmark study, Almond *et al.* (2005) examined the long-term consequences of low birth weight (LBW) using data on twins born in the US between 1983 and 2000. They examined the correlation between within-twin differences in birth weight and within-twin differences in (1) hospital

charges, (2) other measures of health at birth, and (3) infant mortality rates. The authors also estimate the effect of prenatal smoking on a variety of infant health outcomes using singleton births, controlling for sociodemographic variables available on birth certificates. In these analyses, they attribute the entire effect of smoking on infant health to the effect of smoking on birth weight, which is probably an overstatement. The authors cannot fully control for unobserved heterogeneity using this approach – but they can gauge whether the magnitudes of the effects generated using the sample of twins are reasonable.

The cross-sectional estimates suggest that a 1 standard deviation increase in birth weight leads to reduction in hospital costs, reduction in infant mortality, increase in Apgar score, and reduction of assisted ventilator use after birth of .51, .41, .51 and .25 standard deviations, respectively. Based on the twins analysis, however, these magnitudes fall to .08, .03, .03, and .01. The smoking analysis shows that smoking affects birth weight appreciably, but smoking is not related to most infant health outcomes – as a result, cost savings of smoking cessation during pregnancy are modest. Either the true effect of birth weight on infant health has been overstated in prior work; and/or each analysis isolates a different set of determinants of birth weight.

Using a similar approach to that of Almond *et al.* (2005), there have been several studies based on samples of twins which examine the effects of birth weight on long-term educational outcomes. All these studies support the idea that birth weight has long-term consequences for adult education and health outcomes. Black *et al.* (2007), for example, draw on administrative data on twins born between 1967 and 1981 in Norway and study the consequences of birth weight. They build on Almond *et al.* (2005) in that they are able to examine the effects of birth weight not just on short-run health outcomes (infant mortality and 5 min Apgar score) but also on long-run outcomes including adult height, intelligence quotient (IQ), employment, earnings, education, and birth weight of the first child. Like Almond *et al.* (2005), Black *et al.* (2007) found that within-twin differences in birth weight are associated with smaller effects on short-run outcomes compared to cross-sectional, ordinary least squares (OLS) estimates. However, Black *et al.* (2007) report that there are long-term effects of birth weight on adult height, body mass index, IQ, education, earnings, and birth weight of the first born child. For these outcomes, OLS and within-twin estimates are similar in magnitude.

Royer (2009) studies the effects of birth weight on educational attainment, later pregnancy complications, and birth weight among offspring using data on same-sex, female twins born in California between 1960 and 1982. Among these twins, long-term outcomes can be studied for those who survive to adulthood, remain in California, and give birth to infants between 1989 and 2002. Consistent with other research, Royer finds that cross-sectional estimates of the effect of birth weight on short-run health are overstated. The estimated within-twin effect of birth weight on 1-year mortality is similar to that of Almond *et al.* (2005) in magnitude. Royer finds small, long-term effects of birth weight on women's educational attainment. It is interesting and unexpected that Royer finds that the positive effect of birth weight on education is largest for infants who are of normal birth weight (>2500 g). Royer also finds that within-twin differences in birth weight are correlated with women's later pregnancy complications and birth weight of their own children. Currie and Moretti (2003), also using data from California, report a similar finding. They find that birth weight differences within pairs of sisters are correlated with within-sister variation in subsequent birth of an LBW infant. This effect is stronger for women living in low SES neighborhoods.

Behrman and Rosenzweig (2004) also estimate twin-fixed effects models to study the association between birth weight and adult outcomes, including educational attainment. They use a sample of monozygotic twins born in Minnesota between 1936 and 1955. The findings show that fetal growth (weight divided by length squared) is positively associated with both height and educational attainment in adulthood.

Other researchers have examined effects of health at birth using data that include siblings as well as twins. Oreopoulos *et al.* (2008), for example, test whether within-sibling differences in health at birth are correlated with within-sibling differences in later outcomes. The sample includes more than 96% of all children born in Manitoba, Canada between 1978–82 and 1984–85. They examine the effects of infant health not just on infant mortality, but also on long-term educational and employment outcomes, including childhood mortality, language scores in grade 12, physician services utilization during adolescence, reaching grade 12 by age 17, and social assistance receipt. Notably, they use multiple measures of infant health including birth weight, Apgar score, and gestational length. The findings from this paper based on twins are consistent with those from Almond *et al.* (2005) – the effect of poor infant health on mortality rates diminishes when twin differences are examined. However, infant health – especially birth weight and Apgar score – are associated with educational attainment at age 17 and public assistance receipt, suggesting that there are long-run effects of infant health on human capital accumulation.

Johnson and Schoeni (2010) also find long-term effects of LBW and early economic disadvantage on educational attainment, labor market, and health outcomes measured in adulthood. They use data from the Panel Study of Income Dynamics (PSID) and sibling fixed effects models. Similarly, Fletcher (2011), using data from the National Longitudinal Study of Adolescent Health (Add Health), estimates the effects of LBW on education outcomes using siblings fixed effects models. He finds that LBW is associated with early grade repetition, special education placement, and diagnosis of learning disability. However, unlike Oreopoulos *et al.* (2008) and Johnson and Schoeni (2011) does not find effects of LBW on longer term educational outcomes such as educational attainment.

In addition to examining effects of health at birth, there are many papers examining the effects of prenatal shocks to health, including inter-uterine exposure to famines, religious fasting, illness, adverse economic conditions, and toxins. Chen and Zhou (2007), for example, test for causal effects between exposure to the 1959–61 famine in China and health and labor market outcomes in adulthood among those who survived. They find that children born in 1962 (who were in

utero during the famine) became shorter adults than they would have been had they not been exposed to the famine. Among those exposed during early childhood, famine exposure is associated with reduced labor supply and earnings in adulthood. Almond *et al.* (2009) study effects of prenatal exposure to radiation stemming from the 1986 Chernobyl nuclear accident in the Ukraine. These authors study effects on academic outcomes among children in Sweden who were exposed 8–25 weeks post-conception to varying degrees of fallout from the accident. The findings show that low levels of prenatal exposure to radiation has no discernible effects on children's health, but it is associated with worse academic performance in high school. The effects are stronger for children from more disadvantaged backgrounds.

Almond (2006) use US data to test for long-term effects of prenatal exposure to the 1918 influenza pandemic on economic outcomes including education. They find that such exposure is associated with about a 15% reduction in the likelihood of graduation from high school and a 5–9% fall in men's wages, as well as with increases in physical disability and receipt of public assistance. Maccini and Yang (2009) estimate reduced-form models to examine the effect of rainfall around the time of birth on Indonesian adults' socioeconomic and health outcomes. They find that rainfall in utero does not affect adult outcomes. However, rainfall in the first year of life is positively associated with health and educational attainment among women, presumably because higher rainfall increases agricultural yields and household resources. Almond and Mazumder (2011) study long-term effects of prenatal exposure to Ramadan, a period of religious fasting. Using data from Michigan, they find that prenatal exposure is associated with lower birth weight. Using data from Uganda and Iraq, these authors report that exposure to Ramadan in utero is associated with large increases in the likelihood of adult disability. Case and Paxson (2009) use data from the Health and Retirement Study and find region-level infant mortality and disease rates in the first 2 years of life are associated with cognitive function in old age (Case and Paxson, 2009). In sum, there is a convincing body of evidence that prenatal health conditions and health at birth have long-term effects on later educational attainment and other adult outcomes. In some cases, the causal mechanism appears to be adult health, but in other cases, mechanisms linking early health to later outcomes are not clear.

Health during Youth

There also is a small but growing literature on the effects of health during childhood on educational outcomes in developed countries. Case *et al.* (2005), for example, examine this relationship using the 1958 National Child Development Study. This survey includes data collected from birth until age 42 on all children born in the UK during the week of 3 March 1958. The results show that chronic health conditions in childhood, as well as LBW, are associated with reductions in educational attainment, employment, social status, and adult health. Although this study draws on unusually rich data which should minimize problems of unobserved heterogeneity, the methods do not directly address the problem of disentangling causality from correlation.

Some researchers, however, have used sibling fixed effects models to difference out family-specific factors that may drive both children's health and educational outcomes. These studies generally support the idea that health during childhood affects educational attainment. Some studies have used self-rated overall health rankings to measure child health. Smith (2009), for example, estimate sibling fixed effects models using data from the PSID to examine the effect of child health on adult labor market outcomes. Child health is measured using a retrospective self-report of overall health before age 17. The sibling fixed effects model findings do not show a statistically significant relationship between health in childhood and educational attainment. However, there are positive effects of child health on family income, household wealth, individual earnings, and labor supply.

Chay *et al.* (2009) focus on how access to and quality of health care early in life affects later educational outcomes. They examine the effects of desegregation and forced integration of hospitals in the US during the 1960s and 1970s on racial disparities in test scores in the 1980s. They find that access to better health care in early childhood reduced African-American/white disparities in achievement test scores later in life.

Other studies estimate effects of specific chronic health conditions during childhood on later educational and labor market outcomes. Fletcher *et al.* (2010), for example, use data from the National Longitudinal Study of Adolescent Health (Add Health) to examine the effect of childhood asthma on missed days from school and work, obesity, and adult health. They use sibling fixed effects models and find large, detrimental effects of childhood asthma on absenteeism. Rees and Sabia (2011), also using Add Health, find that migraine headaches detract from educational outcomes. Sabia (2007), using data from Add Health, finds a negative association between body weight and grades for white females, but not for other sociodemographic groups. Grossman and Kaestner (2009), however, using data from the NLSY79, do not find any statistically significant association between body weight and children's achievement test scores.

There is also evidence that exposure to tropical disease in childhood affects later educational outcomes. Bleakley (2007) studies the effect of hookworm on long-term educational outcomes in the US, taking advantage of a natural experiment in which a public health campaign was instituted in the early 1900s to eradicate the disease. Bleakley finds that childhood hookworm has very large effects on adult wages, mostly through reducing the returns to schooling. In another paper, Bleakley (2010) finds that childhood malaria reduces income in adulthood. In this study, to identify effects of malaria on outcomes, he takes advantage of malaria eradication campaigns instituted in the US and in Latin America.

Results from several studies highlight the importance of mental health for educational and other human capital outcomes. Currie *et al.* (2010) draw on administrative data from Manitoba, Canada, and examine whether childhood health problems are associated with adult educational attainment, test scores, and social assistance receipt. The primary estimation strategy is sibling fixed effects models. The results show that childhood health problems, especially mental health problems, detract from adult educational attainment and other outcomes. These findings are consistent with those of Currie and Stabile

(2006). They employ sibling fixed effects models and use national survey data from the US and Canada and find that hyperactivity symptoms during childhood are associated with worse educational outcomes, such as grade repetition and special education placement. Fletcher and Wolfe (2008) are able to replicate these findings of the effects of hyperactivity on short-run educational outcomes using a different data source (Add Health). However, Fletcher and Wolfe find that hyperactivity does not affect longer term educational outcomes, such as educational attainment.

In addition to these studies that focus on hyperactivity, other economics studies show that depressive symptoms during youth are associated with lower grades and lower educational attainment (Eisenberg *et al.*, 2009; Fletcher, 2010). In addition, a few new studies using data from the US show that having genetic markers for depression and attention deficit hyperactivity disorder are associated with adverse educational outcomes (Ding *et al.*, 2009; Fletcher and Lehrer, 2009). However, Contoyannis and Dooley (2010), using data from the Ontario Child Health Study, examined the association between child health (measured by conduct or emotional disorder, and by chronic condition or functional limitation) on a range of educational attainment and labor market outcomes measured in adulthood. They find that child health is negatively associated with educational attainment and labor market outcomes, but these findings do not persist when sibling fixed effects are included in the models.

Effect of Education on Health

Maternal Education and Child Health

Maternal education is a powerful correlate of children's health outcomes, but whether this relationship is causal remains an open question. Several recent papers focus on testing whether a causal relationship exists between maternal education and child health. Currie and Moretti (2003) make important progress in this area by examining the effect of maternal education on infant health at birth using data from US individual birth certificates from 1970 to 1999. They hypothesize four potential causal pathways linking maternal education to infants' health: (1) effects of maternal education on prenatal care; (2) effects of maternal education on spousal earnings; (3) effects of maternal education on health behaviors (prenatal smoking); and (4) effects of maternal education on fertility (quality/quantity tradeoff). They use an IV method with availability of colleges at the county level as an instrument for maternal education. Currie and Moretti find that higher maternal education improves children's birth weight and gestational age at birth. This is a large effect – an additional year of college is estimated to reduce the incidence of LBW by 10%. Their results show that maternal education increases the probability of marriage, increases husband's education, reduces parity, increases use of prenatal care, and reduces smoking. These pathways, therefore, may be mechanisms through which maternal education affects infants' health.

McCrary and Royer (2011), however, use US birth certificate data and come to different conclusions. They test whether maternal education affects fertility and infant health (birth weight, prematurity, infant mortality) using large samples of birth records from Texas and California which include the exact date of birth. They rely on school entry cutoffs, which allow them to compare birth outcomes of women born just before and just after their states' school entry cutoffs. Although women born just after the school entry date do complete less education than women born just before, their infants are as healthy as those of women born just before the school cutoff. These findings, then, suggest that for women whose educational decisions are affected by school cutoff policies, maternal education does not appear to play a causal role in infant health.

Carneiro *et al.* (2011) examine the effects of maternal education on children's cognitive test scores, behavior problems, and the home environment using data from the National Longitudinal Survey of Youth 1979 (NLSY79). They instrument for maternal education using local labor market conditions, college tuition, and the existence of a 4-year college in the county where the mother lived at age 14. The findings show that maternal education is positively associated with test scores and negatively associated with behavioral problems among children.

Chou *et al.* (2010) estimate the effect of maternal and paternal education on LBW and infant mortality using birth certificate data on infants born in Taiwan between 1978 and 1999. They take advantage of a natural experiment related to educational attainment. In 1968, Taiwan extended compulsory schooling from 6 to 9 years and opened 150 new junior high schools. Before 1968, junior high enrollment was restricted by a difficult exam. The findings show that maternal education and paternal education both affect infant health, but maternal education appears to be more important.

Finally, Chen and Li (2009) use Chinese data to examine whether maternal education affects the health of adopted versus biological children. They find that maternal education is associated with better child health for both adopted and biological children. This finding does not definitely establish a causal relationship, but it is revealing that maternal education is strongly associated with child health, even when genetic explanations are eliminated.

Education and Health

There is a large literature on the effects of education on one's own health. In this literature, economists have studied the effects of education on mortality, chronic health conditions, and a wide range of health behaviors. In an influential paper, Lleras-Muney (2005) uses a quasinatural experiment to determine whether the association between education and mortality represents a causal relationship. The natural experiment consists of states changing their compulsory schooling and child labor laws between 1915 and 1939, inducing some individuals to obtain more schooling than they would have otherwise. Data come from the US Censuses from 1960, 1970, and 1980. Her sample includes whites born in 48 states who were 14 years old between 1914 and 1939, with available data on education. She creates synthetic cohorts by aggregating Census data into groups by gender, cohort, and state-of-birth, calculates mortality rates for these groups, and examines direct effect of changes in compulsory schooling on mortality rates

by comparing mortality rates of cohorts immediately before and after there was a change in legislation. This regression discontinuity approach offers only suggestive evidence of an effect of education on mortality. She then uses the compulsory education laws as instruments, and finds statistically significant negative effects of education on mortality. The effect is large in magnitude – a 10% increase in education lowers mortality by 11%.

Albouy and Lequien (2009) examine the effect of education on mortality in France and come to different conclusions. They rely on changes in compulsory schooling laws as a natural experiment and use regression discontinuity and IV methods, as was done by Lleras-Muney (2005). However, their findings show that while changes in schooling laws affected education, there was no effect on mortality.

Numerous studies examine the effect of education on health and health behaviors using variation in school policies to instrument for education. These studies have yielded mixed findings. Arendt (2005), for example, examines the relationship between education and health (measured by self-reported overall health, body mass index, and smoking) in Denmark. He instruments for education using school reforms intended to expand access to secondary school education. The findings suggest that better education is associated with better health, but the instruments do not perform well empirically in this study, making it hard to draw conclusions from the IV results. Kemptner *et al.* (2011) explore the relationship between education and health using German data, instrumenting for education using changes in compulsory schooling laws. They find evidence of causal effects of education on having a long-term illness for men, for results for other health outcomes are less consistent. Braakmann (2011) studies the effect of education and a range of health and health behaviors using data from the UK. He instruments for education using month of birth, because in the UK, school policies interact with the month of birth such that children born after 30 January are forced to attend school longer than those born before 30 January. The IV results show no effects of education on health. Other studies using compulsory schooling laws for identification show that additional schooling improves self-reported health (Oreopoulos, 2007; Silles, 2009), and may decrease the likelihood of having hypertension (although these findings are mixed) (Powdthavee, 2010).

In addition to school policies, researchers have drawn on other natural experiments to isolate the causal relationship between education and health. de Walque (2007), for example, tests whether the correlation between post-high school education and smoking behaviors (measured by the likelihood of current smoking and the likelihood of having quit smoking) is causal, using the risk of induction into Vietnam War as an instrument for education. He uses data from the smoking supplements of the NHIS between 1983 and 1995. The sample includes persons born between 1937 and 1956 with the age of 25 years and above at the time of the survey. The findings indicate that college education is causally related to a reduction in the likelihood of smoking. However, it can only be concluded that this effect occurs among individuals induced to attend college because of Vietnam draft. Grimard and Parent (2007) address the same question using a similar identification strategy, but different data. They find similar, but less consistent, evidence that education is causally related to smoking.

Siblings/twins fixed effects models also have been used to study the effect of education on health. Webbink *et al.* (2010), for example, use fixed effects models and data on identical twins from the Australian Twin Register to examine the causal effect of education on body weight. They find a strong association between education and overweight status, but this association only persists within twins for males (not for females). Fletcher and Frisvold (2009) estimate the association between college attendance and investments in preventive care using longitudinal data on a sample of individuals who graduated from high school in 1957 in Wisconsin. These individuals are followed for approximately 50 years. The findings show strong associations between college attendance and preventive care usage. These results persist when sibling fixed effects are included in the models. These findings are consistent with those of Lange (2011). Using data from the National Health Interview Survey (NHIS), he finds that more educated people are more likely to respond to individual risk factors for cancer by investing in preventive care than less educated people. This study suggests the mechanism through which education affects use of preventive care may be individuals' understanding and processing of health information.

There is growing interest not just in the effect of the quantity of education on health, but also on the effects of school quality on health. Frisvold and Golberstein (2011) use data from the 1984 to 2007 NHIS, linking respondents to race-specific state-year of birth measures of school quality (such as pupil teacher ratios). A range of health outcomes are examined, including overall self-rated health, mortality, and obesity. Their findings show that higher quality schooling magnifies the effect of education on health. Similarly, Johnson (2010) uses data from the PSID and shows that within siblings, long-term childhood exposure to desegregated schools is associated with adult health, suggesting that school quality has long-run effects on health. Similarly, Kenkel *et al.* (2006) find that high school completion is associated with lower rates of smoking and higher rates of quitting smoking, but there are lower health returns to the GED versus the traditional high school diploma. These results also suggest there is some interaction between schooling quality and the effects of schooling on health.

Drawing Conclusions from Health Economics Research

From a policy perspective, it is critical to disentangle causal relationships between education and health from associations. If more and/or better education causes better health, then public policies that expand access to and/or improve the quality of education will also be effective in improving health. Similarly, if better health causes individuals to obtain more education, health policies can be used to increase education. If causal relationships do indeed exist, health policy and education policy are intertwined.

Economists have made important contributions in this area. There is now a convincing body of economics research supporting the idea that early health is causally related to

long-term education and other economic outcomes. Health measured in utero, at birth, and during childhood and adolescence, affect outcomes such as educational attainment, labor supply, and wages in adulthood. There is also some evidence to support the idea that education causes better health, but these findings are inconsistent and vary by the health outcomes studied and the data used.

For research on education and health to be useful in shaping health and education policies, it is important not just to test for causality but also to identify causal mechanisms. Cutler and Lleras-Muney (2010) take an important step in this direction by examining the education gradient in health behaviors using data from a range of national data sets from the US and the UK. Their approach is to estimate a model in which education affects health behaviors and then include increasingly richer sets of controls in the model to see how inclusion of additional covariates affects the estimated coefficient on education. Overall, the authors conclude that material resources account for approximately 20% of the effect of education on health behaviors. Ability also accounts for a portion of the effect of education on health behaviors. This paper is an important addition to the literature because mechanisms through which education may affect health can now be understood.

Moreover, it is important to understand whether the effects of education on health, and the effects of health on education, are heterogeneous in the population. For example, some research suggests that the effects of education on health vary by individuals' sociodemographic characteristics (Cutler and Lleras-Muney, 2006). Other studies support the idea that education causes better health, but the results are relevant to only subpopulations (often the lowest part of the education distribution), and, based on existing research, cannot be generalized to the entire population (Lleras-Muney, 2005). It is essential to know which groups are most likely to respond to changes in education, or to changes in health. Economics research has the potential to answer these questions about mechanisms and heterogeneity of effects, and thus help in shaping the development of effective health and education policies.

Efficiency and Equity in Health: Philosophical Considerations

JP Kelleher, University of Wisconsin–Madison, Madison, WI, USA

Concepts of Efficiency

The everyday concept of efficiency is fairly straightforward. It connotes an optimizing relation of gains to losses, as well as the avoidance of wastage. Within economics, more technical notions of efficiency include Pareto efficiency and potential Pareto efficiency. These are central notions for cost-benefit analysis (CBA), which seeks to identify efficiencies across multiple policy domains. CBA converts each policy domain's benefits into monetary equivalents and assumes that maximizing overall monetized benefits is a worthy goal (even if not the only worthy goal). By contrast, domain-specific analyses seek locally efficient policies and often employ the notion of cost-efficiency or cost-effectiveness. Within health policy, for example, cost-effectiveness analysis (CEA) seeks to identify policies that would maximize certain health-related outcomes given a fixed budget. Here, there is no need to convert relevant outcomes to monetary equivalents because there is no need to express both health and nonhealth benefits in terms of some common unit.

This article's discussion on efficiency will focus on the notion of cost-effectiveness as it is employed within health policy. Two issues in particular are addressed: first, because the idea of cost-effectiveness suggests the importance of maximizing something, some specific health-related benefit(s) must be identified as the maximand at the individual level; and second, after an individual-level maximand is determined, many philosophical and ethical considerations bear on the selection and interpretation of the social maximand that will ultimately inform policymaking at the population level. These two issues are explored in the Sections Individual-Level Maximands and Social Maximands and the Ethics of Maximization, respectively.

Individual-Level Maximands

Health

It is natural to think that efficiency in health policy should be construed as maximizing health itself. However, two related reasons have been put forward against that proposal. First, it can be difficult to make the assessments of overall health that it requires. Second, asking if someone is in 'good health' is often a way of asking if their health adversely affects their life. If health's impact depends on the way it interacts with other features of one's situation, then it may be misguided to focus on health itself rather than on the ways health, together with other factors, affects people's lives.

Some have replied to these and similar worries about focusing on health itself by noting that it is clearly possible to make at least some relevant comparisons, such as when it is said that someone with a mild sore throat is healthier (assuming all else is equal) than someone who cannot walk. This judgment is a plausible assessment of health itself, not a judgment about health states' impact on the goodness or badness of a life. But is it possible to build a rigorous assessment of population health around specific health-focused judgments? Doing so would require a large number of health-state assessments, but many such judgments are not as clear-cut as the example just offered. To illustrate the difficulty, Daniel Hausman presents the example of a person with a mild learning disability and someone with quadriplegia. Although the first person is presumably in better health than the second, Hausman doubts that there is an objectively defensible framework for comparing units of mobility with units of cognitive functioning. This, he argues, highlights the difference between saying the first person literally has more health (a descriptive judgment) and saying that it is better to be in his health state than to suffer from quadriplegia (an evaluative judgment). Given the conceptual difficulties with measuring a population's literal health (especially when health is multidimensional), and given that health policy's main interest is in how good a population's health is or can be, it is reasonable to conclude that the maximand at the individual level should be evaluative, rather than descriptive. This in effect would bypass the need to measure health itself, but it also raises new questions about how health should be valued.

Well-Being

If one seeks to evaluate the goodness or badness of a health state, a natural proposal is to focus on the impact the state has on individual well-being. Of course, much would turn on the nature of well-being, and philosophers have identified important problems for several accounts of it.

One central candidate is subjective well-being, i.e., the sense of satisfaction with one's life and prospects. A central worry with this approach is that it could ignore significant health improvements that accrue to those who already enjoy high subjective well-being. Ronald Dworkin used the example of Dickens' Tiny Tim to make a similar point. If the magnitudes of relevant health benefits are tied to improvements in subjective well-being, then an intervention that restores Tiny Tim's mobility may bring very little health benefit, given Tim's already cheerful disposition. A similar problem concerns adaptive and even malformed preferences: intuitively significant improvements in health will be downplayed if they would go to individuals who are already subjectively satisfied with very little because of exposure to aspiration-numbing deprivation or injustice.

Preference Satisfaction

Economists often equate well-being with the satisfaction of preferences, and many assessments of health policy draw on valuations derived from data about respondents' preferences over health states. 'Satisfaction' can be a misleading term here,

because what is relevant is getting what one wants, not a subjective feeling that may (or may not) come from getting what one wants.

There is strong reason to keep individual well-being and preference satisfaction separate, and to avoid tying the importance of health improvements to individual preferences. For example, one may prefer a policy in part for altruistic reasons, i.e., because of its impact on third parties. In such cases, satisfying one's preferences could actually come at a cost to one's own well-being. Second, it is possible for individuals self-interestedly to want and prefer things that are not in fact good for them, that do not in fact promote their well-being. This can be due both to false empirical beliefs and to misguided prudential outlooks. Prudential preferences are hardly ever brute 'gut' preferences. As TM Scanlon put it, "My preferences are not the source of reasons but reflect conclusions based on reasons of other kinds" (Scanlon, 2003, p. 177). This opens the possibility that individuals' preferences may be insensitive to objective reasons for thinking that a given health state is better or worse for them.

Opportunities and Capabilities

Many take examples like the one involving Tiny Tim to justify focusing on more objective consequences of deficits in health. Regardless of its impact on his subjective welfare, Tiny Tim's impairment reduces the opportunities that are available to him in significant ways. Amartya Sen has long advocated for a metric of policy evaluation that focuses on people's objective capabilities. Such a framework would divorce the public importance of health-related capabilities from any given agent's personal preferences about them: one person in a given health state may be made miserable by it, whereas another in a similar state may have adjusted fully and now lives a flourishing life. From a perspective of opportunity and capability, these individual viewpoints (and their aggregation) may not matter as much as the disinterested assessment of whether the health state generally impedes or closes off life opportunities that society deems it morally important for citizens to have access to. A view of this sort will therefore not base the valuation of population health on individual preferences or subjective well-being, because these capture the state's importance along the wrong evaluative dimension. The main questions raised by opportunity-based frameworks concern which health-related capabilities should be the focus of health policy, and how they can be measured in a scientifically respectable way. Hausman (2010) has offered the most detailed current proposal, which suggests using deliberative groups to evaluate health states "with respect to the relation 'is a more serious limitation on the range of objectives and good lives available to members of the population'" (p. 280).

These are the most prominent individual-level maximands on offer, and it is important for health economists to be able to distinguish between them and to keep in mind the reasons for and against them. Consider again economists' most common maximand, preference satisfaction. If the value of a health state is determined by individuals' (aggregated) preferences about it, then questions arise about whose preferences should count. One natural thought is that relevant preferences should be adequately informed, and this leads to the suggestion that the preferences of those who are most familiar with the health state should count for more. But here the issue of adaptation arises, because it is possible to live an excellent life after adapting to a given health state. If adaptive preferences inform society's ultimate appraisal of health states, then the importance of having a range of opportunities open to one will be downplayed: At a certain stage in life, what matters from the first-person perspective is that one is able to lead the kind of life one has decided on for oneself; and once one has decided on living a certain kind of life, it is less important that one be able to choose from among options one has already ruled out. Further, from the perspective of a healthy person who views health states P and Q as equally terrible because of how they conflict with his current life plans, an imagined change from P to Q may not seem all that meaningful, even if in objective terms the change would significantly enhance the range of life opportunities open to the average person in P.

Much of the practical relevance of these debates lies in their bearing on how CEA should be carried out. CEA typically uses quality-adjusted life-years (QALYs) as the individual-level maximand. QALYs are designed to integrate longevity considerations with quality of life considerations in a way that enables comparisons between health interventions targeting very different dimensions of health. Because they are built by aggregating individual preferences over health states, QALYs should not be viewed as a measure of literal health; they are rather a measure of the value of changes in health, where the value of a change is interpreted as the difference in the values assigned to the two relevant health states. However, just as it is possible to carry out a CEA using a decidedly descriptive maximand (e.g., number of surgical complications averted), it should also be possible to employ CEA's techniques in the context of different evaluative individual-level maximands. Whatever individual-level maximand is chosen, it remains to be determined how interpersonally comparable benefits and losses to individuals should be combined and valued at the aggregate level in the service of shaping and guiding public policy. Notwithstanding the ethical issues already raised for preference-based evaluative metrics, the following discussion of aggregate-level 'social maximands' will, purely for ease of illustration, be conducted using QALYs as the illustrative individual-level benefit.

Social Maximands and the Ethics of Maximization

The term 'social maximand' seems to suggest that health policy should aim, at least in part, to maximize something. And many philosophers criticize CEA precisely because they believe it embodies a single-minded focus on maximizing QALYs (or on whichever individual-level maximand is ultimately chosen). But this appraisal is too quick. For CEA can be put forward as an assessment of efficiency only, rather than a complete decision-making framework. And even if CEA is proposed as a complete decision-making framework, it is possible within CEA to employ a social maximand that ranks policies on the basis of their interpersonally comparable effects on individuals but which also places differential evaluative weight on otherwise similarly sized benefits depending

on who receives them. To use the language of welfare economics, different CEAs can thus operate with different social welfare functions as the social maximand, thereby operating with different adjustments to efficiency. This even opens up the possibility of what might be called an equity-sensitive social maximand. One problem with this approach, however, is that efficiency and equity are usefully viewed as distinct concepts, and an equity-sensitive social maximand blurs the distinction between them. Thus, to keep these dimensions of evaluation distinct, this section begins with ethical concerns that arise when CEAs employ an equity-insensitive social maximand – that is, when CEAs recommend the single-minded pursuit of efficiency, and when efficiency is construed simply as QALY-maximization. The section will close by noting a difficult issue that arises if one seeks to incorporate a certain equity consideration into the social maximand.

Few would claim that QALY-maximization is an irrelevant goal. The question is whether and when it should be constrained by other ethical factors. Philosophers have identified four main factors that are neglected by what shall here be called 'pure' CEAs, i.e., CEAs that recommend straightforward QALY-maximization.

Aggregation

Pure CEA permits small benefits to lots of people to be summed up to outweigh large benefits to a smaller number of people. For example, a government-sponsored commission in Oregon (US) in 1990 released a draft priority list of health care services that prioritized some oral and dental treatments over life-saving procedures like appendectomy and surgery for ectopic pregnancy. Dollar for scarce dollar, providing appendectomies was not as cost-effective as those nonlife-saving services.

Discrimination against the Disabled

Suppose that subpopulation A is disabled whereas subpopulation B is not; each subpopulation is the same size and all individuals are otherwise equally healthy. Now suppose an epidemic afflicts both populations and leaves all individuals with a life-threatening illness. Assume also that logistical limitations allow for life-saving treatment to be administered to just one subpopulation; all members of the treated subpopulation will be restored to their preillness condition and if saved each would live the same number of additional years. Pure CEA recommends against choosing the disabled population, because this generates fewer QALYs. Many find this a troubling form of discrimination.

Priority to the Worse Off

Pure CEA cannot explain why one should give priority to the worse off when this intuitively seems required. Suppose the individuals in Group A generate 0.3 QALYs per year and could be brought to produce 0.5 instead. And suppose that equally numerous individuals comprising Group B generate 0.8 QALYs per year and can be brought to full health (1.0). Once again suppose that scarcity or logistics require choosing just one group to assist. Pure CEA recommends flipping a coin, because from the standpoint of the maximizer, adding 0.2 QALYs per year to a person's life has the same importance regardless of that person's initial condition. Many find this counterintuitive and believe there is a moral presumption in favor of treating the worse off.

Fair Chances versus Best Outcomes

Suppose the members of two equally numerous groups, A and B, each currently generate 0.5 QALYs per year. Now suppose that either A can be helped or B can, but not both: members of A can be brought to generate 0.8 QALYs per year, or members of B can be brought to generate 0.95. Pure CEA favors helping B and neglecting A, but many find this problematic. As Frances Kamm puts it, although the members of B can be helped a bit more, it is true both that members of A are capable of gaining the major part of what members of B can gain, and that this major part is what each cares most about – namely, a substantial improvement in health. This way of describing the situation leads some people to support giving equal or perhaps proportional chances to A and B, rather than choosing to only help B.

Each of these stylized scenarios raises equity concerns, but there is no consensus on how to incorporate equity considerations into health-economic analysis. Consider, for example, the problem of aggregation. Employing different variations of Oregon's methodology and personal valuations of health states from respondents, Ubel *et al*. found that pure CEA can equate the successful treatment of 10 cases of appendicitis with the successful treatment of between 111 and 1000 cases of mild hand pain. Yet when the same respondents were asked directly how many cases of mild hand pain would be equivalent to 10 cases of appendicitis, 17 of 42 respondents said it would take an infinite number of cases. This finding comports with a common response to Oregon's draft proposal: Many believe that, morally speaking, no number of capped teeth could equal or outweigh saving a life with an appendectomy. But this raises a puzzle, as virtually no one claims that it is always wrong to give priority to less serious but more numerous needs over more serious but fewer needs. Suppose, for example, one could either prevent 10 000 people from developing paraplegia or one could save one person's life, but not both. It seems clear that the relative numbers tip the ethical scales toward the 10 000. But note that there are no people among the 10 000 who, if not helped, could reasonably complain that they were left without mobility while someone else's life was saved. In that respect, this case parallels the case involving dental services and appendectomy: There are not people among candidates for tooth capping who could reasonably complain that their tooth will be left uncapped if the legislature pays for appendectomies instead. But then if it can still be permissible to favor large numbers in the case involving paraplegia, why not also in the case involving tooth capping? The difficult question, therefore, is not whether aggregation can be morally permissible, but rather when and on what basis aggregation is permissible.

Partially in response to the equity concerns connected to the problem of aggregation, health economists have explored ways to build respondents' direct rationing preferences into an 'impure,' equity-sensitive CEA framework. Such preferences

can be elicited using the so-called 'personal trade-off' (PTO) exercises of the sort Ubel *et al*. used to uncover the discrepancy between pure CEA and respondents' direct rationing judgments. One notorious problem with the PTO methodology is the problem of multiplicative intransitivity. The problem is nicely described by Ubel (2000), pp. 168–169:

> Imagine a person who thinks that curing one person of condition A is equally beneficial as curing ten people of condition B, and that curing one person of condition B is equally beneficial as curing ten of condition C. To be consistent, this person ought to think that curing 1 person of condition A is equally beneficial as curing 100 people of condition C. However, when we conducted PTO measurements for three such conditions and multiplied the PTO values of the two "nearer comparisons" (such as A vs B and B vs C), we calculated a different value for the relative importance of the "far comparisons" (such as programs A and C) than people told us when they were directly asked to compare these programs [i.e. A and C].

Because no survey can ask respondents directly to compare every possible pair of competing health interventions, health economists seek a solution to the problem of multiplicative transitivity that could license inferences from discrete preferences about 'nearer comparisons' (A vs. B, B vs. C, . . . , Y vs. Z) to preferences about 'far comparisons' (A vs. Z). One problem not mentioned in the economics literature is that success in this endeavor would conflict with some of the equity concerns that raised the problem aggregation in the first place. Suppose that a very long chain of near comparisons begins by comparing an appendectomy that saves one person's life with an intervention that cures some number of cases of paraplegia. Suppose the next comparison on the chain compares the curing of one case of paraplegia with the curing of some number of cases of one paralyzed arm. Now suppose the chain continues down the line until one gets to the near comparison between curing one case of mild tendonitis with curing some number of cases of individuals who suffer very mild headaches once per week. The worry now is that any solution to the problem of multiplicative transitivity would entail that there is some noninfinite number of mild headaches that would be granted priority over curing a case of appendicitis. There is a deep divide in the philosophical literature as to whether a result like this is tolerable or whether it should be avoided at all costs.

In light of these ongoing and potentially intractable philosophical issues, it may be advisable for health economists simply to rank policies with respect to QALY-maximization only and then to explicitly leave it to policy-makers to decide for themselves whether and when to depart from maximization for equity-related reasons.

The Concept of Health Equity

The most commonly cited definition of health equity is Margaret Whitehead's (1991, p. 219):

> The term 'inequity' has a moral and ethical dimension. It refers to differences which are unnecessary and avoidable but, in addition, are also considered unfair and unjust.

This definition leaves open the possibility that some differences in health are neither unfair nor unjust. This seems to be a virtue. It is not clear, however, that a health inequality must be avoidable before it can be counted an inequity. Here is what Whitehead says about this aspect of equity (1991, p. 219):

> We will never be able to achieve a situation where everyone in the population has the same type and degree of illness and dies after exactly the same life span. This is not an achievable goal, nor even a desirable one. Thus, that portion of the health differential attributable to natural biological variation can be considered inevitable rather than inequitable.

There are two ideas at work here. First, there is the idea of the desirability of equality: everyone being the same in some respect or respects. But, second, Whitehead also refers to the impossibility of equality, and it is this that seems to motivate the condition that an inequity in health must be an avoidable inequality.

There is a problem with Whitehead's avoidability condition. To see this, suppose a subset of the population is afflicted by a health impairment that cannot be avoided or resolved medically – perhaps an unalterable genetic defect makes amputation below both knees a necessity for this group. Suppose also that the legislature is considering whether to pay for wheelchairs for those afflicted by the disorder. On Whitehead's definition, considerations of equity might say nothing about whether the state should provide these assistive devices. This is because wheelchairs arguably cannot eliminate the differences in health caused by the disorder. Whitehead's definition therefore seems flawed, because it definitionally entails that the provision of assistive devices is not a demand of equity (Wilson, 2011).

If the concept of health equity should not prejudge substantive issues that a theory of health equity is intended to address, it is better to start from a much more modest version of Whitehead's definition. Thus, health inequities are simply health differences that are unjust, all things considered. The 'all things considered' qualification means that if a difference is an inequity, then there exists a moral requirement on the part of (certain) agents or institutions to do something about them. It clearly follows from this definition that some view of justice is required before a health difference can be counted a health inequity. But at least this new definition does not rule out the possibility that unavoidable health differences raise issues of equity, because an unavoidable health difference could still be unjust if it is not compensated for in the right way.

Unfairness and Equality

Whitehead's 'necessary and avoidable' condition is therefore problematic. Recall, however, that Whitehead's definition included another condition, viz. that an inequity is an inequality that is unfair. It might seem that this unfairness condition adds nothing to the definition, because whatever is unfair is unjust. But whether unfair inequalities are also unjust depends on what unfairness is, how it is related to justice and moral obligation, and whether other considerations can outweigh or displace fairness in the final determination of what is, all things considered, just and unjust.

How does Whitehead's definition of health equity connect up with the moral value of equality? In the quotation above, she argues that it is neither achievable nor desirable to have everyone in exactly the same health. Setting aside the question of achievability, why would equality not be a desirable goal? Imagine that medical progress has left us with just one disease – heart disease, say – that sets in at the age of 100 years and leaves us dead at 105 years. Would this not be desirable? Surely it would. Imagine a slightly different scenario in which heart disease sets in at the age of 100 years for both men and women, but men tend to die at 105 years whereas women die at 110 years. If one then had to choose between giving males an extra 5 years of life expectancy and giving females an extra 6 years, would not there be something to be said in favor of closing the gap rather than widening it with the more efficient female-focused policy? And might not the value of equality explain why it would be unfair to help the women before helping the men?

These considerations might suggest that equality is indeed intrinsically desirable, so long as its place is known. Having human beings be equal in each and every respect would surely be undesirable, and this may be all Whitehead is saying. But this does not entail that it would be undesirable to promote greater equality of health prospects. In some contexts, equality may be very important, and in others it may simply be less important than some other moral considerations.

Equality of Outcomes versus Process Equity

This last point is sometimes invoked in the context of sex differences in longevity. In 1994, the World Health Organization's Global Burden of Disease team used high-income populations in low-mortality countries to peg the biologically-determined sex-based inequality in longevity at 2–3 years. It might therefore be suggested that if one is committed to equity in health, health care systems should tilt in favor of treating men, as a way to achieve equality of health. However, Amartya Sen and Angus Deaton distinguish between equality of outcomes and process equity (Sen, 2002, pp. 660–661; Deaton, 2002, p. 24). Process equity is the idea that procedural fairness – for example, in health care access and delivery – is of independent moral importance. In Sen's and Deaton's view, process equity can sometimes be more important than equality of outcomes. This line of argument would enable one to give some value to equality of health outcomes without letting it dictate health policies that seem intuitively unjust for other reasons.

There is, however, a response that can be made by someone skeptical of process equity. Indeed, it is a response that Deaton himself has made. He first concedes that the inequality in life expectancy between men and women may justify tilting medical research toward understanding the factors that disproportionately affect men (Deaton, 2011). This is the sort of bias that seems defensible in cases where diseases disproportionately afflict racial minorities. It is, therefore, not clear that it should be ruled out in the context of sex differences in longevity. But if a bias in state-funded research and development can be justified, then why not a bias in health care delivery?

Here Deaton provides an answer that invokes the importance of equality of outcomes, not process equity. He notes that although women have lower prevalence of conditions with high mortality, they have a higher prevalence of conditions with high morbidity. Thus, in some contexts, providing equality of access to health care could actually be one way of equalizing overall health between men and women, because women's advantage in life expectancy might offset the morbidity disadvantages they face. Indeed, there are surely many health and nonhealth disadvantages faced by women that a few extra years might help (partially) to offset. Thus, perhaps process equity seems to conflict with equality of outcomes only when one is focused on the wrong outcome. For example, if we instead focus on guarantying that a certain range of life opportunities is open to all, there may be no reason at all to eliminate women's current advantage on the single dimension of longevity.

Questioning the Value of Equality

So far no reason has been identified to reject a form of egalitarianism that is prominent in the philosophical literature and that nicely explains the connection between Whitehead's reference to fairness and the close linguistic relation between equity and equality. The egalitarian philosopher Larry Temkin puts it thus (Temkin, 2003, p. 775):

> The essence of the egalitarian's view is that comparative unfairness is bad, and that if we could do something about life's unfairness, we have some reason to. Such reasons may be outweighed by other reasons, but they are not…entirely without force.

Temkin maintains that unfairness exists when some are worse off than others through no fault of their own. Temkin identifies two objections that might be used to rebut his view that undeserved inequality is intrinsically bad. These are the so-called Raising-Up and Leveling-Down objections (**Figure 1**).

Consider first the choice between scenarios A and B. There are two social groups in each of A and B. The width of the bars reflects the size of the group's population, and the height reflects how well-off each individual within a group is. Height may here capture years of life lived, quality-adjusted years of life enjoyed, life expectancy, etc. Taking A as the status quo, one is asked to consider whether an otherwise benign policy should be implemented that would lead to scenario B. The Raising-Up objection to a Temkin-style egalitarianism simply points out that, insofar as one is an egalitarian, one must condemn the move from A to B. The antiegalitarian who

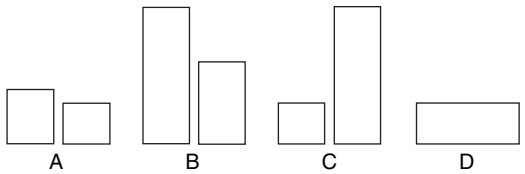

Figure 1 Depicting the Raising-Up and Leveling-Down objections. Adapted with permission from Figure on p 247 in Temkin, L. (1993). *Inequality*. Oxford: Oxford University Press.

makes this objection emphasizes that the move to B makes everybody better off. How, she will ask, could there be any reason not to improve the lives of everybody? (The assumption here is that the improvement is welcomed and not forced on anyone who does not want it.)

Temkin's response to this objection underscores a point made above, namely, that if equality has value, it does so only in the context of other important values. To use an example of Joseph Raz's, it is not important that everyone be equal with respect to the number of hairs on their shirts. That sort of egalitarianism is precisely the sort that Whitehead would be right to call undesirable. So where it makes sense to talk about the value of eliminating undeserved differences, there will always be other genuine values that are also relevant. But then if equality is not the only value, it is possible that equality can be outweighed by the other values whose presence makes equality relevant. This is Temkin's response. He agrees that a move from A to B may be the right choice once all values and reasons are given their due. He simply notes that one consideration, equality, counts against the move. To some, this is a fine response in defense of egalitarianism. True, it may seem strange to deflate equality's relative importance this much, but that seems necessary if one is attracted to Temkin's brand of egalitarianism.

The second objection to Temkin-style egalitarianism seems much more damaging. Imagine that scenario C is the status quo and one is deciding whether to support a move to scenario D (which would bring everyone in C down to the level of C's worst-off group). Plainly, D is superior with respect to equality. But there is also no one for whom D would be better than C. And yet the Temkin-style egalitarian is forced to say that there is something to be said in favor of moving from C to D. Here again Temkin insists that despite being easily outweighed by other considerations, equality still has some value even in this case.

Again, this rebuttal is clearly open to Temkin. But here the antiegalitarian's reply seems even stronger. She will highlight how bizarre it is to say there could be any reason to move from C to D, especially because no one is benefited and many people are significantly harmed. That is the Leveling-Down objection.

From Equality to Priority

The Raising-Up and Leveling-Down objections lead many to give up entirely their belief in the intrinsic value of equality. But others, like Temkin, remain steadfast. Consider the following diagram, which replicates a diagram first drawn by Michael Marmot and discussed in his book The Status Syndrome (Marmot, 2004, p. 246) (**Figure 2**).

The diagram graphs the mortality effects of a policy change on four social groups arranged from left to right in descending order of social advantage. The top line (call it Diamond) depicts the current situation and the top line (call it Square) depicts what the situation would be after implementing the proposed policy. Thus, the policy widens inequalities in mortality. But Square also offers Pareto improvements over Diamond, because each social group in Square has lower mortality than the corresponding social group in Diamond. Marmot drew the graph during a conversation with Deaton. Deaton wanted to know if

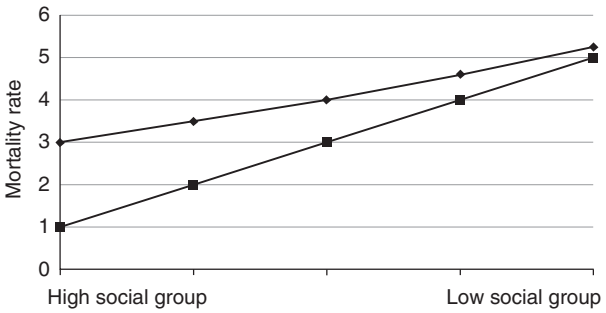

Figure 2 Social position and mortality rate: Two versions. Adapted from Marmot, M. (2004). *The status syndrome: How social standing affects our health and longevity*, p 246. New York: Henry Holt, with permission from Sir Michael Marmot.

Marmot cared more about reducing inequalities than he did about reducing sickness and death. Marmot writes:

> I demurred. [Deaton] was in no doubt that all economists would choose the bottom graph because everyone is better off…[He] suspected that I went for the one with less inequality where everyone suffered more…It is my view that we should reject both alternatives and aim for a society where health for everyone has improved and inequality is less (Marmot, 2004, pp. 245–246).

The economists Deaton referred to will likely be motivated by a commitment to Pareto improvements. In contrast, many philosophers who agree with Deaton's choice of Square over Diamond will be driven by a belief in prioritarianism. There are a number of versions of prioritarianism, but its general thrust is that, morally speaking, benefiting people matters more the worse off they are. Although prioritarians will agree that there is often reason to promote greater equality, they do not think equality is intrinsically important. Rather, a system that tilts in favor of helping the worse off will often end up more equal merely as a side effect of the prioritarian focus on improving the disadvantaged. But if improving the lot of the worse off should require or entail increases in inequality, prioritarians (like many economists) will not care.

Once prioritarianism is introduced, an intrinsic concern with equality can seem like an esthetic preference rather than a moral conviction. Where the egalitarian claims that things have gotten more unfair even though everyone is doing much better and even if the worst off are as well-off as possible, the prioritarian demands to know who (other than the egalitarian!) is complaining about unfairness. It cannot be the best off, because they are doing better than anyone and so have no right to complain. And it is unlikely to be the worst off, because they surely would not demand to be worse off than they already are.

The Value of Equality Revisited

Without concluding that Temkin-style egalitarianism is false, consider further the alternative of 'opportunity prioritarianism,' i.e., the view that social policy should tilt in favor of promoting the substantive life opportunities of those worse off (at least to the extent consistent with respecting individual

choice and personal responsibility). Such a view sees nothing intrinsically valuable in distributive equality.

Consider now an objection to opportunity prioritarianism. When one looks outside the narrow sphere of personal prospects for pursuing worthwhile life opportunities, one encounters other spheres of life within which equality seems to have intrinsic importance. Consider the spheres of political liberty and social mobility. Many believe there is a presumption in favor of equality of access to political influence and equality of opportunity (whereby no child is systematically disadvantaged in their life prospects because of their parents' socioeconomic status). If it seems appropriate to stress the intrinsic importance of equality in these political and socioeconomic domains, should this be interpreted as support by analogy for the intrinsic importance of equality within the narrower domain of personal life prospects?

The first thing to note is that the spheres of political influence and social mobility are zero sum. So even if one is a consistent prioritarian across the three domains of personal life prospects, political influence, and social mobility, equality will be the only distribution available for the last two domains: it is simply impossible to boost one social group's share of political influence or social mobility without making another worse off. This does not of course prove that equality in these realms has no intrinsic value. But it might explain why one would remain attracted to distributive equality in some spheres even if one's most fundamental ethical framework was prioritarian.

Further, if inequalities in life prospects led to unequal political influence, unequal social mobility, and to significant improvements in the range of worthwhile life plans open to those in lower- and middle-income groups, then the trade-off might be worth it on prioritarian grounds.

Of these two considerations – (1) that prioritarian inequalities are not possible in the local spheres of political liberty and social mobility and (2) that there may be prioritarian reasons to tolerate inequalities in more local spheres – neither proves conclusively that equality in these spheres is of no intrinsic importance. Indeed, there is one more way of conceiving of equality and its importance that differs from Temkin's approach and that raises the possibility that egalitarian and prioritarian concerns are both valid and in fact closely related.

The Possibility of an Egalitarian Prioritarianism

It was suggested near the end of the Section From Equality to Priority that once prioritarianism is introduced, a commitment to distributive equality can begin to resemble an esthetic preference for uniformity rather than a commitment to the real needs of individuals. However, many who hold egalitarian views about equal political influence and equal social mobility are not primarily motivated by a general desire to eliminate undeserved disadvantages between individuals. Rather, they are often moved by the independent values of nondomination, reciprocity, and equal social status. According to an increasing number of philosophers, these are the values that should ground egalitarian political convictions, as they are specially relevant for societies that care about treating all persons as moral equals. To say that each person is the moral equal of all is not yet to say that goods should be distributed in a particular way. So the ideal of moral equality is not, at bottom, a distributive ideal, although many claim that it has implications for the distribution of specific sorts of goods and for life opportunities generally. For example, distributive implications may flow from considerations about the demands of reciprocity and benevolent concern that are warranted when moral equals stand in particular social and political relationships with one another.

Some philosophers suggest that when prioritarian distributions are demanded by justice, this demand is ultimately grounded in these nondistributional premises about moral equality and ethically mandated concern (Miller, 2010). A stylized example of Thomas Nagel's provides a useful illustration. In an essay that in many ways sparked the contemporary philosophical debate between distributive egalitarians and prioritarians, Nagel describes a fictional scenario in which he has one healthy child and one suffering from a painful disability. He imagines that he must make a choice between moving to a city where the second child could receive medical treatment but which would be unpleasant for the first child, or moving to a semirural suburb where the first child alone would benefit. He stipulates that "the gain to the first child of moving to the suburb is substantially greater than the gain to the second child of moving to the city." Nagel then claims that, "If one chose to move to the city, it would be an egalitarian decision. It is more urgent to benefit the second child, even though the benefit we can give him is less than the benefit we can give the first child" (Nagel, 1991, p. 124). In response, Derek Parfit claims that Nagel has misdescribed his own moral commitments. Nagel says that the duty to attend to the disabled child's needs is an egalitarian duty. Parfit insists that Nagel is not concerned with distributive equality between the two children at all, and that Nagel instead appears motivated by prioritarian concern for the worse off child. One might reply on Nagel's behalf by claiming that Parfit works with a false dichotomy. In insisting that Nagel must be a prioritarian, Parfit ignores the brand of egalitarianism that stresses the moral demands of distinctive interpersonal relationships, including relationships that call for the display of equal and robust concern for those to whom one is specially related. When multiple individuals compete for that concern (as they may when they are our children or – plausibly but more controversially – our fellow citizens) it is reasonable to conclude that treating all of them as equals requires a prioritarian response to their diverse needs.

This last brand of egalitarianism – call it egalitarianism of concern – may hold great promise to unify and explain many intuitions about the demands of equity across multiple policy domains, including the domain of health policy. If, for example, it can be shown that compatriots or indeed 'global citizens' owe robust duties of equal concern for one another, then the distribution of medical care and other resources bearing on health should arguably follow whatever pattern is required to address the relevant needs of the worst off.

Efficiency in Health Care, Concepts of

D Gyrd-Hansen, University of Southern Denmark, Odense, Denmark

Glossary

Allocative efficiency A situation in which resources are allocated to production processes and the outputs of those processes to consumers or clients so as to maximize the net benefit to society. The net benefit may be some weighted measure of 'health'.

Asymmetry of information A situation in which the parties to a transaction have different amounts or kinds of information as when, for example, physicians have a greater knowledge than patients of the likely effectiveness of drugs while the patients have greater knowledge of the likely impact of drugs on their family circumstances, or people seeking insurance have more reliable expectations of their risk exposure than insurance companies.

Contingent valuation A survey method of eliciting valuations of goods or services by which individuals are asked to state their maximum willingness to pay or the minimum willingness to accept going without contingent on a specific hypothetical scenario, like descriptions of health states, and a description of options available.

Cost–benefit analysis A form of economic evaluation by comparing the costs and the (money-valued) benefits of alternative courses of action.

Cost–effectiveness analysis A method of comparing the opportunity costs of various alternative health or social care interventions having the same benefit or in terms of a common unit of output, outcome, or other measure of accomplishment.

Incremental cost–effectiveness ratio The ratio of the difference between the costs of two alternatives and the difference between their effectiveness or outcomes.

Kaldor–Hicks criterion A test for judging whether a proposed change (say, the introduction of a new drug or the demolition of a new hospital) is welfare-enhancing. It is named for Nicholas (Lord) Kaldor (1908–86) and Sir John Hicks (1904–89). The Kaldor criterion says that if the minimum the gainers from the change are willing to pay is more than enough to compensate the losers fully, then the project is welfare-enhancing. The Hicks criterion says that if the maximum amount the losers are prepared to offer to the gainers in order to prevent the change is less than the minimum amount the gainers are prepared to accept as a bribe to forgo the exchange, then the project is welfare-enhancing. The Kaldor compensation test takes the gainers' point of view; the Hicks compensation test is made from the losers' point of view. If both conditions are satisfied, both gainers and losers will agree that the proposed activity will be welfare enhancing.

Opportunity cost The value of a resource in its most highly valued alternative use. In a world of competitive markets, in which all goods are traded and where there are no market imperfections, opportunity cost is revealed by the prices of resources: The alternative uses forgone cannot be valued higher than these prices or the resources would have gone to such uses. Within a health service with fixed budget, opportunity cost has to be judged in terms of the alternative outputs (like health) forgone when expenditure on some activity increases.

Production efficiency A given output is produced using the least-cost technically efficient combination of inputs, or conversely, output is maximized for a given level of cost.

Revealed preference A person's willingness to pay for a good or service as revealed by market transactions or a controlled experiment.

Technical efficiency A given output is produced using no more inputs than are technically necessary – there will normally be a wide variety of different combinations arising out of their substitutability.

Willingness to pay The maximum sum an individual (or a government) is willing to pay to acquire some good or service, or the maximum sum an individual (or government) is willing to pay to avoid a prospective loss. It is usually elicited from controlled experiments.

Introduction

Being efficient means 'doing something well without wasting time or energy.' To economists, efficiency is a relationship between ends and means. What is important to note is that economists refer to the relationship between the value of the ends and means, not physical quantities. In economic terms, the value of using resources is equivalent to the maximum value that the resources could have generated in alternative use, and is often referred to as the opportunity cost. The acknowledgment that all actions are associated with various degrees of opportunity costs is at the core of economics, the goal being to generate the maximum benefit with available resources. This goal requires two conditions to be fulfilled: (1) that benefits are generated at the lowest minimum cost, so that overall benefits can be maximized and (2) that the right goods or services are produced in order to generate the maximum benefits. Basically it is a question of what should be produced and how is it best produced.

How and what to produce are questions that are answered differently depending on perspective. The 'how' mainly relates to how the production of a given health care service is organized. A leader of a health care firm may want to minimize production costs to his/her firm, thus keeping focus on

minimizing costs relating to his/her own part of the production line, without keeping an eye on overall societal costs. Cost shifting may take place, and an efficient production of health care services from a hospital manager's perspective may not necessarily mean that the production is efficient from the perspective of society as a whole. The 'what' should be produced is also a matter of perspective. Which services generate the most benefit can be defined in terms of a consumer's or patient's willingness to pay (WTP) for the health care service. Alternatively, it can be defined in terms of health gains or other goals that are thought to be beneficial to the recipients of health care services or society. When reading health economic analyses that seek to portray efficiency issues, one should be wary of which budgetary perspective is being applied and on whether one believes that there is focus on the relevant utility generating components of the specific health care production.

Two concepts are important for ensuring overall efficiency: production and allocative efficiency. Production efficiency addresses the issue of using optimal combinations of resources to maximize health output. It is about choosing different combinations of resources to achieve the maximum output for a given cost. Allocative efficiency involves ensuring the right allocation of resources across programs such that the overall good is maximized. 'Utility' is an economic term, which measures the value/good of a produced outcome as perceived by the recipient. Utility-generating outcomes include factors beyond health outcomes, such as process utility or disutility and the value of information and choice. Alternatively, if allocative efficiency is defined more narrowly, it is about achieving the right mixture of healthcare programs in order to maximize the health of society.

Production Efficiency: Minimizing Cost of Production

Production efficiency corresponds to accomplishing a job with minimum expenditure of time and effort. In the production of health care services, this can be translated into having an optimal combination of operating theaters and staff. If the hospital is understaffed, the operating theaters will not be utilized efficiently, and if there are too many staff members some will at times be redundant. In ensuring production efficiency, focus may be on improving staff ratios, shortening length of stay in hospitals, or eliminating unnecessary diagnostic procedures. An array of combinations of minimum input factors that can produce the same level of output are identified, and production efficiency is obtained by considering unit costs in order to determine which of the possible combinations of input factors minimizes overall costs. In the case that unit costs differ across regional health care authorities due to variations in the scarcity of specific resources (and thus opportunity costs), different combinations of input factors may represent production efficiency across regions. Some people will distinguish between technical efficiency (which focuses on the minimum amount of factors required for a specific level of output) and production efficiency (which in addition considers unit costs). For ease of presentation, no distinction is made between these concepts in the text that follows.

Allocative Efficiency: Determining What Should be Produced

Allocative efficiency is about allocating resources such that the maximum utility is generated in terms of either health outcomes or a broader definition of utility-generating outcomes. An allocative efficient distribution may be Pareto efficient: A given distribution of resources that is not Pareto efficient implies that a certain change in allocation of goods may result in some individuals being made 'better off' with no individual being made worse off. A reallocation of resources can, therefore, improve overall welfare and a Pareto improvement is feasible. A less restrictive criterion for allocative efficiency is the Kaldor–Hicks efficiency, where an outcome is considered more efficient if those individuals that are made better off could in theory compensate those that are made worse off despite compensation not actually taking place.

Why Measuring Efficiency is Pertinent in the Context of Health Care

In theory the market for goods will automatically reach production and allocative efficiency if certain criteria are fulfilled. On the demand side, buyers in the market must be facing the full price of the good at the point of purchase and they must be able to make rational choices based on perfect and full information of the good. On the supply side, suppliers must be profit maximizers, there should be many competing suppliers, and there should not be factors deterring suppliers from moving easily in and out of the market.

In the market for health care services, these criteria are not fulfilled. First, there is a high degree of asymmetry of information, and those demanding health care services are not necessarily fully aware of which services they need, nor are they always able to judge the effectiveness of the services. Moreover, there is uncertainty regarding when the services are needed and how much they will cost. The economic uncertainty creates a market for health insurance, which means that the condition of the buyer facing the full price of the good is often not fulfilled. On the supply side, suppliers have been restricted from freely accessing the market in order to protect the less than perfectly informed patient/consumer. For example, doctors and other health care personnel have to be certified. Further, there has been a push for establishing nonprofit health care organizations on the market, again in order to protect the patient from profit-seeking suppliers.

Hence, on the supply side there are factors, which undermine a competitive market and thus the mechanisms, which will ensure that health care services are produced at minimum cost. This means that production efficiency is not guaranteed. At the same time, consumers/patients are often not equipped to judge which health care services they require and are unlikely to face the full price at the time of purchase. This means that there is insufficient basis for ensuring allocative efficiency. Consequently, production efficiency and allocative efficiency are not guaranteed by market forces, and ensuring efficiency on the market for health care services is, therefore, an important issue for health care planners, politicians, and health economists.

Methods of Measuring Efficiency in Health Care

Production and allocative efficiency are not independent concepts. Clearly, the unit of production that has to be maximized at minimum cost when focusing on production efficiency should be produced at the levels of quantity and quality that ensure allocative efficiency. In other words, one may be able to produce an inferior health care service very efficiently, but if there is no demand for the service, it is not worth bothering. Moreover, in ensuring a high level of production efficiency, one may be compromising allocative efficiency if the quality of the service is undermined when costs of production are reduced.

In the following are presented various methods of measuring production and allocative efficiency along with comments on the strengths and weaknesses of different methods.

Measuring Production Efficiency

Production efficiency entails producing the maximum output at a given level of employed resources. To measure and monitor production efficiency, it is essential to define the output produced as well as the production process that is under scrutiny. Outputs are typically measured in terms of services (hospital discharges, episodes of care, or covered lives) or in terms of health outcomes (postprocedure mortality rates, life expectancy, infant mortality rates, etc). There are two tools, which are typically applied in order to measure production efficiency in the context of production of health care services: productivity analysis and cost-effectiveness analysis (CEA). These will be described in turn in the paragraphs below.

Productivity analyses typically focus on an organizational unit's ability to produce maximum output at minimum costs. The output measured is often the most obvious, i.e., number of treated patients or number of consultations. The cost is most often the cost to the organization (i.e., hospital costs). Productivity analyses are often used to benchmark hospitals or hospital departments in order to identify hospitals or hospital departments which demonstrate inefficiency in production.

The level of production efficiency of a particular hospital is characterized by the relationship between observed production and some ideal or potential production. The measurement of efficiency is based on deviations of observed output from the best production or efficient production frontier. If a hospital lies below the frontier, then it is inefficient, with the ratio of the actual to potential production defining the level of efficiency of the individual firm. There are two distinct methods for estimating production efficiency: parametric and nonparametric methods. Some general concerns and challenges in applying such methods should be mentioned. The cost of production is generally limited to that of the hospital or the hospital department and may, therefore, ignore other costs involved in the production process if these lie outside the organization which is analyzed. An observed improvement in production efficiency from this narrow perspective may, therefore, not necessarily reflect cost savings from a wider (societal) perspective. Moreover, the measure of output in productivity analyses is often reliant on available output measure such as number of patients discharged or number of hospital bed days. To the extent that these intermediate measures of output do not adequately reflect utility-generating outcomes, allocative efficiency may be compromised. This is especially the case if there are strong incentives to ensure cost savings, although the quality of services produced remains unmonitored. Recently, there is an increasing focus on refining productivity analyses by incorporating dimensions of quality in output (such as mortality and wound infections) in addition to number of hospital discharges.

As in productivity analyses, CEA focus on comparing predefined outputs and comparing these with costs of production (where a perspective is chosen which may be more or less restrictive with respect to what cost items are included). If a CEA focuses on intermediate outcomes (such as numbers of cancers detected or reduction in blood pressure), the analysis is as restricted as a productivity analysis in the conclusions that can be drawn. Comparisons can only be made across interventions producing the narrowly defined unit of production, and only if an intervention is less effective and more costly or as costly as another intervention, can it be concluded that the former is inefficient. Note that for this type of CEA as well as for productivity analyses no conclusions can be drawn with respect to the relative merits of the efficient interventions (i.e., those interventions that lie on the production possibility frontier (PPF)). Figure 1 gives an example of such a frontier, where each triangle denotes a potential colorectal cancer screening strategy (target group and screening interval is varied) and the line represents the PPF (Gyrd-Hansen and colleagues, 1998). Program options that lie within the PPF are inefficient as they are dominated by at least one other program, which is either cheaper and/or more effective. Those programs that lie on the PPF represent programs that are technically efficient. However, which (if any) of these programs that fulfill the criteria for allocative efficiency is undetermined.

CEA can be applied as a tool for guiding resource allocations across the health care sector as a whole. In this case, the production unit is either defined in terms of the health care sector or society as a whole and the output of interest is quality

of life years (QALYs) gained. The broader definition of output ensures that CEA can guide the allocation of resources across various types of health care interventions aimed at different patient groups. The key parameter in this case is the cost per QALY, also referred to as the incremental cost-effectiveness ratio (ICER). Many health economists would define CEA applied in this way as a tool for ensuring production efficiency within the health care sector, i.e., ensuring that the maximum amount of output (QALYs) is produced at a given level of cost (given by the health care budget constraint). Other health economists perceive that we are in essence dealing with issues of allocative efficiency (within the bounds of the health care sector), where the aim is to ensure the optimal allocation of resources across services in the health care sector, and the maximization of QALYs is equivalent to maximizing benefits. Clearly, any disagreement on how the role of CEA is best defined is a matter of whether one defines allocative efficiency as necessarily meaning the allocation of resources across society as a whole or whether one can accept QALYs as a sufficient measure of benefits.

A more pertinent question is how CEA and ICERs are used in practice to inform decision making. In the ideal and very unrealistic scenario where all candidate health care interventions are subjected to economic evaluation and only those which are most cost effective (i.e., those with lowest ICERs) are included in the health insurance package subject to the given budget constraint, the CEA can fulfill the role of ensuring efficiency. In the more realistic scenario where resources are currently being used to run existing health care services, and there is only information on the ICER of a new intervention, the usefulness of the cost-effectiveness information is likely to be reduced. If the new health care intervention is cost saving or cost neutral, but more effective than the present intervention, the decision is straightforward. The intervention should clearly replace current practice. And vice versa if the intervention is cost neutral or cost generating and less effective. However, in many cases, new interventions are cost generating as well as more effective. In this case, it is not easy to draw any conclusions as to the welfare implications of introducing the new intervention. Introduction of the new intervention will necessarily incur opportunity costs in terms of health foregone, as there will be fewer resources available for other activities. It cannot be determined whether the health benefits foregone are larger or smaller than the acquired health benefits. Only if the health care services that may be deferred can be identified and evaluated, can an informed decision be made.

To improve the usefulness of ICERs as a tool for decision making, researchers have sought to identify a cost-per-QALY threshold as an indicator of whether an intervention is sufficiently cost-effective to warrant implementation. However, such a threshold is of little use as long as the true opportunity costs remain unidentified, which is likely to be the case if decisions are made under a predetermined budget constraint. Thresholds, as produced by way of a citizen's WTP (out of own pocket) per QALY, are only useful instruments so long as the introduction of new interventions that pass the threshold requirements are facilitated through expansion of the health care budget, thus incurring opportunity losses from reduced private consumption.

QALY league tables rank (candidate) health care interventions according to their cost-effectiveness (cost per QALY). Such tables can be useful to identify whether efficiency could be improved if some interventions take the place of others, but this necessitates the inclusion of both existing and new interventions. The more exhaustive a QALY league table is, the more useful it can be as a means of improving overall allocation of resources. However, in presenting ICERs in QALY league tables, or elsewhere, it is important that the ICERs presented are those that most precisely reflect the cost-effectiveness of the given policy relevant choice. In many cases, it is not only a question of whether or not to implement a health care service but also of how to implement it and to whom it should be offered. Interventions such as neonatal care, screening programs for cancers, prophylactic treatment of high blood pressure, etc. can be designed in many ways. Offering a health care intervention to all may appear reasonably cost-effective on the basis of the average cost per QALY. The average value may, however, hide some very expensive QALYs if a specific group of recipients experience little health gain at a high cost. It is important to choose the right comparator, and the corresponding ICER, in order to appropriately inform on efficiency implications.

Measuring Allocative Efficiency

Measuring allocative efficiency is about determining which aspects of health care services are of value to citizens, and to determine the relative importance of health care services. Measuring allocative efficiency must, therefore, in principle involve consumer preferences. In CEA, allocative efficiency (more frequently labeled production efficiency) within the bounds of the health sector is obtained by measuring benefits in terms of QALYs. Although quality adjustments are to some extent based on consumer preferences, it has been argued that this measure of benefit may in some cases be too restrictive because it does not include other utility-generating aspects of health care services such as process disutility or the value of information. Although such factors are not present in all contexts, ignoring these may result in some degree of inoptimal resource allocation.

A guide to efficient resource allocation is cost–benefit analysis. Cost–benefit analysis is based on the Kaldor–Hicks criterion, where an outcome is more efficient if those that are made better off could in theory compensate those that are made worse off. In the case of a publicly funded health care service, the losers would be the taxpayers who are financing the service and the winners are those citizens who can expect to receive the service, should they need it. Assuming that individuals are rational and fully informed about the quality of a good, consumers will be willing to pay equivalent to the marginal utility that they anticipate from buying the good. Allocative efficiency is obtained when goods in society are produced at a level where price is equal to marginal cost. Cost–benefit analysis seeks to replicate the demand side of the market by using market observations (revealed preference studies) or laboratory experiments (typically contingent valuation studies or discrete choice experiments) to establish consumers' WTP for health care services.

Contingent valuation methods and discrete choice experiments typically involve asking people how much they are willing to forego (out of their private budget) in order to ensure access to a health care service. If a cost–benefit analysis demonstrates that WTP is higher than costs, this implies that allocative efficiency is improved if the health care service is introduced. For this conclusion to hold, additional resources must be taken from private funds. If it is instead a question of determining resource allocations within a predetermined health care budget constraint, it is necessary to evaluate all the specific programs that are competing for funds. Allocative efficiency (within the health care sector) is attained when the last dollar invested across all areas of health care services generate the same level of marginal utility.

One advantage of the cost–benefit approach is that it in principle can guide resource allocations across various sectors of society. Where CEA seeks to prioritize health care services within a given budget restriction, cost–benefit analysis could ideally indicate the size of the health care budget. The benefit measure used in cost–benefit analysis also has the advantage that it is broader and far less predetermined than the benefit measures in CEA. It rests on the notion that all preferences count, which necessarily opens up for a discussion of whether the goal of the health care sector is to serve needs or wants. The Achilles' heel of cost-benefit analysis in the context of health care is whether rational and robust preferences based on a full understanding of the merits of the health care services can be derived. More research into how best to ensure that respondents understand and adequately respond to the information that is provided to them is warranted. Also, measures of allocative efficiency, which rely on private interests only, may neglect to incorporate societal benefits that are not reflected in preferences of the consumers (externalities). To the extent that there are significant positive or negative externalities involved when providing a health care service (e.g., herd immunity), these should be valued and included in the cost–benefits analysis. The extension of allocative efficiency to encompass externalities is sometimes called social efficiency.

Emerging Infections, the International Health Regulations, and Macro-Economy

DL Heymann, Centre on Global Health Security, Chatham House, UK, and Infectious Disease Epidemiology, London School of Hygiene and Tropical Medicine, UK
K Reinhardt, Centre on Global Health Security, UK

The Economic Impact of Emerging Infections

By the end of 2009, the year in which Mexico first reported human infections with the H1N1 influenza A virus that then spread globally to cause a pandemic, 70 715 Mexicans had been reported with confirmed H1N1 infection of whom 1316 (~5%) had died. During this same period, though there were no official travel or trade bans from th,1e Mexican Government or international bodies such as the World Health Organization (WHO), Mexican tourism and trade in pork decreased both nationally and internationally. Temporal decreases in output from the pork industry contributed to a pork trade deficit of an estimated US$27 million, whereas an estimated loss of one million overseas visitors translated into an estimated economic loss of approximately US$2.8 billion.

The economic losses related to H1N1 outbreak in Mexico were clearly influenced by the unfounded perception by tourists and travel agencies that the risk of becoming infected with H1N1 was somehow greater in Mexico than elsewhere, even though the virus had spread throughout the world; and by a misunderstanding among pork trade partners that the pandemic was being amplified by infected pigs, despite the fact that it was human to human transmission, in which swine played no role, that was responsible for the global spread of the pandemic. In other countries, there were official recommendations, apparently based on this same misunderstanding that also caused negative economic impact. In Egypt, for example, slaughter of pigs was ordered by the Egyptian Government early in the pandemic, even though the H1N1 virus had already been demonstrated to be highly transmissible from human to human, and despite the recommendation of the World Health Organization for Animals that culling of pigs was not scientifically justifiable.

Countries around the world were affected as the H1N1 pandemic spread, and economies suffered. In Spain, for example, the direct economic impact of illness from H1N1 influenza on health services utilization, and indirect costs from work absenteeism, for example, has been estimated at €6236.00 per hospitalized patient. In Canada, it is estimated that the cost of the increased patient load to hospitals caused by H1N1 between April and December 2009 was Canadian$ 200 million.

The World Bank predicts that a pandemic caused by a different influenza virus, the highly infectious and virulent avian (H5N1) influenza virus, could cost the world economy as much as US$800 billion a year from direct patient costs, and indirect costs from lost lives, travel, and trade. The H5N1 virus is currently continuing to cause disease among poultry, but is only able to infect humans sporadically when they come in contact with infected chickens.

As influenza viruses are highly unstable, however, the H5N1 influenza virus could mutate or combine with other influenza viruses circulating in nature to a form that spreads easily from human to human, resulting in an influenza pandemic with much higher mortality than the H1N1 pandemic. To prevent such a scenario, attempts are being made to eliminate the H5N1 virus by culling entire flocks of infected poultry, mainly chickens. This precautionary measure, recommended by the World Health Organization (WHO) and the Food and Agriculture Organization, is causing lost revenue and poultry-replacement costs that have been estimated to be in billions of US dollars.

Emerging infections such as H1N1 and H5N1 influenza are the newly identified infectious diseases in humans caused by viruses that have breached the species barrier between an infected animal and a human. They are by definition new, and sometimes they are called novel infections. As they are new they are poorly understood, and their full potential to cause disease and death in humans is not known.

Unlike influenza, there are other emerging infections that cause human disease but are unable to spread from human to human. Economic cost associated with these infections is due to patient management and decreased work productivity while sick; and if there is death, from the lost years of work. An example is rabies: humans are infected by the bite of a rabies-infected animal, become sick and die, but do not spread the infection to other humans unless an organ is obtained from them postmortem, and grafted into another human. The direct cost of treating persons exposed to rabies has been estimated (conservatively) to be US$40 in Sub-Saharan Africa and US$49 in Asia, a cost that equals 5.8% and 3.9%, respectively, of the average annual per capita gross national income. Additional indirect costs attributed to persons with rabies occur because of death and permanent removal from the workforce. It is estimated that the economic impact from rabies each year in the United States is approximately $300 million, where an average of two human infections occur each year.

Bovine spongiform encephalopathy (BSE) is another example of an emerging infection that does not spread from human to human. BSE, or mad cow disease, was identified in the United Kingdom (UK) during the 1980s. To rid cattle populations of infection, precautionary culling of herds with infected cattle was required. When it was understood that humans could be infected with BSE from cattle and cattle products in 1996, culling activity increased, and the economic loss in the UK during the following year was estimated to be US$1.5 billion. Countries that had imported cattle from the UK also culled infected herds at a considerable economic loss.

Another emerging infection – monkeypox virus in the United States – was caused by human contact with infected

 doi:10.1016/B978-0-12-375678-7.00624-6

prairie dogs bought as pets. The prairie dogs had been infected with the monkeypox virus in pet shops by other animals imported from West Africa as exotic pets. The outbreak was stopped and there were no deaths. Though the overall direct costs for diagnosing and managing illness were not calculated, nor were the costs from the bans on pet sales by pet shops and their furnishers, they were significant to health insurance companies and to the trade in animals as pets.

Occasionally, an infection emerges at the human/animal interface, is able to spread easily from human to human, and then becomes endemic in human populations with long-term associated economic cost. HIV is one such emerging infection. Thought to have crossed the species barrier from nonhuman primates to humans sometime during the early twentieth century, it is spread from human to human mainly by intimate sexual contact. Owing to the long, symptom-free incubation period, HIV had already spread throughout the world's population by the time it was first identified in 1981. Since then the cumulative economic impact of AIDS on GDP has been estimated by various economists with a wide range of costs – one of these, the estimated direct costs in 2009 to achieve universal access to treatment and care alone was US$7 billion.

Severe Acute Respiratory Syndrome (SARS): A Case Study on the Economic Cost Associated with Emerging Infectious Disease Outbreaks

An outbreak of an emerging infection, Severe Acute Respiratory Syndrome virus, occurred in the Guangdong Province of China in late 2002. In China, SARS spread from infected persons to other family members and to health workers, and from them to others in the community, causing an outbreak associated with severe illness and death. In February 2003, when SARS was still unrecognized as a new and emerging infection in China, it crossed the border from the Guangdong Province to Hong Kong in a doctor, who had been treating patients with SARS. He himself had become sick, and during a one-night stay in a Hong Kong hotel spread SARS to other hotel guests. Before they had any major symptoms, infected hotel guests travelled by plane to other Asian countries, North America, and Europe where they became sick and spread infection to others.

SARS had never before been seen in humans. There were thus no vaccines, medicines, or predetermined measures that could be used for its control. As the virus continued to spread from human to human, there was concern that like HIV, it would become yet another endemic infection, sustaining itself indefinitely in humans. Precautionary measures to prevent international spread of the infection were immediately recommended by the WHO – it was first recommended that persons who were ill with similar symptoms and contact with geographic areas where outbreaks were occurring defer their travel until they were well.

These precautionary measures caused a decrease in international air travel from geographic areas where outbreaks were occurring. Concern and panic ensued, however, among populations from other geographic areas as well – clearly demonstrated in a decrease in passenger movements through international airports. The precautionary prevention measures recommending that persons who were ill with SARS-like symptoms postpone travel resulted in a decrease of passengers who were ill, but many well passengers perceived the risk of travel as being great. This resulted in a steady decrease in passenger movement, clearly shown in **Figure 1**, where

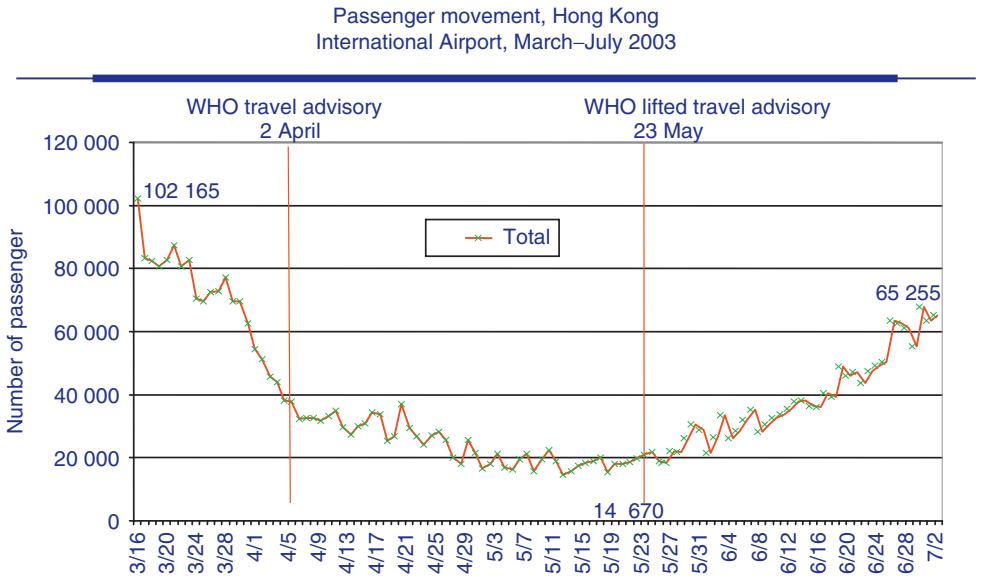

Figure 1 Passenger movement through the Hong Kong Airport from 16 March 2003, the day after the announcement of the SARS outbreak, to July 2003 when the outbreak was declared over. Passenger movement decreased immediately after the epidemic was announced on March 15, continued to decrease after a travel advisory to postpone travel was made by WHO, but increased again beginning 23 May when WHO lifted the travel advisory. Reproduced from Hong Kong International Airport and WHO.

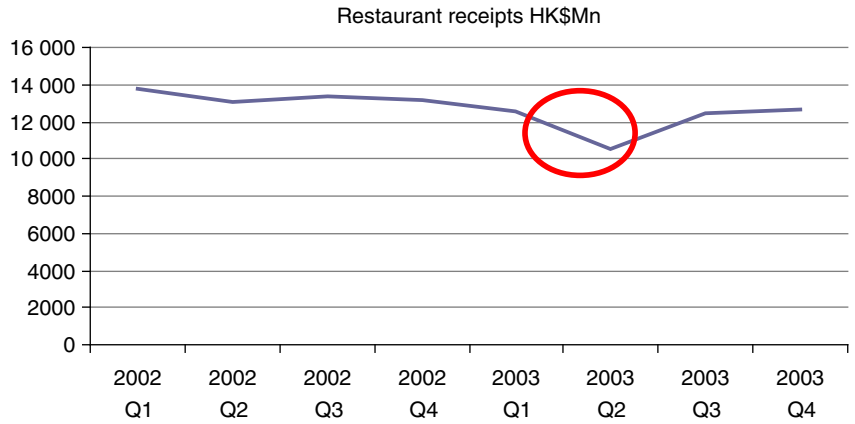

Figure 2 Restaurant receipts Hong Kong, 2002–03.

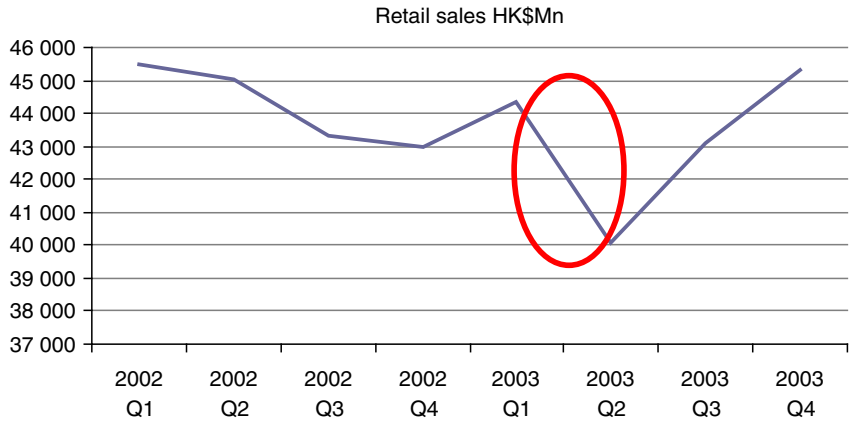

Figure 3 Retail Sales, Hong Kong, 2002–03.

passenger movements at the Hong Kong International Airport decreased soon after the outbreak was announced.

When SARS spread throughout a major housing complex in Hong Kong, among persons who had not been in contact with each other it was hypothesized that SARS might be spreading through an environmental factor such as an insect or water in addition to face to face contact. This led to stronger precautionary recommendations – to postpone or cancel travel to areas where outbreaks of SARS were occurring and a human contact could not be identified as a source of infection for each person with SARS. When WHO made this stronger precautionary recommendation on 2 April, a sustained decrease in passenger movement occurred in Hong Kong throughout the month of April and until 23 May, when the WHO removed the precautionary travel advisory.

Overall, Hong Kong International Airport had had an approximate decrease of 70% in passenger movements in April 2003 compared with April 2002, and aircraft movements decreased by an estimated 30%. In April 2003, the number of flights cancelled each day was approximately 164, representing more than 30% of all flights cancelled, and resulting in an estimated loss in landing fees of a minimum of $3.5 million per day.

During this same period, income from restaurants, hotels, and retail sales decreased because of panic and misperception of the risk among the Hong Kong population that resulted in decreased consumer activity. Figures 2–4 provide clear examples of the decreases in economic activity that occurred.

The SARS outbreak caused ended in July 2003, with 8096 reported cases from 37 countries of which 1706 (21%) were fatal. The Asian Development Bank estimated the economic impact of SARS at approximately US$18 billion in East Asia – around 0.6% of gross domestic product. However, fortunately recovery was rapid once international spread had been stopped.

The International Health Regulations and International Spread of Infectious Diseases

Attempts to limit the international spread of infectious diseases were first recorded in Venice in the fourteenth century when quarantine was used to keep ships and individuals at land border crossings in isolation for 40 days in an attempt to stop the spread of plague. Quarantine was widely used during the following centuries to attempt to limit the spread of plague and other diseases such as cholera, yellow fever, and smallpox; and during the nineteenth century a series of sanitary conferences within and between Europe and the Americas focused on these same four diseases demonstrated the concern. In the

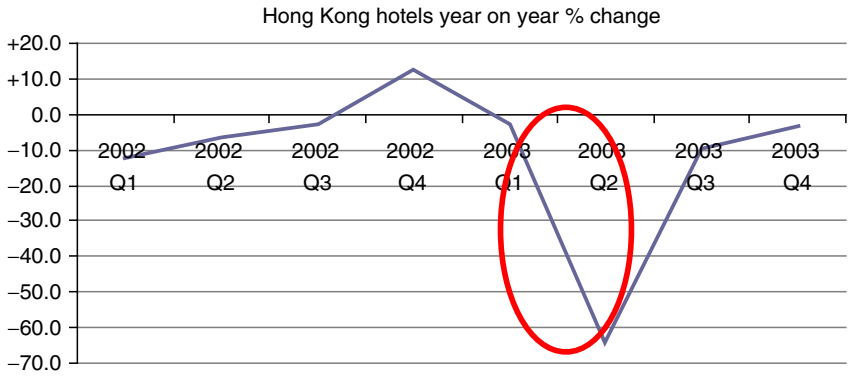

Figure 4 Year on year percentage of change in revenue, Hong King Hotels, 2002–03.

early twentieth century these sanitary conferences were broadened, under the League of Nations, to include all its member states. In 1969, the WHO Member States had agreed to a set of regulations aimed at ensuring the maximum security against the international spread of diseases with a minimum interference with world traffic.

The IHR 1969 were revised in 2005, incorporating many of the lessons learned during the SARS outbreak, and now ensure broader disease coverage, and in addition require countries to develop core capacities in public health laboratory and epidemiology in order to detect and respond to diseases where and when it occurs, and before it spreads internationally (Box 1).

Several disease threats have occurred since the revision of the IHR, including the H1N1 pandemic in 2009. The risk assessment when H1N1 first emerged was conducted by WHO and the IHR emergency committee. Though WHO recommendations based on this risk assessment clearly stated that travel and trade should continue as before, irrational trade and travel measures were imposed by several countries as described earlier in this article, and they resulted in the consequent economic losses described.

The outbreak of *Escherichia coli* (*E. coli*) that caused hemolytic-uremic syndrome in Germany occurred after the revision of the IHR as well. Though the outbreak resulted in an unexpected direct economic burden on the German health system, it also resulted in a severely negative economic impact on the European agricultural sector. Initial laboratory testing wrongly suggested that the outbreak was associated with consumption of salad greens and tomatoes imported from various countries neighboring Germany, and with consumption of cucumbers imported from Spain. Once this link was published in the mass media, the market for cucumbers fell and Spanish farmers began to experience losses of up to an estimated US$ 200 million per week. Polish, Dutch, and Italian farmers had similar losses, and German vegetable farmers had a drop in real income of 2.8%.

At the same time, Russia banned vegetable imports from the entire European Union (EU), an annual 600 million Euro market for EU farmers. As the outbreak investigation continued, however, it became clear that the outbreak was linked to ingestion of bean sprouts from an organic farm in Lower Saxony and the EU then compensated farmers in the European vegetable industry with 200 million Euros.

These two outbreaks suggest that the IHR 2005 are not completely effective in clear and effective risk communication, nor in preventing unnecessary negative economic impact. A recent outbreak of a novel coronavirus in the Middle East,

Box 1 The International Health Regulations

At the World Assembly in May 2003 based on lessons being learned from the ongoing SARS outbreak, a resolution was agreed by Member States of the WHO that helped to speed up the revision of the International Health Regulations (IHR).

The IHR first agreed by the WHO Member States in 1969, and had as a goal maximum prevention of the international spread of infectious diseases with minimal interruption of world traffic and trade. By setting out certain border requirements, and targeting four infectious diseases – cholera, plague, yellow fever, and smallpox (removed after eradication in 1980) – it was hoped that these four diseases could be stopped at international borders. However, countries often did not report these diseases when they occurred because of fear of irrational trade and travel measures and the severe negative economic impact that could occur.

In addition, as knowledge about emerging infections grew, it became clear that there were other infectious diseases of equal or greater potential for international spread than those that were covered by the IHR, and a revision of the IHR was begun in the late 1990s.

By the time of the SARS outbreak, a new way of detecting and responding to infectious disease outbreaks had been developed by WHO as a precursor to the revision of the IHR, and it was these ways of working that led to the coordinated global response to SARS. One of the major lessons learned was that strong national disease detection and response systems were of great importance in order that countries could detect and response to infectious disease outbreaks where and when they occur, thus preventing human suffering and death, and minimizing the risk of international spread.

This concept was incorporate into the revised IHR that now required all countries to develop a minimum core public laboratory and epidemiology capacity in order to detect and respond to outbreaks when and where they occur. The revised IHR also continue a requirement for reporting of disease outbreaks, and the requirement has been broadened to reporting all public health events of international concern (PHEIC) after risk assessment using a decision tree provided in the IHR.

however, gives cause for hope that the revised IHR do indeed offer a means of ensuring maximum security against the international spread of infectious diseases, while minimizing interference with travel and trade.

Reports of persons infected with this newly identified SARS-like virus were made to the WHO from countries treating patients with origins in the Kingdom of Saudi Arabia, Qatar, Jordan, and the United Arab Emirates. The initial reports originated at the time of religious pilgrimage for Hajj. An irrational response could have caused great confusion and a heavy economic and spiritual loss to pilgrims and to Saudi Arabia, which has increased its investment each year to provide for the health security of pilgrims.

An immediate and transparent risk assessment was made under the framework of the revised IHR, and the risk was then communicated widely. The Hajj was unaffected by the reports of the risk assessment, and surveillance of Hajj pilgrims for severe respiratory symptoms was conducted during the pilgrimage and after pilgrims had returned to their home country.

Only time will tell whether the new ways of working and communicating risk under the IHR will continue to help prevent unnecessary panic and confusion when an outbreak occurs and spreads internationally; and prevent the irrational reaction that increases their negative economic impact.

Empirical Market Models

L Siciliani, University of York, Heslington, York, UK

Introduction

This article reviews econometric techniques and studies aimed at characterizing the market structure in the health sector. It focuses on the following issues: (1) the effect of competition on hospital quality, efficiency, and prices (if they are not fixed by a regulator); (2) differences in behavior that arise from different types of ownership status (non-profit vs. for-profit); (3) the extent to which demand for healthcare responds to quality; (4) the effect of mergers on cost savings, prices, and quality; and (5) the use of report cards and their impact on quality and providers' incentive to select low-severity patients.

These research questions have potentially important policy implications. Governments can encourage or discourage competition, or regulate it. They can favor one ownership status over another by introducing favorable tax regimes or by making a certain ownership mandatory. They may forbid or allow mergers through antitrust authorities and legislation. They can make report cards mandatory and publicly available.

The article focuses on key theoretical predictions, econometric strategy, empirical specification, and possible biases which may arise in testing such predictions. It also summarizes the main empirical findings for each theme. Moreover, because space is limited, the focus is on the hospital sector. Therefore, issues related to insurance markets, the pharmaceutical industry, provider labor markets, and the market of nursing and care homes are not investigated.

Effect of Competition on Quality and Prices

The effect of competition on hospital behavior has been the subject of an extensive empirical literature. One key focus has been on testing the effect of competition on the quality of hospital care under two main institutional settings: (1) a fixed-price regime of the Diagnosis-Related Groups (DRG) type, where each hospital receives the same price to treat a patient with a given diagnosis (this is the case in Medicare in the USA and in many European countries); (2) a variable-price regime, where each hospital is free to set prices in a private competitive market (like in the USA) or prices are the result of a bargaining procedure between the purchaser of health services (a private or a public insurer) and the hospital.

Under the first regime, the standard prediction from economic theory is that higher competition should lead to higher quality. Because more competition makes the demand more responsive to a marginal increase in quality (and prices are fixed), hospitals have a stronger incentive to increase quality because it will attract a larger volume of patients and generate higher revenues. Under the second regime, the prediction is less clear-cut. More competition will also reduce price and the price-cost margin of each hospital, therefore, weakening the incentive to increase quality. This effect goes against the former one (in terms of higher demand responsiveness) so that competition may lead to an increase or a reduction in quality depending on the size of the two opposing effects. A similar ambiguous prediction is that if prices are easily contractible, whereas quality is not, more competition may lead to a large reduction in price at the expense of a large drop in quality.

The basic empirical strategy within a cross-sectional framework to test the above predictions is the following:

$$q_i = \alpha + \beta c_i + \gamma z_i + \varepsilon_i, \qquad i = 1, \ldots, N \qquad [1]$$

where q_i is the quality provided by hospital i, c_i is a measure of competition, and z_i is a vector of control variables which also affect quality (e.g., volume of patients treated to control for learning-by-doing, dummies for different types of hospital, etc.).

There are different ways to measure competition in the health sector, which involves two main steps. The first step involves the definition of the catchment area of each hospital i, which gives the geographical area covering the potential competitors of hospital i (the area over which the hospitals 'compete'). There are two main approaches to define catchment areas, which is based on: (1) a fixed radius, that draws a circle of 30 km (or an alternative distance of 20, 40 km) from the hospital; or a fixed travel time, that uses road maps to define a catchment area of 30 min travel time from the hospital (or alternative times: e.g., 20 or 40 min); (2) a variable radius technique, where the catchment area is based on the residence (as measured by their postcode) of the patients going to hospital i: the catchment area is defined, for example, on the residence of the 70% of patients living closest to the hospital (or an alternative proportion like 60% or 80% decided by the researcher). Note that not all patients are included (100%) because this would often imply that the catchment area of some hospitals includes the whole country, which is clearly unrealistic (there will often be at least one odd patient who traveled from far away or whose postcode is mistakenly recorded). Fixed radius models are simpler to compute but ignore the actual residence of the patients going to each hospital i. Variable radius models are more accurate because they address this problem but computationally more intensive. They also raise some endogeneity issues: hospitals with higher quality may have larger catchment areas. This is usually addressed by defining catchment areas on the basis of predicted rather than actual hospital choice. In practice, this involves estimating a multinomial logit model of a patient's choice as a function of distance and other key regressors. Predicted market shares are then computed for each hospital and used to compute a competition measure.

Once the catchment area has been defined, the second step involves measuring the degree of competition within this area. The simplest way to measure competition is to count the number of hospitals (N) within the catchment area. Equivalently, the degree of concentration can be measured by

$1/N$. However, this measure has the disadvantage that it implicitly assumes that all hospitals have the same size: the market structure of a duopoly where each hospital has 50% of the market can be quite different from one where one hospital has 90% of the market and the other only 10% of the market. In the latter case, the market is less competitive than in the former one because one provider has a dominant position.

A modified version of the simple competition measure is the number of hospitals in the catchment area divided by the population of the catchment area (P): the measure is therefore N/P. For a given number of providers, areas with larger population effectively imply a lower degree of competition.

A second measure which takes into account the different size of each hospital is the widely used Herfindahl Index (HI) define the market share of each hospital i as $s_i = \gamma_i/Y_i$, where γ_i is the number of patients treated by hospital i and Y_i is the total number of patients treated within the catchment area of hospital i. The HI is given by the sum of the square of each market share: $HI_i = \sum_{i=1}^{n} s_{ji}^2$. Note that if all hospitals are identical, then the HI_i is equal to $1/N$, and the two measures (HI and the reciprocal of the number of hospitals) coincide. However, if the market shares are different then the two measures will differ. Suppose there are only two providers ($N=2$) and that one hospital has 25% of the market whereas the other hospital has 75% of the market. Then, the HI is $1/4+9/16=0.81$, which is larger than 0.5 (the HI when each provider has 50% of the market). The idea is that an asymmetric market is a less competitive one. As mentioned above, one problem with the computation of the HI based on 'actual' market shares is that these can be endogenous if, for example, hospitals with higher quality have larger market shares. To address this problem, the HI is often computed on the basis of predicted market shares (based on multinomial choice models).

Quality of care is the other key variable in the empirical model described in eqn [1]. It can be measured in a variety of ways. The most common one in recent literature makes use of mortality rates for (emergency) patients with acute myocardial infarction, more commonly known as 'heart attack.' These are considered to be a marker of the quality in the hospital. Other measures include total hospital mortality rates (adjusted by casemix), mortality rates for patients with stroke, pneumonia, heart failure, and other specific conditions, readmission rates within a month of discharge, and infection rates. In general there have been mixed findings in the literature on the effect of competition on quality with prices either fixed or variable and endogenously determined (see Gaynor and Town (2011) for a detailed review).

A similar approach to the one described in eqn [1] can be used to estimate the effect of competition on prices charged by hospitals by replacing the dependent variable q_i with price p_i. The empirical evidence is mainly from the USA, for the market not covered by Medicare and Medicaid (where prices are fixed), and confirms the expected negative effect between competition and prices. There is limited evidence from Europe where prices are regulated (and therefore fixed) in several publicly funded systems: Competition on price occurs mainly in the private sector, which is often small and data on prices are difficult to collect.

Ownership

A long-standing question in the health economics literature is whether profit and non-profit hospitals differ in their behavior. Most of the literature has focused on differences in quality and efficiency (with more recent studies focusing on quality). A fewer number of studies has focused on differential incentives to upcode (also known as DRG creep) and to select more profitable patients. Regarding quality, on one hand non-profit hospitals may have an incentive to provide higher quality as they are under less pressure to increase profits; on the other hand, they are less responsive to demand variations. Standard economic theory also predicts non-profit hospitals to be less efficient because they cannot appropriate the financial surplus (or distribute it), they may have weaker incentive to keep costs down (or to be more efficient).

The typical basic regression for quality differences in a cross-sectional framework is the following one:

$$q_i = \alpha + \beta s_i + \gamma z_i + \varepsilon_i, \qquad i = 1, \ldots, N \qquad [2]$$

where q_i is the quality provided by hospital i, s_i is a dummy variable for hospital status and is equal to 1 if hospital is for profit, and z_i is a vector of control variables. Quality can be measured through mortality rates and adverse events such as surgical complications and medical errors. The empirical evidence from the USA is extensive but mixed. The recent review by Eggleston *et al.* (2008) find that whether for-profit hospitals provide lower or higher quality than non-profit ones depends on the specific context like the region, the data source, and the period of analysis. As an overall conclusion they suggest that as a whole quality seems to be lower among for-profit hospitals.

Some recent studies rely on a panel-data approach as opposed to a cross-sectional one, focusing on the effect of changes in ownership status over time (either from non-profit to for-profit or from for-profit to non-profit). This approach allows controlling for unobserved heterogeneity, i.e., the possibility that differences in quality between for-profit and non-profit hospitals simply reflect different location, catchment areas, casemix, or other unobservable variables. The econometric framework is therefore modified as follows:

$$q_{it} = \alpha + \beta n_{it} + \delta f_{it} + \gamma z_i + d_i + d_t + \varepsilon_{it}, \qquad i = 1, \ldots, N, \quad t = 1, \ldots, T \qquad [3]$$

where n_{it} is a dummy variable equal to 1 from the time a hospital converts from for-profit to non-profit, f_{it} is a dummy variable equal to 1 from the time a hospital converts from non-profit to for-profit, d_i accounts for hospitals' fixed effects to control for unobserved heterogeneity, and d_t is a vector of year dummies to control for a time trend (e.g., health outcomes improve over time due to technology development).

Some literature finds that the change in status from non-profit to for-profit reduces quality as measured by higher mortality rates for patients with heart attacks (deaths at 1, 6, and 12 months). One potential problem with such approach is that the switch from non-profit to for-profit status may not be random. For example, it can be argued that hospitals with declining quality are more likely to change status. To address this issue, authors have interacted the dummy variables on

hospital conversion *(f, n)* with time dummies for the years preceding and following the conversion. This allows detecting whether the converting hospitals were already exhibiting a decline in quality before the conversion.

Others instead have addressed the issue by using a matching-estimator approach, for example, using propensity score matching to identify a control group which has a distribution of covariates that is in line with the distribution of the covariates in the treatment group. The estimation procedure first estimates the conditional probability of a hospital being for-profit for a given set of covariates (the propensity score) and then it matches each hospital (which switches from non-profit to for-profit) with a control hospital which has the closest propensity score. The covariates on which the hospitals are matched include hospital size, patient types, and financial state.

Most studies treat ownership as exogenous in eqn [2]. However, that may not necessarily be the case. For instance, patients may choose the type of hospital (for-profit vs. non-profit) based on how severe they are and this may generate endogeneity: the quality of care (the dependent variable) affects who goes to a profit versus a non-profit hospital. One strategy is to use an instrumental-variable approach with instruments that include the distance to the closest non-profit hospital, and the difference in the distance between the closest non-profit hospital and the closest hospital (regardless of being for-profit or non-profit). Distances will affect the choice between a for-profit and a non-profit hospital, but should not be correlated with patients' severity.

For-profit and non-profit hospitals may also differ in their incentive to upcode, i.e., to code patients in more remunerative fields. Payment systems of the DRG-type are complex and involve at least 500 different prices that depend on patient's diagnosis and treatment. There is evidence in the USA that for-profit hospitals tend to upcode more than non-profit ones. Moreover, private hospitals, regardless of the for-profit or non-profit status, may engage in cream-skimming of patients leaving the unprofitable ones to the public sector.

Regarding differences in efficiency, in his review of 317 published papers on frontier efficiency measurement, Hollingsworth (2008) concluded with some caution that public/non-profit hospitals tend to be more efficient than for-profit ones. The intuitive result that for-profit hospitals are more efficient than non-profit ones is therefore not confirmed in general. Efficiency is generally measured through parametric models, i.e., the estimation of stochastic frontiers, or nonparametric ones, i.e., data envelopment analysis. Some parametric studies focus on technical efficiency and derive efficiency scores by estimating the following production frontier model (within a cross-sectional framework):

$$y_i = \alpha + \beta x_i + \gamma z_i - e_i + \varepsilon_i\,, \qquad i = 1, \ldots, N \qquad [4]$$

where y_i is typically the number of patients treated by hospital i (weighted by DRG weight to control for different casemix of the hospital), x_i includes a range of inputs (number of beds, doctors, nurses), and z_i includes a range of control variables (ideally quality); e_i is hospital efficiency and ε_i is the error term. This model requires assumptions about the distribution of the efficiency term. The most common ones are the Half Normal, Truncated Normal, and Gamma. The efficiency scores derived following this methodology have been criticized for two main reasons: (1) they seldom control adequately for quality differences, so that efficiency scores may reflect higher quality; (2) they may be sensitive to outliers and the specific distributional assumptions of the efficiency term. The approach in eqn [4] has been extended to allow for multiple outputs (e.g., patients in different specialties, emergency vs. nonemergency patients, outpatients vs. inpatients). This can be pursued with a 'Shepard distance function' approach that ultimately involves using one output on the left-hand side (LHS) and the other 'normalized' outputs on the right-hand side (RHS) or a 'polar coordinates' approach using the Euclidian norm of the outputs on the LHS and polar coordinates angles on the RHS. These approaches can be criticized on the ground that output variables appear both on the LHS and the RHS of the regression model, possibly generating endogeneity.

Equation [4] focuses on technical efficiency. Other studies focus on allocative efficiency as well by estimating a cost frontier as opposed to a production frontier. In such a case the model is:

$$C_i = \alpha + \beta y_i + \gamma w_i + \sigma z_i + e_i + \varepsilon_i, \qquad i = 1, \ldots, N \qquad [5]$$

where C_i is total cost of hospital i, y_i is (a vector of) output, w_i is the (average) salary for different types of workers (doctors, nurses, administration), and z_i is a range of control variables (quality, whether the hospital has teaching functions, etc.). This approach has also the advantage of accommodating multiple outputs without any additional assumptions.

As mentioned above, stochastic frontier techniques have been criticized for imposing distributional assumptions on the efficiency term and to rely on these to disentangle efficiency from noise. These assumptions can be relaxed by using panel data and estimating models of the following type:

$$y_{it} = \alpha + \beta x_{it} + \gamma z_{it} - e_i + \varepsilon_{it}, \qquad i = 1, \ldots, N \qquad [6]$$

where e_i is a fixed effect at hospital level. The distributional assumptions are weaker. This approach still relies on having good control variables (e.g., on quality) so that e_i can be interpreted as efficiency as opposed to a control for unobserved heterogeneity (where efficiency is only one determinant). Once the efficiency scores are obtained, the second step simply involves regressing the efficiency scores on hospital's ownership type and other determinants.

Choice Models

At the heart of many health economic models is the assumption that demand of healthcare providers responds to quality. Providers with higher quality establish a good reputation and attract a larger number of patients. The estimation of the magnitude of the demand elasticity to quality has implications for policy design. For example, if hospital elasticity is high, policymakers will need to rely less on costly audits to ensure high standards of quality. Providers will have an incentive to provide high quality in order to attract patients and increase revenues. Similarly, one precondition for competition to encourage quality of care (already discussed above) is that demand responds to quality.

The assumption that providers' demand responds to quality has been tested empirically by modeling patients' choice of a hospital among a set of alternative ones. A common model is the conditional logit model which can be motivated within a random utility framework (McFadden, 1974). Suppose that the utility of patient j choosing hospital i is equal to $U_{ji} = \beta d_{ji} + \gamma q_j + \varepsilon_{ji}$, where d_{ji} is the distance between patient's j residential address and hospital i address, q_j is the quality of hospital j (e.g., mortality rates, readmission rates), and ε_{ji} is the unobserved component of utility. If ε_{ji} are independently and identically distributed, and follow type 1 extreme value distribution, then the probability of patient j choosing hospital i out of a total of N hospitals is given by:

$$p_{ij} = \frac{\exp(\beta d_{ij} + \gamma qi)}{\sum_{l=1}^{N} \exp(\beta d_{lj} + \gamma ql)}, \qquad i = 1, \ldots, N \qquad [7]$$

which is known as the conditional logit model.

The analysis is usually conducted for patients in need of a specific treatment (i.e., coronary bypass, percutaneous transluminal coronary angioplasty, kidney transplant, cataract surgery, hip replacement) or with a certain condition (i.e., acute myocardial infarction, pneumonia). A key regressor (or control variable) is the distance between the patient's residence (postcode) and the hospital, which in all models turns out to be the main predictor of patients' choice. The hospital choice is also affected by quality, as proxied by mortality rates, readmission rates, complication rates, and waiting times. Overall, this empirical literature finds that higher quality (as well as distance) increases the probability of choosing a provider, though the demand elasticities with respect to quality are small for most procedures and conditions.

To control for time-invariant unobserved heterogeneity, some studies estimate the conditional logit with panel data including hospital fixed-effects, therefore relying on variations in quality (mortality rates, readmission rates, waiting times) over time to identify the causal effect of quality on demand. One limitation of the conditional logit is that the relative probability of choosing any two hospitals is independent of any other alternative hospital (known as the independence of irrelevant alternatives). The logit models can also be extended to allow for latent classes (latent-class multinomial logit) and therefore allow the responsiveness of demand to quality to vary for different classes of patients (normally two), which are not observable to the researcher.

Mergers

A growing empirical literature has investigated the effect of mergers on efficiency (cost savings), prices, and quality. From a theoretical perspective, hospital mergers can lead to reductions in costs and an increase in efficiency through better management, exploitation of scale economies, and elimination of duplicate services. From an antitrust perspective, a merger also increases the market power of merging hospitals, which may allow them to increase prices at the expense of consumers. Therefore, one may expect price to reduce following a merger when the efficiency savings, which tend to reduce price, overcome the reduced competition effect, which tends to increase price. The lower degree of competition may also induce merged hospitals to skimp on quality because demand is less responsive to quality changes.

The basic econometric framework is the following:

$$y_{it} = \alpha + \beta m_{it} + \gamma x_{it} + d_i + d_t + \varepsilon_{it}, \qquad i = 1, \ldots, N, \quad t = 1, \ldots, T \qquad [8]$$

where y_{it} is either cost, quality, or price, m_{it} is a variable equal to 1 from the time the hospital has merged (and 0 otherwise), x_{it} includes a range of controls. Note that for 'merging' hospitals, i refers to the sum of the costs of the two merged hospitals or the average price or quality in the merging hospitals.

One econometric problem with empirical studies evaluating the effects of mergers is that mergers may be endogenous: for example, a hospital merges because costs are high or quality is low (so that m_{it} depends on y_{it}). One way to account for such endogeneity is through the use of propensity score matching. This involves the estimation of a probit that models the probability of merging for each hospital i as a function of set of characteristics (the number of hospitals in the market, whether the hospital is for profit, non-profit, or a teaching hospital, etc.). Hospitals are then matched on the basis of predicted probabilities, i.e., the propensity to merge. Another potential econometric issue is that nonmerging hospitals may also react to mergers, for example, by also increasing prices or reducing quality, and may therefore not act as a good control group (Dafny, 2009). To address this issue, she uses as an instrument a variable which measures whether hospitals are colocated, the idea being that distance should be correlated with the probability of merging but not with the outcomes. 'Regression to the mean' may also be an issue if hospitals with high cost are followed by periods of low cost.

Most studies find that prices increase following a merger (Gaynor and Town, 2011). Dranove and Lindrooth (2003) find that in the USA mergers reduce hospital costs by approximately 14% during the 2–3 years following the merger. Previous studies have generally not found much evidence of cost savings. Ho and Hamilton (2000) find that mergers in California have no effect on the quality of care as measured by mortality rates for patients with heart attack and stroke, though readmission rates and early discharges for newborns increased in some cases. Gaynor Laudicella and Propper (2012) examine the impact of large number of mergers in England on a range of outcomes including financial performance, productivity, waiting times, and clinical quality. They find that mergers had no effect on quality.

Report Cards

Report cards are increasingly used in the healthcare sector to provide information on the quality of healthcare providers. They are intended mainly to help patients choosing the provider which matches better the needs of the patient, to improve choice and to encourage providers to increase quality in order to attract more patients. Typically, report cards provide mortality rates and readmission rates for specific conditions or procedures, coronary bypass being the most

common one. In the USA, the State of New York was among the first to introduce such cards and for this reason has been intensively investigated in the empirical literature. Report cards can be provided at hospital or at doctor/surgeon level.

Because report cards have been introduced in different states at different times (and never introduced in some states), their effect is often investigated within a natural experiment set up with some states in the USA acting as the control group. There is evidence that market shares may be influenced by report cards with providers with better reports having larger market shares. One potential adverse effect of report cards is that they may encourage providers to treat (select) patients with lower severity who are at a lower risk of mortality and readmission. Dranove *et al.* (2003) provide evidence for such selection behavior, observing that the introduction of report cards was followed by a reduction in the average severity of illness, as measured by hospital utilization before admission, with the severity of patients in teaching hospitals instead increasing.

Conclusion

This article has reviewed econometric techniques and studies aimed at characterizing the market structure in the hospital sector. A range of econometric techniques have been employed to investigate the effect of competition, differences in behavior by ownership status, demand responses to quality, mergers, and report cards. Several studies make use of natural experiments exploiting exogenous shocks (e.g., in the evaluation of competition or report cards). If control groups are not well defined, propensity score matching has been used to account for self-selection and create pseudo control groups (e.g., in the case of conversion of for-profit to non-profit hospitals and mergers). When natural experiments are not available, endogeneity caused by unobserved heterogeneity or reverse causality is an issue. In such cases, panel data and instrumental variables have been used (e.g., in the evaluation of for-profit vs. non-profit hospitals). Conditional logit models have been usefully employed to estimate the responsiveness of hospital demand to quality.

As a whole these studies suggest that the market structure matters in the health sector, though not always in the expected way, and that the results may differ depending on country, outcome measure, and econometric methodology employed.

Equality of Opportunity in Health

P Rosa Dias, University of Sussex, Brighton, UK

Background

Normative Context

In recent years, the concept of inequality of opportunity, rather than inequality of achieved states, has received growing attention in the economic literature. The simple advocacy of equal health, for example, fails to hold individuals accountable for their choices. This can be seen as significant limitation.

Equality of opportunity co-opts one of the sharpest ideas in the antiegalitarian arsenal: The notion of responsibility. By compensating for the impact of circumstances beyond individual control, yet holding individuals responsible for the consequences of their choices, equality of opportunity is an appealing compromise between strict equality of health and mere equity of formal rights. It has thus been increasingly advocated by policy makers, as is made clear in World Bank (2005) which focuses on the inequality issue.

This theoretical evolution reflects a number of recent developments in political philosophy, arguably prompted by the seminal work of John Rawls and Amartya Sen. Both Rawls' equality of social primary goods and Sen's proposed equality of capabilities move away from the social goal of equalizing subjective welfare. They propose that, once primary goods or capabilities are equally distributed, any residual inequality should be deemed a legitimate consequence of individual choice, hence of individual responsibility. Ronald Dworkin advanced this proposal by arguing that equality of welfare cannot be a valid equity criterion for it fails to make individuals accountable for their preferences, namely, those preferences they are happy to have. The problem thus becomes one of finding the distribution of resources that appropriately compensates individuals for their dissimilar endowments (physical resources, talents, and handicaps), while making them responsible for their preferences. This rationale leads Dworkin to propose the criterion of equality of resources, which attracted important criticisms, such as those raised by Richard Arneson and Gerald Cohen. Cohen shows that Dworkin's separation between preferences and resources can be intractable in practice: Should one be made responsible for childhood preferences that are chiefly instilled by one's social environment? This debate has prompted key progresses in social choice theory, which have rendered these new ideas operational within an analytical framework known as the equal-opportunity approach.

The Roemer Model of Equality of Opportunity

Equality of opportunity has been given different formal expressions in the social choice literature, such as in early proposals by Marc Fleurbaey and Walter Bossert. A related strand of research focuses on measuring opportunity sets, taking into account the intrinsic value of individual freedom in the ranking of social states. Despite the theoretical appeal of these contributions, they have proved too abstract to prompt related empirical work. Largely for this reason, the workhorse of the applied literature on inequality of opportunity in health has been the model proposed by Roemer (1998, 2002).

The Roemer model sorts all factors influencing individual attainment between a category of effort factors, for which individuals should be held responsible and a category of circumstance factors, which, being beyond individual control, are the source of illegitimate differences in outcomes. It should be noted that, in this framework, effort is not limited to human exertion and comprises all the determinants of health outcomes over which individuals have control. Also, the classification of the determinant of human achievement as either circumstances or effort is partly normative and partly informed by available empirical evidence. In the case of health, we may think of the outcome of interest as health as an adult (H) and define a health production function, $H(C,E(C))$ where C denotes individual circumstances and E denotes effort. Circumstances affect the health outcomes of individuals and social groups, directly and through their influence on effort factors.

The recent medical and economic evidence on the early determinants of health has emphasized the importance of a number of circumstantial factors. The fetal origin hypothesis stresses the role of parental socioeconomic characteristics as key determinants of *in utero* fetal growth which, in turn, condition long-term health. The life course models, which emphasize the impact of deprivation in childhood on adult health and longevity, and the pathways models, suggest that health in early life is important mainly because it will condition the socioeconomic position in early adulthood, which explains disease risk later in life. There is also evidence on determinants of health that, although affected by circumstances, are, at least partially, within individual control and therefore constitute effort factors in the context of the Roemer model. Lifestyles such as diet and physical exercise are good examples of such factors.

The Roemer model defines social types consisting of the individuals who share exposure to identical circumstances. Types can thus be defined using the set of observed individual circumstances in the data. In practice, it is up to the researcher to identify circumstances that lead to a meaningful partition of the population of interest. Factors such as parental socioeconomic background and region of birth have often been used by applied economists to partition the population, but other variables such as inborn cognitive ability and childhood health have also been used. It is assumed that the society has a finite number of T types and that, within each type, there is a continuum of individuals. A fundamental aspect in this setting is the fact that the distribution of effort within each type (F^t) is itself a characteristic of that type (t); because this is beyond individual control, it constitutes a circumstance.

 doi:10.1016/B978-0-12-375678-7.00210-8

In general, it is not possible to compare directly the levels of effort expended by individuals from different types because circumstances partly determine outcomes. For example, the number of times per week one does physical exercise is partly determined by individual choice (effort) and also influenced by parental background, social milieu, and peer pressure (circumstances). Thus, two individuals who exercise exactly the same number of times per week, may be interpreted as exerting very different levels of effort, depending on their circumstances. To make the degree of effort expended by individuals of different types comparable, Roemer proposes the definition of quantiles of the within-type effort distribution (e.g., the distribution of weekly frequency of physical exercise within each type): Two individuals from different types are deemed to have exerted the same degree of effort if they sit at the same quantile (π) of their type's distribution of effort. When effort is observed, this definition is directly applicable. However, if effort is unobservable, an additional assumption is required: By assuming that the average outcome, health in this case, is monotonically increasing in effort, i.e., that healthy lifestyles are a positive contribution to the health stock, effort becomes the residual determinant of health once types are fixed; therefore, those who sit at the πth quantile of the outcome distribution also sit, on average, at the πth quantile of the distribution of effort within this type.

How is the equality-of-opportunity policy characterized in this framework? Ideally, this policy should ensure identical health across types at identical levels of effort. Let us assume that, given our health production function, the highest health level attainable by type (t) given quantile level of effort (π) and policy (ϕ) is given by the indirect outcome function $v^t(\pi, \phi)$. In this setting, the equality-of-opportunity policy πth equalizes the highest attainable health level across types for identical values of π, i.e., $v^t(\pi, \phi^{\mathrm{E-opp}}) = v^{t'}(\pi, \phi^{\mathrm{E-opp}})$.

In addition, because the resources available for policy interventions are generally finite, one also needs to ensure that $\phi^{\mathrm{E-opp}}$is feasible. However, this poses a problem: As shown in Roemer (2002), it will not be possible, in general, to find an equality-of-opportunity policy that simultaneously satisfies the feasibility requirement. Thus, in practice, instead of literally equalizing v between types at each π, one maximizes the minimum value of v across types at each π.

But we are not finished yet. In general one is not interested in finding the equality of opportunity for a sole particular value of π: Healthcare policy does not usually apply only to those at say, the qth quantile of weekly frequency of physical exercise. The problem is that there are different optimal policies for different values of π, even if interest in the subset of efficient policies is restricted. So how is the equality-of-opportunity policy found? A number of compromise solutions have been suggested in the literature. The most widely used in practice (proposed by Roemer (2002)), consists of aggregating over all policies (each defined for a particular value of π) and giving each of them the same weight.

Ex Ante and *Ex Post* Inequality

So far, this account of inequality of opportunity has focused on inequalities between groups of individuals, called types, who share exposure to identical circumstances. This approach is the most prevalent in applied work and is known as the *ex ante* approach. The term *ex ante* refers to the fact that this approach can be used in cases where circumstances are known, but effort has not (yet) been exerted by the individuals.

There is, however, an alternative approach to the concept of equality of opportunity. Assume that effort is observed. The population of interest can thus be split into groups, known as tranches, which correspond to levels of exerted effort (e.g., number of times per week one does physical exercise). In this setting, inequality of opportunity corresponds to differences in outcomes within each tranche, i.e., amongst individual who have exerted the same level of effort. The source of unjust inequalities is still the variation across individual circumstances, but this line of research is known as the *ex post* approach, because it requires information on the level of effort already exerted by individuals.

An important question is the extent to which the *ex ante* and the *ex post* approaches are similar. Although they share points in common, they are fundamentally different. As mentioned earlier, equality of opportunity requires the elimination of differences in outcomes that are due to circumstances but not to effort. This is known as the principle of compensation. It should however be noticed that this principle of compensation leads to different compensatory policies according to whether one takes the *ex ante* or the *ex post* approach. In the *ex ante* case, compensation requires transferring resources from individuals in the most advantaged types to people in least advantaged ones. But in the *ex post* approach, the required transfers are within-tranche transfers, amongst individuals who exert the same level of effort. Thus, *ex ante* and *ex post* compensation are generally incompatible.

Another important aspect concerns the definition of fair rewards to effort. Individuals with the same circumstances are considered. The theory of equality of opportunity described so far is silent regarding the fair way of rewarding different levels of effort amongst such individuals. There is at present an intense debate on the way to combine the compensation principle with a suitable reward principle, but a definite solution has not yet been reached. Fleurbaey and Schokkaert (2012) describe a number of possible avenues for achieving this within the framework of equality of oportunity, although J. Roemer has recently argued that the definition of what constitutes fair rewards to effort should instead come from an ancillary theory, which limits the degree of inequality that is acceptable. In addition, Fleurbaey and Peragine have shown that the available options for combining the principles of compensation and reward depend vitally on whether the researcher adopts the *ex ante* or the *ex post* approach. Although, in general, the principles of compensation and reward are theoretically incompatible, this conflict can be avoided when one adopts the *ex ante* approach (but not the *ex post* one).

Partial Orderings and Inequality Measures

How can inequality of opportunity be identified in practice? A number of different approaches have been proposed, based on partial equality-of-opportunity orderings. The most widely

used in applied work defines equality of opportunity based on stochastic dominance conditions. The rationale is the following. Denoting by $F(.)$ the cumulative distribution function of health (CFD), a literal translation of the idea of equality of opportunity would correspond to the situation in which the distribution of health outcomes does not depend on social types, i.e., $F(.|t) = F(.|t')$. This condition is, however, unlikely to hold in any society and hence is too stringent to be applied to real data. Instead one could assume that the data be deemed consistent with the existence of inequality of opportunity when the social advantage provided by different circumstances can be unequivocally ranked by stochastic dominance criteria, i.e., $F(.|t) \succ_{SD} F(.|t')$. First-order stochastic dominance (FSD) holds for the whole class of increasing utility functions; thus if the distribution of health outcomes of type t FSD dominates that of type t', this means that all individuals with an utility function that is increasing in health (i.e., who prefer better health to worse health) would prefer the outcomes of type t to those of type t'. Although one may extend this partial ordering to second- and even third-order stochastic dominance criteria, most of the applied literature has been focused on first-order comparisons. These are better suited for the ordinal outcomes that are often used in health economics, such as self-assessed health. Moreover, in addition to their clear meaning in terms of welfare and preferences, these conditions have an important attractive feature: They are statistically testable in practice.

Partial orderings are useful but often inconclusive, hence complete orderings have been proposed to measure inequality of opportunity. In this literature, an analysis of inequality of opportunity in Brazil carried out by Bourguignon *et al.* (2007) prompted a number of methods collectively known as the parametric approach to the measurement of inequality of opporunity. The idea is intuitive. Earlier, the definition of the health production function of individual health outcomes, $H = f(C, E(C))$ was given. The same specification applies to the health outcomes of social groups. Thus, a parametric regression model can be used to estimate the counterfactual distribution of outcomes that would be brought about by assigning the same circumstances to all the individuals, i.e., $\tilde{H} = f(\tilde{C}, E(\tilde{C}))$. Inequality of opportunity can then be measured by an index $\Gamma = 1 - \frac{\tilde{H}}{H}$.

A different approach, known as nonparametric supposes that one replaces each individual outcome in H by one's type-specific mean (μ^t), obtaining the smoothed distribution of outcomes H^C. This eliminates, by construction, all within-type inequality, hence a relative inequality index $I(H^C)$ measures exclusively between-types disparities, which constitute inequality of opportunity. Alternatively, one may replace the outcome of each individual i outcome (h_i) by $\frac{\mu}{\mu^t} h_i$, where μ is the mean in the population of interest, obtaining the standardized distribution H^E. In this case, all the between-types inequality is eliminated, leaving solely within-type inequality. As a result, inequality of opportunity corresponds to the difference between the total inequality in health outcomes, $I(H)$, and the inequality measured by $I(H^E)$.

Two important practical issues arise in this context. The first concerns the choice of an appropriate inequality index I, given that, in general, the smoothing and standardizing approaches lead to different results. There is a class of measures (known as path-independent decomposable measures, for which these two approaches lead to the same result. Amongst this family of measures, the mean-log deviation has been very widely used in applied work. The second issue of interest is that of choosing between the parametric and the nonparametric approaches. Nonparametric methods are, in general, more robust in the sense that they do not depend on parametric assumptions. They are, however, more data-hungry: When the information on the circumstances set is rich the number of types increases, leading to data insufficiency. This is less of a problem for the parametric approach, which, in addition, allows the estimation of partial effects, namely, circumstance-specific inequality shares. Nonetheless, this comes at the expense of an increased reliance on structural assumptions.

Another index that has been increasingly used in applied work is the Gini-opportunity index proposed by Lefranc *et al.* (2009). This is a modified Gini coefficient that quantifies the inequality between the different types' opportunity sets. The area underneath a type's generalized Lorenz curve, and hence the value of its Sen evaluation function $A_j = \mu_j(1 - G_j)$ constitutes a cardinal measure of this type's opportunity set (G_j denotes the Gini coefficient and μ_j the average outcome within that social type). Thus, in the context of inequality of opportunity, one may rank types (not individuals) according to their respective values of the Sen evaluation. For any pair of types, denoted i and j, and starting from the one with the smallest value of the Sen evaluation function, the Gini-Opportunity index across types i to k is defined as: $G - \text{Opp} = \frac{1}{\mu} \sum_i^k \sum_{i<j} \left[p_i p_j (A_j - A_i) \right]$. This index gives the weighted average of the differences between the types' opportunity sets in which the weights (p) are the sample weights of the different types. The value of all these indices is highly sensitive to the number of types; this can be a problem because, as seen before, the number of types is, in practice, defined subjectively by the researcher.

It should finally be noted that a good measure of inequality of opportunity in health should be able to bring together multiple circumstances and, given that health is an inherently multidimensional concept, multiple dimensions of health outcomes. This also applies to the case of inequality of opportunity in healthcare, which incorporates a number of different dimensions, such as general practitioner visits and specialist visits. Rosa Dias and Yalonetzky (2013) have recently addressed this issue by drawing on the segregation literature and proposing new measures that are applicable when health (or healthcare) is proxied by a finite number of ordinal indicators.

Inequality of Opportunity in Health Economics: Theoretical Contributions and Empirical Evidence

Theoretical Contributions in Health Economics

It is possible to argue that inequality of opportunity is already the implicit equity concept in some earlier contributions in health economics, such as Alan Williams' fair innings argument and the Rawlsian approach to the measurement of health inequalities proposed in Bommier and Stecklov (2002). Yet, although the volume of applied research on

inequality of opportunity in health has grown rapidly over the past few years, the amount of theoretical work, has been comparatively smaller.

Fleurbaey and Schokkaert (2009) make an important contribution toward incorporating the analysis of inequality of opportunity in health in the broader framework of responsibility-sensitive egalitarianism. They propose analyzing inequality of opportunity in health within the framework of a complex structural model that encompasses simultaneously the demand for health, lifestyle and healthcare, labor supply, and income distribution. In this model, the health stock depends on a range of factors, encompassing the consumption of healthcare and other goods, job characteristics, socioeconomic background, genes, and unanticipated health shocks. Labor income is endogenous and depends on various factors including individual ability. The demand for healthcare also depends on multiple factors, including supply-side variables and individual demand for supplementary health insurance.

This model can be solved in two stages. First, individuals decide on their desired level of supplementary health insurance. Second, for that level of insurance coverage, they maximize utility subject to income constraints, time constraints, and to the supply of healthcare constraints. This allows for the joint determination of the demand for health care, consumption goods, and individual labor supply. Finally, armed with the optimal values for these, the optimal levels of health, income, and utility are endogenously determined by the model.

This complex structural model is the most encompassing framework proposed for the analysis of unfair health inequalities (including inequality of opportunity). However, the multiple and reciprocal causal relationships that it embodies poses serious operational challenges to the empirical identification of the model.

Another aspect that has received attention in the health economics literature relates to the fact that, in practice, it is often not possible to observe the full set of relevant circumstances influencing health outcomes. Fleurbaey has shown that this issue, known as the partial-circumstance problem, may bias the measurement of inequality of opportunity in health. At present, there has not yet been found a reliable way to derive theoretical bounds for this bias. Rosa Dias (2010) examines the practical relevance of this matter by proposing a simple behavioral model of inequality of opportunity in health that integrates Roemer's framework of inequality of opportunity with the Grossman model of health capital and demand for health. The model generates a recursive system of equations for the health stock and each of a series of effort factors such as the weekly consumption of calorific food, alcohol, and the weekly frequency of physical exercise. To take into account the role of unobserved heterogeneity, the system is then jointly estimated by full information maximum likelihood with freely correlated errors. The results suggest that, when unobserved heterogeneity in the set of circumstances is taken into account, the estimates of the recursive relationship between circumstances, effort, and health outcomes change considerably, thereby corroborating the empirical relevance of the partial-circumstance problem. García-Gomez *et al.* (2012) use an analogous estimation strategy to implement the framework of Fleurbaey and Schokkaert (2009), thereby modeling the channels through which circumstances affect health outcomes in adulthood. Armed with this behavioral model, García-Gomez *et al.* (2012) showed that distinguishing between these different channels is useful not only as a means of avoiding the partial-circumstances problem, but also in order to perform a sensitivity analysis of the results with respect to different normative positions regarding the factors that should be considered, i.e., circumstances and effort.

A different, although related, issue concerns the correct way to treat the partial correlations between circumstances and effort. Jusot *et al.* (2013) examine the practical relevance of this issue for the measurement of inequality of opportunity in health by applying a reduced-form approach to data from a large French survey. Interestingly, their results suggest that adopting fundamentally different normative approaches to this matter makes little difference, in practice, for the measurement of health inequalities.

Empirical Evidence

In recent years the number of applications of the inequality-of-opportunity framework to health has grown rapidly. Rosa Dias (2009) and Trannoy *et al.* (2010) examine the existence and magnitude of inequality of opportunity in health using, respectively, data from the UK and France. Employing the stochastic dominance testable conditions proposed by Lefranc *et al.* (2009), they find that, in both countries, there is clear inequality of opportunity in self-reported health between individuals of different parental background (defined according to the father or male head of household's occupation). Furthermore, these empirical applications show that shifting the focus from inequality in health to inequality of opportunity changes the results significantly: For example, in the case of the UK, Rosa Dias (2009) shows that an unusually rich set of circumstances that include parental background, childhood health, ability, and social development account for just approximately one-fourth of the total inequality in health.

These articles also show that inequality of opportunity in health is substantial in the countries studied: Trannoy *et al.* (2010) show that a hypothetical complete nullification of the influence of observed circumstances on health would, in the case of France, leads to a 57% points reduction in the self-reported Gini coefficient. Jusot *et al.* (2010) pursue this line of research further by using data from the 2004 Survey on Health Ageing and Retirement in Europe to compare the extent of inequality of opportunity in health across 10 European countries. Their results suggest that the magnitude of this type of inequality is markedly different between blocks of countries: Inequality of opportunity in self-assessed health is systematically higher in Southern Europe than in Northern European countries. In addition, this article makes clear that there are also differences regarding the most important circumstances in each of the countries.

Another important aspect concerns the evolution of inequality of opportunity in health over the lifecycle: Do circumstances affect health outcomes more heavily in the early years of life, young adulthood, or in old age? Rosa Dias (2009) provides some empirical evidence on this issue, using data from a UK cohort study; results from this study show that the influence of circumstances on self-reported health at 23, 33,

42, and 46 years of age is remarkably constant. This issue has been reexamined in greater depth by Bricard *et al.* (2012). This article proposes two alternative strategies for quantifying inequality of opportunity in health over the lifecycle. From an *ex ante* perspective, an aggregate measure of the lifetime health stock is estimated for each individual; inequality of opportunity in this aggregate health is then measured between individuals or groups. Alternatively, from an *ex post* perspective, health inequalities are measured across individuals at each stage of their lifecycle, before aggregating inequalities over the lifetime. Bricard *et al.* (2012) show that these two perspectives are grounded on different normative principles, and that they lead to different results when applied to real data.

Finally, an area that is, at present, receiving growing attention is the application of the inequality-of-opportunity framework to the normative evaluation of concrete policy interventions. Figheroa *et al.* (2012) propose a methodology to evaluate social projects from an equality-of-opportunity perspective by looking at their effect on the distribution of outcomes conditional on observable covariates. They apply this approach to the evaluation of the short-term effects of Mexico's well-known Oportunidades program on children's health outcomes. Jones *et al.* (2012) also proposes a normative framework, but designed for the evaluation of complementary policy interventions such as the health effects of educational interventions. This article grounds this proposal on Roemer's (2002) model of inequality of opportunity, and applies it to data from a large-scale UK educational reform. Although Figheroa *et al.* (2012) focus on the evaluation of short-run policy effects, Jones *et al.* (2012) center on their long-run impact on health and lifestyle.

Although considerable evidence on inequality of opportunity in health has been amassed, there are still important unanswered questions in this field. First, virtually all the available evidence relates to developed countries. It would be interesting to know more about the magnitude, causes, and the channels of influence of inequality of opportunity also in developing countries. Second, further research is needed on the impact of health policy on inequality of opportunity in health. Although over the past years much has been learnt about the size and evolution of this type of inequality, little is still known about the ways to tackle it effectively.

Glossary

Aggregation A process of adding up smaller parts to make a greater whole. In health policy the issue arises of how to weight the health experience of different individuals in arriving at a statement about the health of a population.

Autonomy The general ethical principle in medicine of respecting an individual's freedom from external interference and their right to self-determination.

Communitarianism The doctrine that individuals' welfare cannot be properly understood or measured without regard to their membership of a community and the roles they play in it.

Consequentialism The doctrine that the moral worth of an action, policy, etc. is to be judged in terms of its consequences.

Externality An externality is a consequence of an action by one individual or group for others. There may be external costs and external benefits. Some are pecuniary, affecting only the value of other resources (as when a new innovation makes a previously valuable resource obsolete); some are technological, physically affecting other people (communicable disease is a classic example of this type of negative externality); some are utility effects that impinge on the subjective values of others (as when, for example, one person feels distress at the sickness of another, or relief at their recovery).

Informed consent 'Consent' in general is usually legally grounded either on the principle that a physician has a duty of care or that a patient has a right to self-determination. In most countries the informed consent of patients to treatments is based on the idea of what information a reasonable person might expect to be told in a given situation. In the UK, however, informed consent is based upon what professionals regard as reasonable to provide and hence on what information in any given case a physician's peers would provide.

Utilitarianism The ethical doctrine, a variant of which underlies nearly all normative economics, which specifies utility (sometimes equated with 'happiness') as the principal moral good of society and the entity that humankind as a whole ought to maximize. The popular moral slogan for a society (of given population) to pursue under utilitarianism is 'the greatest happiness of the greatest number.'

Introduction

Public health, unlike medicine, is not about doctors treating individual patients. Public health is about population health. It is a collective social effort to promote health and prevent diseases – both communicable and noncommunicable – and disability that involves population surveillance, regulation of determinants of health (such as food safety and sanitation), and the provision of key health services with an emphasis on prevention. Because private actors lack sufficient incentive and ability to undertake population-wide measures, public health is a vital resource for which government is the crucial provider, enabled by its police powers and its ability to regulate, tax, and spend. The exercise of government powers for the health of its population raises ethical issues, such as public welfare, individual autonomy and freedom, privacy and confidentiality, just distribution of benefits and burdens, transparency, and public accountability. These ethical concerns sometimes conflict, pitting values against one another. How they should be balanced will vary on a case-by-case basis. This article discusses justifications for government action in public health, the tension between individual freedom and public health, issues of distributive justice in public health, and ethical guidelines for public health policymaking.

Justifications for Government Intervention

Given that the government is best placed to undertake the work of public health, what are justifications for public health policies?

Ethical Justifications

Public health has utilitarian and consequentialist aspects. In a utilitarian sense, its goal is to maximize public welfare through the protection and promotion of population health. From a consequentialist point of view, public health policies are justified and judged largely by their outcomes, achieved by means of acceptable procedures. Public health measures seek to minimize harm from communicable and noncommunicable diseases, from exposure to health-endangering substances and environments (e.g., cigarette smoke and poor sanitation), and from high-risk behaviors (e.g., substance abuse and unprotected sex). Welfare is promoted through policies aimed at encouraging and facilitating behavior conducive to health (e.g., hand washing, smoking cessation, education about the dangers of drugs, and unprotected sex), and establishing more healthful environments (e.g., smoke-free public spaces, mosquito extermination, and adequate nutrients).

In the course of protecting and promoting public health, government authorities have the responsibility to ensure that public health policies themselves do no harm, or at least that their harms are outweighed by their benefits. Public health policies are not entirely utilitarian, however, in that individuals are not considered expendable for the greater good. The rights of individuals are important considerations in the formulation and implementation of public health measures, as discussed later.

The protection of vulnerable groups is another ethical motive for public health action. Vaccination and nutrition supplements, for example, protect children from disease and malnutrition, and smoking bans in bars and restaurants safeguard the health of workers who may not otherwise have the leverage to demand a smoke-free environment. Publicly funded health services can in principle help address the health needs of those who cannot afford private medical care or insurance. Such measures also may contribute to reducing health inequalities, by bringing the health of vulnerable groups more in line with the general population. Reduction of inequalities can itself be considered an ethical justification, as people with equal status (e.g., citizenship) should not suffer from those types of health inequalities that are due to morally arbitrary reasons (e.g., birth into a poor family and other bad luck).

Economic and Other Justifications

Poor health has collateral effects. On an individual basis, illness, disability, and their associated expenses can lead to absenteeism and decreased productivity that diminish income, inability to pursue education, reductions in essential consumption such as food and shelter, bankruptcy, and poverty. High infant and child mortality may lead to the compensatory decision to have more children, which decreases resources available for investment in health and education for each child. High adult mortality leaves orphans with bleak prospects. On a societal level, employers and the health system also suffer economic losses from lower worker productivity and greater healthcare burdens. Poor population health can even be economically and politically destabilizing. A particularly grim example is the Human immunodeficiency virus (HIV)/Acquired immune deficiency syndrome (AIDS) crisis in Africa, which lowered life expectancy by decades in some countries, killing adult men and women in their prime productive years. This is economically devastating for individual families and can potentially have larger implications. If deaths cause an overall decrease in economic output, the tax base funding health, education, police, and the military would also shrink, thus diminishing the perceived legitimacy of government. Lower life expectancy discourages long-term investment in education; it also means fewer and less experienced civil servants, reducing government administrative capacity. Low income and low government capacity create incentive for crime, violence, and radicalism, which in turn may trigger more state repression. Foreign investment may be deterred by lack of productive workers and instability. Weak states are also more vulnerable to armed conflicts and terrorism, increasing regional and international security risks. Public health problems can stand as obstacles to economic, political, and human development. What can be achieved with a population debilitated and dying *en masse*?

Good population health, however, can be part of a virtuous cycle of development. Higher life expectancy provides higher returns to education and human capital investment; lower infant and child mortality helps lower fertility, which results in greater health and educational resources available per child. A healthier, more educated work force is more economically productive, and more capable to generate the tax revenue for crucial infrastructure and services that would further development and attract investments. The connection between public health and development is less pronounced in developed countries that have long attained a high standard of population health; in impoverished countries, however, public health is a key component of the fight against poverty. Generally speaking, the justification for government public health action is ample; it is the justifications for specific public health measures that tend to be more contentious.

Individual Freedom versus Public Health

Public health policies are population oriented. Because individual health – for example, whether one is vaccinated, infected, a smoker – affects the health of others, public health measures regulate individual behavior in order to achieve population health goals. Such policies apply broadly and are not tailored to specific individual circumstances. They typically mandate certain behaviors (e.g., vaccination) and prohibit others (e.g., congregating with others while infected with quarantinable diseases), and sometimes take individual choice largely out of the picture (e.g., water fluoridation). All raise questions about how individual autonomy and freedom should be balanced against public health interests.

Public health ethicists often invoke the 'harm principle,' which respects individuals' sovereignty over their bodies and actions as long as their actions do not harm others. Ethicists generally agree that the greater the intrusion on individual autonomy and freedom, the greater the public health benefit must be to justify the policy. The public health situation that most starkly pits individual freedom against population health is infectious disease control. The liberty of individuals and their right to associate with others are curbed by protocols to separate infected patients from the population to prevent exposing others (isolation), and to separate or restrict the activities of people who are not diagnosed as infected but who may have been exposed to infection or who may be ill without symptoms (quarantine).

Disease control in the age of globalization has global health implications. The conflict is no longer between individual freedom and domestic population health, but between individual freedom and global population health, as demonstrated by the rapid spread of HIV, Severe acute respiratory syndrome (SARS), and pandemic flu via air travel. The economic toll of outbreaks is also potentially significant; losses from the 2003 SARS outbreak have been estimated to run in the billions. Domestic efforts are an integral part of global outbreak prevention. Given the high health and economic stakes in disease containment, the isolation of infected

individuals to prevent spread of disease is fairly uncontroversial. Quarantine, which applies to those who are not evidently ill, is a more disputed practice, sparking debates on its necessity and effectiveness: Only a small number of quarantined individuals are likely to be actually sick, although rights and freedom are infringed for all individuals placed under quarantine. A 2006 study by Day *et al*. suggests that quarantine is likely to be more useful and justifiable when isolation is ineffective, or if disease can be transmitted asymptomatically, when the consequences of exposure to others are severe, fatal, and/or irreversible, or if there is an intermediate asymptomatic period that is not too short or too long.

Isolation and quarantine can be voluntarily observed or coercively imposed. To the extent feasible, public health measures should secure the voluntary compliance or participation of affected individuals, allowing individuals the autonomy of informed consent. The public health, legal, and ethical reasons for observing isolation or quarantine – and potential consequences for violating it – should be clearly communicated to affected individuals, such that they have the relevant information to assess individual and societal benefits, costs and risks, and to make the decision to comply. Should an individual refuse to comply, authorities should have a system in place to impose isolation or quarantine to protect public health. There may be circumstances in which the urgency and gravity of a public health crisis may make a complete informed consent procedure less practicable. For example, an outbreak in progress of a virulent, highly fatal disease like Ebola may require swifter separation of the infected and the exposed from the general population.

One person's infection has clear and direct negative health impact on others, but public health policies also concern activities like smoking, obesity, and the wearing of motorcycle helmets that are arguably 'lifestyle choices,' with more indirect (or minimal) negative externalities. Smoking is an individual activity that may cause lung cancer, emphysema, and other diseases for the smoker, but there is also substantial evidence for its harm to others through secondhand smoke. Illness from smoking and secondhand smoke can result in losses from lower economic productivity, and greater burdens on the health system. How should public health authorities weigh a smoker's right to smoke versus other people's right to a smoke-free environment? Do smokers really have full autonomous choice over smoking, given that nicotine is an addictive substance? Should smokers be refused tax-funded health services for smoking-related illness? To what degree should smoking be discouraged (e.g., through sin tax) or prohibited to protect especially vulnerable groups like restaurant workers, who are exposed to secondhand smoke, and the poor, among whom smoking is more common and difficult to stop?

Different people have different answers for those questions, reflected in the large variation in smoking regulations among the 50 US states and among countries worldwide. Such variation is also seen in laws governing the wearing of seat belts and vehicle helmets, the consequences of which are confined overwhelmingly to the individual making that choice. The fewer the negative public health externalities associated with particular behaviors, the more paternalistic the government regulation of these behaviors. Policies are paternalistic when they seek to protect or benefit individuals against their expressed preferences – for example, by legally requiring people to wear motorcycle helmets when they otherwise would not.

Paternalism comes in 'hard' and 'soft' versions. Hard paternalism interferes with choices of individuals who, according to Childress *et al*., are 'competent, adequately informed, and free of controlling influences' and is therefore hard to justify. Soft paternalism, however, deals with behaviors of individuals who are considered not competent, not adequately informed, or not free from external control to make that choice. For example, smokers may decide to smoke because they were insufficiently aware of the health consequences, and they may continue to smoke because they have become addicted to nicotine. Obesity may be exacerbated by food marketing and the pricing and availability of healthy versus unhealthy foods, among other factors. Such situations provide more valid grounds for government intervention, which may take the form of education, incentives (e.g., taxes or subsidies to influence price and therefore consumption), marketing restrictions, and even outright bans, if the benefits of strong regulation are deemed to outweigh the infringement of individual freedom. A 'libertarian' version of paternalism has been proposed by Thaler and Sunstein that would structure the choice environment such that people could more easily choose to act in their own best interest (e.g., placing healthy foods at eye level in the store), as a way to preserve greater individual freedom.

The privacy and confidentiality of individuals are also important factors to consider in public health policymaking. Certain conditions and diagnoses – such as HIV/AIDS or mental illness – may carry social stigma, or impede one's ability to gain employment or acquire health insurance if publicized. The right to privacy and confidentiality must be balanced against the need to collect and disseminate information to achieve valid public health goals, such as infectious disease contact tracing, providing patients with treatment, and screening to prevent transmission of diseases through blood or organ donation, or from mother to child.

Distributive Justice in Public Health

In the context of limited resources – which is always and everywhere – the question is how should resources be allocated? The distribution of benefits and burdens is another ethical consideration in public health policy. Resource allocation and policy application should be fair. Extermination of mosquitoes, for example, should not be implemented in some communities while excluding others; minority groups – such as homosexuals – should not be singled out for disease screening. Targeting programs and interventions could be justified if supported by empirical evidence, but the costs of targeting should be weighed against the benefits. Targeted intervention may be a more efficient way to reach particularly affected groups and may help reduce health inequalities, but it may also come with negative effects. Stigma may become attached to groups singled out for disease programs, and the health of the nontargeted groups and individuals may be compromised if they do not receive the relevant health

education and do not receive screening because they are not considered at sufficient risk. Where possible, a universal, voluntary screening policy should be implemented.

The use of sin taxes to discourage consumption of unhealthful products like cigarettes is another instance of a targeted public health policy. The sin tax affects smokers, and redistributes that revenue to the rest of the population. This unequal burden aims to discourage cigarette consumption, which benefits the health of smokers and those subject to their secondhand smoke. However, cigarette taxes may also disproportionately affect lower income and minority individuals, who are more likely to be smokers (at least in the US), which makes the tax regressive in practice. Just how regressive may depend on how the revenues would be spent (e.g., funding other tobacco control efforts? or folded into general revenues?). Again, public health authorities must balance the benefits against the costs.

The distribution of benefits and the allocation of scarce resources are important issues in designing publicly funded healthcare packages. What kind of services should state-funded healthcare packages include? How much emphasis should prevention receive relative to treatment? Should resources go toward improving average health, which can be done without special attention to people with special health needs, or should resources be devoted to reducing health inequalities, which implies greater resources to the least healthy to bring them closer to the general population? What should be done about people who have exorbitantly expensive health conditions with little prospect of big improvement?

The consequentialist orientation of public health and limits in resources make the balancing of costs and benefits a major concern in public health policymaking. Costs are weighed against benefits using methods such as cost-benefit, cost-effectiveness, and cost-utility analyses. Cost-benefit analysis translates all benefits into monetary units that account for direct (e.g., medical) and indirect (e.g., productivity) effects; cost-effectiveness analysis shows the cost of each unit of gain in health, as indicated by measures such as years of life gained or deaths averted. Cost-utility analysis presents costs associated with a subjective measurement unit that combines preferences for length of life with preferences for quality of life. These kinds of analyses are used in the hopes of maximizing health benefits while minimizing cost. The National Institute for Health and Clinical Excellence in the UK, for example, draws on cost-effectiveness analyses to help direct coverage of medicines and treatments under the National Health Service.

The use of such welfare economic assessments in public health policymaking is not without controversy. For instance, the US, despite extremely high healthcare costs, has so far rejected using such measures in health policy. Although welfare economic methods offer a way to maximize health value for money in an evidence-based fashion, they have other implications that can be politically and morally difficult to accept. These methods account only for aggregate welfare, without considering the distribution of benefits and burdens. They tolerate significant health inequalities. Inequalities may even be exacerbated for the disabled, old, and very sick, the health benefits for whom cost-utility analysis assigns less weight due to their reduced capacity to benefit from health resources. This goes against people's intuition, found in research, to prioritize resources for the sicker and the more disabled even though they are less able to benefit.

Aggregation problems can result when weighing a small benefit for many against a large – perhaps vital – benefit for a few, yielding counterintuitive assignments of priority to minor procedures such as tooth-capping ahead of a life-saving surgery for ectopic pregnancy, which Hadorn reported from the Oregon Medicaid experiment in which policymakers attempted to determine a Medicaid (state-funded healthcare for the poor) health package using cost-utility analysis. Welfare economic methods also treat all health conditions as directly comparable, but blindness and loss of limb, for instance, are arguably not comparable to cardiovascular disease or high blood pressure, which further suggests that those methods alone may not be sufficient to direct resource allocation. Efforts to include weights (e.g. age or distribution) and other modifications have not satisfactorily solved these problems.

Resource allocation issues go beyond healthcare. Because poverty and social class are strong predictors of health, some ethicists also argue that public health has a role in poverty reduction and improvement of social conditions – such as housing, education, sanitation, and female empowerment – in order to address the structural causes of ill health and to increase people's ability to protect health for themselves and others (e.g., more educated and empowered women are better able to secure nutrition for and prevent diseases in their children).

Public health-related distributive justice can take on a global dimension. Poor countries often have more acute resource allocation problems in that they have little resources to begin with, and what resources they have they must devote significant portions to servicing foreign debts. Because poor countries must often reduce social spending in health and sectors with impact on health in order to pay debts or to comply with loan conditions, wealthy creditor countries and international financial institutions such as the World Bank and the International Monetary Fund have been urged on moral grounds to forgive loans and reverse structural adjustment policies that hinder vital public spending, in addition to providing more assistance.

Conclusion

Broad questions of how resources should be allocated involve conceptions of what justice and equity entail, and what obligations a state has in ensuring the health of its populations – whether it should aim for a basic minimum standard or something higher, within the constraints set by resource availability and the needs of legitimate state duties besides health. On a global level, there are additional questions about the existence and extent of duties to redistribute resources between rich and poor countries. Different moral perspectives (e.g., humanitarianism, human rights, communitarianism, and realism) will have different answers for those questions.

For specific public health measures, conflicts in ethical concerns will vary on a case-by-case basis, but scholars have presented guidelines to help assess ethicality. One example of such guidelines is the 5 'justificatory conditions' formulated

by 10 ethicists in 2002. The satisfaction of these conditions would justify the pursuit of a given public health measure over competing ethical values. These five conditions are effectiveness, proportionality, necessity, least infringement, and public justification. The effectiveness condition requires the public health measure to have a good chance of protecting public health; proportionality demands that the probable health benefits exceed adverse effects. The necessity condition directs policymakers to show 'good faith belief' and plausible reasons for using their proposed approach over a less coercive alternative, that is, to show that a given degree of coercion is indeed necessary. Out of all effective, proportional, and necessary options, the option that least infringes other ethical values should be chosen. And policymakers should publicly offer justification for their public health measure as well as explanation and justification for infringement, in a transparent process that truthfully and fully discloses the risks, scientific uncertainty, and moral values to relevant parties and those who will be affected by the policy, whose input should also be solicited.

These five criteria are representative of basic elements of public health ethical guidelines, which also tend to advocate respect for individual privacy and confidentiality. A transparent, participatory public process to justify policy proposals and to deliberate the weighing of benefits, costs, and risks is appropriate for developing and evaluating both narrower public health interventions and more general public resource allocation. Allowing people to take part in the public health policymaking process can build and maintain trust in public health authorities; it also strengthens agency and autonomy, and gives fuller meaning to informed consent.

Evaluating Efficiency of a Health Care System in the Developed World

B Hollingsworth, Lancaster University, Lancaster, UK

Introduction

The way economists look at the production of health care is to examine the relationship between the inputs into and the outputs from a production process as illustrated in Figure 1.

Figure 1 is a flow diagram showing how inputs such as medical staff and equipment produce health care, for example, the services offered by a hospital, and how use of these type of available health care inputs are converted into actual health itself, for example, curing a disease. Health itself, of course, is influenced by matters other than the health care system – such as housing conditions, education levels etc., which are often also accounted for in such models of how health is produced. Economists are interested in how one can make these production flows as resource efficient as possible because health care is very expensive, on average using up over 10% of developed countries GDP. To do this, the most efficient use of the inputs to these processes to produce the desired output is looked at – in most cases, to maximize health. In the top half of Figure 1, one can see how health care is produced given certain inputs, such as medical staff time. In the bottom half of Figure 1, health care becomes an input to a person's health, along with all the other things outside the health care system that contribute to health itself.

Mostly, research in this area has concentrated on the top half of Figure 1, as the inputs to, and the outputs from a health care organization can be measured, for example, a hospital. So, what sort of things would be inputs and outputs to the production of health care? It can be thought about in terms of a hospital, the most recognizable unit of health care production in a developed country, and the largest consumer of resources. Inputs include things like doctors and nurses, equipment and drugs, and capital, such as buildings and beds. Outputs are produced by the hospital – so, for example, numbers of patients treated – ideally adjusted in some way for the quality of care they produce – numbers of different operations undertaken, or diagnostic tests.

This article will describe how the relationship between inputs and outputs can be measured, and how information that improves the efficiency of how these services are delivered can be provided – the benefit being an improvement in the efficiency of production of service delivery and ultimately the production of patient health. It begins with a discussion of alternative techniques for measuring efficiency. Theoretical foundations are based on the pioneering work of Farrell (1957).

Two alternative approaches to measuring efficiency in the health care sector are described: data envelopment analysis (DEA), and stochastic frontier analysis (SFA). The article then describes how best to make use of techniques such as these in terms of a system of protocols and gives guidelines for how to provide the most appropriate information to those involved in policy making and service delivery.

Efficiency Measurement

In economic terms technically efficient combinations of inputs are those which use the least resources to produce a given level of output (for a given state of technology). Alternatively, technical efficiency (TE) may be defined in terms of maximizing output for a given level of inputs. By contrast, full

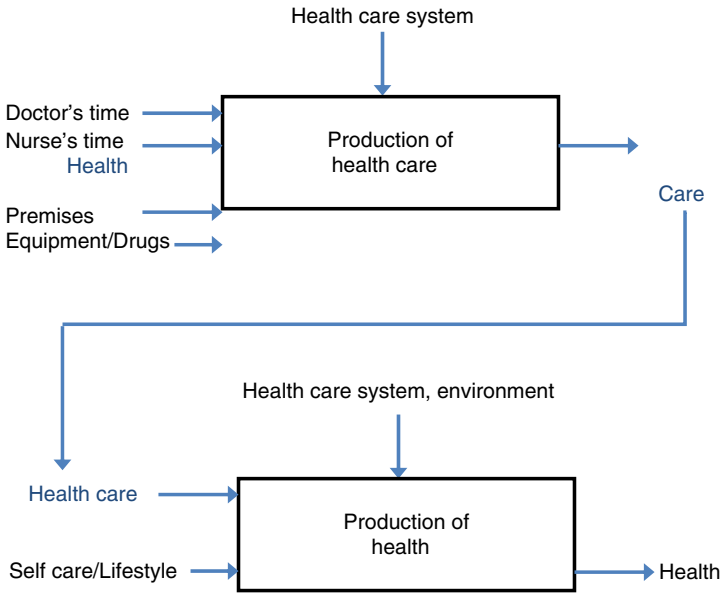

Figure 1 The production of health care and health.

 doi:10.1016/B978-0-12-375678-7.00204-2

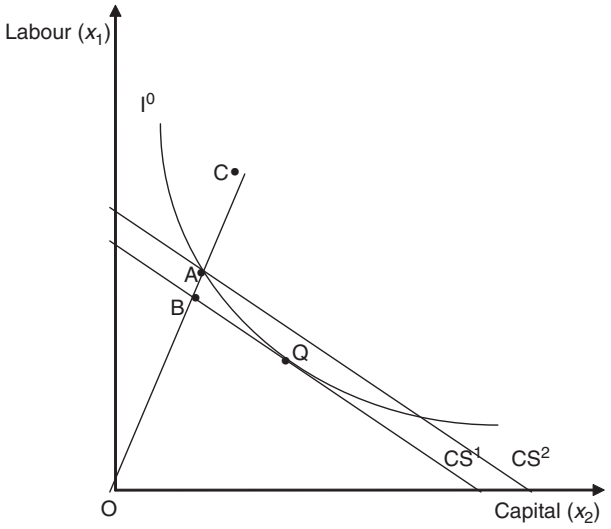

Figure 2 Radial efficiency measurement.

allocative efficiency is achieved by selecting combinations of inputs (e.g., mixes of labor and capital) which produce a given amount of output at minimum cost (given market prices for inputs), i.e., there can be no improvement in output by simply reallocating resources. The first measure looks at physical quantities, the second introduces a cost element.

Farrell's seminal work introduced two further concepts: radial measures of efficiency; and overall (economic) efficiency. These concepts are illustrated in Figure 2. The figure considers a simple example of producing a single aggregated output 'health care' from two inputs: medical labor (x_1) and capital (an example often used is beds)(x_2), The parallel lines (CS^1 and CS^2) represent isocost lines (which show relative input combinations that cost the same) and I°, an isoquant (simply a line drawn through a combination of input points used to produce the same level of output). Assuming a hospital chooses a desired health care output level y°, to be technically efficient they should choose a combination of inputs which lie on I°. Producing quantity y° using inputs at point C would be technically inefficient because the hospital could produce y° using both less labor and beds. Keeping the same mix of inputs, a hospital would be technically efficient if they are produced at point A, which lies on the isoquant. Farrell's measure of TE is based on the line OC, which passes through A and C. OC is often referred to as a radial measure of efficiency as it measures efficiency in terms of distance from the origin. TE at point C is given by the radial measure:

$$\mathrm{TE} = \mathrm{OA}/\mathrm{OC} \tag{1}$$

where TE must take a value greater than zero and less than or equal to one ($0 < \mathrm{TE} \leq 1$). If TE = 1, the hospital is technically efficient and is operating on the isoquant. If TE < 1 the hospital is technically inefficient.

If a hospital wishes to minimize costs, they will choose the combination of labor and beds at point Q where the isocost line CS^1 is tangential to I°, and where the combinations of inputs cost the least to produce the given level of output. If the hospital chooses an input mix (e.g., they may be legally obliged to have a certain number of doctors employed to offer certain services) along the line OC and is technically efficient they will produce at point A, which, lies on the isocost line CS^2. However, this implies they are not minimizing costs. The allocative inefficiency of choosing the input mix at point A (which is technically efficient) can be captured as the ratio of the costs of producing at A compared to the costs of producing at the allocative efficiency level, point Q, where the latter costs are given by the icocost line CS1 (the ray OA intersects this isocost line at B). This is the ratio:

$$\mathrm{AE} = \mathrm{OB}/\mathrm{OA} \tag{2}$$

where similarly AE must take a value greater than zero and less than or equal to one ($0 < \mathrm{AE} \leq 1$). When AE is less than 1 this implies that production is not allocatively efficient. AE can be interpreted as a measure of excess costs arising from using inputs in inappropriate proportions. If producing at 0Q the hospital would be technically and allocatively efficient, otherwise, if, for instance, a particular input mix is imposed on the hospital, it can achieve TE but not necessarily allocative efficiency.

Farrell's TE and AE terms can be combined to generate a measure of overall (economic) efficiency (OE) for production at point C:

$$\mathrm{OE} = \mathrm{TE} \times \mathrm{AE} = (\mathrm{OA}/\mathrm{OC}) \times (\mathrm{OB}/\mathrm{OA}) = \mathrm{OB}/\mathrm{OC} \tag{3}$$

where OE also lies in the range ($0 < \mathrm{OE} \leq 1$).

Empirical measurement of these concepts can now be considered.

Data Envelopment Analysis

DEA is by far the most common method for analyzing efficiency in health care. It has now been applied over 400 times in health care settings. DEA is a mathematical technique which makes use of linear programming methods. It is based on the idea of efficiency as the relationship between the outputs from an activity and the amount of inputs that the activity uses. In the simple case of a single output/single input firm a measure of TE can be defined as:

$$TE = \frac{y}{x} \tag{4}$$

where y = output and x = input.

The greater this ratio, the greater the quantity of output for a certain amount of input, as measured in natural (noncost) units. For a multiple-output/multiple-input firm, like a hospital which treats different types of cases using staff of different types, various equipment and so on, an overall measure of a hospital's TE is:

$$TE = \frac{\sum_r y_r}{\sum_i x_i} \tag{5}$$

where i is input, and r is output.

The problem with this is that inputs and outputs cannot be simply summed as they usually measure very different things, for example, numbers of doctors, and numbers of operating theaters). Rather, weights to each of the inputs and outputs are

given so that:

$$TE = 0 < \frac{\sum_{r=1}^{p} u_r \cdot y_r}{\sum_{i=1}^{m} v_i \cdot x_i} \leq 1 \qquad (6)$$

where: y_r = quantity of output r; u_r = weight attached to output r; x_i = quantity of input i; v_i = weight attached to input i; and p and m are the numbers of outputs and inputs. As is explained below, the weights are chosen so that $0 < TE \leq 1$. Thus, DEA is founded on an indicator of efficiency which can be calculated for each firm and, if u and v are fully flexible, is defined as the ratio of a weighted sum of the outputs relative to a weighted sum of its inputs.

The efficiency of any firm or unit, say a hospital (or nursing home, GP practice etc.), can be measured relative to other units within a peer group. Because the weights are unknown a priori, they must be calculated. Of all of the possible sets of weights which would satisfy all of the constraints, the linear program optimizes the ones that give the most favorable view of the unit. This is the highest efficiency score, the one that shows the hospital in the best possible light. This problem can be expressed as a fractional program. Such programs are difficult to solve, but can be reformulated into a straightforward linear program (LP) by constraining the numerator or denominator of the efficiency ratio to be equal to unity. This recognizes that in maximizing a ratio it is the relative values of the numerator and denominator that are important, not their absolute values. The problem then becomes to either maximize weighted output with weighted input equal to unity, or minimize weighted input with weighted output equal to unity. The output-maximizing LP is:

For h_0 in a sample of n hospitals,

$$\text{maximize} \quad h_0 = \sum_{r=1}^{p} u_r \cdot y_{rj0}$$

subject to:

$$\sum_{i=1}^{m} v_i \cdot x_{ij0} = 1 \qquad (7)$$

$$\sum_{r=1}^{p} u_r \cdot y_{rj} - \sum_{i=1}^{m} v_i \cdot x_{ij} \leq 0 \quad j = 1,\ldots,n$$

$$u_r \geq \varepsilon,\ r = 1,\ldots,p$$
$$v_i \geq \varepsilon,\ i = 1,\ldots,m$$

where: h_0 is the measure of relative TE of hospital 0, j is the reference set of $1 \ldots n$ hospitals, and ε is an infinitesimal.

In eqn [7], the denominator (weighted inputs) has been set equal to unity and the numerator (weighted outputs) is being maximized. One model must be solved for each hospital in the sample in turn, and can be solved using standard LP methods to give an efficiency score for each hospital.

The minimization rather than the maximization of this LP is simpler to solve and has a useful interpretation. If one now calls h_0 Z_0 to represent the opposite (or dual) measurement one is taking in a sample of n hospitals,

$$\text{minimize} \quad Z_0 - \varepsilon \sum_{r=1}^{p} S_r - \varepsilon \sum_{i=1}^{m} S_i$$

subject to

$$x_{ij0} Z_0 - s_i = \sum_{j=1}^{n} x_{ij} \cdot \lambda_j \quad i = 1,\ldots,m$$
$$\sum_{j=1}^{n} y_{rj} \cdot \lambda_j - s_r = y_{rj0} \quad r = 1,\ldots,p \qquad (8)$$

where: λ_j, s_r, $s_i \geq 0$ $\forall j$, i and r; λ_j are weights on units, sought to form a composite hospital to outperform j_o; s_i are the input slacks; and, s_r are the output slacks.

Essentially, the dual finds a set of weights for each hospital which minimizes an inefficiency measure subject to constraints. The hospital will be efficient if $s_i = s_r = 0$ and $Z_o = 1$, that is, a composite hospital cannot be constructed which outperforms it. This is the best that can be achieved in production terms using the combinations the hospital has available to it. If $Z_o < 1$ and/or $s_i > 0$, $s_r > 0$, the hospital will be inefficient. The composite hospital provides targets for the inefficient hospital and Z_o represents the maximum inputs a hospital should be using to attain at least its current output. The weighted combination of inputs over outputs for each hospital forms the production frontier. The hospitals which lie on this frontier, that is those which have a TE score of one using the weights of a reference unit, are called the 'peers' of the reference hospital.

DEA uses the assumption of either constant or variable returns to scale (CRS or VRS). The LP in eqn [7] or eqn [8] calculates the CRS production frontier. A VRS frontier is obtained by adding a further constraint to the dual of the LP:

$$\sum_{j=1}^{n} \lambda_j = 1 \qquad (9)$$

The extra constraint requires more units. Because the production function is not directly observable, DEA estimates a production frontier based on input and output data. The frontier maps the least resource use input combinations and is assumed to be convex to the origin. The DEA frontier is illustrated in Figure 3 and (like Figure 2) considers a simple, single output, two input example. The dots represent different producers and the quantities of inputs they use to produce the same given level of output. The DEA frontier ($1^{\circ}I^{0}$) consists of straight lines joining the points that represent the most efficient producers. Inefficient producers lie to the right of the frontier. The complete production frontier covering all levels of output can be inferred, and the analysis can be extended to cover both multiple inputs and outputs, and the assumption of CRS can be dropped.

Figure 4 illustrates DEA frontiers under CRS and under VRS. The frontier is drawn slightly differently to Figure 3 to introduce how the concepts VRS and CRS are important in DEA. The section AB of the VRS frontier exhibits increasing returns to scale (output increases proportionately more than inputs), BC exhibits CRS, and CD decreasing returns to scale (output changes proportionately less than the change in inputs). For a given hospital, G, the distance EF measures the

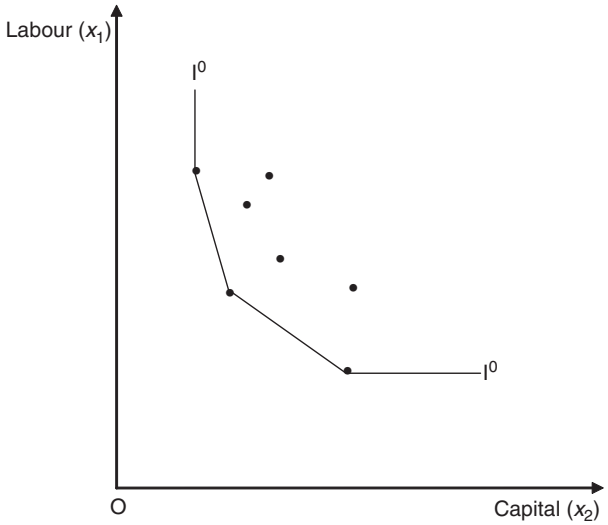

Figure 3 The DEA production frontier.

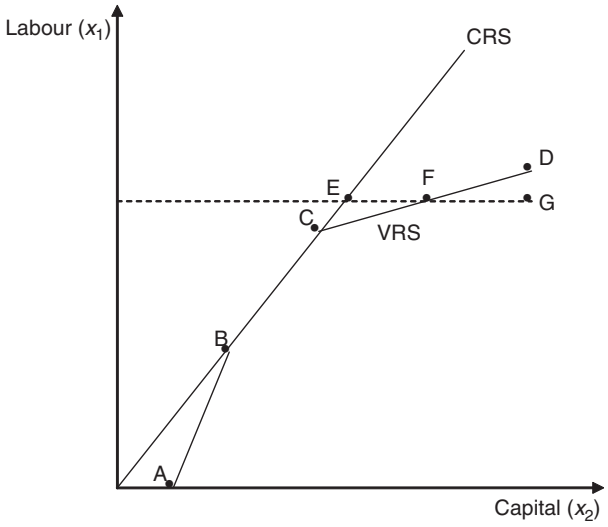

Figure 4 Constant and variable returns to scale under DEA.

effects of economies of scale in production, and FG measures 'pure' inefficiency. Clearly, more hospitals will be deemed to be efficient under variable returns to scale, as under an assumption of CRS any economies of scale are included in the measure of inefficiency.

DEA (in the formulation presented above) does not account for the influences of the distribution of medical case complexity (casemix) on producer efficiency in the production of health care. One approach to modeling the effects of casemix is to include the patient characteristics (for patients at different health care hospitals) as a type of input in the production frontier. However, this approach may be inconsistent with economic theory, as patients are not inputs which are transformed to make the final product (which in this case is a health care intervention). Instead, patients consume treatments to (hopefully) produce improvements in their health status.

The characteristics of patients and their illness will influence the production of health care in order to produce these health status improvements, hence patient illness differences (e.g., the intensity of a heart attack, or the stage of a cancer) may be better viewed as factors which shape the outputs rather than inputs in the production process. DEA models can incorporate this approach to patient illness characteristics (casemix factors) by modeling the effect of casemix on the overall production process by adjusting outputs by casemix group. Another method involves adding a second stage of analysis to the DEA approach. The first stage of the model involves running a DEA model based on physical inputs and treatment-based outputs to yield efficiency scores for units (say hospitals again), as shown above. The second stage then takes these efficiency scores and regresses them against hospital level casemix variables to assess the impact of the patients' socio-demographic and clinical characteristics on the production process and efficiency. This allows the inclusion of variables which do not fall neatly into the input–output analysis and potentially see if they have a significant impact on the efficiency scores obtained in the first stage, but there are many statistical issues with undertaking such second stage analysis (Fried *et al.*, 2008).

Some Limitations

Before proceeding, it is important to note that DEA has several major limitations which require some care on the part of those constructing models and others interpreting the results. There are major statistical issues to account for. The technique is deterministic and outlying observations can be important in determining the frontier (made up of the most efficient units). Closer investigation of these outliers is often warranted to ensure the sample is actually uniform in nature, i.e., one really is comparing like with like. Care must be taken in interpreting results as the DEA frontier may have been influenced by stochastic variation, measurement error, or unobserved heterogeneity in the data. DEA makes the strong and nontestable assumption of no measurement error or random variation in output. Small random variation for inefficient hospitals will affect the magnitude of the inefficiency estimate for that hospital. Larger random variation may move the frontier itself, thereby affecting efficiency estimates for a range of hospitals.

DEA is sensitive to the number of input and output variables used in the analysis. Overestimates of efficiency scores can occur if the number of units relative to the number of variables used is small. A general rule of thumb is that the number of units used should be at least three times the combined number of input and output variables.

DEA only provides a measure of relative efficiency in the sense that: a hospital which is deemed efficient using DEA is only efficient given the observed practices in the sample which is being analyzed. Therefore, it is possible that greater efficiency than that observed could be achieved in the sample.

The Malmquist Index

Efficiency can change over time, and DEA based Malmquist indices (named after a pioneering researcher in this area)

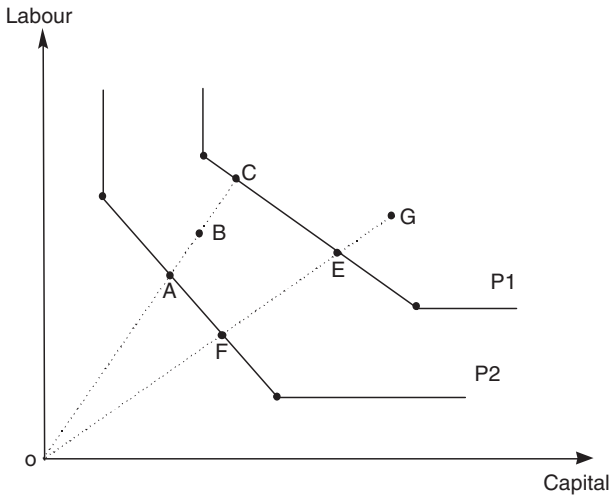

Figure 5 Malmquist index.

reused to measure this concept of productivity. The Malmquist productivity index (Fried *et al.*, 2008) is defined as (with reference to **Figure 5**, a two input, one output model, two time period, where G and B represent a hospital in two different time periods):

$$MPI = \left[\frac{OE/OG}{OC/OB} \times \frac{OF/OG}{OA/OB}\right]^{0.5} \tag{10}$$

The index is the geometric mean of two indices. In the first the production frontier of period 1 (P1) is taken as given and measures the distance of the two production points, G and B, from it. The second index is similar except the reference frontier is that of period 2 (P2). A score greater than unity indicates productivity progress as a hospital delivers a unit of output in period 2 using less inputs. In other words, the hospital in period 2 is more efficient relative to itself in period 1. Similarly, a score less than unity implies productivity regress and constant productivity is signaled by a unit score. The index can be decomposed:

$$MPI = \frac{OE/OG}{OA/OB}\left[\frac{OA}{OC} \times \frac{OF}{OE}\right]^{0.5} \tag{11}$$

The component outside the brackets is the ratio of TE in each period and measures efficiency change when moving from period 1 to period 2. It indicates whether the hospital gets closer to its production frontier, i.e., becomes more efficient (with a score greater than unity), or moves further away from the frontier, i.e., becomes less efficient (with a score of less than unity), or stays the same (with a unit score). The second component of the Malmquist index in eqn [10] captures technological change evaluated from both time periods, i.e. movements of the actual frontier itself – the technology with reference to which a sample operates. The frontier (i.e., technology) can progress (with a score greater than unity), regress (with a score of less than unity), or stay in the same position (with a unit score). Malmquist indices are increasingly used in health care.

Stochastic Frontier Analysis

SFA, see Coelli *et al.* (2005) has been used in a much smaller number of efficiency analyses in health care than DEA, but the number of papers is increasing. SFA on cross sectional data decomposes a regression error term into two parts. Given a model of the form:

$$y_i = \beta_i \cdot x_i + u_i + v_i \tag{12}$$

where y_i is the vector of outputs, x_i is the vector of inputs, β is the vector of parameters (of little interest in the context of these models) u_i is the one sided inefficiency term ($u_i \geq 0$ for all i), v_i is the two sided error term which is assumed to follow the usual classical linear regression model error term, and u_i and v_i have zero covariance. Note i,u,x,v all are now discussed with separate and new meanings to the equations in the DEA models above.

The first of the two error terms is a one-sided 'error' term that acts as a measure of inefficiency. By constraining this term to be one-sided, production units can only produce on or below the estimated production frontier. The second part is the 'pure error' term that captures random noise, and has a two sided distribution. The one sided constraint on the distribution of the inefficiency term allows a realized production frontier to be estimated, and each producer's efficiency to be measured relative to that frontier.

The use of SFA in the production of health care has received increasing attention over recent years. This is partly because of increased interest in efficiency measurement in general in health and health care, as discussed earlier, as discussed earlier but also because of advances in modeling techniques and increased computing capabilities.

To allow multiple outputs to be modeled (as outputs in health care are typically heterogeneous) researchers often estimate cost rather than production frontiers. Estimation of an SFA production frontier requires that all outputs can be meaningfully aggregated into a single measure. This assumption is questionable in the health context. However, costs can be easily aggregated into a single measure using monetary units such as dollars. The estimation of the cost frontier remains a valid method for examining productive efficiency as it is the dual of the production function. The cost frontier formulation of the model is:

$$c_i = \mathrm{f}(p_i, y_i, z_i) + u_i + v_i \tag{13}$$

where c_i is expenditure at hospital i, p_i is a vector of input prices, and z_i is a vector of producer characteristics which includes casemix variables. The inclusion of variables capturing casemix and producer characteristics in the model allows statistical testing of hypotheses concerning the relationship between these factors and producer efficiency.

The stochastic frontier model is estimated by maximum likelihood and requires that the researcher specifies an appropriate distribution for the inefficiency term. The most commonly adopted approach for cross-sectional data is to assume that u_i follows a half-normal distribution:

$$u_i^* = |u_i| \tag{14}$$

and

$$u_i^* \sim \mathrm{N}(0, \sigma_u^2)$$

Other distributions suggested for cross-sectional data include the exponential and gamma distributions. However, there are no strong a priori theoretical reasons for choosing any of the above distributions over each other. It has been argued that this has led to arbitrary and nontestable assumptions about the distribution of the inefficiency term, which are a potential source of model misspecification. Another approach adopted has been to use panel data which has the advantage that it requires no specific assumption about the distribution of u_i (Fried *et al.*, 2008).

Assumptions concerning the error term v_i in SFA may also be important. If the assumption of normality in the error term does not hold, and its distribution is skewed, inefficiency may be under or over estimated (Jacobs *et al.*, 2006). Because the error term v_i is assumed to show zero skewness, any skewness is attributed to the inefficiency term u_i. For instance, periodic capital repairs to a hospital may lead to a positive skew in total cost and hence in the error term. Under a stochastic cost frontier model this will result in inefficiency being detected, even if the hospitals studied are perfectly efficient. Conversely, a negative skew on the error term will bias the estimate of inefficiency downwards. Further, SFA may also reject the null hypothesis of no inefficiency too readily.

The SFA cost frontier is often estimated using a generalized functional form known as a 'translog' function, which allows the testing of a wide range of assumptions about the nature of the cost function, and does not impose restrictive a priori assumptions on its functional form. Translog multiproduct cost functions can also be used easily to test for the presence of economies of scale and scope. However, this approach requires a large number of degrees of freedom. In hospital studies, where sample sizes are often small, this may introduce measurement error and bias in inefficiency estimates through the inappropriate aggregation of inputs and outputs. An alternative approach is to impose a functional form which is less demanding on the data (e.g., Cobb-Douglas), but this may come at the price of introducing misspecification into the model.

Making Best Use of Efficiency Measures in Health Care

It has been postulated that efficiency measurement studies in health care are being produced at an increasing rate, but there is a limited amount of use of such studies in practical terms. Criteria have been suggested previously for assessing the use and usefulness of such studies, from the perspective of the supplier of such studies, and those who might make use of them (Hollingsworth, 2012).

Use and Usefulness Criteria for Suppliers and Demanders

Suppliers

1. Applied research needs to be placed in a policy context. One important element of any efficiency analyses is to get potential end users involved early on. This helps 'ownership' of the research from the users' perspective, and keeps the researcher on track. This may initially involve finding the right person, or group of people (having a number of people involved reduces risks, e.g., staff moving positions). Meetings to feedback results at various stages, and to different levels of users, for example, hospital managers, health department staff, will help make sure information is provided to those who want to use it. An advisory group to initially help set up model specification may be useful.
2. Hospital managers may have concerns about health authorities using efficiency measures as 'big sticks' and are generally interested in more detailed information on their specific unit, whereas health authority staff tend to be more interested in the overall picture and comparisons between hospitals. The researcher has to balance these views and providing all the information to everyone may help. One should also ask what information it would be useful to provide that the data/modeling is not providing right now, and try and accommodate this, or suggest means (e.g., extra data) which could help.
3. Hase the objective of giving end users the information been met? Surveying them, perhaps including a short report, may help refine the measures. Disseminate the results as widely as possible. Make sure users know the limitations of efficiency measures, and that they are a useful policy tool, not the useful policy tool. Results can be manipulated so full provision of information to all may be helpful.
4. Are the right questions being asked?
5. What is the underlying economic theory of production (or cost, does duality theory and the requirement for cost minimization as an objective really apply)?
6. Is the model specified correctly? Hasan extensive sensitivity analysis been undertaken? Ask the advisory group if there are any obvious omitted variables.
7. Are the data really good enough to answer the questions, particularly the output data?
8. Is there any data on quality of care? What will results using just quantity (throughput) data really show? Will any inefficiency be just made up of omitted quality data?
9. If quality data is available, how will it be weighed relative to quantity data, to avoid it being 'swamped' by relatively large numbers of throughput information? Unless carefully weighted, potentially vital information on quality may have little impact on results.
10. Is the sample inclusive enough,and is one comparing like with like? Exploratory analyses are useful. Just because all hospitals in the sample have the sample categorization, there may be a rogue specialist unit or teaching hospital that may confound the results. Frontier techniques are very susceptible to outliers. Sample size is also an issue.
11. If one is happy with the data and models, what techniques will be used, DEA, SFA or both? If there are multiple inputs/outputs, nonparametric techniques have an advantage (when comparing DEA and SFA) in terms of disaggregation (Coelli *et al.*, 2005). They allow one to feedback more detailed information on areas of inefficiency. Panel data techniques will also allow one to feedback more information, not only on what happens

between units, but also what happens over time. Looking at trends over time is more useful than a snap shot.
12. Is two stage analyses being undertaken, if so how are any statistical problems being accounted for?
13. Does one need to generate confidence intervals? Unless one is certain that the sample is all inclusive, then one might wish to account for sampling variation.

Demanders

Table 1 presents a checklist for assessing if an efficiency analysis should be judged as potentially useful. This (again) is a starting point, based on the Drummond *et al.* (2005) list for assessing economic evaluations. Suppliers of efficiency studies may also wish to take note of these points. The following two assessment questions asked by Drummond *et al.* (2005) are also pertinent here: Is the methodology appropriate and are the results valid; and if the answer to this is yes, then – do the results apply in this setting? As Drummond *et al.* (2005) acknowledge, it is unlikely every study can fulfill every criteria, but criteria are useful as screening devices to identify strengths and weaknesses of studies, and of course to identify the value added by comprehensive extra analysis of this nature.

Table 1 A checklist for assessing efficiency measurement studies

1. Is the question well defined, and answerable?
   - Are the inputs and outputs clear?
   - Is there a particular viewpoint stated (whose objectives are accounted for – managers, Government policy makers, patients?), is any decision making context established?
2. Is a comprehensive description of the sample given?
   - Can you tell if any relevant comparator units are excluded?
   - Is the sample strictly comparable, are there potential outliers?
3. Are the quality and quantity output data clear and comprehensive?
   - Where do the data come from, who collected them, and why?
   - Are quantity data case mix adjusted?
   - Are quality data useful, for example, can individual patients be followed through the system?
4. Are all the relevant inputs and outputs included?
   - Is the range wide enough to answer the research question?
   - Do they cover all relevant viewpoints (e.g., hospital mortality may be of interest to patients, scale of operation to policy makers, and range of services to managers).
   - Are there measures of physical quantities of inputs as well as costs (although in a number of contexts costs alone may be appropriate)?
5. Are inputs and outputs measured accurately in appropriate units?
   - Are all resources used relevant to the analysis accounted for?
   - Are any data omitted? If so what is the justification?
   - Are there any special circumstances, which make measurement difficult, for example, joint use of staff? Were these circumstances handled appropriately?
6. Were inputs and outputs (or objectives) valued (or weighted) correctly?
   - Were the sources of all values clearly identified? for example, market prices for inputs, case mix weights?
   - Was the value of outputs appropriate? Were the right weights placed upon the relationship between quantities (and qualities) of outputs?
7. Were analyses over time undertaken?
   - Were values (and outputs) adjusted to present value?
   - How are the specific techniques justified, for example, are random or fixed effects models used, how is scale accounted for, how is efficiency decomposed?
8. Do techniques add incremental value?
   - For example, is data envelopment analysis used? Or stochastic frontier analysis? Which cross sectional or panel data (over time) techniques are used?
   - Are the techniques used justified clearly, for example, what incremental value do they add beyond how efficiency is currently measured?
9. Was allowance made for uncertainty?
   - Were appropriate statistical analyses undertaken?
   - Were sensitivity analyses performed, which dimensions are tested?
   - Were the results sensitive to the statistical/sensitivity analysis?
10. Did the presentation and discussion of study results include all issues of concern to users?
    - Were the conclusions based on an overall measure, or individual comparisons of efficiency?
    - Were the results compared with others who have investigated the same question?
    - Did the study discuss the generalizability of the results to other settings?
    - Did the study allude to other important factors in the decision or choice under consideration, for example, ethical issues, or access issues, or equity?
    - Did the study discuss issues of implementation, such as the feasibility of adopting efficiency changes, given existing operational constraints, and whether freed resources could be redeployed to other more efficient programmes?

Source: This checklist relies heavily on Box 3.1 in Drummond, M., Sculpher, M., Torrance, G., O'Brien, B. and Stoddart, G. (2005). *Methods for the economic evaluation of health care programmes*. Oxford, UK: Oxford University Press.

Summary

The number of studies which seek to measure health service efficiency and productivity continues to increase quite dramatically. Research in this area should be reviewed carefully and the results of studies interpreted and used cautiously, as it is still an area under development. Estimated results can be sensitive to changes in the basic assumptions and specifications of the models used, and the characteristics of the environment in which the units operate. Thus, as concluded previously, the results may only be valid for the units under investigation raising generalizability issues.

A number of criteria are suggested for judging whether research published in this area is potentially useful in a policy context. It should be noted that, as with the original economic evaluation criteria on which they are modeled, these criteria should be used as a means to interpret results, not a checklist for dismissing the usefulness of individual studies on a generic basis. What is of no use to one user may be very useful to another, working from a different viewpoint in a different health system.

In terms of 'best practice' for undertaking efficiency studies, it may be that the use of multiple techniques might help indicate trends in inefficiency. If the multiple techniques (parametric and nonparametric, including techniques which can account for multiple objectives) point to the same inefficient organizations, and the organizations cannot sensibly explain them away (i.e., omitted variables and policy shocks), then perhaps some form of inefficiency is being picked up. Of course it may be that in certain circumstances one method is obviously more useful: for example, when there are multiple outputs, SFA may not be appropriate because of problems with having to aggregate variables. Justification of the method used is sometimes difficult at present as there are few criteria for which is 'best,' although in practice different measurement methods often show similar results. Another danger at present is relying on exact numbers: small differences in inefficiency may not truly reflect inefficiency, and should be viewed with caution. Trends over time may be more reliable.

As economists the basics of what is meant by efficiency should be kept in mind. However, not only must one decide how efficiency and productivity is measured (efficiency changes over time in the context here), but also why, and how important it is relative to other societal objectives in terms of the delivery of health care. These are all questions left to be answered in a research context.

Fertility and Population in Developing Countries

A Ebenstein, Hebrew University of Jerusalem, Jerusalem, Israel

Glossary

Demographic dividend Term describing the benefit to a country of having a large working population following a fertility slowdown.

Demographic transition Theoretical model used to explain population changes over time from a context characterized by high fertility and mortality rates to low fertility and mortality rates.

Dependency ratio An age–population ratio of those typically not in the labor force and those typically in the labor force. It is calculated by dividing the number of people younger than 15 years and older than 65 years by the number of people aged 15–64 years.

Hypergamy Marriage into an equal or higher caste or social group.

Missing women Pattern of high sex ratios in census data indicating sex discrimination toward females.

Patrilocality Custom in many societies with son preference that adult children live with the husband's parents.

Replacement rate The number of children each woman needs to have to maintain current population levels.

Sex ratio Ratios of males to females in the population.

Introduction

In the mid-twentieth century, many developing countries experienced a 'demographic transition': a transition from a society in which women had many births and many infant deaths, to a society with lower fertility and lower infant mortality. This pattern was particularly pronounced in China and India, which enjoyed rapid improvements in public health and steep declines in death rates among infants and children. In the early 1960s, following sharp declines in infant mortality which had exceeded 100 per 1000, the total fertility rate (TFR) – the number of children a woman would have in her lifetime at prevailing age-specific rates – of both countries exceeded six births per woman, resulting in massive young cohorts. Government policies and changing social norms led to rapid fertility decline in the 1970s in China and in the 1990s in India, leaving both countries with massive cohorts born during their respective baby booms, and much smaller cohorts before and after. This peculiar age structure is associated with a set of advantages and challenges that will be discussed later in this article.

A similar story has begun to play out in sub-Saharan Africa, where recent declines in mortality have led to a rapid increase in population growth. Much of Africa's population is extremely young, posing a challenge in the short run but possibly aiding economic growth in the long run. Africa's age structure is also affected by the human immunodeficiency virus (HIV)/acquired immune deficiency syndrome (AIDS) epidemic, which generally affects young adults, leaving children and the elderly behind to fend for themselves. This has resulted in a very young age distribution in Africa, similar to the situation in China and India in the 1970s and 1980s. The lesson of China's and India's present may be useful for Africa's future.

The rapid fertility decline in China and India was also accompanied by an alarming pattern: the 'missing girls' phenomenon. The combination of traditional son preference, the need to reduce fertility, and the diffusion of ultrasound technology led to a sharp increase in the sex ratio at birth in both countries. Scholars estimate that more than 100 million girls are missing worldwide, 80 million of which are due to sex discrimination in China and India alone. Both countries are at the cusp of an explosion in the sex ratio of the adult population, which may have important implications for society in general, and health in particular. Recent increases in China's syphilis rate have alarmed policymakers, and the dynamics of both countries' populations could generate a challenging scenario for public health officials.

In this article, the author examines the causes and consequences of these population patterns, focusing on health as an outcome. The author begins in Section A Modern History of Fertility in Developing Countries with a general overview of fertility trends that gave rise to rapid demographic transition. The experiences of China, India and Africa are examined, as each are at a different stage of the demographic transition. In Section Demographic Transition and the Implications for Economic Growth and Public Health, issues related to where each country finds itself in the context of its demographic transition are examined. For China, the most pressing concern is to provide old age support for its rapidly aging population. For India, the challenges the country faces in providing medical care to its large young population are described. How the African experience with HIV/AIDS will shape its country's future, in light of the disease's pronounced effect on the age distribution is examined. In Section Missing Women and Implications for Public Health, the focus is on the impact of China's and India's skewed sex ratios on health in a variety of contexts, including its impact on sexually transmitted infections (STI), care for infants, and other pathways, such as the emergence of a large unmarried elderly population. In Section Conclusion, the author concludes with a brief discussion of policy recommendations for public health planning in the developing world as it relates to the demographic patterns observed.

A Modern History of Fertility in Developing Countries

The demographic transition involves four stages. In the first stage, society is characterized by high birth and death rates that keep the population in balance. All human populations

 doi:10.1016/B978-0-12-375678-7.00110-3

are believed to have had this balance until the late eighteenth century, when this stage ended in Western Europe. Developing countries found themselves in this predicament of high birth and death rates until the twentieth century.

In the second stage of the demographic transition, the death rate drops due to improvements in food supply, sanitation, and access to medical care, leading to lower infant mortality rates and longer life spans. The size of the population grows rapidly during this phase, and the decline in death rates among infants and children result in a very young population. In the third phase, birth rates fall due to several factors. These include increased access to contraception, reduced need for farm labor, and increased participation of women in the workforce. A key factor in lowering the fertility rate is a growing recognition among parents that births will likely survive to adulthood, reducing the need for very high fertility to compensate for high child death rates. This gives way to the fourth phase, where countries experience low birth and low death rates, and balance reemerges, slowing population growth.

The Demographic Transition in China, India, and Africa

The current phase of each region analyzed is shown in Figure 1, showing China near the conclusion of its transition, India in the transition process, and Africa which is yet to experience transitional fertility decline.

China

In China, the demographic transition narrative fits the country's population history tightly, and the country has now entered the last stage. In China, throughout the 1960s the TFR exceeded six births per mother. This rapid population growth alarmed Chinese officials, and the Communist Party subsequently enacted a series of fertility control policies, including new restrictions on women having more than two children during the 1970s. These early policies were immensely successful and from 1970 to 1980, the TFR fell from 5.8 to 2.3 births per woman. Family planning officials were instructed to enforce an even stricter policy starting in 1979, when China instituted its one-child policy. Under this policy, China's TFR declined to 1.5, below replacement and among the lowest rates in the world.

In the short run, the benefits to China's fertility program are indisputable. At present, the fraction of China's population that is in their working years (ages 15–64) is 73.5%. This has contributed to the country's stellar growth record, which, in turn, has been an important factor in the improvement in health outcomes. Recent estimates from nationally representative surveys put life expectancy at birth at 74.8 years for females and 72.8 for males, levels that approach those of the world's more developed countries. However, a crisis is looming. The size of the country's population aged 60 and above will increase dramatically in the coming years, growing from 200 million in 2015 to more than 300 million by 2030. The challenges stemming from this rapid population aging is discussed in the next section.

India

The Indian population narrative is similar to China's, but occurred roughly two decades later. Between 1951 and 1976, India's crude death rate dropped by more than half, from 28.6 to 13.8 – and the crude birth rate only fell by a quarter, from 45.9 to 34.4. This period featured rapid population growth, and India's improvements in infant health continued during the 1980s and 1990s.

The population explosion has left India with a very young population, and on the cusp of becoming the world's most populous nation – possibly by 2020. At present, more than half of India's population is under 25 and more than 65% is below the age of 35. In recent years, Indian fertility has slowed, partly due to government mandates and partly through the normal mechanisms highlighted in the demographic transition framework, such as increasing female education, which has led to wider take up of contraception. Birth cohorts in recent years are smaller than in the previous decade, as reflected in Figure 1. Still, India's explosive population growth for several decades has left the country with an extremely young population.

As a result of this currently favorable age distribution, India is currently enjoying its demographic dividend, with economic growth exceeding 7% every year since 1997. The country continues to enjoy a low dependency ratio, with 65.2% of the population in their working years. However, the country still lags behind developed countries in life expectancy. Life expectancy at birth for men is 66.1 years and for women 68.3 years, reflecting challenges in providing adequate health care to its massive population. The country has also struggled with providing sufficient primary and secondary education. Further investments in health and human capital can position the country to continue cashing in its demographic dividend. However, although India is still decades away from facing an aging population, the country will almost certainly face challenges similar to those that China will face, albeit in a delayed fashion.

Sub-Saharan Africa

During the 1980s, the population of sub-Saharan Africa grew at a rate of 3.1% per year, the highest of any developing region. The population growth occurred due to rapid mortality decline and only moderate fertility decline. In 1970 Africa's TFR was 6.7. By 1990 it had declined 12% to 5.9 with an additional decrease of 24% to 4.5 by 2010. However, childhood mortality rates declined more rapidly, with the under-five mortality rate declining from 180.6 to 125.3, a 31% decrease, between 1980 and 2010. The combined impact of rapid declines in mortality and more modest declines in fertility have left sub-Saharan Africa with a very young population, with 44% of the population under the age of 15. If the Indian and Chinese precedent is followed, it is reasonable to expect that fertility will begin to level off in Africa, though when this will occur is unclear, and less effective government fertility regulations imply that intervention will need to come from voluntary family planning participation. Should Africa succeed in encouraging faster fertility decline, the region may enjoy its demographic dividend earlier. In any scenario, however, the population should continue to grow at robust rates for many years, leaving the continent with a very young

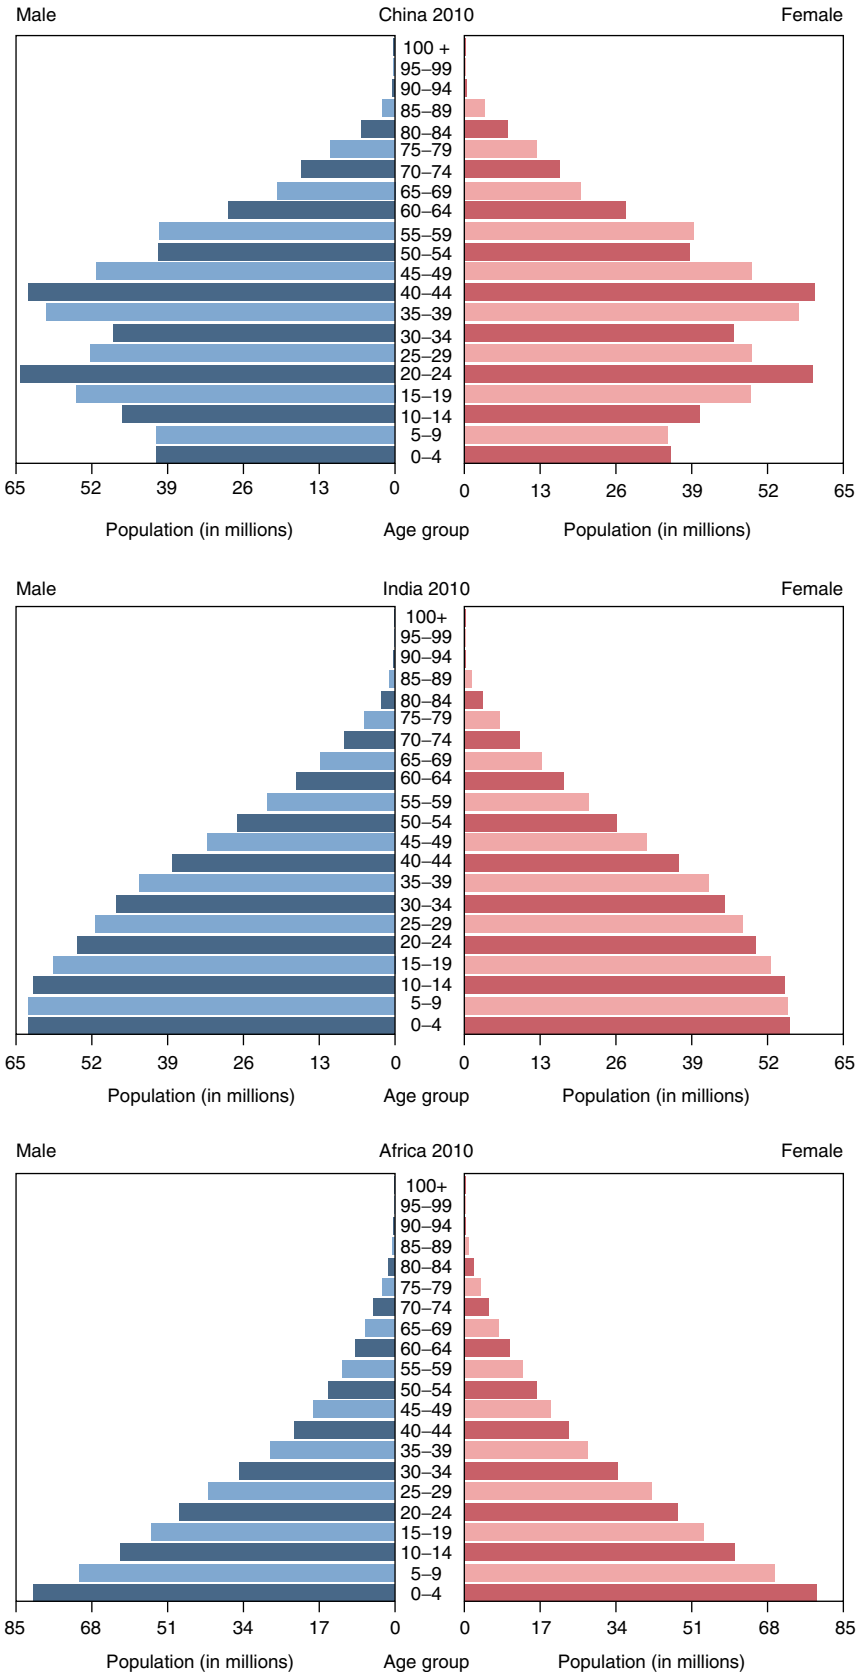

Figure 1 Age pyramid in China, India, and Africa – 2010. US Department of Commerce (http://www.census.gov/population/international/data/idb/informationGateway.php).

population in the coming decades. This could prove to be a boon to economic growth, as the eventual fertility decline and subsequent population aging will leave Africa with a huge working population. Some policymakers, however, fear that poor management of African economies may leave them unable to capitalize on the favorable age structure.

However, as shown in Figure 1, the massive young cohorts in Africa may pose a challenge in the near-term, as the region grapples with a high dependency ratio. Note that this is in part related to the consequences of the HIV/AIDS epidemic, which has resulted in millions of deaths to people who are in their prime working years, as the disease peaks in prevalence among individuals between ages 20 and 49. There is little reliable national-level data describing the distribution of deaths by cause for sub-Saharan Africa, and the World Health Organization's mortality database lists HIV-related causes for only one sub-Saharan nation (South Africa). An examination of cause-specific death data available for two countries, Tanzania and South Africa, revealed an increase in the probability of dying between ages 15 and 50 from HIV-related causes of up to 127% for males and 153% for females. Recent evidence indicates, though, that deaths from HIV have begun to plateau, which is an encouraging sign that the epidemic will not continue to worsen. However, for several high-prevalence countries such as Botswana and Zimbabwe, HIV has shortened life expectancies by several decades. A lack of further progress containing HIV could prevent the region from enjoying the benefit of its favorable age distribution, should the population of workers continue to suffer from high mortality.

The Missing Girls of China and India

As China and India experienced rapid fertility decline, many parents were unwilling to complete fertility without having a son. The value of sons is in part religious, as both Confucianism and Hinduism designate the son as having the responsibility to perform certain rites. However, a primary explanation for son preference is the custom of patrilocality, practiced in both countries. Patrilocality refers to the firmly-entrenched cultural norm for elderly parents to coreside with their adult son, and for a woman to 'marry in' and assist him in this function. Patrilocality is the custom in almost every country with missing women. In a world without social security and with limited ability among individuals to generate financial wealth, this is the primary method of guaranteeing support in one's old age. In this context, it is perhaps unsurprising that parents have resorted to sex selection in a period of fertility decline, when parents will have to rely on fewer children to care for them in their old age.

When Amartya Sen first coined the term 'missing girls' in a 1990 New York Review of Books article, it was unclear exactly how these women went missing. Although some presumed that daughters suffered higher mortality rates throughout childhood, later scholarship documented that infanticide and sex-selective abortion were the primary explanations, with the latter becoming increasingly prominent after ultrasound's diffusion in China in the late 1980s and early 1990s in India.

Historically, Chinese and Indian parents discriminated against girls on birth and throughout childhood to ensure the survival of a son to adulthood. However, this practice was muted during the baby boom of the 1960s, which allowed the vast majority of parents to have an adult son without engaging in sex selection. However, in both China and India, increasingly strict enforcement of fertility limits put parents in a more difficult position. Strict enforcement of China's one-child policy throughout the 1980s forced parents to curb fertility. In India, overzealous promotion of family planning occurred through activities such as sterilization camps, and the country later adopted a two-child limit for public officials. In both countries, the need to have a son at an early parity became paramount. Following the introduction of ultrasound technology, parents were able to identify the sex of the fetus after 4 months of pregnancy, a technology that significantly lowered the time and psychic cost of engaging in discrimination against girls. A steep rise in the sex ratio at birth was observed in both countries in the 1990s, and has remained disturbingly high. As shown in Figure 2, this increase was concentrated among births following daughters, when parents would have felt compelled to have a son but be in violation of the one-child policy.

The most recent census data for both countries indicates that the sex ratios are at the highest levels ever recorded for each country. The naturally occurring sex ratio at birth is 106 (106 boys for 100 girls). In China, the 2005 Chinese Population Survey and the 2010 census reported that the sex ratio at birth was 118 and 119 males to females respectively, suggesting that the distorted sex ratios will continue to be a problem well into the twenty-first century. In India, the problem is somewhat less severe, though still shocking in magnitude. India's 2011 sex ratio among ages 0–6 was 109 as a ratio of males to females, representing deterioration from the 2001 sex ratio of 108. In Northern Indian states with strong son preference such as Haryana and Punjab, the ratios are similar to those in China, with reported sex ratios of 120 and 118, respectively. This long running problem has left both countries with extremely distorted sex ratios among the young. In China, there were nearly 25 million more boys than girls under 20 in the 2010 census.

Demographic Transition and the Implications for Economic Growth and Public Health

As the large cohorts born during the second phase the demographic transition enter their prime working years, a window of opportunity is provided for rapid economic growth, as slowing fertility yields a large mass of workers. However, as these cohorts enter old age, they place pressure on the system; the large mass of elderly, with smaller population cohorts before and after them, represents a challenge.

In this section, the author briefly describes a set of unique challenges facing China, India, and sub-Saharan Africa, related to the demographic transition in each context. In China, how the country will deal with a large elderly population without extensive pension programs is examined. In India, the challenges with providing health care to its large, poor, and rural population is discussed. In sub-Saharan Africa, the focus is on the most pressing concerns in the area of public health, which

The consequences of the 'missing girls' of China. *World Bank Economic Review* **23**(3), 399–425, with permission from Oxford University Press.

are to lower infant and maternal mortality, and provide wider access to contraception.

China

In China, the chief implication of the age distribution is that the country has to rapidly prepare for a heavy burden on each worker to support multiple retirees. For example, the one-child policy has resulted in a 4-2-1 problem, where four grandparents turn to two adult children for support, who only have one child of their own, leaving a great burden on each young person to provide old age support. The need for pension programs in China is acute, but programs are limited. The rural pension programs attracted reasonable participation rates, especially among individuals without sons, but complications in implementing the programs prevented their expansion. The massive expansion in the elderly population forecasted has already led many to call for a relaxation of the one-child policy. However, government officials have ignored these proposals and called for an extension to the policy in its most recent five-year plan.

China's age distribution is highly skewed, relative to the US (Figure 3). China experienced two baby booms: the first in the 1960s, and the second in the late 1980s, when the earlier boom cohorts had children. However, in the wake of government-mandated fertility control, each successive cohort in China is now smaller than the last. The magnitude of

China's baby boom cohort dwarfs that of the US's that occurred following World War II. Although the US is anticipated to converge to a normal population distribution with a modest fraction of elderly in the population, China is predicted to have a massive population of retirees. This will place pressure on the system to provide for these retirees later in the twenty-first century. Forward-thinking policy would dictate that the government access funds from the current generation of workers to provide for the future generation of retirees, as it seems unlikely that the next generation of workers will be able to support the large population of retirees.

India

In India, a critical challenge is how to provide proper care to the massive young, poor, and primarily rural population. India's young population, if provided proper access to education and health care, should allow the country to be highly productive for several decades. New initiatives have been launched in India, such as the National Rural Health Mission, which will serve to increase access to medical professionals in India's rural areas. Challenges have also plagued the expansion of rural health insurance. While 70% of India's population lives in villages, less than 2% is insured. Issues of cost sharing and access to services have made insurance either not financially viable or unattractive.

In many rural areas, there is an insufficient supply of properly trained physicians. In areas with skilled physicians, absenteeism is a challenging issue. It has been estimated that absenteeism can be as high as 40% among primary health providers and among teachers. They found absenteeism rates were related to the quality of infrastructure, and doctors were often working more hours at private facilities instead of publicly accessible facilities. This highlights the challenge of making medical services affordable and available.

Sub-Saharan Africa

Sub-Saharan Africa faces a set of unique challenges in the context of its demographic transition. The two primary issues are the need to (1) lower infant and maternal mortality and (2) expand access to contraception. Maternal mortality in sub-Saharan Africa with 500 deaths per 100 000 births is twice as high as in the next highest region, South Asia with 220 deaths per 100 000 births. More than half of all maternal deaths worldwide occur in sub-Saharan Africa. Likewise, under-five mortality exceeds 100 deaths per 1000 births, higher than in any region in the world. Although both of these rates have declined from even higher levels, they both represent challenges to development. High childhood mortality rates prevent the proper allocation of parental resources to children who will survive, and high maternal mortality rates leave many children without proper parental support. Both represent challenges necessary for sub-Saharan Africa to overcome in order to exit the poverty trap.

Sub-Saharan Africa's high fertility rate also poses a challenge for policymakers. For the region to enjoy a demographic dividend, fertility must be slowed. Fertility rates are highly negatively correlated with female educational attainment. This occurs through several channels affecting both desired family size and access to contraception to achieve the desired family size. Higher female education is associated with later marriage, greater autonomy of women in the household and over their fertility choices, and perhaps most importantly, higher opportunity costs of childbearing due to foregone wages. More educated women also have greater knowledge of an access to contraceptives, which is also partly responsible for lower fertility among more educated women. As such, increasing female education may be an effective policy tool for lowering Africa's fertility rate. In light of recent evidence that fertility declines in Africa are stalling, policy makers may wish to consider more proactive strategies for lowering fertility.

Missing Women and Implications for Public Health

In this section, the author examines how China's and India's 'missing girls' will affect public health in the coming years. The focus is on a set of health issues that have been examined by scholars that are related to the high sex ratios in Asian countries.

Unmarried Men in China

China is on the cusp of a dramatic deterioration in men's marital prospects. As shown in Figure 4, the sex imbalance between potential spouses is forecast to be at its worst by 2025, when the cohorts with the highest sex ratios (those born under the one-child policy) reach adulthood. China's one-child policy in combination with legislation regulating minimum age at marriage generates a problematic scenario. As birth cohorts age, they find that each successive generation is smaller than their own, giving rise to a 'kite-shaped' age distribution common in many Asian countries. It has been estimated that the fraction of men aged 25 and older who fail to marry will exceed 5% by 2020 and 20% by 2030. In the most optimistic scenario simulated, where the sex ratio returns to normal immediately, the share of men who fail to marry in 2060 will stabilize just below 10%. In light of historical patterns of hypergamy in China, it will likely be the men of lowest status who fail to marry, and the poorest regions of the country will have the highest rates of bachelorhood. This will generate a challenging situation for providing old age support at the local level as the population of 'bare branches,' or men who fail to marry and represent bare branches on the family tree, increases.

Trends in Sex Work and Sexually Transmitted Infections

Prostitution in China is widespread and has increased dramatically in recent years. Following Deng Xiaoping's campaign for economic reform in 1978, the market for sex work increased dramatically, as migration of both men and women to urban areas provided both increased demand and supply. Current estimates indicate that between 3 and 10 million women participate in this market, a steep increase from the hundred thousand estimated as recently as 1989. Informal prostitution rackets are common throughout China,

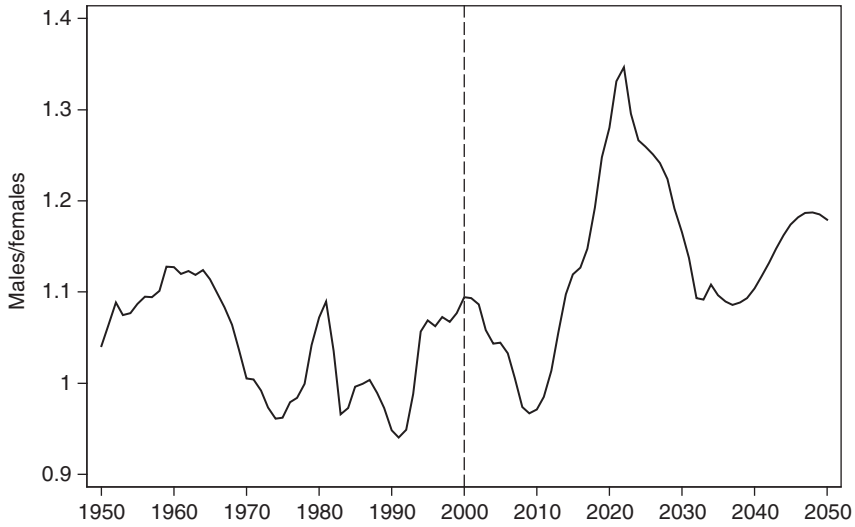

Figure 4 Sex ratio of the marriage market in China, 1950–2050. The marriage market is defined as men aged 22–32 and women aged 20–30. The sex ratio for each year is calculated using data from the 2000 census, modeling population changes with age-sex-year specific mortality rates. The population is simulated forward from 2000 using fertility assumptions described in Ebenstein and Sharygin (2009) and a sex ratio at birth of 1.09 from 2005 and beyond. The vertical dotted line indicates the year 2000. Reproduced from Ebenstein, A. and Sharygin, E. (2009). The consequences of the 'missing girls' of China. *World Bank Economic Review* **23**(3), 399–425, with permission from Oxford University Press.

sometimes involving high-school girls. However, government response is generally limited in China. Authorities attempt crackdowns through controversial 'shame parades' where Chinese prostitutes are forced to endure the embarrassment of being marched down a public street. In spite of these efforts, most scholars believe that the government is unwilling or unable to seriously tackle the problem.

In a parallel and alarming trend, China has experienced a steep increase in the syphilis infection rate, with maternal transmission rates to newborns increasing by a factor of five between 2003 and 2008 in Shanghai. Although sex work may often have ambiguous welfare consequences, in the Chinese context, the concern is clear. Chinese men visit prostitutes frequently and they are reluctant to wear condoms, which are in combination a cause for concern. The low condom use rates, lack of institutional will to reduce prostitution, and the rising sex ratio will likely create challenges as men fail to marry. In light of evidence that many women participate in prostitution while being married in general and in China in particular, this is a serious concern for the future, as concurrent sexual relationships may speed the diffusion of HIV and other STIs.

Patterns in Breastfeeding

The differential fertility behavior after the birth of sons and daughters also manifests itself in subtle ways in India. In a recent paper, it was shown that boys are breastfed for longer than girls. The mechanism is not explicit gender discrimination among living children, but driven rather by the fact that sons are often the last child. Because breastfeeding makes women less fertile, mothers looking to have another child, as is often the case after a female birth, will discontinue breastfeeding their daughters sooner than after sons. As such, boys are treated to longer durations of breastfeeding, which is documented to have important health implication in India, where drinking water is often unsafe relative to breast milk. The difference in duration for boys and girls is shown in Figure 5, and it is estimated that this explains 14% of the excess child mortality for girls relative to boys. Although historically parents exhibited explicit bias in allocation of resources to boys over girls, now developing countries are faced with more subtle but no less problematic forms of discrimination.

Sex Ratios and Social Unrest

An additional concern in China is that the high sex ratios will lead to social unrest. There are several reasons for concern over having millions of surplus males, including the possibility for China to seek out an armed conflict, as occurred in the nineteenth century following a prior episode of elevated population sex ratios. One 2007 study focuses more narrowly on the incidence of crime rates and exploits timing of the implementation of the one-child policy by province, which generates variation in sex ratios regionally. Modest effects of the adult sex ratio on violent crime and property crime were found, with the rise in sex ratios responsible for roughly one seventh of the overall rise in Chinese crime rates during the period 1988–2004. The possibility that unmarried men will generate social unrest is very plausible, and has been advanced in popular media such as newspapers. Unfortunately, the literature is scarce as the hypothesis will not be fully testable using the Chinese experience until the cohorts with extremely skewed sex ratios reach adulthood, which will occur in the next decade. This is, however, an important issue that will need to be monitored.

The Gender Gap and Female Suicide

Chinese suicide rates exhibit several unique and alarming patterns. Suicide rates in China are twice the international

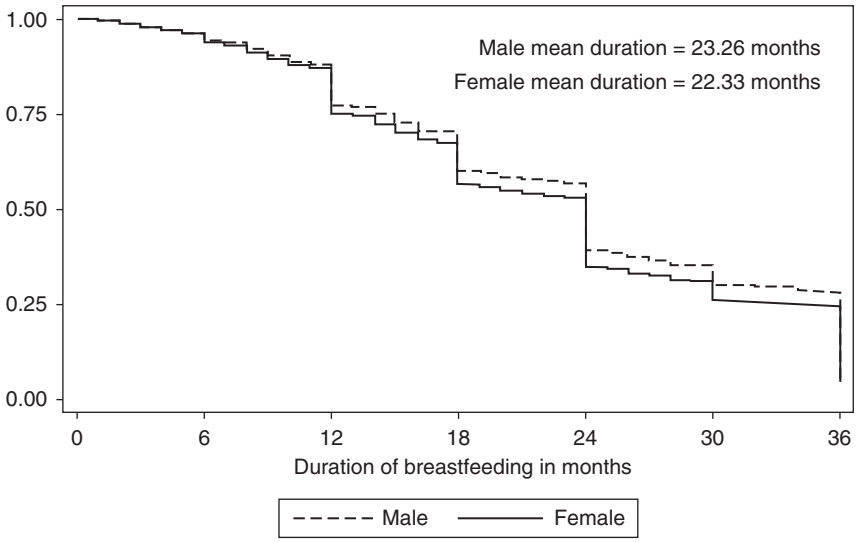

Figure 5 Breastfeeding duration by gender in India. The figure plots the proportion of children, by gender, who are still being breastfed at the duration (age) given on the horizontal axis. average, and are nearly six times higher in rural China than urban China. China is also the only country where suicide rates are higher for women than men, with suicide accounting for nearly a third of deaths to young women in rural areas. In recent years, female suicide rates have declined sharply, with no parallel decrease for men, as shown in Figure 6. What explains these striking patterns in Chinese suicide? And what role has the rapid economic and social change in China played in the decline in suicide rates among women? India has also had challenges dealing with suicide among farmers, often after poor harvests, and high rates have been observed among the young. Among men, 40% of suicides were among people aged 15–29 but for women, it was nearly 60%. These patterns indicate that women continue to have difficult lives in these countries with traditional son preference. The high suicide rates in China and India among young women speak of a welfare gap by gender that has led to a serious public health concern, and is an area for future research.

Conclusion

The developing world is characterized by extreme population patterns. The rapid demographic transition of China and India has left both countries primed to capitalize on their favorable age distribution in the short run, but with challenges in the long run. Africa is now at the cusp of its own fertility decline, provided proper family planning is implemented it could likely begin to enjoy its own demographic dividend. The role that fertility change has played in determining economic outcomes in these countries is important, and will continue to be so as they each deal with the unique challenges associated with population aging, providing access to health care, and lowering mortality rates.

The high sex ratios in Asia also represent a complicated policy issue, as they relate to a set of health challenges in a wide range of contexts including crime, old age support, and prevention of STI. The impact of missing women on the future health status of these populations is not yet clear, as the cohorts born following the introduction of ultrasound technology have not yet reached sexual maturity. However, it is certain that this will be an important and challenging issue in the coming decades, and in the near future in China.

The policy lessons of the history of China and India are important for countries earlier in their demographic transition, such as those in sub-Saharan Africa. Sharp changes in fertility can generate rapid economic growth, and pull a country from a poverty trap. However, a highly skewed age distribution also generates a new set of challenges. For policymakers, it is critical to capitalize on the opportunity presented by having a large working population. This requires investment in education and health, to ensure these cohorts are productive. Eventually, these cohorts will age and represent a large responsibility, as will occur in China's near future. As such, it is critical to prepare for population aging during the period of demographic dividend. These lessons will be important as India and sub-Saharan Africa enter the next stage of their respective demographic transitions.

Glossary

Complement A good or service whose demand rises or falls as the price of another good falls or rises is said to be a complement.

Elasticity of substitution A measure of the degree to which one input in a production process can be replaced by another without reducing the output rate. Technically, it is the proportionate change in the ratio of the amounts of two inputs to their marginal productivities.

Flow A variable having an interval of time dimension: so much per period. Compared to a stock, which is the value taken by a variable at a particular date.

Health production function A function showing the maximum impact a variety of variables can have on a person's or people's health.

Human capital The stock of human skills embodied in an individual or group. In terms of value, it is usually measured as the present value of the flow of marketed skills (for e.g., the present value of expected earnings over a period of time). It is determined by basic ability, educational attainment and health status, among other things.

Inputs The variables that generate outputs in a production function. It includes capital, labor and the quality of such variables (e.g., health status).

Stock The value taken by a variable like health, or the services of a piece of machinery at a particular date, compared with a flow, which is a variable having an interval of time dimension: so much per period.

Introduction

Recent work in economics suggests that adverse health shocks experienced *in utero* can have long-lasting effects. Studies have linked fetal health to a variety of outcomes in adulthood, such as schooling, labor market activity, and mortality. These studies have also identified a broad array of 'nurture shocks,' including ambient pollution levels, infectious disease, and mild nutritional deficits, that can generate long-lasting consequences.

The fact that maternal health has such important consequences for the child stands in stark contrast to conventional medical wisdom of the early twentieth century, which held that the womb effectively protects the fetus. For example, during the 1950s and 1960s, expectant mothers were routinely told it was fine to drink and smoke. Policymakers felt there was little cause to aim health policy at pregnant women.

Recent findings by economists on the fetal origins of adult outcomes should help change policymakers' focus. Environmental regulation that decreases the exposure of pregnant women to pollutants, for example, may have important ramifications on the educational attainment of their children. However, understanding the exact mechanisms that tie fetal health to later-life outcomes remains a developing area of research.

Early Evidence

The 'thalidomide episode' in the late 1950s and early 1960s was a watershed event in establishing the importance of the *in utero* period. Thalidomide was licensed in 1957 and widely prescribed to pregnant women for morning sickness until 1961, when it was identified as the cause of an epidemic of severe birth defects such as missing arms and legs. This episode revealed that the fetus was more vulnerable than previously thought, and led researchers to wonder: Could shocks to maternal health have other long-term health effects?

Several aspects of this historical episode facilitate analysis of the causal effects of fetal malnutrition. First, the famine was unexpected, so the Dutch were unable to stock up on food or leave the country in anticipation. Second, it was sudden, meaning that researchers can clearly identify which children were *in utero* during the famine versus those that were unaffected. The fact that food supply was adequate beforehand means that children born shortly before the famine serve a good control, or comparison, group. Finally, famines tend not to occur in countries with good vital statistics data systems in place, the Netherlands being an important exception.

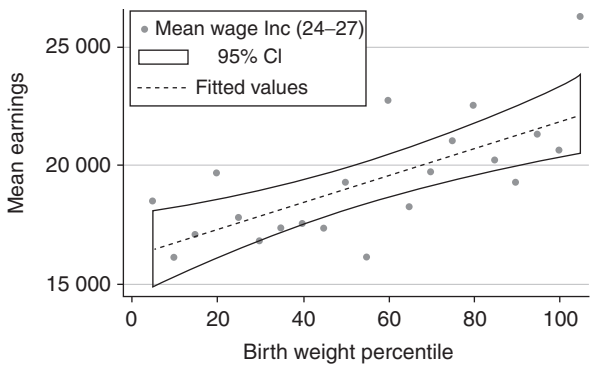

Figure 1 Mean wage earnings (age 24–27) vs. birth weight in the US, using data from the US National Longitudinal Survey of Youth.

Epidemiologists found widespread effects of the 'Hunger Winter' on maternal and fetal health. These studies show that the famine affected fertility, weight gain during pregnancy, maternal blood pressure, and infant birth weight. Results on the long-term effects on children *in utero* during the famine were initially somewhat mixed, in part because birth weight did not always seem to mediate the long-term damage (as many expected). As the affected birth cohorts aged, a more consistent pattern of adult health damage has emerged, including chronic health conditions like coronary heart disease, glucose intolerance, hypertension, and obesity.

Motivated by this evidence (and perhaps the initial controversy surrounding it) economists wondered whether adverse conditions *in utero* might: (1) affect outcomes traditionally studied in economics, such as schooling, employment, wages, and retirement, and (2) extend to a broader range of *in utero* environmental influences.

In Figure 1, wage earnings are plotted against birth weight using data from the US National Longitudinal Survey of Youth. This survey began with young people between the ages of 14 and 21 in 1978. Children born to women in this cohort have now been followed into young adulthood. As the figure shows, there is a positive correlation between birth weight and mean earnings. Descriptive findings like this encouraged economists to believe that there might be a causal relationship between fetal health and human capital.

The finding that test scores were lower in low-birth weight children was surprising as epidemiologists had posited fetal 'brain sparing' mechanisms, whereby adverse *in utero* conditions were parried through a placental triage that prioritized neural development over the development of other parts of the body.

Economists have subsequently explored the idea that fetal insults manifest later in life with numerous studies. In these studies, economists such as Janet Currie, Douglas Almond, and Michael Greenstone have looked at both the effects of large natural experiments, like the 'Hunger Winter,' as well as smaller, every-day shocks, such as pollution. Some studies compare across siblings – where one is affected by the shock but the other is not – whereas others compare across affected and unaffected cohorts. Before these studies are reviewed, a simple framework to help organize concepts will be discussed.

Conceptual Framework

One reason economists have become interested in the fetal origins hypothesis is that it holds important implications for the modeling of human capital development. In the classic health production framework, developed in 1972 by economist Michael Grossman of City University of New York, health behaves like a physical stock that serves as both an investment good and a consumption good. In this classic framework, the impact of shocks to the stock of health fades away over time. This model is applicable to many scenarios – if a child suffers a broken bone, it can heal as time passes. More formally, the formula for the health stock at time t in Grossman's model is often written as:

$$H_t = (1-\delta)H_{t-1} + I_t$$

where I_t represents investments in health capital and δ represents the depreciation rate. So, if health capital depreciates and is responsive to new health investments, then the effects of shocks to health capital tend to also depreciate over time, so that events further in the past will have less-important effects than more recent events.

Figure 2 shows how persistent a 25% negative shock to the birth endowment would be given alternative annual depreciation rates δ. Even under the lowest annual depreciation rate of 5%, half of the endowment shock is gone by the mid-teen years. For the higher depreciation rates of 10% and 15%, one

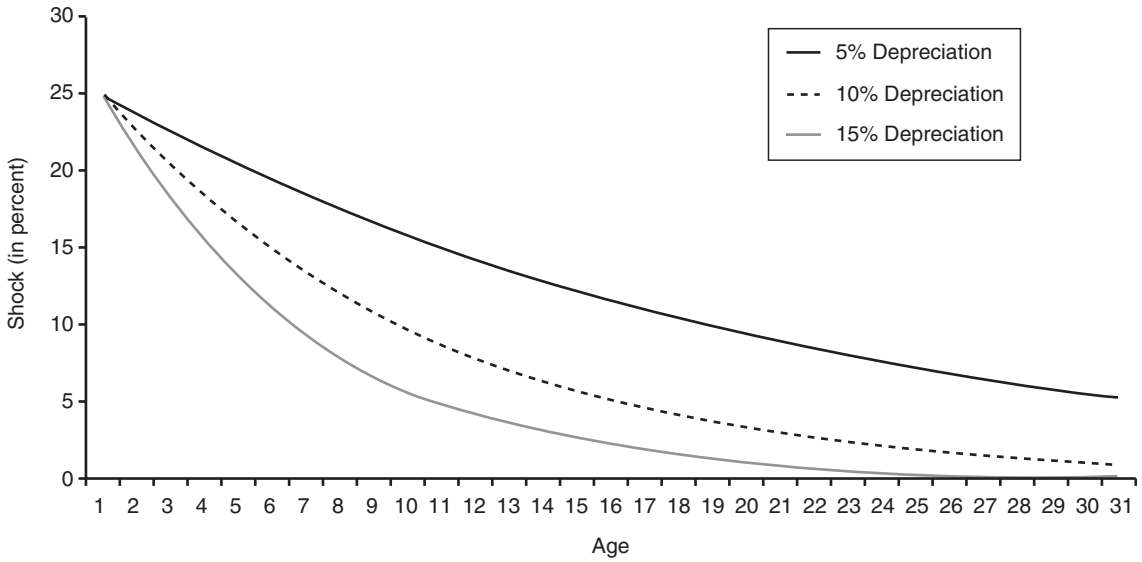

Figure 2 Shock persistence by age in the Grossman framework. Reproduced with permission from Almond, D. and Currie, J. (2011b). Killing me softly: The fetal origins hypothesis. *Journal of Economic Perspectives* **25**(3), 153–172.

would be hard-pressed to detect any lingering effects of the shock after age 30.

More formally, in the simplest two-input constant elasticity of substitution model capital and labor inputs are replaced with investments *in utero* and those occurring during the rest of childhood, writing:

$$H_{\text{adult}} = A[\gamma I_{\text{prenatal}}{}^{\Phi} + (1-\gamma) I_{\text{postnatal}}{}^{\Phi}]^{1/\Phi}$$

By allowing for varying complementarities between investments in different periods, the model is able to generate a number of rich theoretical predictions. If fetal and childhood health are complements, for example, this underscores the persistent importance of a 'good start,' as opposed to the 'fade out' implication of the Grossman model. This would occur, for example, if healthier newborns benefit more from breastfeeding or other nutrition. An extreme version of this technology includes perfect complementarity, whereby investments made *in utero* restrict the maximum level of lifetime capacity. Further, by allowing different dimensions of capacity to affect the productivity of investment, cross-capacity complementarities can shape investment decisions. For example, one might expect good childhood health to facilitate the development of cognition.

Empirical Evidence

Empirical evidence shows that investments in early childhood explain much of the variation in adult health. An intuition is that if early investments are especially effective and have had a longer time to feed through the dynamic system, their effect might be especially persistent. That said, it may be useful to distinguish conceptually between an early-life health shock and responsive investments: actions made in response to health shocks. What is observed in adulthood combines the effect of the shock and the responsive investments, should they exist. For example, there may be individual or institutional responses to health shocks, such as government aid following an earthquake. Importantly, families may provide investments that either remediate or reinforce shocks experienced *in utero*. Hence, when examining longer-term outcomes, it is important to keep in mind that these can represent both biological and social factors.

The 1918 Influenza

An influential study in the field of fetal origins research is Douglas Almond's paper on the 1918 Influenza Pandemic. Almond, a Professor of Economics at Columbia University, linked *in utero* exposure to the Influenza Pandemic to deteriorations in human capital accumulation and labor market activity decades later. Like the Dutch 'Hunger Winter' associated with the Nazi occupation of the Netherlands the Influenza Pandemic was sudden, short, unexpected, and widespread, providing an appealing research design.

Almond used data from the US Census, which record quarter of birth in some decades, to identify which infants were exposed to the flu. Although the Census does not tell us which mothers were infected, the flu was widespread enough that roughly one-third of infants born in early 1919 had mothers who contracted influenza while pregnant. As a control group, those born in early 1918 had essentially zero prenatal exposure to the 1918 pandemic. Figure 3 shows the high school graduation rates by birth year as recorded in the 1970 Census.

Further, Almond also used variation across US states in the severity of the pandemic to construct a second, difference-in-differences estimate of the pandemic's effect. Both econometric approaches yield large estimates of long-term effects. Despite the brevity of the health shock, children of infected mothers were approximately 20% more likely to be disabled and experienced wage decreases of 5% or more, as well as reduced educational attainment. These results have now been

replicated using data from other countries including Great Britain, Brazil, and Taiwan.

Identification

The fact that the fetal origins hypothesis applies to a well-defined developmental period means that it lends itself well to testing. In particular, the hypothesis predicts that later-life health outcomes should be worse only for those cohorts whose pregnancies overlapped with the shock. This means that economists can compare outcomes among these affected cohorts against two other cohorts: the cohort that was about to be conceived when the shock occurred (and is therefore too young to be affected) and the cohort that was already born at the time of the shock (and is therefore too old to be affected prenatally).

Still, seeking to quantify *in utero* effects through such comparisons gives rise to several problems. First, most birth cohorts are neither exposed to an identifiable shock *in utero*, nor were born just before or just after such a shock (and thus cannot serve as good controls). Rather than looking at all the data on births, the researcher is immediately pushed to looking at particular episodes in which an identifiable shock occurred and then attempting to draw defensibly generalizable conclusions from these episodes.

Second, the ideal shock would be shorter than the length of gestation, so as to differentiate between fetal and early-childhood exposure and perhaps stages of gestation. Many important prenatal factors, however, may last longer than pregnancy or may indeed shift permanently (e.g., the beginning of the US Food Stamp Program during the 1960s). The effect of fetal exposure may still be identified but constitutes the additional effect on top of any early-childhood effects. In general, it can be more challenging to isolate the effect of 'early-childhood' exposure because it is both less well defined and longer than the prenatal period.

Finally, one needs to be able to link data on adult outcomes to data on the affected cohorts. Economists have been creative in linking large-sample cross-sectional datasets back to ecological conditions around the time of birth. Most often, they have used information on when and where a respondent was born to link that person back to *in utero* health conditions. This has enabled economists to consider historical events featuring relatively well-defined start and/or end points. But many prominent datasets, such as the Current Population Survey, do not include information on where someone was born or the precise date of birth. As a result, many interesting and policy-relevant experiments linked to a certain time and place may never be analyzed.

In the next section, the empirical evidence in the context of these issues will be discussed.

Evidence from Sudden Shocks

A number of studies use sudden shocks like the 1918 Influenza to study the fetal origins hypothesis. These types of episodes often provide clean identification through sharp timing and, if far enough in the past, allow the researcher to examine outcomes over the full lifecourse, including mortality. A drawback is that predictions associated with large-scale or historical events may be difficult to generalize.

Large-scale shocks that have been studied in association with fetal origins include: a prenatal iodine supplementation program rolled out across Tanzania in the 1980s (by Field and colleagues), radioactive fallout from Chernobyl (by Almond and colleagues), and ambient temperature and rainfall shocks during pregnancy (by Maccini and Yang and colleagues). Outcomes examined include many different measures of health and human capital.

Identification in these studies is often based heavily on birth timing vis-à-vis the shock. Where possible, robustness is assessed by comparing effects within a certain time period across locations that experienced differing severities of the shock. Thus, the researcher is able to control for seasonal events that might coincide with the timing of the shock. Further, some datasets include a sibling link, allowing the researcher to control for fixed characteristics of families, including selective uptake of the treatment, though it is of course possible for parents to treat some siblings differently than others.

The studies referenced above produced a number of interesting findings. For example, the study on iodine supplementation found large and robust educational impacts – on average approximately half a year of schooling, with larger improvements for girls. Health measures, in contrast, appeared to be unaffected by this intervention. Subsequent work by Adhvaryu and Nyshadham has considered whether postnatal investments made by parents seem to respond to the iodine supplementation program, finding that parents reinforce iodine-related cognitive increases. Similarly, Chernobyl radiation in Sweden seems to have had its largest impact on human capital formation, not on health per se, suggesting the possibility of parental response to health endowment at birth.

Longer Natural Experiments

Many potential pathogens are more persistent than the shocks considered in Section Evidence from Sudden Shocks. Recent research has sought to maintain identification while considering slower-moving experiments, for example, to ambient pollution levels. Empirical evidence shows that these insults often have large effects on fetal health. Such findings are of particular interest because these exposures are often more common and generalizeable than with sudden shocks. A case in point is to consider the impact of slower-moving climate change as opposed to weather shocks, where adaptations and responses may differ.

As before, studies have also considered longer-term changes in the infectious disease burden. Infections can affect fetal health by diverting maternal energy toward fighting infection, by restricting food intake, or through negative consequences arising from the body's own inflammatory response. These studies have exploited variation in infectious disease in the US across seasons and states, including policy-related improvements in malaria in South US. Results show that reductions in infectious disease *in utero* lead to improvements in mortality and schooling later in life. For example, estimates show that early-life malaria can account for a quarter of the difference in long-term educational

attainment between cohorts born in malaria-afflicted states and non-afflicted areas in the early twentieth-century US.

There is evidence that some milder health shocks such as relatively low-level exposures to every-day contaminants as automobile exhaust and cigarette smoke also have negative effects on fetal health (see studies by Janet Currie, Michael Greenstone, Kenneth Chay, and others). Yet there has been little research to date linking fetal exposures to future outcomes. An exception is a study by Saunders that links the US recession of the early 1980s to reduced pollution and, through increased fetal health, improvements in high school test scores years later. Pollution levels experienced by these cohorts were high when compared to today but low when compared to many developing countries, such as China.

Studies found that being *in utero* during the annual Ramadan fast is associated with a broad spectrum of damage later in life, both to health and human capital. Daytime fasts that fall during early pregnancy have been found to have particularly large effects, despite being relatively mild when compared to famine events previously analyzed. This effect may arise because some pregnant women may fast without knowing they are pregnant.

Finally, a number of recent papers consider the effects of aggregate economic conditions around the time of birth on fetal health. Here, health in adulthood tends to be the focus (rather than human capital), and findings are less consistent than in the studies of nutrition and infection described above. One problem may be that the shocks are more diffuse in terms of timing so comparisons are less sharp. (A notable exception considers the effect of income shocks from crop blight across France.) A second issue is that the mechanism is less clear as economic downturns may affect fetal health through multiple pathways including effects on nutrition, smoking, and stress. Research by Van Den Berg and colleagues found that those born during economic downturns in the Netherlands had shorter lives, whereas a study by Cutler and colleagues on cohorts born during the Dust Bowl era in the US did not find any long-term effects.

Further Issues: Measurements of Fetal Health

All of the previously discussed studies show this maternal health shocks can be transmitted to the fetus. The most commonly used measure of fetal health is birth weight, but it may not be a particularly comprehensive or sensitive measure. In studies of the Dutch famine, for example, cohorts who were exposed to famine during the first half of pregnancy were found to have relatively normal birth weight but later showed evidence of health effects such as incipient heart disease.

Birth weight is, however, the most widely available measure of fetal health and there has been no convergence on an alternative, superior measure. An ideal metric would be sensitive for (even latent) fetal insults at all stages of pregnancy, be easy to measure, and be available for all mothers (or at least a large sample of mothers) in a cohort at the time of birth. Finding this measure of health at birth would obviate the need for data on later-life outcomes, enabling the researcher to examine current shocks rather than having to focus on those far in the past.

The lack of an ideal measure of fetal health has not, however, prevented economists from addressing the fetal origins hypothesis. This may be because economists are accustomed to considering many variables to be latent – like the potential wages of non-workers. On a practical level, economists' focus on identification strategies enables them in many circumstances to sidestep the question of finding a better measure of fetal health.

Further Issues: Bias from Selective Prenatal Mortality

A final issue to beconsidered is that of fetal mortality. Depending on the severity of a given shock, it may be that some fetuses die in response. Given that this type of selective mortality is unobserved in most birth data, researchers may underestimate fetal health shocks if the fetuses with higher baseline health are the ones that survive (but are 'scarred'). This becomes a serious problem if the negative scarring effects are sufficiently strong among the survivors to overwhelm the positive effects of selection.

Although this issue has been acknowledged outside of economics, economists have contributed by devising ways to model unobserved fetal mortality somewhat more formally. Such an exercise can be used to help quantify the selective effect due to mortality, and thereby isolate the 'scarring' effect of prenatal health conditions.

Conclusion

This article has summarized the current state of economics research on the fetal origins hypothesis. This hypothesis states that many important adult health and labor market outcomes may originate with fetal health conditions. Leveraging large-scale datasets and the sharp predictions associated with *in utero* exposure, economists have confirmed the link between fetal health and later-life outcomes. These results may hold true not only for large shocks but also for relatively mild and common shocks, such as reductions from already relatively low levels of air pollution and seasonal infections. Understanding the exact propagation mechanisms and how best to design remedial policies remain important research areas.

Global Health Initiatives and Financing for Health

N Spicer, London School of Hygiene and Tropical Medicine, London, UK
A Harmer, University of Edinburgh, Edinburgh, UK

Glossary

Aid architecture It refers to actors, institutions, systems and approaches at the international and country level that are concerned with the transfer of financial, technical, and human resources from donors to recipient countries.

Alignment A term used when donors design their development priorities and programs to be consistent with those of a recipient country, for example by using country procedures and institutions rather than those that are externally introduced.

Bilateral donor It refers to an agency that manages the transfer of aid from one country to another.

Country ownership It refers to recipient country leadership in development priorities and programs. An absence of country ownership suggests limited capacity in the government of the recipient country or overly prescriptive donor programs.

Fungibility A term used to describe the substitutability of one entity for another. For example, (1) money is fungible, in that a ten dollar bill is equivalent to ten one dollar bills, (2) In aid policy, the phenomenon of external funding intended for one purpose but ultimately used by a recipient government for another.

General budget support The money given directly to a recipient country government, generally to the ministry of finance or equivalent that is channelled into the general public spending budget.

Global health initiative (GHIs) The international initiatives for raising and disbursing additional financing for infectious diseases such as human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS) tuberculosis and malaria, and for immunization and strengthening the health systems of low- and middle income countries. GHIs share a common set of functions: to finance, resource, coordinate, and/or implement disease control globally.

Harmonization An attempt in making uniform or mutually consistent the rules and other arrangements of different jurisdictions or international organizations and initiatives. It may refer to financial, organizational or procedural arrangements, including aid programmes and global health initiatives.

Health systems strengthening The procedures for supporting a country's health care system through means such as leadership training, principles of good governance, quality assurance in service delivery, affordable financing arrangements, investment in evaluative skills and in other human and clinical resources for health.

Multilateral agencies It refers to agencies representing multiple countries working together on a given issue which includes the United Nations, the World Health Organization, the World Bank, and the World Trade Organization.

Vertical programs The programs that tackle one or few diseases or health issues; an approach often contrasted with horizontal programs which tackle multiple diseases or health issues – usually at the primary healthcare level.

Introduction

Recent years have seen important shifts in global development assistance for health (DAH). Global health initiatives (GHIs) – consisting of bilateral donor and multilateral programs, and global public–private partnerships – have mobilized significant new financing for health programs, and equate to a considerable proportion of overall overseas development aid (ODA) for health in many low- and middle-income countries (LMICs). This has enabled a dramatic scaling up of health interventions, especially for HIV/AIDS. GHIs emerged from shifts in thinking about DAH in the 1990s/early 2000s, which was hitherto characterized by donor-prescribed projects and programs financed principally by bilateral donors and the World Bank. The shift in policy focus from international to global health, an increasing number of global financial actors, and the pressing need to meet persistent and newly emerging global health threats meant that a new response was required to coordinate global efforts to raise more money for health. Although GHIs share a common set of functions: to finance, resource, coordinate and/or implement disease control globally, the term global health initiative encompasses a range of financing and implementing entities (bilateral and multilateral actors, and global public–private partnerships) with diverse governance arrangements and programmatic foci.

In this article the focus is on four of the largest GHIs: the Global Fund to Fight AIDS, Tuberculosis and Malaria (Global Fund), the Global Alliance for Vaccines and Immunizations (GAVI Alliance), the President's Emergency Plan for AIDS Relief (PEPFAR), and the World Bank's Multi-country AIDS Program (MAP, which ceased financing in 2008). **Table 1** summarizes the main features of these GHIs and other key initiatives and partnerships. The discussion is restricted to these four GHIs primarily because evidence is now beginning to emerge from empirical studies of their effects on country health systems – particularly the Global Fund; also because there is fairly limited data beyond these four large initiatives. GAVI, launched in 1999, was the first of the GHIs to disburse substantial funds at the global level, shortly followed by the MAP. High expectations surrounded the launch of the Global

Table 1 Examples of major global health initiatives

Global health initiative	*Institutional type*	*Date established*	*Total financing*	*Disease/health issue focus*
GAVI Alliance	Public–private partnership	1999	$4.5 B by 2009	Immunizations, prioritizing pneumococcal and rotavirus
Global Fund to Fight AIDS, Tuberculosis and Malaria	Public–private partnership	2002	$18.1 B by 2010	HIV/AIDS, tuberculosis and malaria
Multi-country AIDS Program (World Bank)	Multilateral program	2000	$3.1 B (total World Bank financing for HIV/AIDS programs 1989–2009)	HIV/AIDS
President's Emergency Plan for AIDS Relief (PEPFAR)	Bilateral program	2003	$19 B 2004–08	HIV/AIDS
Stop Tuberculosis Partnership	Public–private partnership	2001	Secretariat has received $396 M (2001–09) in cash contributions	Tuberculosis
Roll Back Malaria	Public–private partnership	1998	Not available	Malaria
Global Alliance for Improved Nutrition (GAIN)	Public–private partnership	2002	Total donations (2003–10) $133 M	Malnutrition
International AIDS Vaccine Initiative (IAVI)	Public–private partnership	1996	Revenue for the period 2006–09 $354 M	Vaccines to prevent HIV infection and AIDS

Fund in 2002: the initiative aimed to raise consciousness about important health issues, attract new partners, leverage substantial new funds, benefit from economies of scale in drug procurement, and promote coordination through pooling funds. There was, however, some reversal of the multilateral models of GAVI, MAP, and the Global Fund when PEPFAR was launched by the Bush Administration in 2003, a move criticized for operating in parallel to other actors and initiatives, and for adopting a prescriptive approach to determining the content of HIV/AIDS programs.

Reflecting the experimental nature of these new financing mechanisms and their sheer size, decision makers are inevitably curious about what impacts – both positive and negative – they have on recipient countries. There is an emerging literature on the effects of global initiatives and partnerships – most of which focuses on the largest HIV/AIDS initiatives – the Global Fund, PEPFAR and World Bank MAP, although there are also several studies on the GAVI Alliance. In this paper current knowledge on GHIs is reviewed, focusing on issues of healthcare financing. The achievements are reflected on, and also on the real and potential challenges that these initiatives create or reveal.

To What Extent Have Global Health Initiatives Increased Health Financing?

At the beginning of the 1990s, DAH was $5.7 billion. By the end of the decade, it had risen to just under $10 billion. A decade into the new century and DAH is pushing $25 billion annually, an increase of 124% in ten years. A 2010 report published by the Institute for Health Metrics and Evaluation discerns shifts in the balance of financial contributions to global health from traditional multilateral funders to GHIs. However, since 2007–08 when growth in DAH reached a peak of 17.5%, the rate of funding has been slowing down. In 2008–09 it dropped to just 6%. The proportion of bilateral funding has increased from 30% in 2001 to 45% in 2010, boosted by PEPFAR. So too has the proportion of funding from the Global Fund: from just 1% in its inaugural year to 11% by 2010. During the same period, UN agencies' contributions have shrunk sharply from 24% in 2001 to 14% in 2010. The World Bank's contribution has seen a dramatic reduction from 17% of total DAH in 2001 to just 5% in 2010.

For disease-specific health interventions, the Global Fund has punched well above its weight, and funding for HIV/AIDS, tuberculosis and malaria has increased dramatically. In 2009, this GHI disbursed just over $1.35 billion for these diseases. Financing HIV/AIDS, tuberculosis and malaria inevitably benefits maternal, neonatal, and child health (MNCH), and in this respect the Global Fund and GAVI have also contributed sizeable sums. In sub-Saharan Africa, for example, HIV/AIDS, tuberculosis and malaria are responsible for 52% of deaths among women of childbearing age and malaria alone accounts for 16–18% of child deaths. As funding for HIV/AIDS and other infectious diseases increased, funding for health systems and populations has experienced a corresponding decline. Between 1992 and 2003, funding for HIV/AIDS increased from 8% to a third of all commitments; during the same period, aid for population health experienced precisely opposite fortunes, decreasing from 32% to 8% of donor aid.

Does this shift mean that financing for specific diseases is displacing – or 'crowding out' – much-needed funding for other health priorities such as health system strengthening or non-communicable diseases; or conversely, has increased financing for specific diseases had a knock-on effect and increased funding for other health priorities? In terms of displacement of funds, there are multiple trends that indicate possible HIV/AIDS displacement effects, such as an increasing share of donor health and population funds. But there are also indications that HIV/AIDS funding is raising other health funding levels, particularly for control of other infectious diseases, though not for non-communicable diseases. At the

same time that funding from global health financing partnerships is increasing, a widening mismatch between ODA and health need is becoming apparent, with high visibility global health problems and measurability of outputs being major drivers of funding.

Neither is it clear whether additional funding for health has been used in the manner intended by funders – namely on the health sector. The term used to describe the phenomenon of funding intended for a specific purpose but ultimately used for another is fungibility, and this is typically used when governments receiving donor funding reduce their own spending on the same health issue and therefore aid substitutes rather than increases local funding. Evidence whether financing from global initiatives and partnerships results in governments reallocating funds to other health areas, or indeed to non-health programs is inconclusive: in some cases domestic finances stay the same or decreases, in other domestic financing increases. For example, in Ghana there is no evidence that Global Fund support had led to deductions in government or other donor financing, whereas in Tanzania receipts of external financing for HIV/AIDS and tuberculosis had led the government to reallocate resources away from the health sector.

GHIs and Innovative Financing

To achieve the Millennium Development Goals, developing countries will have to spend approximately $60 per capita by 2015, or 100% more than they are currently spending. It is unrealistic for many countries to achieve this increase. In 2001 members of the Organization of African Unity (OAU) met at Abuja, Nigeria. The resulting 'Abuja Declaration' committed all members of the OAU to ensure that at least 15% of the domestically financed government expenditure went to health. Even if low-income countries were able to meet their Abuja commitments and divert 15% of government budget to health very few of them would generate enough funds to meet the $34 per capita threshold that the Commission on Macroeconomics and Health in 2001 deemed sufficient to meet basic health needs. Admittedly, this $34 has now appreciated to approximately $50, and some countries would not achieve that target even if 100% of the government budget was diverted to health. DAH from multiple donors, including GHIs, will go some way towards filling this gap, but in addition, GHIs – particularly GAVI and the Global Fund- have championed innovative mechanisms for raising even more funds. Tasked with the challenge of identifying a range of innovative ways to raise money for health systems, a Taskforce for Innovative International Financing (TIIF) was established up in 2008 through the auspices of the International Health Partnership. It identified a tax on airline tickets, a currency transaction levy, and levies on other products and services such as mobile phone use, amongst other innovative ideas (Table 2). If brought to fruition, these mechanisms could increase ODA by $10 B. Through these innovations GHIs are proving to be essential vectors for new ways of raising much-needed money.

These issues are discussed in the 2010 World Health Report which notes, if donors honored their international pledges, external funding would double and there would be no need for innovation (http://www.who.int/whr/2010/en/index.html).

Is Financing from Global Health Initiatives Predictable?

In September 2008, development agencies met in Accra for the Third High Level Forum on Aid Effectiveness. Here, there were promises to increase the predictability of aid to enable developing countries to effectively plan and manage their short- and medium-term development programs. Unpredictable aid makes it difficult for countries receiving financial assistance to budget and implement their development agenda efficiently. Indeed, lack of predictability can shave off substantial value of aid and is believed to be one of the biggest constraints on its effectiveness. There is a fundamental missmatch between medium to long-term development strategies of recipient country governments (which would often include employing more doctors and nurses), and many donors, including GHIs, relatively short-term funding commitments. Typically, donors only commit aid 12 months in advance, and levels of aid can vary greatly from year to year. This weak alignment runs counter to funders' stated commitment to country ownership, undermining governments' authority to manage their health development programs.

For full details of Accra for the Third High Level Forum see: http://www.oecd.org/dac/aideffectiveness/thirdhighlevelforumonaideffectiveness2–4september2008.htm

A further problem is that unpredictable aid can increase fiscal and monetary instability, which in turn can lead to inflation and macroeconomic disruption. Ensuring macroeconomic stability is the raison d'être of the International Monetary Fund (IMF), an international financial institution that lends money to ailing economies. IMF loans typically come with a set of economic conditions – such as raising interest rates – derived from a set of economic principles sometimes referred to as the 'Washington consensus.' One controversial principle is the insistence on low – single-digit – inflation. The twin goals of raising interest rates and disinflation come with a high 'sacrifice ratio' (the amount of GDP growth a government 'sacrifices' to achieve the prescribed low level of inflation). As a country's economy cools, negative consequences for health become apparent from resulting cuts in health spending and wage ceilings for health workers. Early experiences from countries in sub-Saharan Africa revealed tensions between IMF loan conditions and GHI funding for health. In Uganda, disbursement of a large tranche of Global Fund money ($201 M) was delayed in 2002 because of concerns by the Ugandan finance Minister – on the advice of the IMF – that receiving such large amounts of 'additional' funds would increase the value of the Ugandan currency and render its economy less competitive. In Kenya, the heath workforce was reduced by over 30% during the 1990s in response to IMF loan conditions, and was only able to use Global Fund and other global health initiative financing to hire new nurses after intense pressure from international nongovernmental organizations and strong leadership from the Kenyan Ministry of Health.

Do GHIs Commit Aid More Predictably Than Bilateral Donors?

It is suggested that GHI funding commitments are generally more predictable than bilateral commitments. Indeed, GAVI's

Table 2 Innovative financing mechanisms championed through GHIs

Financing innovation	*GHI*	*Established*	*Funding source*	*Amount raised*	*Type of innovation*	*Health issue*	*Aim*
UNITAID	Global Fund, Clinton Foundation	2006	Tax on airline tickets	$1 B	Drug purchase facility; market intervention	HIV/AIDS, malaria	Decrease the price of medicines for priority diseases; increase the supply of drugs and diagnostics
International Finance Facility for Immunization (IFFIm)	GAVI	2006	Bonds issued in capital markets	$3 B	Front-loading cash from long-term donor commitment	Vaccine development; immunization service utilization	To rapidly accelerate the availability and predictability of funds for immunization
Debt2Health	Global Fund	2007	Debt relief	Germany has cancelled €40 M debt with Pakistan and ¢50 M with Indonesia	First ever trilateral debt relief arrangement involving a multilateral organization	AIDS, tuberculosis and malaria	Using debt swaps to free up domestic resources for Global Fund approved programs
AMC	GAVI	2005	Front-loaded financing from donors	Cost to GAVI – according to Light (2011) initial claim of $180 M yr^{-1}, likely to cost $576 M yr^{-1}	Advanced market commitment from donors to purchase pre-agreed quantity of vaccine. But some argue it is a 'large volume surplus contract' not a true AMC (Light 2011)	Pneumonia	To stimulate the development and manufacture of vaccines for developing countries

third strategic commitment was to improve the predictability and sustainability of financing for national immunization programs. According to the OECD, the Global Fund had a predictability ratio of 82% (where 100% meant that a donor disbursed the same amount as it initially planned). However, disbursement is tied to a country's performance, and so this can have a negative effect on predictability of financing. In an effort to address problems associated with short-term funding cycles, the International Finance Facility for Immunization (IFFIm) was launched by the GAVI Alliance in 2006. The IFFIm is an innovative mechanism through which national donors raise money up-front by issuing bonds which are paid back over 23 years. So far IFFIm has raised more than US$3 billion for the GAVI Alliance's immunization programs. A total anticipated IFFIm disbursement of US$4 billion is expected to protect more than 500 million children through immunization (Table 2).

Some aid modalities are more suited to predictable funding than others. General budget support – aid channeled directly into the budget of a recipient country – is arguably more effective than other modalities as it avoids project-based inefficiencies and is easier to align with country priorities. It does, of course, run the risk of mismanagement of funds in countries with weak economic governance. Budget support is not without its own problems – some of which go against other measures of aid effectiveness such as country ownership including, it can be argued, that budget support allows donors direct access to country decision making. Although there are positive examples of PEPFAR disbursements in sub-Saharan Africa, including Mozambique, Uganda, and Zambia, others argue that PEPFAR has been less predictable than other donors. Although GAVI, the Global Fund and the World Bank have been able to secure multi-year replenishments, long-term pledges, and innovative financing arrangements to accumulate funds, other GHIs, such as PEPFAR, are constrained by legal restraints on their primary funders. Although the Global Fund has contributed to more predictable financing through its shift to general budget rather than program support, the premium the partnership places on performance has had an adverse effect on predictability. Indeed the Global Fund's requirements for frequent reporting were a major burden on recipients that caused delays in disbursement and resulted in the perception that its money is unpredictable. Indeed the Fund's temporary suspension of grants in Uganda had a negative effect on perceptions of predictability by recipients which led sub-recipients to favor PEPFAR funding that was seen as more quickly disbursed and predictable.

Detailed country case studies of PEPFAR and Global Fund financing flows can be found on the Center for Global Development's website (http://www.cgdev.org/).

Do GHIs Disburse Aid on Time or Are Delays or Interruptions Commonly Experienced?

Difficulties have been reported drawing down Global Fund and MAP finances because of problems created by certain countries' low absorptive capacity, and also because of performance-based funding conditions. In contrast, PEPFAR has disbursed finances more quickly since these finances are not routed through government implementers and do not rely on government systems. There are mixed experiences from different countries on timeliness of GHI funding. In Kenya, PEPFAR disbursements were reported as timely, whereas the Global Fund grant application process was lengthy and complex. In Haiti and the Central African Republic delays between Global Fund grant approval and disbursement were experienced. In the Central African Republic this stemmed from human resource constraints delaying the reporting required to trigger disbursements. The Global Fund delayed disbursements in Laos because of the country's weak financial monitoring and evaluation systems, and interruptions in Global Fund disbursements to nongovernmental sub-recipients in Kyrgyzstan were reported as a key reason for intermittent HIV/AIDS service delivery.

Are Global Health Initiatives Financing Sustainable Health Programs?

GHIs have aimed to provide short- to medium-term finances with the intention of stimulating increases in longer term financing for health programs from country governments or other domestic sources. However, in countries with high levels of external financing from GHI vertical programs serious concerns have been raised about increasing aid dependency, while few or no strategies are in place for longer term financing.

Country evidence is thin on whether they are stepping up domestic financing in parallel with GHI financing leading to sustainable programs. In some countries such as Ethiopia, Mozambique, Uganda and Zambia GHI financing is linked to reductions in domestic financing for focal diseases programs, and in Haiti – which received substantial PEPFAR and Global Fund financing – it is expected that when these grants finish focal health programs will need to end. The problem is not confined to low-income countries. A study in the middle-income country of Georgia showed that scale-up of HIV/AIDS, tuberculosis and malaria programs financed by relatively modest Global Fund grants led to government diverting financial resources to non-focal disease healthcare priorities. At the same time rising recurrent cost requirements in focal service areas aggravated the potential for longer term funding shortages with the government unlikely to be in a position to replace GHI financing.

The Global HIV/AIDS Initiatives Network website provides extensive resources on the country effects of GHIs including county case studies and a searchable database of research-based evidence (http://www.ghinet.org/).

GHIs are increasingly seeking to make investments in longer term health systems strengthening (HSS) interventions, thereby creating a more tangible legacy of their programs. For example, PEPFAR invested US$ 640 million to systems strengthening work including health worker training in 2007. Global Fund financing has supported a range of HSS strategies including those relating to strengthening human resources for health and has expanded support of HSS in Global Fund applications. However, the imperative of the initiative to rapidly disburse finances and demonstrate their impacts is reflected in the tendency for programs to place most attention on in-service

training, task shifting and expanding the numbers of lower cadre workers, and in some countries on the recruitment of nongovernmental workers on short-term contracts, rather than training and recruiting new highly skilled health workers. In those countries nongovernmental organizations acting as implementers of HIV/AIDS Global Fund financed HIV/AIDS programs were reported as heavily dependent on Global Fund financial support, which jeopardized their long-term existence.

Before 2010, it seemed as though the Global Fund was in a strong position to continue to fund countries' health needs. However, in 2010 cracks began to appear in the strength of donor support for the Fund. Donors committed far less to the Fund for the period 2011–13 than was expected or hoped for. However, towards the end of 2011 in the following year, the Global Fund announced that it had insufficient funds to finance any new projects until 2014. This was a catastrophe for the Fund. In mid-May 2012 the Global Fund was able to release $1.6 billion to spend on new projects – still far less than was anticipated. The future of the Fund is now uncertain, although under the new leadership of Mark Dybul confidence may be returning. Despite its dramatic reversal of fortune, it is nevertheless true that before 2010, the Fund had generated massive scale-up of new funds. These have had undeniably positive effects on health.

Is Financing from Global Health Initiatives Harmonized and Aligned?

The proliferation of global health actors, including new GHIs, has heightened concerns about the lack of harmonization of health programs, and poor alignment between GHI programs and country priorities, systems and procedures. This concern is central to the aid effectiveness agenda that recognizes that while substantial new resources are being mobilized for focal health issues and disease areas, this aid may not be used as effectively as it might. Indeed, GHI funding may have some damaging effects on recipient countries with fragile health systems. The principles articulated in the Paris Declaration on Aid Effectiveness and the Accra Agenda for Action have sought to galvanize global commitments to improve the ways aid was disbursed by ensuring that aid is better harmonized and aligned, more predictable, based on country ownership and demonstrate greater mutual accountability; an agenda embodied in the health sector with the launch of the International Health Partnership in 2007. This raises the question – have GHIs stepped up to the expectations of Paris and Accra?

GHIs have embraced a disease-specific 'vertical' financing approach to target particular health issues, in part because this enables donors to demonstrate a link between their financial inputs and impacts. In this context many commentators agree that the expectation that GHIs would simplify aid architecture has not been achieved. Country experiences reveal misalignment between predominantly vertical GHI programs and country priorities and/or country disease burdens. Duplication and lack of coordination have inevitably stemmed from the introduction of parallel initiatives and donor programs, although experiences vary between initiative and recipient country and have improved over time. For example, Global Fund, PEPFAR and World Bank MAP programs each adopted different procedures for procurement and disbursement of drug supplies, and the Global Fund's requirement for a country coordinating mechanism (CCM) differed from the requirement of the World Bank and was perceived as a Global Fund rather than country-owner structure.

It is widely accepted that high transaction costs of the Global Fund and PEPFAR, and indeed other donors, impose different reporting procedures that place substantial demands on fragile country health systems, including institutional capacities and staff. PEPFAR's imposition of rigid budget allocations to prescribed interventions had undermined the initiative's commitment to country ownership, lack of transparency and lack of willingness to coordinate with other donors. Global Fund programs were reported as not engaging with pre-existing country coordination structures such as SWAps, and this reinforced vertical tendencies against government priorities to integrate health interventions at the primary healthcare level, as experienced in Georgia. In other countries in Africa, Global Fund, GAVI and PEPFAR financing is believed to be driven by global agendas that gave recipients limited flexibility to allocate finances according to their own priorities.

Nevertheless there are improvements in some countries: the Global Fund has fared well in terms of use of country procurement systems, improving alignment between Global Fund programs and national priorities and having greater country ownership than other donors, although less well in terms of alignment with national M&E systems and country cycles. Country studies reveal improved alignment between Global Fund programs and health reforms in Benin and Ethiopia, and engagement in SWAps in Mozambique and Malawi. In Rwanda, Global Fund financing allowed greater country ownership of focal disease programs than other external financing; the CCM had enabled country actors to make resource allocation decisions that were in line with country priorities. There is also some evidence that PEPFAR's programs were becoming better aligned with national plans over time.

To What Extent is GHI Financing Transparent?

Although the Five-Year Evaluation of the Global Fund suggests that Performance-Based Funding (PBF) has contributed to a culture of accountability, it also accepts that the approach has 'evolved into a complex and burdensome system,' and there remain weak monitoring, evaluation and information systems limiting the PBF approach. Similarly in the Central African Republic and Rwanda the introduction of PBF by initiatives including the Global Fund and GAVI served to improve performance, transparency and management thereby fostering accountability and reducing waste. In Haiti, PEPFAR and Global Fund financing made grantees more efficient, accountable and strengthened administrative and managerial capacity, as had Global Fund financing in Ukraine and Kyrgyzstan, although in Kenya and Kyrgyzstan performance-based monitoring had delayed grant disbursement. PEPFAR funding practices were reported as lacking transparency in some countries such as Rwanda.

The Global Fund launched a major review of its progress in 2006, known as the Global Fund Five-Year Evaluation. This multi-country assessment of the health impacts of the Global

Fund, including health systems effects can be found at: http://www.theglobalfund.org/en/terg/evaluations/5year/

Conclusion

Global health initiatives have raised and disbursed substantial new financing for major diseases and health issues. Although there are clear benefits of this increased financing in terms of significant programmatic scale-up, GHIs have revealed and in some cases aggravated weaknesses within fragile health systems. Particular concerns remain about the longer term legacies of these initiatives on the countries they aim to benefit. There are multiple problems: first, the global financial crisis puts at risk donors' commitments to make longer term financial pledges to GHI programs, threatening to undo the important gains so far; second, the ability of initiatives to strengthen country health systems in the longer term has been limited by their vertical, disease-specific nature; and third, recipient governments' strategies to scale up domestic financing to supplement or replace external health support have been restricted by international loan conditions that indirectly restrict domestic spending on health, thereby jeopardizing the sustainability of focal disease programs beyond the life of current GHI financing.

Generating evidence on the effects of GHIs is not without methodological problems: GHIs and other donors have financed complex, multi-level country programs making it difficult to attribute the effects of a single initiative or program and findings are often context-specific and quickly out of date in the context of evolving, multiple financing streams. Considerable evidence is derived from mixed quantitative–qualitative studies and the synthesis of cross-country qualitative evidence, approaches that are not as universally accepted as traditional quantitative study designs. GHIs have introduced new models of financing major health programs, yet the contrast between different models – global public–private partnerships in the form of the Global Fund and GAVI Alliance, the multilateral World Bank MAP and the bilateral PEPFAR initiative – reflects what is very little global consensus about which financing models are best. Nevertheless all four initiatives have demonstrated their willingness to learn from and respond to emerging evidence, and a number of promising 'course corrections' over their relatively short lives have been apparent.

The global health arena is a dynamic one and GHIs have become pivotal actors. There are discussions on establishing a joint GAVI Alliance, World Bank and Global Fund Funding Platform for HSS, and there have been calls to amalgamate major GHIs programs to form a Global Health Fund to coordinate global funding for broader health programs. Evidence will be needed to capture and assess the impacts of these and other changes, as GHIs evolve and effects of the global financial crisis become fully apparent.

Global Public Goods and Health

R Smith, London School of Hygiene and Tropical Medicine, London, UK

Introduction

Public goods have, for centuries, been part of the economic analysis of government policy at the national level. This has included many goods associated with improving population health, such as water and sanitation. However, in an increasingly globalized world, health is an ever more international phenomenon. Each country's health affects, and is affected by, events and processes outside its own borders. The most obvious example of this is in communicable disease, where an outbreak such as sudden acute respirator syndrome (SARS) or pandemic influenza in one country very rapidly spreads and affects many others.

It is becoming clear in many areas that matters which were once confined to national policy are now issues of global impact and concern. This has been evidenced, for example, in dealing with environmental problems such as carbon emissions and global warming. These not only affect the nation involved in their production but also impact significantly on other nations; yet no one nation necessarily has the ability, or the incentive, to address the problem. Similarly, health improvement requires collective as well as individual action on an international as well as national level. Initiatives such as the Global Fund to Fight human immuno-deficiency virus (HIV)/aquired immune deficiency syndrome (AIDS), Tuberculosis, and Malaria reflect a growing awareness of this. However, initiating, organizing, and financing collective actions for health at the global level presents a challenge to existing international organizations. Recognition of this led initially to the development of the concept of Global Public Goods, and more recently the consideration of Global Public Goods for Health, as a framework for considering these issues of collective action at the international level.

What are Global Public Goods?

The global public good concept is an extension of the economic tradition of classifying goods and services according to where they stand along two axes – one measuring rivalry in consumption, the other measuring excludability – as illustrated in Table 1.

Pure private goods are those that are most used to dealing within day-to-day lives, and are defined as those goods (like a loaf of bread) that are diminished by use, and thus rival in consumption, and where individuals may be excluded from consuming them. At the opposite end of the spectrum are pure public goods, which are nonrival (not diminished by use) and nonexcludable (if the good is produced, it is freely available to all). For example, broadcast radio is nonrival (many can listen to it without preventing others from listening to it) and nonexcludable (it is difficult to exclude someone from receiving it). In between these extremes are 'impure' goods, such as 'club goods,' which have low rivalry but high excludability, and 'common pool goods,' which have low excludability but high rivalry. In these cases, exclusion may occur through geographic, monetary, or administrative prohibition, and some goods are rival relative to capacity (e.g., a sewage system with spare capacity is nonrival, but once at capacity, its use becomes rival).

One of the fundamentals of public economics is that the free market – the interplay of individual supply and demand decisions mediated through the price system – will result in the provision of less than the collectively optimal level of public goods. Thus, the nation state has a role to play either in producing the good directly (the traditional approach) or at least in arranging for its production by a private firm (the increasingly popular 'outsourcing' strategy).

Note that, importantly, a good need not be a pure public good to suffer from a collective action problem. Collective action problems also apply to private goods which have substantial positive externalities, as these too will be undersupplied (because externalities are not taken into account by private suppliers and consumers). For example, an individual secures only part of the benefit from his/her treatment for tuberculosis, as others benefit from the reduced risk of infection. However, it is only this private benefit that the individual will take into account when considering whether to

Table 1 Classification of goods by rivalry and excludability

Rivalry in consumption	*Excludability*		
	At negligible cost (high excludability)	*At moderate cost (moderate excludability)*	*At infinite cost (low excludability)*
No congestion (no rivalry)	(Impure) Public goods (e.g., books)	(Impure) Public goods (e.g., cable TV)	Pure public goods (e.g., clean air)
Congestion (moderate rivalry)	Club goods/local public goods (e.g., gyms)	Mixed public and club goods (e.g., toll road)	Common property resources (e.g., streets)
Infinite congestion (high rivalry)	Pure private goods (e.g., chocolate bars)	Natural resources, closed access (e.g., fish stocks)	Natural resources, open access (spring water)

 doi:10.1016/B978-0-12-375678-7.00623-4

seek treatment. Where the private benefit is less than the cost to the individual, they will not seek treatment, even though the population as a whole (including the individual sufferer) would be better off if the individual received treatment.

Thus, from a policy perspective it makes little sense to draw too categorical a distinction between private goods with large positive externalities and the pure public good case. In a sense, an intervention that would counter a nonpublic good-related collective action problem, so as to correct the under- or oversupply of positive or negative externalities, widely spread among the population, can itself be considered a public good. For example, providing infrastructure capable of delivering timely and effective treatment for tuberculosis, and the policies to provide an incentive for individuals to seek and complete treatment, may have the characteristics of public goods, even though the treatment of an individual is essentially a private good with positive externalities.

Turning to the global level, a reasonable functional definition of global public goods would be public goods that occur across a number of national boundaries, such that it is rational, from the perspective of a group of nations collectively, to produce for universal consumption, and for which it is irrational to exclude an individual nation from consuming, irrespective of whether that nation contributes to its financing. The key issue facing provision of these goods is how to ensure collective action in the absence of a 'global government' to directly finance and/or provide the public good.

For an interesting panel discussion of global public goods more generally, which includes the 2001 Nobel Prize winner for economics Joseph Stiglitz, http://www.youtube.com/watchv=2hmMWADaPJA

How do Global Public Goods Relate to Health?

As should be apparent from Table 1, 'health' itself is a private good, as are the majority of goods and services used to produce health. One person's (or one country's) health status is a private good in the sense that he/she (or it) is the primary beneficiary of it. To illustrate this, consider the parallel of a garden: if someone cultivates an attractive garden in front of his/her house, passersby will benefit from seeing it; but it remains a private good, the main beneficiary of which is the owner, who sees more of it and is able to spend time in it. An individual's health remains primarily of benefit to that individual, although there may be some (positive or negative) externalities resulting from it; typically exposure to communicable disease.

Further, in terms of the goods and services which are necessary to provide and sustain health, such as food, shelter, and use of curative health services, 'health' is often rival and excludable between individuals and nations. Nonetheless, there are two important externality aspects of health, both at the local level and across national borders, which may be amenable to conceptualizing as having global public good (GPG) properties: (1) prevention or containment of communicable disease and (2) wider economic externality effects (Box 1). However, there are several global public goods for health which are public goods yielding improvements in health globally. These include aspects of knowledge (and technology) production and dissemination, policy and regulatory regimes, and health systems (Box 2).

Box 1 Global public good aspects of health

Prevention or Containment of Communicable Disease

Preventing one person (country) from getting a communicable disease (or treating it successfully) not only benefits the individual concerned but also provides a benefit to others (countries) by reducing their risk of infection. Yet, although communicable disease control is nonrival in its effect (one person's lower risk of contracting a disease does not limit the benefits of that lower risk to others), its production requires excludable inputs, such as vaccination, clean water, or condoms, as well as nonexcludable inputs, such as knowledge of preventive interventions and best practice in treatment. In this sense, it is a 'club good' (nonrival but excludable), although its nonrival effect implies that even if it is feasible to exclude people, it may not be desirable as the marginal effects on the health of others may outweigh the marginal savings from exclusion. However, since not all communicable diseases are global, only the prevention or containment of some communicable diseases may be considered as global public goods: HIV/AIDS, tuberculosis, eradicable disease (e.g., polio), and antimicrobial resistant disease. Others such as malaria (a regional public good) or acute respiratory infection (population subgroups) are not global public goods.

Wider Economic Externality Effects

The economic effects of ill health on households may be considerable. Although these effects are essentially private, the cumulative effect on the economy of the resulting loss of production and income, and thus the potential gains from health improvements, may be substantial. For example, the difference in annual growth accounted for by life expectancy at birth between a typical developed and developing nation is approximately 1.6%. The close, mutual, relationship between poverty and disease – particularly communicable disease – has been recognized for generations. Not only does disease reduce the productivity and incomes of people and nations, as indicated, but also the resultant poverty impacts on health through its effects on nutrition, education, housing, and health care, creating a cycle of ill health and poverty which is hard to break.

The last of these may not be immediately apparent, as it is not a public good but what is termed an access good. These are private goods that are required such that a public good may be accessed. For instance, taking the example of broadcast radio earlier, to obtain this public good one requires a radio (which is excludable and rival) to access it. Thus, in many cases, public goods, such as disease eradication, require a minimum health system (e.g., access to vaccinations) to enable access to them (or, alternatively, to allow production of them). Such private goods may often be considered as if they were public goods to the extent that their provision is a vital element of provision of the public good itself.

Production and Finance

Clearly, global public goods need to be produced and financed, and the precise details of each of these will vary according to the specific issue at hand. For instance, production of disease eradication will require production to be locally

Box 2 Global public goods for health

The scope of potential global public goods that affect health is wide but can be broadly divided into those which address in-country health problems with cross-country externalities (primarily communicable disease control, but perhaps also noncommunicable disease control to the extent that it has economic effects) and those which address the cross-border transmission of factors influencing health risks (e.g., food safety, tobacco marketing, and international trade in narcotics). Within each of these categories, global public goods may then be classified into three broad areas.

1. *Knowledge and technologies*: Information per se, such as on health risks and treatment regimes, is a global public good. However, in practice, it may not be (e.g., control of communicable disease relies on countries to produce and to act on information, which requires an effective health infrastructure). Similarly, much of the technology for curative and preventive interventions is embodied in private goods such as pharmaceuticals and vaccines, and thus a club good.
2. *Policy and regulatory regimes*: The collective nature of policies makes them public goods. Regulatory regimes (e.g., for food and product safety or pharmaceuticals) are 'club goods,' as groups can be included or excluded by a regulation, but once a regulation exists, it can apply to one or many.
3. *Health systems, as an access good*: Many global public good aspects of health depend on the existence of a functioning health system and so they are so integral that they may thus be treated as if they were themselves global public goods.

based in the distribution and administration of vaccines, but may be financed through a variety of organizations and with different mechanisms, from local health services to Non-Governmental Organization (NGOs) to private companies, through gifting of vaccines, provision of local health service personnel, and international surveillance. In this respect, the example of polio eradication is provided in **Box 3**.

The core issue in provision and finance is that national public goods are dealt with by government intervention, through direct provision, taxes, subsidies, or regulation, but in the case of global public goods, the absence of a 'global government' means that the collective action problem becomes more complex with the increased number of players involved and the need for effective incentives for compliance. The main potential contributors to provision and/or finance are: (1) national governments; (2) international agencies (including philanthropic foundations and NGOs); and (3) commercial companies. However, these players' agendas (their preferences or priorities) do not necessarily coincide with each other. The more divergent these agendas are, the lower the chance of the good being produced. Impediments to international cooperation, and the role of international bodies in facilitating it, are, therefore, central to consideration of the provision and financing of GPG.

A significant constraint in global collective action is the ability of countries to pay according to the proportion of the benefits they receive from the good in question, as this undermines the political will to cooperate and limits effective participation. Even the creation of a legal duty does not ensure compliance, as this depends on having adequate resources to fulfill such obligations. Further, where countries with inadequate resources do participate in global programs, financial and human resources may be diverted from other essential activities, with possible adverse effects on health. The opportunity cost of these resources is far greater in developing than developed countries, creating tensions in securing global cooperation and reducing the net health benefits. Circumventing this problem requires that financial and other contributions reflect each country's ability to contribute, as well as its potential benefits. In practice, this means that financing needs to come predominantly from the developed world. However, it is important here to understand that this does not imply the use of overseas development assistance. Global public goods are not substitutes for aid but a complement to it: presenting an added rationale for international cooperation and assistance. Developed countries benefit from global public goods; yet because their provision is rooted in the national level, it is, therefore, in the self-interest of wealthy nations to assist poorer nations in contributing to the production of such goods. Thus, investment in poor countries is encouraged, not because they are poor per se, but to enable them to make their contribution to goods essential to developed countries.

The provision of global public goods depends on the ability to create arrangements that account for differing incentives and means of developed and developing countries. Thus, where developed countries have the incentives to produce the good and developing countries do not, but where the participation of the developing country is vital, developed countries will be required to fund the costs to developing countries of participating in production of the good. In contrast, when incentives exist for developing countries, but not for developed countries (where diseases are disproportionately incident in poor countries), developed countries might assist in providing incentives for the commercial sector ('push and pull' mechanisms such as subsidization for research, advance purchase commitments, and expansion of orphan drug laws) or facilitate market access. This brings us on to mechanisms for financing global public goods.

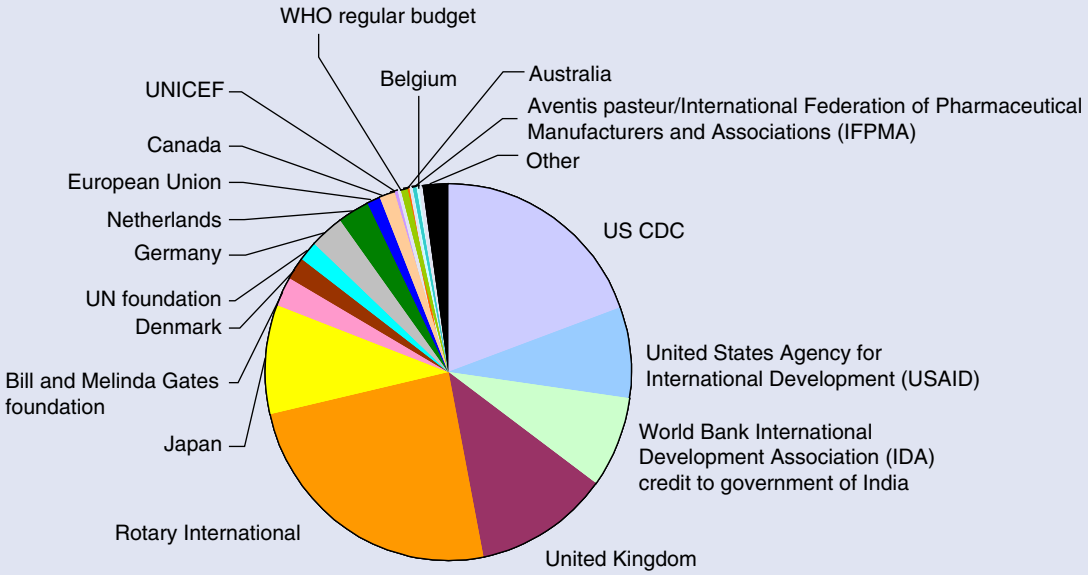
Here, voluntary contributions are the most straightforward option but are particularly prone to the free-rider problem as each country has an incentive to minimize its contribution. More formal coordinated contributions, negotiated or determined by an agreed formula, are commonly used to fund most international organizations (e.g., the World Health Organization (WHO)). Although limiting the 'free-rider' problem, each country has an incentive to negotiate the lowest possible contribution for itself (or the formula that will produce this result). Rewarding contributions with influence, to avoid this problem, skews power toward the richest countries (e.g., the international monetary fund (IMF) and World Bank); but without such incentives (or effective sanctions), countries have little incentive to pay their contributions in full (e.g., the US contributions to the United Nations (UN)). Global taxes, although theoretically the most efficient means for financing global public goods, face substantial opposition, limiting the prospects of securing funding from this source for the foreseeable future. More 'market'-based systems have been advocated, but as the USA's withdrawal from the carbon-trading system proposed in the Kyoto Agreement demonstrates, without effective enforcement mechanisms, the

Box 3 Global Polio Eradication Initiative

In the 1960s, two effective vaccines were licensed against polio, and by 1990 routine childhood immunization coverage against polio had risen to >70% worldwide, yet significant disparities in immunization coverage remained. In 1988, the World Health Assembly launched the Global Polio Eradication Initiative (GPEI). Everyone would be protected from polio (nonexcludable) and one person's protection will not reduce another's (nonrival). The problem was that the effort required to eradicate polio correlated inversely with income. In particular, the National Immunization Days required huge numbers of people and vehicles, and surveillance and laboratory work reporting standard data to the WHO regularly was also costly. So, how was it achieved?

Specific polio eradication activities were led, coordinated, and implemented by the governments of polio-infected countries but financed by a public–private partnership spearheaded by the WHO, Rotary International, the US communicable disease control (CDC), and United Nations Children's Fund (UNICEF). Rotary International especially played a central role through its 'PolioPlus' Program. The International Red Cross and Red Crescent Movement, The International Federation of the Red Cross, Médecins Sans Frontières, Save the Children Fund, World Vision, CARE, and the US-based NGO umbrella-organization CORE have also facilitated strategy implementation in the field. The United Nations Development Program, World Food Program, Office of the United Nations High Commissioner for Refugees, and others facilitated activities at the country level through the provision of transport, human resources, security, and communications. Civil society advocates, special ambassadors, business leaders, and celebrities from the arts, sciences, entertainment, and sports fields supported the GPEI, particularly in the areas of advocacy and communications.

Implementation of the GPEI required substantial in-kind and financial contributions from endemic and polio-free countries. Conservatively, polio-endemic countries are estimated to have contributed at least US$1.8 billion in volunteer time alone for polio eradication activities between 1988 and 2005, whereas external sources provided at least US$2.75 billion. External financing comes from a broad range of public and private sector sources (see figure below), channeled through multilateral funding through the WHO or UNICEF and direct bilateral funding to recipient countries, which allows the needs of both donors and recipient countries to be accommodated, although maximizing the efficient use of funds.



Overall, framing the GPEI as a global public good for health helped in understanding and presentation of the costs, financing and benefits of eradication, especially the emphasis on 'fair shares,' identification of the bearer of burden and opportunity cost, helping establish and sustain societal and political support.

free-rider problem remains. More recently, the constructive use of debt has been suggested, to allow the world to consume more goods that are global sooner and pay for them over a longer period. For certain diseases, the risks that they pose and the consequences of poverty that they perpetuate, debt (and hence loans) might make good sense. Buying time also allows the possibility that those countries not able today to help to pay for global public goods, borrow to do so in the future when their economies are more productive. The appropriateness of the precise mechanism chosen will depend on the specific good being considered.

Conclusion

The problem with public goods is that market mechanisms undersupply them. National governments usually provide finance and/or production. At a global level there is no world government. Thus global public goods require some means to ensure collective action to correct market failure at a global level. The advantage of the global public good concept in areas requiring global collective action is that it frames issues and objectives of policy – improving heath – in ways that make explicit the inputs needed (mix of public and private goods, domestic and international inputs, and incentives required) to produce and disseminate the final 'good.' Treating the final product as a 'good' in this way rather than a policy objective facilitates the analysis of who benefits and loses from its production, identifying (dis)incentives involved and thus facilitating the design of appropriate financing mechanisms.

The concept makes it clear that policy makers and their constituencies need to recognize interdependencies and the futility as well as the inefficiency of attempts to act unilaterally – porous borders have globalized health issues, and

international cooperation in health has become a matter of self interest.

Health and Health Care, Macroeconomics of

R Smith, London School of Hygiene and Tropical Medicine, London, UK

Introduction

Public expenditure targets, inflation, tax policy, and exchange rates, among other factors, will have effects on the provision of health care and the health status of the population. For instance, national income and fiscal targets will constrain how much a government can spend on health care, the exchange rate will be a factor determining the cost of vaccines and drugs, and tax policies relating to tobacco, alcohol, and 'fast food' will influence people's demand for these products and ultimately their health. Conversely, of course, the health of a population can significantly influence macroeconomics, affecting a country's rate of economic growth for example.

Macroeconomics, which encompasses these and other factors, is thus increasingly important for health and health care, especially as economies become more integrated in international trade and financial systems. This article outlines the key concepts within macroeconomics, and their application with respect to health and health care.

What is 'Macroeconomics'?

Economics is broadly divided into microeconomics and macroeconomics. Microeconomics is essentially concerned with choices and activities at the individual or firm level. It is concerned with what goods firms decide to produce and what goods households decide to consume. The interaction of households and firms takes place within a market, where price movements seek to equate demand and supply. Typically these markets are combined to form what are termed 'sectors,' such as agriculture, manufacturing, or health care. Together the interaction of these sectors comprises 'the economy.' Macroeconomics is then concerned with choice and activities across a number of these markets and sectors, and thus 'the economy' as a whole. In doing so, a whole set of terminology different to microeconomics is found, the main ones outlined in the glossary in Box 1.

International Trade

An important element of macroeconomics is international trade. According to the 'law of comparative advantage,' free trade (i.e., exchange of goods) between countries encourages countries to produce the goods that they are best placed to produce compared with other countries. A comparative advantage exists when an individual, firm, or country can produce a good or service with less forgone output (opportunity cost) than another. This differs subtly from 'absolute advantage'; for instance, where a country with lots of sunshine and wide open spaces could be seen to have an absolute advantage in agriculture compared to a country with little sunshine and mountains. Thus, call centers are increasingly located in countries such as India, not because their location there involves fewer inputs for any given number of calls or because wages are lower than elsewhere (which would confer an absolute advantage), but because the lost output from using people in this way rather than another way is smaller than it would be in, say, most European countries or North America. Conversely, research-based industries, like innovative pharmaceutical firms, are located mainly in high-income countries despite their relatively high wage levels because they too have a comparative advantage. Clearly, some countries may have an absolute advantage in producing nearly everything, but it is impossible for them to have a comparative advantage in everything. Conversely, some countries have an absolute advantage in virtually nothing, but they too necessarily have a comparative advantage in something. Given certain assumptions, total world production will therefore increase, and consumption possibilities increase, if countries specialize according to their comparative advantage and trade these goods with each other. Those countries that engage in trade will therefore see increasing gross domestic product (GDP), a wider selection of available goods and services, higher employment, and higher government revenues (due to higher income).

The problem of course is that, in practice, many countries create barriers to trade to 'protect' domestic industries, including tariffs, import restrictions, and bans. The effect of such protection is that it enables countries to continue to produce goods in which they have no comparative advantage, but at the same time discourages those countries who do actually hold the comparative advantage in such products. Why would a country do this? Typically this is specific political lobbying by an industry/sector or relates to an area deemed important for national security. However, the period since World War II has seen significant initiatives targeted to increase free trade, and has witnessed unprecedented increases in global trade activity.

How Does Macroeconomics Relate to Health and Health Care?

In this article, the term macroeconomics is used to refer to consideration of issues that fall outside of the health (care) sector. Thus it is not concerned with the inner workings of the health sector – such as how doctors are paid, or the cost-effectiveness of alternative screening programs – but the wider interactions between health and economy, health versus other sectors, and trade impacts on health. In this respect, there are a range of proximal and distal linkages between macroeconomics and health; illustrated in Figure 1. The lower half of the figure represents the individual country under

Box 1 Glossary

Appreciate

When a currency is rising relative to other currencies, it is appreciating in value.

Balance of payments (BOP)

Measures currency flows between countries. Payments are usually measured in the currency of the country that is paying. Payments made to other countries are seen as debits (e.g., imports) and payments received from other countries are seen as credits (e.g., exports). So an important indicator of a country's performance in international trade and investment is the level of surplus or deficit in their balance of payments.

Constant dollars

Constant dollars or currency correspond to values that have been adjusted for inflation and so reflect their 'real' or actual purchasing power as perceived from some base date.

Current dollars

Current dollars or currency refer to the actual dollars spent, with no adjustment for inflation.

Depreciation

When a currency is falling relative to other currencies, it is depreciating in value.

Depression

A sustained, long-term, downturn in economic activity – more severe than a recession, often judged as a 10% decrease in real Gross Domestic Product.

Economic growth

A positive change in the level of production of goods and services by a country, usually measured annually.

Exchange Rates

Exchange rates tell you how much one country's money is worth in another country's currency. If the value of a currency is going down relative to another, it is depreciating; if it is rising relative to other currencies, it is said to appreciate in value. Fluctuations in exchange rates are very important as every country imports and exports goods and services.

Fiscal policy

Policies introduced by the government to influence the economy through taxes and government spending.

Gross Domestic Product

GDP is the total expenditure by residents and foreigners on domestically produced goods and services in a year. It is the main indicator used to measure the size or output of an economy.

Gross national income

Gross National Income (GNI) measures the economic activities undertaken by residents and firms of that country regardless of where they take place. GNI is GDP plus income earned by its residents from abroad minus income earned in that country by residents of other countries abroad.

Inflation

General rise in prices over time. This means that money loses its value (purchasing power) through time.

Monetary policy

Policies by the government of adjusting interest rates and the amount of money in circulation.

Price index

A price index is created by selecting a bundle of goods and services according to the purpose of the index. Their prices are collected in a base year and compared with prices of the same bundle in another year. The overall price change of the goods in the bundle measures inflation. The price index is set at 100 for the base year and subsequent changes in prices are compared with this base year.

Purchasing power parity

An exchange rate that equates the prices of a basket of identical traded goods and services in different countries.

Recession

A downturn in the rate of economic activity, with real GDP falling in two successive quarters.

consideration, and the upper half the aspects of the international system. The arrows between the various components indicate the major linkages. This is a deliberately simplified picture to provide a concise and understandable frame of reference.

Taking the lower half of the figure first, what may be termed as the 'standard' influences on health are illustrated. These include risk factors, representing genetic predisposition to disease, environmental influences, and infectious disease. Next is the household, which represents factors associated with how people behave and, crucially, invest in their health. There is then the health sector, which comprises those goods

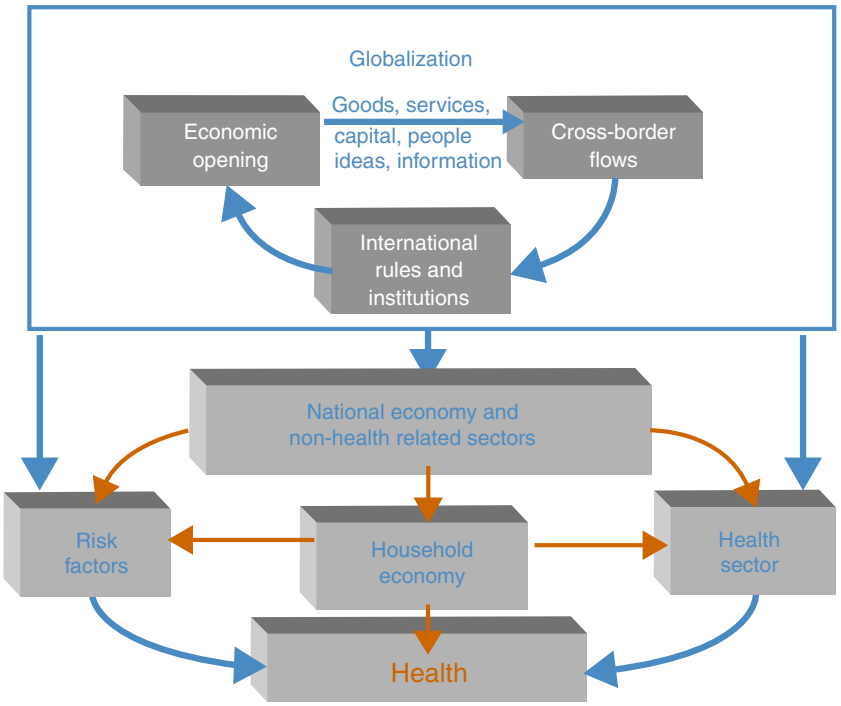

Figure 1 Major elements and linkages between macroeconomics and health.

and services consumed principally to improve health status. Finally, encompassing all these, there is the national economy, representing the metainfluences of government structures and other sectors.

In the upper half of the figure, the influences of factors that are usually outside national government jurisdictions are illustrated. For example, there is a wide variety of international influences directly upon risk factors for health, including an increased exposure to infectious disease through cross-border transmission of communicable diseases, marketing of unhealthy products and behaviors, and environmental degradation. Increased interaction in the global economic system will also affect health through influences upon the national economy and wealth. It is well established, for instance, that economic prosperity is 'generally' positively associated with increased life expectancy. Finally, health care will be affected through the direct provision and distribution of health-related goods, services, and people, such as access to pharmaceutical products, health-related knowledge and technology (e.g., new genomic developments), and the movement of patients and professionals. Also note that in this upper half of the figure, the importance of international legal and political frameworks that underpin much of these activities, such as bilateral, regional and multilateral trade agreements is seen.

In terms of linkages between these influences, increased macroeconomic trade will bring associated changes in risk factors for disease. These will include both communicable diseases, as trade encourages people and goods to cross borders, and noncommunicable diseases, as changes in the patterns of food consumption, for instance, are influenced by changes in income and industry advertising. Increased macrolevel interaction will also impact upon the domestic economy through changes in income and the distribution of that income, as well as influencing tax receipts. This will influence the household economy and also the ability of the government to be engaged in public finance and/or provision of health care. Finally, there will be direct interactions in terms of health-related goods and services, such as pharmaceuticals and associated technologies, health care workers, and patients. Let us explore these in a little more detail.

Macroeconomics and the Household

Macroeconomic policy is concerned with economic growth – increasing levels of GDP – as higher GDP leads to greater opportunities to consume which will, *ceteris paribus*, improve health (although it may not!). The relevant factors in this relationship are improved nutrition, sanitation, water, and education. In this respect, engaging in global macroeconomic integration – or international trade – is a key factor leading to economic growth through specialization. However, although trade liberalization may be poverty-alleviating in the long run, at least in the short term it is often the adverse consequences, particularly to the most poor, that are observed (e.g., increased cost of living, development of urban slums, chronic disease, pollution, and exploitative and unsafe work conditions) and lead to significant ill-health.

One of the criticisms of conventional macroeconomic approaches is the inadequate attention paid to distributional impacts – most are generally based on the aggregate indicators such as 'total' income, trade volume, employment, etc. This reflects a focus on growth and efficiency over equity. Thus, although trade liberalization may be advantageous, the crucial

factor in how advantageous and to who depends on how countries manage the process of integrating into the global economies. For example, employment creation through economic growth is often also accompanied by job destruction as labor moves from one sector or industry to another. In the absence of social safety nets, not only does such economic insecurity potentially push people into poverty, but it can also impact on health through the stress caused by economic and social dislocation.

Another important aspect of macroeconomic growth and health is that of the stability of the growth. Economic instability results in volatile markets, increased frequency of external shocks, and increased impact of such shocks. These translate into economic insecurity for an individual, which is closely linked to increased stress-related illness. It will also affect the adequacy of financial planning for ill-health by the household and the (public and private) health sector, and generate investor reluctance (including within the health sector itself).

Economic stability is affected, among other things, by the proportion of income/growth dependent on trade, with the general view that trade liberalization, especially in financial services and in the movement of capital, results in volatile markets. Of course, being an open economy does not automatically lead to economic instability/shocks – it is smaller, often developing countries, where trade contributes a much higher share of GDP that are more vulnerable as they rely more on imports and exports.

Macroeconomics and Risk Factors for Disease

It is well documented that there are many 'social determinants of health,' which refer to the general conditions in which people live and work and which influence their ability to lead healthy lives. These include factors such as employment, nutrition, environmental conditions, and education. These 'social determinants' contribute to the risk of different diseases and are often seen to differ in their role in influencing communicable and noncommunicable diseases.

The contribution of macroeconomics to the spread of communicable diseases is made in two ways. First, the overall environment in which people live (concerned with pollution, sanitation, etc.) is determined – in large part – by their income and wealth. Second, the increased international movement of people, animals, and goods associated with increased trade will affect the movement of disease. This is illustrated well by the example of SARS and other areas.

Perhaps less obvious is the relationship between macroeconomic activity and noncommunicable disease. Although macroeconomic growth can be beneficial when it leads to an expansion in the consumption of the goods that improve health, such as clean water, safe food, and education; it also facilitates the increased consumption of goods which may be harmful or hazardous to health, which may be termed 'bads.' Trade liberalization will reduce the price of imported 'bads' through reduced tariff and nontariff barriers, and increase the marketing of 'bads,' such as tobacco, alcohol, and 'fast food.' In the case of alcohol and tobacco, the development of regional trade agreements have helped to significantly reduce barriers to trade in tobacco and alcohol products, by breaking up the hitherto protected markets, contributing to enhanced consumption.

In terms of food-related products, increased macroeconomic integration will affect the entire food supply chain (levels of food imports and exports, foreign direct investment in the agro-food industry, and the harmonization of regulations that affect food), which subsequently affects what is available at what price, with what level of safety, and how it is marketed. For example, in what is termed the 'nutrition transition,' populations in developing countries are shifting away from diets high in cereals and complex carbohydrates, to high-calorie, nutrient-poor diets high in fats, sweeteners, and processed foods. Increased trade liberalization is one driver of the nutrition transition because it has had the effects of increasing the availability and lowering the prices of foods associated with the growth of diet-related chronic diseases, as well as increasing the amount of advertising of high-calorie foods worldwide. Furthermore, trade and economic development encourages the use of labor-replacing technologies, such as cars, and creates greater leisure time, both of which in turn can be seen to encourage more sedentary lifestyles.

Macroeconomics and the Health Sector

Perhaps the most visible link between macroeconomics and health is at the overall level of health care spending. Most nations, rich or poor, face the problem of rising health care costs and confront two basic questions: How to finance this rising burden and how to contain the pressures for health expenditure growth. Here, the critical issues relate to government-funded health care, where the ability to finance and/or provide public services is determined by tax receipts. Tax income is broadly dichotomized into taxes that are 'easy to collect' (such as import tariffs) to those that are 'hard to collect' (such as consumption taxes, income tax, and value added tax). Tariff revenues are a very important source of public revenues in many developing countries.

Trade liberalization, by its nature reduces the proportion of government income from 'easy to collect' sources. Although theoretically, governments should be able to shift tax bases from tariffs to domestic taxes, such as sales or income taxes, in practice, developing countries, especially low-income countries, find this difficult, especially because of the informal nature of their economies with large subsistence sectors. Low-income countries are usually able to recover only approximately 30% of the lost tariff revenues resulting in a decline of government income available to pursue public policies, be it through health care, education, water, sanitation, or a social safety net.

The exchange rate is also a key determinant of the relative prices of imported and domestically produced goods and services. For many countries, products such as pharmaceuticals, but also various elements of other technologies, such as computer equipment, surgical tools, and even lightbulbs, used to provide health care are imported. Changes in the exchange rate brought about by macroeconomic developments may therefore see the price, and hence cost, of health care

increase or decrease. Conversely, changes in demand for domestically produced goods from overseas importers may see the price of those goods domestically change in response (e.g., increased foreign demand may push up local prices). Increased linkage between economies at the macrolevel thus generates greater levels of exogenous (i.e., beyond the domestic health sector control) influences over prices, and hence cost of health care.

Finally, the health sector is increasingly involved in the direct trade of health-related goods and services. For instance, spending on pharmaceuticals represents a significant portion of health expenditure in all countries. Pharmaceuticals are also the single most important health-related product traded, comprising approximately 55% of all health-related trade by value (the share of the next most significant health-related goods traded, small devices and equipment, is $<20\%$). The market is highly concentrated, with North America, Europe, and Japan accounting for approximately 75% of sales (by value). Overall, high-income countries produce and export high-value patented pharmaceuticals and low- and middle-income countries import these products; although some produce and export low-value generic products. This leads to many developing countries experiencing a trade deficit in modern medicines, which often fuels an overall health sector deficit.

Trade in health capital and services has also expanded greatly in the last decade, in large part due to improvements in information and communication technology. These improvements have contributed, for instance, to the remote provision of health services from one country to another, known as 'e-health.' Examples of services provided include diagnostics, radiology, laboratory testing, remote surgery, and teleconsultation.

Another type of trade in health services arises from the consumption of health services abroad. This is also known as 'health tourism' and it entails people choosing to go to another country to obtain health care treatment. This attracts approximately four million patients each year, with the global market being estimated to be US$ 40–60 billion.

As liberalization increases and migration becomes easier, the movement of people across borders also increases. As a result, many health professionals choose to leave their home countries for richer, more developed ones. This is the case for doctors, nurses, pharmacists, physician assistants, dentists, and clinical laboratory technicians. It is estimated that in the UK, the total number of foreign doctors increased from 20 923 in 1970 to 69 813 in 2003. These figures may not seem that significant, but they often represent a large share of a country's total doctors. In Ghana, for example, the number of doctors leaving accounts for 30% of the total number of doctors.

Conclusion

Health is essential not only for human development, but also for economic development. Economic development also significantly influences health. This reciprocity means that activities at the macrolevel are increasingly important to population health, and the provision of health care. The growing interconnectedness between countries especially through greater trade and trade liberalization means that health sectors are more vulnerable to shocks from events that are happening around the world. It is therefore of critical importance that those concerned with health and health care have an understanding of the core issues; further articles in this volume are therefore highly recommended.

Health and Health Care, Need for

G Wester, McGill University, Montréal, QC, Canada
J Wolff, University College London, London, UK

Glossary

Capacity to benefit It refers to a particular definition of 'need' (for treatment), whereby a patient only has a need for treatment where his or her health will improve as a result of that treatment.

Cost-effectiveness A measure of the cost per desired outcome or effect of an intervention or course of action. Whether a given intervention is considered cost-effective typically depends on how it compares to other relevant alternatives with similar outcomes; the intervention with the lowest cost per desired outcome is the most cost-effective intervention.

Fair innings It represents the idea that we are all entitled to a fair chance in enjoying a lifespan of ordinary length.

Health equity It refers to the study of differences in the quality of health and health care across different populations. It relates in general to ethical judgments about the *fairness* of the distribution of such things as income and wealth, *cost* and *benefit, access* to health services, exposure to health-threatening hazards and so on.

Life expectancy The expected number of years a person or population may anticipate to live, at birth or at any given age.

Normal functioning The correct working of a person's bodily parts (e.g. a limb or organ), functions (e.g. breathing, digesting) or structures (e.g. teeth, bones).

Opportunity range The array of activities and projects available to a person, referring both to the variety and quantity of possible undertakings.

Rationing The rationing of health care refers to the denial of a treatment to a patient, or a class of patients, who would have benefited from that treatment. The usual ground for such a decision by the patient is that the price has been judged to be too high relative to their expected benefit. The usual ground under public or private insurance is the high cost of treatment relative to its expected benefit as judged by third party payers.

Severity of health state An evaluation of how bad that health state is for the person.

Introduction

Any society must come to a decision concerning the allocation of health resources, of which access to medical services, or health care, is the clearest focal point. For many theorists and ordinary citizens health care services are a 'special' type of good that should not be distributed on the market-based principle of ability to pay. Rather, it is often said, health care should be distributed on the basis of 'need'; if there was ever a place for Marx's dictum 'each according to their need' it would seem that health care would be a good candidate. Bernard Williams (1973, p. 240), for example, suggested that "the proper ground of distribution of medical care is ill health: this is a necessary truth." Of course not all societies have organized themselves entirely on this basis, but virtually all countries include a significant element of distribution of health care resources on the basis of some notion of need, whether as the main criterion for allocation, as in most European countries, or in services for the elderly, the poor, and the military personnel, as in the US. But if health care is to be distributed according to need it is necessary to explain what a need for health care means.

It would seem that, because the purpose of health care, broadly speaking, is to promote health, the need for health care must be derived from the need for health. Therefore, one ought to start with a prior question, what is the need for health?

Here it is argued that 'distribution according to need' names a general approach to health policy as opposed to distribution on the basis of ability to pay, rather than a specific principle of distribution. One reason for this claim is that all of the most prominent candidates for specifying a principle of distribution of health resources according to need face difficulties. Accordingly, a policy maker wishing to allocate resources according to health need will be compelled to balance a number of need-related considerations, among other relevant concerns, rather than follow a specific principle of distribution.

The Concept of Health

To discuss different ways in which one can be said to need either health or health care, it is necessary, first, to clarify what is meant by health. But what health is continues to be highly contested. Nevertheless, without claiming to have resolved any of the difficult questions on which these debates center, it is possible to give a rough outline of a concept of health for the purposes of this discussion.

Consider, first, two well-known but rather different definitions of health. According to Christopher Boorse's (1977) definition, health is the absence of disease. How disease, in turn, is defined is one of the most important parts of Boorse's account of health and merits much more discussion than can be accommodated here, but suffice it to say that disease, in his view, is a deviation from the 'normal' functioning of certain parts and processes of the organism. Even disabilities and injuries would fall within the scope of this definition of disease, and as such it leaves a much narrower range left for health compared to how it is ordinarily understood.

In contrast to this definition, the World Health Organization (WHO) adopts a much wider definition of health, according to which health is "a state of complete physical, mental and social well being and not merely the absence of disease or infirmity" (1946).

Although it seems right that health should be closely related to well being, the WHO's definition goes too far: in this view, health problematically appears to be indistinguishable from well being or happiness. Nevertheless, this definition draws our attention to a different aspect of health beyond Boorse's definition in terms of the absence of disease: that of 'positive' health achievement. One can imagine other such positive health achievements, for example, athleticism or living a healthy lifestyle. Furthermore, certain aspects of health such as physique, physical strength, or endurance, can today be enhanced through various drugs and procedures – such enhancements could be said to constitute improvements to one's health, regardless of their impact on the presence or absence of disease.

It cannot be resolved here which of these two, or indeed of the many other definitions that have been proposed, represents the most appropriate account of what health is. However, a disease model of health seems more appropriate in the context of a discussion of health need. Even if it is allowed that 'merely' being free of disease is not the 'best' level of health one can achieve, and that there are other health states that are superior, it is more difficult to see the 'need' for this latter form of health achievement. It might be proposed, then, that the need for health is best captured in terms of the need to be (reasonably) free of disease. For our purposes, the disease concept is narrowed down further, to encompass only such deviations from normal functioning that are harmful to the person.

But it is also necessary to think about the question of time span. The definition of health given so far is silent on the question of how extended a period should be considered. It is clear that one may be afflicted by disease at any given time in one's life. Moreover, the duration of any particular disease can vary greatly; some are short-lasted or can be cured, others are chronic. Clearly, the duration of any disease will matter greatly to how significant a departure from health one thinks that disease state represents. However, health is also a prerequisite for life itself – without health there is no life. So one could also conceive of health in terms of the time passed before the total loss of health, death, occurs.

Thus, time and duration seem of central relevance when health is discussed. One may therefore ask whether duration or longevity should be included in the concept of health. Is the duration of health – the length of life – a dimension of health? It would then follow that a shorter life would be a less healthy life. That would be true even if life had been lived 'in full health,' completely free of disease, in every moment up until the point of death. Alternatively, it could be said that length of life is simply health combined with duration. In that case, the length of life would not affect how healthy one would consider a particular life to be.

For our purposes, health is defined as including duration. That means that not only the absence of disease, but also a lifespan of a certain length, constitute the baseline of health achievement against which health need is measured.

The Logic of Need

It is often argued that 'need' is a three-element relation: in case of human need x – a person – needs y – an object – in order to z – to achieve a purpose or goal. In this framework it is clear that one question of health need is what is needed to achieve health (health as z). Yet one can also ask what may be a logically prior question: What is health needed for (health as y)? This prior question will be considered first.

At least two central dimensions of one's quality of life where one's health will have a considerable impact can be identified. The first of these dimensions is well being. Disease is often accompanied or constituted by various forms of suffering such as pain, nausea, 'feeling ill,' or feelings of anxiety or depression, all of which have a very direct and to varying degrees negative impact on our immediate physical and mental well being. The second dimension is the ability to engage in ordinary human activities. Norman Daniels has discussed this in terms of the importance of 'normal species functioning,' a concept adapted from Boorse's framework, for enjoying a normal opportunity range. The concept of normal species functioning is less clear than can be wished for, but at least a few relatively uncontroversial examples of normal functioning, come to mind such as having all major limbs intact, basic mobility, and being able to see and hear. These and other functionings will clearly be important for the pursuit of a wide variety of goals and projects. Many health conditions will be detrimental to or involve the loss of such functionings, and will hence negatively affect our opportunity range.

Nevertheless, the idea that health is needed for opportunity is not without difficulties. Consider, for example, the extent to which a condition such as paraplegia would affect one's opportunity range. It has been pointed out that, a person living in a poor rural village with only dirt roads is likely to experience paraplegia as a much more disabling condition than a person living in a wealthy, urban environment with a well-developed infrastructure. In other words, the extent to which limited mobility or other functional impairments will restrict one's opportunity range also depends on the nature and quality of one's social and material environment, and not just on the health condition itself.

But even individuals living in the same environment may be affected very differently by the same health condition depending on their own particular circumstances, such as their resilience, ability to adapt, social support network, or their preferences. The level of health achievement that is needed in order to enjoy a reasonable range of opportunities will clearly vary across such individual circumstances as well as the social, cultural, and historical context.

Furthermore, longevity generally tends to be valued, and it is not uncommon to think that a certain length of life is a central aspect of a good life. It is not immediately clear exactly what it is about a shorter life that is unfortunate; after all, a premature death does not in itself, retrospectively as it were, alter the quality of life lived up to the point of the onset of death or the events that led to death (though that is not to deny that having advance knowledge of one's own to be shortened lifespan is likely to affect one's quality of life in various ways). But perhaps one could say that a shorter life is a life with less opportunity, both in terms of variety and the total 'amount' of opportunity. This

diminished range of opportunities due to premature death would not affect the individual in the same way as diminished opportunities due to loss of functionings – perhaps it is not even quite correct to say that the diminished range of opportunities in the former case really 'affects' the individual's lived life as such – but the loss of opportunity still represents an unfulfilled potential and, therefore, a shortfall.

Returning to the idea of need as a three-element relation (x needs y in order to z), it was noted that in addition to the question discussed in the previous section – what is health needed for? – one can ask 'what is needed to achieve health?' This is the central question of 'health need,' which will be considered next.

Health care appears to be the most obvious candidate for what is needed to achieve health. After all, health care is a means to improving health, and thus it would seem that a need for health is simultaneously a need for health care. However, not all health needs indicate a need for health care. Ordinarily, other basic needs such as food, water, sanitation, and shelter must be met as a minimal precondition for health; many health needs arise as the result of a failure to meet these other needs. In such cases, although health care might be necessary for short-term intervention, ensuring that these basic needs are met will clearly be more effective for overcoming population health needs in the longer term. Even in developed societies where basic needs are mostly catered for, it is argued that a level of health need arises as a result of poor quality housing, material insecurity, working conditions, and social exclusion. In many cases, targeting such 'upstream' causes of disease will be a better strategy for reducing health need overall.

A need for health, then, cannot be identified with a need for health care; only some health needs are at the same time health care needs. The concept of health care need will be considered once more in the last part of the article, but first the relationship between a shortfall in health and the need for health will be considered in more detail.

The Health Baseline

For the purposes of this discussion, health is conceived as the absence of harmful disease (understood very broadly). But it is also noted that what is to count as 'harmful disease' can vary culturally and individually. It is also suggested that longevity should be seen as a dimension of health. The notions of the absence of disease, and of living to a certain age, function not only as conceptions of health, but can also be conceived of as a particular baseline of health, against which shortfalls in health can be measured. Thus, premature death and the presence of disease both in different ways represent shortfalls in health achievement.

This baseline of health has a double function. On the one hand it provides an account of what it is to achieve health (as a means to a life of good experience and opportunity). On the other it provides a standard by which other things, such as health care, can be judged as meeting health need or not. The baseline of health, therefore, is central to the concept of need for health and health care. The question of what this baseline of health should be will be considered next.

On the most expansive conception of health need, the highest attainable health would be adopted as the baseline against which health need is measured. Consider the case of life expectancy. The life expectancy at birth in Japan, which is one of the highest in the world at nearly 84 years (CIA: The World Factbook, 2012), is usually used as the standard for the highest attainable life expectancy. Accordingly, if this life expectancy is adopted as the relevant baseline, any shorter life expectancy represents a health need. However, one might be skeptical of the idea that any shortfall from this very high standard of health is appropriately characterized as a health need. The UK, for example, has a slightly lower life expectancy at birth than Japan at approximately 80 years (CIA Factbook). But would one thereby say that the UK has a health need? This seems debatable.

One possible argument is that a shortfall in health is only a health need if it reflects a genuine possibility for health gain. But it is not clear that the highest known life expectancy attained by some is attainable by all. This will depend on what factors determine longevity and the extent to which these factors are within the scope of human control. Perhaps longevity is partly genetically determined. Other determinants, such as diet and lifestyle, are in principle within our control, but in practice it is hard to imagine a government imposing a particular diet on its citizens. One can see why one might think that only cases where there is a genuine possibility for improving health should be considered a health need: after all, to say that there exists a need seems to imply that something ought to be done. And to say that something ought to be done in turn seems to imply that something can be done – or so proclaims that familiar Kantian principle.

This issue can be set aside for now. Instead, consider a different reason to be skeptical that the UK has a health need in this case. One could argue that the highest attainable health is simply the wrong standard of health against which to compare our own health achievement for the purpose of identifying health need. Just as athleticism or other forms of positive health achievements go beyond what one would ordinarily say is needed, this ideal standard also seems to exceed what is required. Reserving the term 'need' for more substantial shortfalls in health seems more intuitive.

This point can be accommodated if a more modest level of health is adopted as the relevant baseline, for example, a level of health that it is reasonable or realistic to expect to attain. Alan Williams has expressed a related view with respect to length of life, arguing that 'we are each entitled to a certain level of achievement in the game of life,' and that anyone exceeding this level, which he refers to as a 'fair innings,' 'has no reason to complain when their time runs out' (Williams, 1998, p. 319). It is possible to extend and apply this concept of a 'fair innings' to the standard of health; the idea is that because it is clearly both possible and desirable to improve health beyond this level, a person or a population that has reached this standard of health has attained a fair or sufficient level of health, and therefore does not have a need for health.

Although it remains true that there is a sense that someone who has lived beyond the age of the 'fair innings' could understandably still claim to have a need for health, just as a wealthy person could claim a need for more money, there is a sense, in both cases, in which one could say that their needs

have been met, and what they claim to need is a form of luxury or excess. On this account, need is assimilated to something like basic need. It is true that one can have further needs even when basic needs have been met, but for political purposes it could be that only basic needs call for action.

It may be that this notion of a fair innings of health does not lend itself equally well to all dimensions of health or all levels of analysis; or perhaps one must approach the notion of sufficiency differently with regard to such different dimensions of health rather than speak of sufficiency of health overall. For example, perhaps only moderate levels of pain will be accepted as 'within' our standard for being 'sufficiently' pain free, whereas our standard for a sufficient length of life could be significantly lower than the known human potential; and having achieved sufficiency in one dimension of health may not imply sufficiency in a different dimension. Clearly, the notion of a fair innings of health requires more work. Nevertheless, one can make sense of the idea that a shortfall from or failure to achieve the highest attainable level of health does not have to indicate a health need.

If this idea of a fair innings of health is accepted, how should one go about determining what level of health it would be reasonable to expect to attain? Health outcomes are partly determined by one's social, material, and economic environment. The quality and nature of this environment in turn depend on a society's level of affluence and on how its resources are distributed. The question of what level of health it is reasonable to expect to attain can only be answered with reference to these further substantive issues, and as such is hardly normatively neutral.

On the global level, there are enormous inequalities in material standards of living. Hundreds of millions of people live in extreme poverty lacking adequate nutrition, clean drinking water, sanitation, and access to basic health care. Whereas these levels of extreme poverty are avoidable, it is perhaps less clear what level of material living conditions would be generally attainable if global resources were distributed more fairly. The standard of living is not the only important determinant of health, and health achievement is unlikely to improve exponentially with improvements in the material standard of living; nevertheless, the realistically attainable standard of living is likely to impose some constraints on the level of health one can reasonably expect to attain. For example, it seems dubious that the exceptionally high standard of living found in Monaco, where citizens are generally extremely wealthy, is attainable for all. Life expectancy at birth here is the highest in the world at nearly 90 years (CIA: The World Factbook, 2012) – but insofar as this health achievement is a result of their wealth and high standard of living, it is not realistically attainable for the world's population as a whole.

The question of what standard of living will be generally attainable aside, within any society there will be other important decisions to be made about how much priority should be given to the promotion of health over other things that are valued. Such questions of priority are likely to arise in many different contexts, but one can illustrate the point by considering the case of reducing or eliminating health risks. How much effort should be expended on this task? Some interventions furthering this objective could have prohibitive costs in other areas of life. For example, road accidents, being one of the top 10 causes of death worldwide (WHO (World Health Organization), 2008), constitute a severe health risk. However, even if banning the use of cars altogether were to improve our health overall, there are obvious reasons why it is neither desirable nor practicable to go through with such a proposal.

The answer to the question of what level of health it is reasonable to expect to attain will depend on other normative judgments, such as 'what is a fair distribution of resources?' and 'how important is health compared to other dimensions of quality of life?' Depending on what answers are given to these and related questions, one will have different ideas about the appropriate baseline of health achievement against which shortfalls in health should be measured, and therefore, about what counts as a health need.

Three Concepts of Health Care Need

Next, consider the question of need for health care. It was established that health care is not always needed to achieve health. But it is necessary to look at the relationship between need for health and need for health care in more detail. Here, three concepts of health care need which each limits the concept of need in different ways are considered: presence of disease, capacity to benefit, and cost-effectiveness of treatment.

The idea that the presence of disease equals a need for health care is very straightforward: if a person is sick or injured, it seems natural to say that he or she is in need of health care. However, not all diseases can be treated or cured. Although one could still consider such cases to be health needs, it is perhaps less clear whether one can say that there is a need for health care in these cases. Arguably, it seems strange to say that there is a need for health care if no health care exists, or if health care provision is at such a primitive or underdeveloped level that it would be harmful rather than beneficial. Many medical practices common in the past are now known to be either inefficient or in fact harmful, such as lobotomy or bloodletting; it cannot be said that there was ever a genuine need for such services.

However, it seems more appropriate to say that such cases represent a need for health care in general, even if there is no specific treatment available at a given time that would be of benefit. Furthermore, one can point to examples where it might be said that effective health care 'ought' to have been available. For example, not much effort has been spent on developing modern effective treatments for a group of debilitating diseases often referred to as 'neglected tropical diseases.' This group of diseases primarily affects poor populations in the developing world, and has typically received little attention from the pharmaceutical industry; there is reason to believe that more funding and research could lead to significant improvement in treatment options. In cases such as these, it also seems right to say that there is a need for health care, even if currently no specific treatment exists.

In other cases, treatment is available, but for different reasons a particular individual may be unable to benefit from the treatment. For example, a treatment may be contraindicated for patients outside a particular age bracket, patients with other, preexisting health conditions, and so on. These

patients would not benefit from the treatment in question. It therefore seems somewhat counterintuitive to say that these patients 'need' this particular treatment.

For reasons such as these, some would reject the proposal that the presence of disease itself is sufficient for there to be a need for health care. That brings us to our second proposed definition of need for health care, as 'capacity to benefit (from treatment).' This definition is often favored by health economists. According to this view, a patient is only in need of a given treatment if the patient can benefit from that treatment. Thus, on this view the patients in the examples above could not be considered to be in need of that particular health care treatment.

In many ways this definition of health care need is intuitive. At the same time, narrowing down the concept of health care need in this way does not seem to take anything away from our sense that something ought to be done. As has already been suggested, it seems important to distinguish between the need for a particular treatment or intervention (or the lack thereof), and a more general need for health care. Furthermore, the reasons why a given treatment will not be effective also seem to matter to our judgment. In some cases, for example, the treatment being effective is contingent on the patient complying with certain behavioral requirements, for example, quitting smoking or losing weight. In this case, it seems somewhat more intuitive to say that the patient needs the treatment, even if he or she is failing to comply with the requirements in question. Alternatively, imagine that the effectiveness of a treatment was contingent on the patient being well nourished before the start of the treatment. In cases where lack of resources meant patients were inadequately nourished, it also seems incorrect to say that the patient had no need of the health care treatment in question.

The ability to offer decent health care may also be limited by resource shortage and competing needs. Many countries limit the availability of health care in accordance with the cost-effectiveness of the various treatments or interventions. Sometimes certain treatments will not be offered, even if they can improve a patient's health, because the cost is considered too high relative to the health benefits it would yield. Our third proposed definition of health care need incorporates considerations of cost-effectiveness, such that a patient is considered to be in need of a given treatment only if that patient will benefit from that treatment, and that treatment is considered to be cost-effective. Thus, a patient does not need a given treatment if that treatment is too expensive or yielding too little health benefit to be cost-effective, even if the patient could benefit from the treatment.

Some very expensive and cost-ineffective cancer drugs for advanced stage disease are sometimes excluded on the grounds that they are not cost-effective. In cases where the cancer cannot be cured, treatment may nevertheless give the patient a few more months of life. In the UK there have been cases where these drugs were not offered through the National Health Service because they were deemed of too limited benefit to justify their very high cost. How many patients can avail of a given treatment can affect the price and hence the cost-effectiveness of that treatment. The so-called orphan drugs is a relevant example here. Orphan drugs are drugs for very rare conditions. If a condition is rare, market demand for the drug will be expected to be low, and it will be difficult for a pharmaceutical company to sell enough drugs to cover the expenditure involved in the research and development of the drug. Therefore, the price of such drugs is often very high, and they will rarely be cost-effective.

In this definition of health care need, the extent of need in a population will be relative to the society's level of affluence. That leads to the interesting implication that as a society becomes wealthier, and can afford to relax the cost-effectiveness constraints, all else being equal, the total need for health care would in fact increase. Although it may seem a surprising result that the need for health care increases in accordance with a society's increased wealth, this view also captures something of importance. For example, in a wealthy society, crooked teeth could be considered a need for dental services. But in a very poor society, the correction of crooked teeth would rather be considered a luxury than an actual need. Something seems right about this judgment. It is possible that what should be considered a need could be somewhat relative. Our sentiments will vary to some extent depending on what it is perceived as 'reasonable' to expect to achieve in a given context with the given level of resources. This echoes the arguments put forward earlier in the discussion about what level of health would constitute an appropriate baseline for measuring health need. Although it is relevant to know what the highest attainable standard of health is, one also ought to consider what kinds of conditions – including the level of provision of health care – will be necessary in order to reach this level of health, and the costs of bringing about such conditions.

Health Care Rationing and the Ranking of Health Care Needs

There is something to be said for each of the proposed definitions of health care need that have been considered so far. But going back to the initial observation that the concept of need is often perceived as the most appropriate guiding principle for the distribution of health (care) resources, one may ask, what would a principle of distributing health care according to need look like on each of these three concepts of health care need?

For the purposes of this discussion, it will be assumed that not all health care needs can be met. How are needs ranked, according to each of the definitions of need? As will become clear each candidate will have different implications for which needs are the greater needs. Assuming that greater needs should be given priority over lesser needs, each definition will imply different strategies for rationing health care resources. Although it is not possible to go into detail for each of the concepts here, a few examples will be pointed out that demonstrate that distribution of resources on the basis of any of these concepts of need on its own will have distributive consequences that are unsatisfactory.

The first definition of health care need that was identified was health care need as the presence of disease. How would needs be ranked on this definition? It is useful to distinguish between a severe and an urgent health state, where severity reflects how poor a health state is, and urgency reflects the

imminence of death. For simplicity, the questions of urgency will be put aside here. If one focuses merely on the severity of a health state, then the greater the health need (i.e., the worse the health state), the greater the need for health care.

Although it seems intuitive that those with the greatest health needs should also have the greatest needs for health care, it is unreasonable to give absolute priority to those with the worst health. The need for treatment can in principle be infinite; one can imagine cases where a health condition is very severe, and incurable, but where medical treatment can nevertheless be of (ever so slight) benefit. In such cases, there is potentially no limit to the amount of health care resources that could be spent in order to improve health, but without fully satisfying and hence eliminating the need. Therefore, a need for health care would remain, no matter how much health care is provided. This is the well-known problem of the bottomless pit. And the bottomless pit problem aside, some increments in health – for example, going from near-complete immobility except being able to wiggle one toe, to being able to wiggle two toes – may simply be too small to be a worthwhile expenditure. But ranking needs for health care entirely on the basis of the severity of the health state cannot accommodate such judgments.

Our second proposed definition of health care need, as capacity to benefit from treatment, avoids this problem. According to this view, need is synonymous with potential for gain; thus, the greater the potential for gain, the greater the need. Naturally, health states that are close to full health do not represent great potential for gain, and thus patients who are not very sick will not be considered to have a great need for health care. Here, the second definition is in agreement with the first definition. But patients who are very sick will only be considered to have a great need for care if effective treatment that can significantly improve the patient's health is available. Considering the example above, it is clear why this definition is so appealing: if there is not much that health care can do, the need for health care is deemed minimal.

However, ranking needs on the basis of who can benefit the most can also be problematic. Consider the following example: Imagine two patients who both need a kidney transplant, but only one kidney is available. Patient A is 30 years old and expected to live for another 40 years after the transplant, whereas patient B is 40 years old and expected to live another 20 years. In this case, allocating the kidney to patient A will yield the greatest health benefit, and therefore patient A is considered to have the greater need. But at least some would object to distinguishing between and ranking the needs of these two patients in this manner; after all, patient B also stands to gain significantly from the kidney transplant. Furthermore, consider a different example: as before, one must decide which of two patients should be allocated a kidney transplant. But in this case, patient C will attain full health after the transplant, whereas patient D will only attain a lower level of health, because this patient also has a permanent disability (which is unrelated to the kidney disease). Say that, on a scale from 0 to 1, where 0 is being dead, and 1 is full health, the kidney disease is rated at 0.3. Without the treatment, both patients have 0.3 in health; although patient D also has a disability, in this case the disability does not 'add' to the severity of the overall health state (this would be true if, e.g., the kidney disease causes you to be constantly hooked up to a dialysis machine, in which case a disability like paraplegia would not add further disadvantage to the overall health state). If paraplegia is rated at 0.7, then patient D would only gain 0.4 (i.e., an increase in health from 0.3 to 0.7) in health as a result of the kidney transplant, whereas patient C would gain 0.7 (i.e., an increase from 0.3 to 1.0). The most effective use of the health resources in this example according to a health maximizing principle would be to allocate the kidney to patient C. This implication is a particularly controversial outcome of ranking needs on the basis of maximizing health benefits.

Finally, these two cases aside, this principle of ranking needs cannot help us distinguish between different health states that have equal potential for health benefit. That is, a patient whose health can be improved from 0.2 to 0.6 will be considered as equally needy as the patient whose health can be improved from 0.5 to 0.9. But here, the severity of the health state would seem to be a relevant consideration for determining which patient has the greatest need for health care; it does not seem right to rank these two patients as having an equally great need for health care, even if their prospective health gain is of the same magnitude.

The last of the proposed definitions of health care need defined need as cost-effectiveness of treatment. That means that the ranking of a need will depend on how much a patient's health will benefit from treatment relative to the cost of that treatment. Even small health gains can be cost-effective, as long as the cost of the intervention is very low. One reason for ranking needs in this manner would be to get as much health as possible with our scarce resources; the money that can be saved by choosing more cost-effective treatments can in turn be used to pay for further treatments. As such there is an overlap with the previous definition of health care needs, which ranking of needs also pushes us to maximize health outcomes.

However, this approach can lead to many small and relatively trivial health gains being ranked as of higher priority than much more substantial health gains. This is exactly what happened in Oregon with the introduction of the Oregon Health Plan in 1990. The prioritization of health care services offered through the Medicaid health plan came about as a result of seeking to extending care to a greater number of people. But in order to achieve this, the system had to be made more cost-effective. An expert group, the Health Services Commission, compiled a list of prioritized health services, on the basis of, amongst other things, the relative cost-effectiveness of different services. The first version of the list ranked tooth-capping as of higher priority than life-saving appendectomy – a controversial result which has been the subject of much commentary and discussion since. Although cost-effectiveness is an important consideration, it seems that focusing solely on this aspect would miss other important considerations.

The discussion thus far has covered the ranking of health care needs in accordance with three different principles: severity of health state, capacity to benefit, and cost-effectiveness of treatment. The discussion has shown that a ranking of needs on the basis of any one of these considerations on its own is unsatisfactory. There is merit to all three of the

considerations, and all of them ought to be taken into account in deliberations on how to allocate our health care resources. Indeed, in practice, most countries will give all three kinds of considerations weight when allocating health care resources. Sometimes those with the worst health will be prioritized, even if a treatment only provides a minor health benefit. Other times it seems important to provide a treatment even if it is not cost-effective to do so. For example, governments sometimes do provide orphan drugs, even if they are not cost-effective.

The question of how such different and often conflicting considerations should be weighed against each other is a task for another day; here, it should simply be noted that such issues cannot be resolved by a stipulative definition of the concept of need. Defining need for health care in terms of one of these considerations does not thereby undermine the force of any of the other considerations.

The question of need aside, there are several other considerations too that are relevant to the distribution of scarce health care resources. Health equity – which is itself an ideal that could be interpreted in many different ways – is one such consideration. For reasons of equity, it might be decided to disregard capacity to benefit or the cost-effectiveness of treatment, and treat like health states alike, regardless of, for example, age or preexisting disabilities. Health care resources can also be rationed with the use of waiting lists or lotteries, without giving particular groups or individual patients greater or lower priority as such. Alternatively, one could interpret health equity as requiring us to reduce inequalities in health outcomes; that could be a reason to prioritize treatment for a patient with worse health, even if the treatment is expensive and of only modest benefit. Desert could be another relevant consideration – it might be decided to give priority in health care to groups that have taken significant risks for the sake of the country, such as firefighters and military personnel.

Conclusion

The notions of need for health and need for health care are clearly important at what one might think of as high-level strategy for resource allocation. If the government announces that it will distribute access to health services on the basis of need, it is clear that it has rejected market-based pricing for services, and will allocate its services according to something like the burden of illness or disease. Yet there is a limit to how much can be done with the concept of need alone. It is not plausible that a health service should allocate services purely on the basis of need. More importantly, however, as the discussion has shown, the concept of need is neither self-evidently clear nor normatively neutral. Defining the concept of need already requires us to take a stand on complex moral questions; one cannot cut through these difficult issues simply by referring to need. 'Distribution on the basis of need' is the name of a social program rather than a principle of distribution, and many different detailed principles of allocation are broadly consistent with a needs-based approach.

Health and Its Value: Overview

E Nord, Norwegian Institute of Public Health, Oslo, Norway, and The University of Oslo, Oslo, Norway

Glossary

Capabilities The set of all possible physical and social functionings for a person.

Cardinal Cardinal measurement in economics has a characteristic that sequences of numbers attached to entities such as health or utility are equivalent measures if they can be related by a simple linear equation such as $X = \bar{a} + bY$. For example, temperature is cardinally measured by either Fahrenheit or Celsius, which are related by the equation $F = 32 + 0.8\ ^{\circ}C$. Distance is commonly measured by ratio scales like miles and kilometers, where the equation is $K/M = 0.6214$.

Decision utility The utility of an option prior to experiencing, consuming it, etc.

Disability-adjusted life-year (DALY) A measure of the burden of disability-causing disease and injury. Age-specific expected life-years are adjusted for expected loss of healthy life during those years, yielding measures of states of health or, when two streams of DALYs are compared, potential health gain or loss by changing from one health care or social intervention to another.

Ex ante A Latin tag meaning a variable as it was before a decision or an event, sometimes used to mean the planned value of a choice variable as in *'ex ante* saving'.

Ex post A Latin tag indicating the value of a variable after a decision or an event, sometimes used to denote the outcome value of a variable as in *'ex post* saving'.

Experienced utility The experienced utility of an episode of illness or wellness is derived experimentally from real-time measures of the attributes of the experience for the subject at the time of the experience.

Perspective The viewpoint adopted for the purposes of an economic appraisal (cost–effectiveness, cost–utility analysis, etc.) that defines the scope and character of the costs and benefits to be examined, as well as other critical features, which may be social value-judgmental in nature, such as the discount rate.

Quality-adjusted Life-year A generic measure of health-related quality of life that takes into account both the quantity and the quality of life generated by interventions.

Well-being An idea related to utility but to be distinguished from health-related quality of life and the inherent 'worth' of people.

What Is Health?

Health is a multidimensional concept. According to a simple definition, one has more health, the more free one is of disease and disability, including being free of diseases at early asymptomatic stages (e.g., high blood pressure and young tumors). In health economics, the concept of health usually refers to observable characteristics such as (1) functionality of bodily organs, (2) ability to move about and do normal activities of daily living, (3) freedom of symptoms in terms of physical discomfort – for example, pain or nausea, and (4) freedom of clinical psychological problems like anxiety disorder, depression, and psychosis.

Health can be viewed as an entity at a given point in time or as an aggregate over a given time period. A person's level of health at a given point in time may be perceived and described in verbal and/or numerical terms along some or all of the above dimensions of symptoms and functioning. This yields a health profile for that person. A number of standardized questionnaires and descriptive systems are available for establishing the health profile of patients. Some of these are disease specific, others are generic, for example, the Sickness Impact Profile and SF-36. Some of the generic ones yield overall index scores that are used in economic evaluation, see below.

Health over a given time period may be understood as an aggregate of the person's health at different stages of that period. If the time period is the future, the aggregate is expected future health and much the same concept as prognosis. If the time period is the whole life, the aggregate is called lifetime health. Both expected future health and lifetime health include longevity (life expectancy).

A description of a person's health over time on one or more dimensions of functioning and symptoms is called a health scenario.

The health of individuals may be used to estimate average, median, or typical health in groups of people, for instance, in a diagnostic group, an age group, a local community or a whole nation. All are examples of estimation of population health.

Both health profiles and scenarios are descriptive entities. They build on measurements of individuals' performance on specific health dimensions, for example, blood pressure, degree of hearing, number of meters one is able to walk without help, score on a pain scale, or score on a depression scale.

The Value of Health

Health profiles and scenarios can be valued. This means judging how good or bad, or how desirable or undesirable they are – all things considered – compared to other possible profiles and scenarios.

 doi:10.1016/B978-0-12-375678-7.00501-0

It is possible to see health as valuable per se, for instance, by regarding good health as something that is the will of God or consistent with a 'natural order.' This would be a deontological view. In health economics, the perspective on valuation is mainly consequentialist: The value of health derives from its positive consequences – or from avoiding the negative consequences of illness.

Consequences of health are of different kinds and may be judged from the viewpoint of different stakeholders.

From individual's personal viewpoint, good health enhances quality of life. This applies both at a subjective and emotional level – in terms of feelings of well-being – and more objectively in terms of capabilities for doing different things and thus opportunities for enjoying a rich life. These are all aspects of health-related quality of life. Good health also enhances longevity and personal income. The personal value of health lies in all these potential consequences.

But individuals' health (or health deficits) may also have consequences for others. Family members may be affected by a person's illness in various ways. Society as a whole may lose production and income as a result of absence from work caused by illness. And communicable disease in one person is potentially harmful to other persons. In short, health has societal value over and above personal value to the individual.

Measuring the Value of Health

In health economics, much attention has been devoted to the value of health for production, i.e., to economic valuation of health from a societal perspective. Key issues in this regard are production losses caused by sick leave and disability and the importance of population health for economic growth.

In personal valuation of health, one main theme is how much individuals are willing to pay out of pocket for improvements in health and for reductions in risks of health losses. Results of research in this area are used as inputs in monetary cost–benefit analyses of health programs.

Another main theme in personal valuation is how highly individuals value life in different states of illness compared to living in full health. In health economics, this is referred to as measurement of health-related quality of life. The quality of life associated with any given health state is expressed as a score on a scale running from zero (corresponding to a state as bad as being dead) to unity (corresponding to being in full health). Alternatively, the scale can be reversed in order to focus on the severity of a state of illness or disability rather than its positive quality. Severity is then expressed as a score running from zero (corresponding to 'no problem') to unity (corresponding to as bad as being dead).

Two different kinds of judgment of health-related quality of life need to be kept apart. One is judgments of own situation made by people with illness or disability. This is often referred to as ex post judgments (judgments made after experience with the illness or disability in question). The other is judgments in samples of the general population of health states that are presented to the subjects as states they might be in. This is often referred to as ex ante judgments (judgments mostly made before experience).

In both approaches, valuations may be elicited at different levels of measurement. Ordinal valuations are verbal reports or crude ratings that allow investigators to rank different health states with respect to value, without saying how much better one state is than another. Cardinal reports allow investigators to compare differences between health states more accurately and say that one difference seems to be X times more valuable than another one.

In health economics, judgments of health-related quality of life at a cardinal level are often referred to as judgments of individual utility. Utility measured as ex ante judgments (in general populations) is called decision utility, whereas utility measured as ex post judgments (in patients and disabled people) is called experience utility.

Research on ex post judgments of health has mainly been conducted by clinicians (physicians, nurses, and others) and by social scientists working more generally with quality-of-life issues. In this research tradition, focus has been on functioning and well-being measured mainly at an ordinal level. But there are also studies of patients' and disabled people's cardinal valuations of the states they are in.

In health economics, research on health-related quality of life has focused mainly on ex ante judgments in general populations. Here, the ambition has been to obtain data with cardinal level measurement properties. For this purpose, various specialized preference elicitation techniques have been developed. Furthermore, various so-called multiattribute utility instruments have been developed that allow investigators to first establish health profiles for patients in question and then translate the profiles into single index estimates of the overall personal value – utility – of the profiles.

The exact interpretation of utility scores for health states is open to debate. On the one hand, they may be understood as the level of personal welfare (subjective well-being, happiness) that individuals derive (or expect to derive) from different states. This interpretation relates to welfare economic theory and is called welfarist. On the other hand, they may be understood as valuations of health itself as judged by some wider criteria that include objective capabilities and levels of functioning. This interpretation is called extra-welfarist.

Utility scores for health states may be multiplied by time spent in the states in question to estimate the aggregate value of health over time for individuals or groups of individuals (including whole populations). The unit of valuation is then 1 year in full health for one individual. This unit is called a quality-adjusted life-year (QALY). Any health scenario may thus be assigned an overall utility in terms of a certain number of QALYs. Similarly, severity scores for health states may be used to estimate the value of aggregate health losses over time.

Health interventions may lead to health benefits both in the present and sometime in the future. Depending on the perspective of the analysis, the value of distant benefits may be considered to be less than the value of benefits that are close in time.

The Utility and Value of Health Care

In health economics, the utility of an intervention for an individual is conventionally estimated by (1) using decision

utilities or severity scores to calculate QALYs or disability adjusted life years (DALYs) and (2) computing the difference between the individual's post- and preintervention health scenario in terms of QALYs or DALYs. The utility of a program for a group of persons is estimated as a sum of the QALY (or DALY) gains of the individuals involved.

Utility estimated in this way is not necessarily the same as the value of care. By their distance from unity, decision utility scores reflect the loss of value – or the 'disutility' – that people in the general population, who mostly are in quite good health, associate with different kinds of health problems. But when people fall ill, their reference points may change. Their valuation of care may then depend on the extent to which the best possible is being done for them, even if they cannot be restored to full health. This source of value is not incorporated in decision utility judgments of health states. Furthermore, societal decision makers' valuations of care for different groups of patients may be affected by various concerns for fairness, for instance, special concerns for the worse off. In sum, there is a difference between expressing health benefits in terms of QALYs or DALYs and valuing care more completely. The importance of the issue is most easily seen in the context of life-saving medicine. All other things being equal, life is better in good health than in less good health. But it does not follow that a person in good health values life itself more – i.e., has a stronger interest in continued life – than a person in less good health. It also does not follow that society as a whole values protection of the former person's life higher than protection of the latter person's life. The value of life itself is not the same as the valuation of health.

Health Care Demand, Empirical Determinants of

SH Zuvekas, Agency for Healthcare Research and Quality, Rockville, MD, USA

Introduction

Economic theory provides a powerful but incomplete guide to the empirical determinants of health care demand. Health economists generally assume that the demand for health care derives from a demand for health. We consume health services as either an investment in our future health, to cope with chronic illness, or recover from acute illnesses or accidents. Rarely medical care is availed simply because it is enjoyed, but we seek it for our health. Health then, along with price (or its proxy health insurance), income, and consumer preferences, play the main role in formal economic models of consumer decision making about health care.

Yet, this theory takes us only so far. Although central to demand, economic theory is agnostic as to how individuals form preferences. It is suspected that individuals vary in attitudes and preferences toward risk, willingness to trade-off better health tomorrow for increased consumption today, and likes and dislikes. As a result, people with the exact same economic resources may respond differently to the same medical circumstances. However, these individual preferences are almost never directly observed – they are difficult to measure outside of controlled experiments. Health care prices and income too are almost never observed in the way we would like.

However, empirical studies consistently demonstrate that a wide range of sociodemographic characteristics including age, ethnicity, sex, and education are strongly correlated with health care use. These rarely appear directly in the theoretical models. Sociodemographic characteristics are intended to be included in empirical models because it is believed that they are correlated with otherwise unmeasured preferences toward health or capture dimensions of a person's health (e.g., age), or both. However, interpretation is difficult because these proxy measures are often confounded with so many different unobserved aspects of individuals and their environment.

Economic theory also posits that health care demand is jointly determined with supply. In practice, empirical models of consumer demand are almost never jointly estimated with models of supply because of data limitations. Instead, these empirical models assume that observed health care use is equal to consumer demand (technically, short-run supply is assumed to be perfectly elastic at the margin). Researchers sometimes add measures of provider supply and other market characteristics on an ad hoc basis to individual characteristics in empirical models of demand. However, interpretation here is problematic. For example, physicians tend to locate in areas with high demand. Thus, a measure of supply, like physicians per capita, will tend to reflect back demand rather than being a causal determinant of demand.

How then do we decide which determinants to include in our empirical models of health care demand? And how do we interpret them? The purpose of this article is to provide guidance to both questions. The discussion begins by introducing some general rules of thumb. Although theory is by no means definitive, economic principles can still be appealed to in understanding the relationships among the theoretical and proxy determinants. Statistical principles also play a role. Overall, competing concerns about usefulness of particular variables as predictors of health care use and the potential biases they introduce must be confronted. A brief survey of the recent literature is next provided to give a flavor of the range of determinants commonly included in recent empirical studies of demand. Finally, a representative empirical example of health care demand to more systematically illustrate the selection, use, and interpretation of empirical determinants has been developed. Because price and income are covered well in separate articles, focus will be on the primary demographic, social, and above all, health characteristics that determine health care demand from the consumer point of view.

Some Rules of Thumb

In its strictest sense, 'determinant' implies causation. Causal interpretation of this theory based observable determinants of health care demand, price and/or insurance, income, and health status is threatened by what is termed as endogeneity bias because they are jointly determined with health care use. First and foremost, the concern is about bias due to adverse selection – those with a greater need or preference for treatment will be more likely to purchase or enroll in insurance coverage. To the extent that health and preferences are unmeasured, their role will be misattributed as determinants thereby overestimating the effect of insurance. As such, this form of endogeneity bias can also be thought of as omitted variable bias. Omission of relevant variables, in this case unmeasured preferences and health status, biases all other variables correlated with it. Endogeneity bias also arises from reverse causality. For example, health care ideally improves health, so that if health status is measured after care is received, the effect of health on demand is underestimated.

Even without reverse causality, postdiction bias might arise when observing health status after treatment occurs. For example, a health condition might develop after an unrelated visit to a doctor, but an empirical model including this post-visit condition will incorrectly attribute some of the reasons for the visit to this condition. One way to minimize postdiction bias is to use the earliest measurement of health status (or other determinant) possible, but this risks an opposite measurement error problem.

Most other determinants included in empirical demand models serve primarily as proxies for unmeasured aspects of individual's health or preferences toward health and health care. Use of proxies is a valid method for including what we think are important unmeasured determinants of demand. But care must be exercised both in the choice of proxies and in

their interpretation because of the obvious omitted variables bias issues that arise, as well as the potential for reverse causality.

Deciding which determinants to include in empirical demand models and then specifying how they are used and interpreted requires balancing often competing objectives and biases. Here a few general guidelines, rules, or thumb for selecting and interpreting empirical determinants have been provided. It is emphasized that these are not hard and fast rules. Reasonable researchers may differ in their beliefs about biases and as a result, make different decisions. Bias generally arises from something unobserved about individuals or their actions making it almost impossible to quantify the true extent of any particular bias.

Rule 1: Include Theoretically Important Demand Determinants Where Possible

The theoretical models of health demand states that price (or its proxy, health insurance), income, and health are primary drivers of health care demand. Therefore it should be sought to use them wherever possible. Preferences, the other main theoretical determinant, are generally unobserved and proxies must be relied on (Rules 3 and 4).

Rule 2: Minimize Bias in Choice Variables

Also, the theoretical models of health demand states that the theoretical determinants are jointly determined with health care use and thus potentially endogenous. Five options are there:

1. Less endogenous versions of determinants should be used. For example, prior year observations of a potentially endogenous variable such as health or health insurance should be used.
2. The amount of endogeneity due to omitted variables bias should be reduced. For example, including better measures of health status can reduce the bias in the effect of health insurance.
3. Econometric techniques to reduce or eliminate endogeneity bias should be used.
4. Potentially endogenous variables are to be used if (1) and (2) are not sufficient. However, interpreting the results is important.
5. Endogenous determinants should be dropped as the last resort.

The choice between (4) and (5) weighs the endogeneity bias of including a determinant against the omitted variables bias introduced by omitting it.

Rule 3: Include Exogenous Proxies

Age, race, ethnicity, and almost always, sex, are thought to be fixed or exogenous characteristics of an individual. That is, they do not depend on our choices of health care use or other determinants and they are not subject to reverse causality. Thus, they serve as excellent proxies for unmeasured health, particularly age, and also for unmeasured preferences. However, as proxies correlated with multiple omitted characteristics of individuals, they generally cannot be interpreted as causal determinants.

For other potential proxies for health and health preferences, it is a matter of degree. What matters most is how these other potential determinants are related to our own choices about health and health care, and the extent that reverse causality is an issue. For example, education clearly depends on individual choices. However, in most contexts we can still treat it as fixed. For example, the choices a 75-year old made about their education 50 or 60 years ago are unlikely to have been closely related to their health and health care use today. However, poor childhood health or a catastrophic illness in late adolescence or early adulthood such as schizophrenia or Crohn's disease could easily affect educational success.

Rule 4: Balance Competing Concerns with Potentially Endogenous Proxies

For demographic or other candidate determinants that are not fixed and subject to bias, several competing concerns must be considered in deciding whether and how to use them: (1) importance as either a direct determinant or proxy determinant of demand; (2) extent of potential endogeneity and/or reverse causality bias; and (3) extent of the omitted variable bias created by excluding the determinant. A potential determinant with uncertainty about the connection to individual decisions about health care use and a high potential for bias probably is not a good choice.

Empirical Determinants of Health Care Demand: A Survey of Current Practices

Here the health status, economic, and socioeconomic determinants included in recent empirical studies of the demand for health care are surveyed. The survey includes 98 empirical studies published over the 12-year period 2000–2011 in the *Journal of Health Economics* and *Health Economics* that estimate the demand or use of health care services using individual or household level data derived primarily from household surveys. A few studies based strictly on claims or administrative data have been excluded because of the limited information about individuals.

The survey is not meant to be exhaustive. However, the 98 articles are broadly representative of empirical studies published in economics, health services research, and medical journals. They are based on a number of different household surveys and cover a broad range of low, middle, and high-income countries. None attempt to estimate a full structural model of all the joint choices that the theoretical health care demand models describe. Together, they give a sense of the range of determinants typically included in health care demand models and how they are used.

Few studies provide explicit rationales for each determinant. Most divide determinants into 'need' variables, measures of health and proxies such as age, and nonneed variables. In the context of economic models of consumer demand, these 'need' variables are simply inputs into an individual's

decisions. Others may think that an individual with a particular disease, say diabetes, needs treatment, but it is the individual that determines their own demand and whether they seek treatment. This issue of need and demand will be discussed later in an empirical illustration. A few studies appeal to an alternate framework in the selection of determinants, the Andersen–Aday behavioral model of health care use. The Andersen–Aday framework is less a formal behavioral model in the way economists use the term and more a catalog of characteristics correlated with health care use.

Economic Determinants

Table 1 provides a summary of the types of determinants included and how often they appear. Among the economic variables, consumer price appears in only 16 of the 98 demand models and even then is generally only partially observed. However, health insurance coverage is widely used as a proxy. Together, 64 of the 98 studies included price and/or health insurance coverage. Price and health insurance coverage were the clear focus of researchers' concerns with bias. Of the 64 studies including either of these determinants, 28 used either experimental data or econometric methods specifically designed to reduce bias. Rarely did researchers use econometric methods to specifically tackle bias in health (four studies) or other determinants.

Table 1 Determinants of health demand, frequency of use in survey of 98 recent empirical studies

Price	16/98
Health insurance	58/98
Time price	13/98
Income	89/98
Wealth/assets	19/98
Employment/main activity	
Employment status	38/98
Occupation and/or industry	18/98
Age	98/98
Life expectancy/time to death	5/98
Sex	97/98
Race and/or ethnicity	49/98
Immigration or citizenship status	16/98
Marital/partner status	69/98
Household size and/or composition	63/98
Educational attainment	86/98
Geographic indicators[a]	65/95
Trend[b]	42/45
Health status	91/98
Self-assessed health	60/98
Scale	18/98
Chronic conditions	65/98
Obesity/body mass index	10/98
Functional limitations and disability	42/98
Acute illness	23/98
Prior utilization	7/98
Other	21/98
Health behaviors (smoking, alcohol, drug, exercise, and diet)	31/98
Health beliefs and preferences	7/98
Health information	4/98
Environmental risks	3/98
Access to regular doctor	6/98
Supply side characteristics	
Physician supply	17/98
Distance to provider	8/98
Provider quality	8/98
Market characteristics	12/98

Source: Author's review of 98 empirical studies of health care use or health care demand based on survey data appearing in the *Journal of Health Economics* and *Health Economics* between 2000 and 2011.

Appealing to the economic notion that the price of consuming health care extends beyond direct out-of-pocket costs to time, 13 of the 98 studies included time price. A typical direct measure of time price multiplies a person's wage rate by the time they spend traveling to health care and wait time. In other cases, proxy measures such as travel time were used. Measures of income were almost always included (89 studies). In most cases, this was total family income divided by the square of the number of household members. This normalization assumes that the larger the family, the smaller the share of resources available to any one member. In a handful cases, wealth or household assets were used as a proxy for income. In 16 studies, wealth or assets were included in addition to income. The theory here is that consumers consider more than just current income.

Although widely available in surveys, employment status (38) and/or information about occupation or industry (18) were included in a minority of studies. These are choice variables that do not directly determine health as per the theoretical models of health demand. A major concern here is reverse causality. Poor health might lead to job loss, and thus employment-related variables will reflect some aspects of health. Reasons for including employment characteristics might be that certain industries and occupations carry greater health risks from accidents, exposure to hazardous materials, or stress. They might also proxy for preferences about health care. In the United States, industry, occupation, and firm size are also correlated with generosity of insurance and access to paid sick leave.

Health and Health-Related Determinants

Direct measures of individual health were included in 91 of the 98 studies. They were uniformly powerful predictors of use. Reflecting the multidimensional nature of health, a wide range of measures was used. The most common were chronic health conditions such as diabetes, asthma, and heart disease (65 studies). Some studies used counts of chronic conditions, others each individual condition. The next most common health status measure were variants of a single-item self-assessed health status scale (60) asking respondents to rate their health (e.g., excellent, good, fair, and poor). A number of studies (42) included measures of disability or functional limitations such as difficulty walking upstairs or lifting. These were more common in studies of older populations. Other studies included measures derived from longer health-rating scales (18), acute illness or symptoms such as fever (23), measures related to obesity (10), and a variety of other measures (21).

All measures of health status raise concerns about reverse causality. Choices of which measures to include are driven by a combination of availability and an individual researcher's beliefs about the trade-offs between relevance in determining demand and potential bias. Chronic conditions are appealing because their very nature makes them less prone to concerns that current health care use changes whether an individual has the condition or not. For example, once you have diabetes you always have diabetes; treatment manages symptoms. Bias is a greater concern with acute symptoms of illness explaining why they are less commonly used, even though it is believed that they drive much use. Acute illness was more commonly included in studies based in low-income countries, where the balance between bias and relevance may be different.

Prior health utilization is a strong predictor of current health care use, and seven studies appeared to include it for this reason. If we are simply interested in obtaining the best possible predictions of current health care use, this is fine. However, if we are interested in the extent to which health explains health care use, it is not fine. For example, if a person has consumed lots of health care in the previous year because of his/her diabetes, then the intensity would also continue the year ahead. Henceforth, the effect estimated for diabetes is diminished. By including last year's use, the estimate for diabetes is greatly diminished.

Seven studies included no measures of health status. In two of them, none were available. The remainder explicitly or implicitly excluded health because of potential endogeneity. The researchers are making the call that the bias introduced by including health is worse than the omitted variables bias created by excluding a powerful determinant. Most make the call the other way.

Another set of health-related determinants commonly included are smoking, alcohol and drug use, exercise, diet, and other health behaviors (31 studies). Many researchers exclude them because they are choices related to health. However, they are also often strongly related to use. For example, a history of smoking can lead to significant health problems today even if one does not currently smoke.

Access and Supply-Side Determinants

Six studies included whether a person has access to a regular medical provider. Although often available, most researchers omit this as a choice variable because of its clear endogeneity with health care use. A larger number of studies included local area physician, hospital or other provider supply (17), distance to provider (8), or market characteristics (12) such as managed care concentration. These are generally used as proxies for availability and access to providers. Some may also proxy for time price. Many researchers omit these because observed health care use is a simultaneous function of supply and demand (though rarely modeled this way) making supply-related variables endogenous.

Demographic Determinants

Among the demographic variables, age and sex appear universally. Five studies used life expectancy (or time to death) in addition to or in place of age, arguing that life expectancy is a stronger predictor of health care use. A number of studies included interaction terms between age and sex, allowing for the effects of age to vary with sex, and vice versa. A few ran separate models stratified by sex, allowing for the effects of all determinants to vary by sex. Measures of race, ethnicity, or cultural group were included in 49 of the studies. Studies without such measures tended to come from countries with more homogenous populations. Education status (number of years or degrees) was almost universal. Similarly, most included some combination of marital status and/or household composition (e.g., number of family members). More than two-thirds of the studies included geographic indicators such as locality and/or living in an urban or rural area.

Finally, almost all the studies that used data pooled across more than 1 year included some time or trend dimension in the model. With health care use generally increasing over time, it is important to capture overall shifts in health care demand.

Other Considerations

Table 1 describes the range of determinants included in empirical demand studies. In aggregate, some are used more regularly than others. The table does not capture that the studies reviewed varied considerably in how parsimonious or expansive the set of demand determinants included in each study were. This ranged from as few as six variables to as many as 87. In some cases, parsimony may be driven by computational demands. Some econometric methods are also fragile when including too many closely related variables. Often, though, individual researchers simply prefer more parsimonious models. If we are interested in only one or two determinants and a model with just a few variables captures these well, we may be okay omitting other potential determinants. However, if the omitted characteristics are correlated with these key determinants, our estimates will be biased.

Empirical Determinants of Health Care Demand: An Illustration

The important roles that various theoretically derived and proxy determinants play in empirical models are illustrated using an example drawn from the author's own work on the demand for mental health treatment. Specifically, treatment related to depression are examined. Depressive disorders are a group of chronic, but episodic diseases affecting millions of Americans. The effects that health, economic, and sociodemographic determinants have on the use of three treatment options for the treatment of depression are examined: nonspecialty visits (generally to primary care providers), specialty visits (psychiatrists, psychologists, and social workers), and antidepressant medications. Aside from obvious convenience, this example has been chosen to illustrate how empirical determinants can vary across different types of treatment. This depression treatment example also conveniently illustrates the difference between need for treatment and individual demand.

Being consistent with the literature, it is not attempted to jointly estimate demand and supply. The dependent variable in the models is observed utilization and is assumed to be equivalent to demand. The empirical example in other respects is simplified. First, using probit equations; it is only modeled whether a person used each type of treatment and not quantities. Second, it is not attempted to jointly model other aspects of consumer decision making (e.g., other goods and services, income, and employment). Third, the main estimates presented do not correct for potential endogeneity of health insurance, income, and health status.

The rules of thumb described above can help guide both selection of empirical determinants and their interpretation using this example.

Data

The data are drawn from the Medical Expenditure Panel Survey (MEPS), a large nationally representative household survey conducted annually in the United States since 1996 by the Agency for Healthcare Research and Quality. The MEPS contains a rich array of information on each household member's health care use and expenditures, health insurance coverage, employment and income, health status and health conditions, and other sociodemographic characteristics. The MEPS is widely used to model the demand for health and to plan and evaluate health policy reforms and changes.

The MEPS utilizes an overlapping panel design to represent the civilian noninstitutionalized population in each calendar year. Households are interviewed in-person for five rounds covering 2 full calendar years. The average recall period for these five rounds is approximately 5 months. Generally, one person responds for all members of the household. In-person interviews are supplemented with self-administered health questionnaires (SAQs) of every adult to assess health status and experiences of care that might not be reliably captured by proxy. Follow-back surveys of physicians, hospitals, home health agencies, and pharmacies are used to collect more detailed information on health care spending and prescription medications.

Current sample sizes for each panel are approximately 7500 households and 18 000 individuals. The analytic sample used here is drawn from the 2004–08 panels of the MEPS and includes 37 173 adults aged 18–64 with two observations each with complete information on treatment use, depression status, and other covariates.

Analyses

Table 2 presents means of the dependent variables and all demand determinants for the full sample and also stratified by an indicator for probable depression. Departing from standard practice, the specification of each demand determinant and its rationale for inclusion one by one with the results and interpretation from the empirical demand model are described.

Economic Determinants: Specification, Results, and Interpretation

Table 3 presents the empirical estimates of the effects of economic, health status, and sociodemographic determinants from three probit equations describing any nonspecialty, specialty, and antidepressant use. The table adds a fourth column, which computes the combined effect of each determinant on the use of any of the three types of treatment. To ease in the interpretation of magnitudes, marginal effects are presented instead of coefficient estimates. For binary indicators, the marginal effects represent the change in the expected probability of using treatment for that group compared to the omitted group. For example, the marginal effect of 0.022 females for nonspecialty services implies that women are 2.2% points more likely to have nonspecialty mental health visits than men. The overall mean use of nonspecialty treatment is 5.9%, men and women combined, so this represents a substantial differential. For continuous measures, the marginal effect represents the change in the probability of use for a one unit change. For example, each additional child in a household less than 6 years (marginal effect = 0.006) is associated with a 0.6% point decrease in the use of nonspecialty care.

Health insurance

Like many surveys, price is only observed in the MEPS among users. Deriving theoretically consistent prices suitable for demand estimation from these partial observations is conceivable but difficult. Health insurance is used as a proxy instead. The MEPS contains extensive insurance coverage information. For simplicity, a three category summary of insurance status provided on the MEPS public use file (INSCOV) is used. In the sample of adults aged 18–64 years, 23% were uninsured the entire calendar year, 64% had private insurance (mainly through employers or unions) for all or part of the year, and 13% had public insurance only, mainly Medicaid or Medicare (Table 2).

It is seen that private and especially public insurance are strongly correlated with treatment. For example, people with public insurance are 10.2% points more likely to use any type of treatment than people without insurance. Although we expect positive effects of insurance on use, there are reasons to believe the estimated magnitudes are too large. First and foremost is adverse selection. Second, public health insurance may proxy in part for unmeasured severity of depression because both Medicare and Medicaid, in part, serve as disability programs. The qualifying process itself, which includes clinician diagnoses, may differentiate between levels of depression in ways that move beyond a limited depression scale. Using first month insurance indicators instead of full-year insurance to minimize postdiction bias does little to magnitudes. However, when the model is reestimated explicitly accounting for the potential endogeneity of insurance, the estimated effects of public and private insurance drop by half (not shown).

Income

Income is included as a theoretically important determinant but discussion on its interpretation has been brief. Following common practice, the log of total family income is divided by the square root of the number of household members. Positive income effects are generally expected, but for antidepressant use, only a small effect is observed. Income may be confounded with unobserved depression severity and other

factors. For example, depression often leads to job loss, thereby biasing downward the effects of income.

Health and Mental Health Determinants: Specification, Results, and Interpretation

Physical health

Three widely used measures of physical health are included from an earlier review. A strong correlation between depression and physical health has long been observed but the causal pathways remain unclear. Certain medical conditions, for example, heart attack, may lead to or exacerbate depression. Or patients might simply be depressed about physical ailments, especially if they lead to job loss or other life changes. On the other side of the equation, depression may lead to poor diet and exercise. In the course of treating people for physical ailments, providers might also detect depression leading to more care.

The first measure is a simple count of a set of 11 chronic conditions that are ascertained in each MEPS panel. Respondents are asked if the doctor ever told the person they had diabetes, arthritis, asthma, emphysema, stroke, high blood pressure, high cholesterol, coronary heart disease, heart attack (myocardial infarction), angina, and any other heart disease. A graph of the 0–11 condition count versus treatment was approximately linear (not shown). The regression results in Table 3 show a strong association between chronic conditions and antidepressant use in particular, with each additional condition increasing the probability of antidepressant use by 1.8% points. The association is used here because, even with reverse causality minimized, these chronic conditions are still likely correlated with depression severity, not captured in the depression index.

The second measure is the physical health summary score from the Short Form-12 (SF-12) contained in the MEPS Adult SAQ asked in the middle to later part of each calendar year. The SF-12 is a well-validated health inventory containing 12 questions on a number of dimensions of physical and mental health symptoms and functioning. This composite index is scaled from 0 to 100 and normalized to approximately 50 with a higher score indicating better health. The effect on nonspecialty use was not significant. Better physical health is associated with a reduced probability of antidepressant use as expected. Curiously, better physical health, controlling for chronic conditions and perceived health status, is associated with a small but statistically significant increase in specialty use.

The third physical health measure is derived from the standard 1-item perceived health status question asked in each of the five rounds of MEPS. Respondents are asked relative to persons their age, whether each member of the household is in excellent, very good, good, fair, or poor health. The poor and fair responses in either of the first two rounds during a calendar year into a single binary indicator (ever poor or fair vs. good/very good/excellent) have been combined. Turning to the actual results in Table 3, there is an independent effect of poor or fair perceived health on treatment, increasing the likelihood of nonspecialty visits by 1.2% points and antidepressant use by 1.3% points.

The SF-12 and poor/fair health measures bring the potential for obvious reverse causality problems because they are measured contemporaneously with treatment. In fact, they could be measured well after treatment if treatment occurred earlier in the year. Using the strategy of minimizing postdiction by measuring health at the earliest possible point during the year or using prior year values, alternative ways of constructing and using these variables have been tested. For the poor/fair measure, the round 1 responses are used only to construct an alternate poor/fair indicator. This had no appreciable effect on magnitudes of the effects. Because the SF-12 is measured later in the year, the first year of each person's observations has been discarded but used their SF-12 (and poor/fair health status) from the first year to estimate the demand models on the second year's observations. Again, nothing changed. Rather than lose half the observations, it has been opted to keep the models as they are.

Interpretation of all three physical health status measures is uncertain because they are likely associated with unmeasured aspects of health and preference. To test this, a version of the demand models presented here has been estimated, which explicitly accounts for these potential correlations. The results (not shown) suggest that the physical health measures indeed are correlated with unmeasured aspects of people's health and preferences toward care, substantially reducing the magnitudes of the observed effects of the three measures.

The MEPS contains a number of other measures related to functional limitations and disability, recent symptoms associated with chronic and other diseases, measures of work or
